TEXTBOOK OF **RESPIRATORY MEDICINE**

Editors

Robert J. Mason, MD

Cetalie & Marcel Weiss Chair in Pulmonary Medicine
Department of Medicine
National Jewish Health
Professor of Medicine
University of Colorado Denver Health Sciences Center
Denver, Colorado

V. Courtney Broaddus, MD

Professor of Medicine
University of California, San Francisco
Chief, Division of Pulmonary and Critical Care Medicine
San Francisco General Hospital
San Francisco, California

Thomas R. Martin, MD

Professor of Medicine
University of Washington
Chief of Medicine and Director
Primary and Specialty Medicine Service Line
Veterans Affairs Puget Sound Health Care System
Seattle, Washington

Talmadge E. King, Jr., MD

Julius R. Krevans Distinguished Professorship in Internal Medicine
Chair, Department of Medicine
University of California, San Francisco
San Francisco, California

Dean E. Schraufnagel, MD

Professor of Medicine and Pathology
Department of Medicine
Section of Pulmonary, Critical Care, Sleep and Allergy
University of Illinois at Chicago
Chicago, Illinois

John F. Murray, MD, FRCP, DSc (Hon)

Professor Emeritus
Department of Medicine
University of California, San Francisco
San Francisco General Hospital
San Francisco, California

Jay A. Nadel, MD, DSc (Hon), DLaw (Hon)

Professor of Medicine and Physiology
Division of Pulmonary and Critical Care
Cardiovascular Research Institute Investigator
University of California, San Francisco
San Francisco, California

Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assumes any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

We dedicate this textbook to Dr. Julius H. Comroe, Jr., who was our mentor during the formative years of our professional development. Dr. Comroe was one of the truly great academicians of his generation. He was an investigator of exceptional merit, an educator whose influence was worldwide, and a medical statesman of exemplary integrity and vision. In dedicating this book, we acknowledge especially Dr. Comroe's scholarly contributions and his commitment to the importance of basic science in the solution of clinical problems.

CONTRIBUTORS

Lewis Adams, PhD
Professor, Griffith School of Physiotherapy and Exercise Science, Griffith University, Gold Coast Campus, Queensland, Australia
Dyspnea

Anthony J. Alberg, PhD, MPH
Associate Professor and Blatt Ness Chair, Division of Epidemiology and Biostatistics, Department of Medicine, and Associate Director for Cancer Prevention and Control, Hollings Cancer Center, Medical University of South Carolina, Charleston, South Carolina
Epidemiology of Lung Cancer

Richard K. Albert, MD
Professor of Medicine, University of Colorado Denver; Chief of Medicine, Denver Health; Adjunct Professor of Engineering and Computer Science, University of Denver, Denver, Colorado
Preoperative Evaluation

Kurt H. Albertine, PhD
Medical Gross Anatomy, Pediatric Fellowship Core Curriculum, and Assistant Dean for Faculty Administration, University of Utah School of Medicine, Salt Lake City, Utah; Editor-in-Chief, The Anatomical Record, American Association of Anatomists, Rockville, Maryland
Anatomy of the Lungs

Devanand Anantham, MRCP, MBBS, FCCP
Instructor in Medicine, Duke-National University of Singapore Graduate Medical School; Consultant, Singapore General Hospital, Singapore, Singapore
Ultrasonography

Douglas Arenberg, MD
Associate Professor of Medicine, Division of Pulmonary and Critical Care, Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, Michigan
Metastatic Malignant Tumors

Najib T. Ayas, MD, MPH
Associate Professor of Medicine, Divisions of Respiratory and Critical Care Medicine, University of British Columbia; Staff Physician, Intensive Care Unit, Providence Healthcare; Staff Physician, Vancouver General Hospital, Vancouver, British Columbia, Canada
Respiratory System Mechanics and Energetics

Ronald C. Balkissoon, MD
Associate Professor, Department of Medicine, National Jewish Health, Denver, Colorado
Disorders of the Upper Airways

John R. Balmes, MD
Division of Occupational and Environmental Medicine, and Division of Pulmonary and Critical Care Medicine, Department of Medicine, University of California, San Francisco, San Francisco, California
Indoor and Outdoor Air Pollution

Srinivas R. Bapoje, MD, MPH
Hospitalist, Department of Hospital Medicine, Denver Health Medical Center; Assistant Professor, Internal Medicine, University of Colorado Denver School of Medicine, Denver, Colorado
Preoperative Evaluation

Joan Albert Barberà, MD
Senior Consultant Physician, Servei de Pneumologia, Institut del Tòrax, and Research Associate Director, Hospital Clínic, Barcelona, Spain
Pulmonary Complications of Abdominal Disease

Peter J. Barnes, DM, DSc, FRCP, FMedSci, FRS
Professor of Thoracic Medicine, Imperial College London, London, United Kingdom
Pharmacologic Principles

Fuad M. Baroody, MD
Professor of Surgery and Pediatrics, and Director, Pediatric Otolaryngology, University of Chicago, Chicago, Illinois
Disorders of the Upper Airways

Margaret R. Becklake, MD
Professor Emeritus of Medicine and of Epidemiology, Biostatistics and Occupational Health, McGill University; Honorary Physician, McGill University Health Centre, Royal Victoria Hospital Pavilion, Montréal, Québec, Canada
Pneumoconioses and Other Mineral Dust-Related Diseases

Joshua O. Benditt, MD
Professor of Medicine, University of Washington School of Medicine; Medical Director of Respiratory Care Services, University of Washington Medical Center, Seattle, Washington
The Respiratory System and Neuromuscular Diseases

Neal L. Benowitz, MD
Professor of Medicine and Bioengineering and Therapeutic Sciences, and Chief, Division of Clinical Pharmacology and Experimental Therapeutics, University of California, San Francisco; Chief, Division of Clinical Pharmacology, San Francisco General Hospital, San Francisco, California
Smoking Hazards and Cessation

Paul D. Blanc, MD, MSPH
Professor of Medicine, and Endowed Chair, Occupational and Environmental Medicine, University of California, San Francisco, San Francisco, California
Acute Pulmonary Responses to Toxic Exposures

Richard C. Boucher, MD
Professor of Medicine, University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, North Carolina
Cystic Fibrosis

Alfred A. Bove, MD, PhD
Emeritus Professor of Medicine, Temple University School of Medicine; Chief of Cardiology, Temple University Medical Center, Philadelphia, Pennsylvania
Diving Medicine

Elisabeth Brambilla, MD, PhD
Department of Pathology, CHU Albert Michallon, and Institut Albert Bonniot, Centre de Recherche, Université Joseph Fourier, Grenoble, France
Lymphoma, Lymphoproliferative Diseases, and Other Primary Malignant Tumors

V. Courtney Broaddus, MD
Professor of Medicine, University of California, San Francisco; Chief, Division of Pulmonary and Critical Care Medicine, San Francisco General Hospital, San Francisco, California
Pleural Effusion; Tumors of the Pleura

Kevin K. Brown, MD
Professor and Vice Chairman, Department of Medicine, National Jewish Health; Professor of Medicine, University of Colorado Denver School of Medicine, Denver, Colorado
Pulmonary Vasculitis

Paul G. Brunetta, MD
Tobacco Education Center, Mount Zion Medical Center, University of California, San Francisco, San Francisco, California
Smoking Hazards and Cessation

Jacques Cadranel, MD, PhD
Department of Pneumology and Respiratory Intensive Care, Université de Médecine Pierre et Marie Curie; Tenon Hospital, Paris, France
Lymphoma, Lymphoproliferative Diseases, and Other Primary Malignant Tumors

David P. Carbone, MD, PhD
Professor of Medicine and Cell Biology, and Director, Experimental Therapeutics Program, Vanderbilt-Ingram Cancer Center; Director, Thoracic Oncology Center, Harold Moses Chair for Cancer Research, and Director, Specialized Program of Research Excellence in Lung Cancer, Vanderbilt University School of Medicine, Nashville, Tennessee
Biology of Non-Small Cell Lung Cancer

Bartolome R. Celli, MD
Professor of Medicine, Tufts University; Chief, Division of Pulmonary, Critical Care and Sleep Medicine, Caritas St. Elizabeth's Medical Center, Boston, Massachusetts
Pulmonary Rehabilitation

Edward D. Chan, MD
Associate Professor of Medicine, National Jewish Health, University of Colorado Denver Health Sciences Center, Denver, Colorado
Bronchiectasis

Moira Chan-Yeung, MBBS, FRCP, FRCPC, FHKAM, FHKCP
Emeritus Professor of Medicine, Department of Medicine, Faculty of Medicine, University of British Columbia, Vancouver, British Columbia, Canada; Professor of Medicine (Honorary), University of Hong Kong, Hong Kong, SAR, China
Asthma in the Workplace and Occupational Asthma

Richard N. Channick, MD
Director, Pulmonary Hypertension Program, Massachusetts General Hospital; Editor-in-Chief, Advances in Pulmonary Hypertension, Boston, Massachusetts
Pulmonary Hypertension

Jean Chastre, MD
Service de Réanimation Médicale, Groupe Hospitalier Pitié-Salpêtrière, Paris, France
Ventilator-Associated Pneumonia

Kian Fan Chung, MD, DSc, FRCP
Professor of Respiratory Medicine, National Heart and Lung Institute, Imperial College London; Honorary Consultant Physician, Royal Brompton Hospital, London, United Kingdom
Cough

Maria Cirino-Marcano, MD
Assistant Professor of Medicine, Division of Pulmonary Medicine, Albert Einstein College of Medicine, Montefiore Medical Center, Bronx, New York
Pulmonary Complications of Stem Cell and Solid Organ Transplantation

R. Edward Coleman, MD
Professor of Radiology, Vice Chair, Department of Radiology, and Director, Division of Nuclear Medicine, Duke University Medical Center, Durham, North Carolina
Nuclear Medicine Techniques

Harold R. Collard, MD
Assistant Professor, Department of Medicine, and Director, Interstitial Lung Disease Program, University of California, San Francisco, San Francisco, California
Diffuse Alveolar Hemorrhage and Rare Infiltrative Disorders of the Lung

Carlyne D. Cool, MD
Associate Clinical Professor, Department of Pathology, University of Colorado Denver School of Medicine, Aurora; Associate Professor, National Jewish Health, Denver, Colorado
General Features of Non-Neoplastic Respiratory Pathology; Pulmonary Vasculitis

Jean-François Cordier, MD
Professor of Respiratory Medicine, Claude Bernard University; Head, Department of Respiratory Medicine, Louis Pradel Hospital, Lyon, France
Lymphoma, Lymphoproliferative Diseases, and Other Primary Malignant Tumors; Eosinophilic Lung Diseases

Tamera J. Corte, MBBS, BSc(Med), FRACP
Clinical Research Fellow in Interstitial Lung Disease, Royal Brompton Hospital, London, United Kingdom
The Lungs and Connective Tissue Diseases

Vincent Cottin, MD, PhD
Claude Bernard University; Department of Pulmonary Medicine, and Reference Center for Orphan Lung Diseases, Louis Pradel Hospital, Lyon, France
Eosinophilic Lung Diseases

Robert L. Cowie, MD
Professor of Medicine and of Community Health Science, University of Calgary; Respirologist, and Director, Tuberculosis Services, Alberta Health Services, Calgary, Alberta, Canada
Pneumoconioses and Other Mineral Dust-Related Diseases

Robert O. Crapo, MD, FCCP
Professor, University of Utah; Director of Pulmonary Function Laboratory, LDS Hospital, Salt Lake City, Utah
Pulmonary Function Testing

Kristina Crothers, MD
Assistant Professor, Division of Pulmonary and Critical Care Medicine, Department of Internal Medicine, University of Washington School of Medicine; Harborview Medical Center, Seattle, Washington
Pulmonary Complications of Human Immunodeficiency Virus Infection

Charles L. Daley, MD
Head, Division of Mycobacterial and Respiratory Infections, and Professor of Medicine, National Jewish Health, Denver, Colorado
Nontuberculous Mycobacterial Infections

Scott F. Davies, MD
University of Minnesota Medical School; Chief, Department of Medicine, and Faculty, Division of Pulmonary and Critical Care Medicine, Department of Medicine, Hennepin County Medical Center, Minneapolis, Minnesota
Fungal Infections

Teresa De Marco, MD, FACC
Professor of Medicine and Surgery, Director, Heart Failure and Pulmonary Hypertension Program, and Medical Director, Heart Transplantation Program, University of California, San Francisco, San Francisco, California
Cor Pulmonale

Lorenzo Del Sorbo, MD
Assistant Professor, Dipartimento di Anestesiologia e Rianimazione, Università di Torino, Ospedale S. Giovanni Battista-Molinette, Torino, Italy
Hypoxemic Respiratory Failure

Gregory P. Downey, MD
Professor of Medicine, University of Colorado Denver; Executive Vice President for Academic Affairs, and Professor, Departments of Medicine, Pediatrics, and Integrated Immunology, National Jewish Health, Denver, Colorado
Injury and Repair of the Lung

Wonder Drake, MD
Assistant Professor of Medicine, Vanderbilt University School of Medicine, Nashville, Tennessee
Sarcoidosis

Roland M. du Bois, MA, MD, FRCP, FCCP
Senior Research Investigator, Imperial College London, London, United Kingdom; Professor of Medicine, National Jewish Health, Denver, Colorado
The Lungs and Connective Tissue Diseases

James Duffin, MA, PhD
Professor Emeritus, Departments of Physiology and Anaesthesia, University of Toronto, Toronto, Ontario, Canada
Hypoventilation and Hyperventilation Syndromes

Richard M. Effros, MD
Clinical Professor of Medicine and Attending Physician, Harbor-UCLA Medical Center, Torrance, California; Emeritus Professor of Medicine, Medical College of Wisconsin, Milwaukee, Wisconsin; Attending Physician, Rancho Los Amigos Medical Center, Downey, California
Acid-Base Balance

Mark D. Eisner, MD, MPH
Division of Occupational and Environmental Medicine, and Division of Pulmonary and Critical Care Medicine, Department of Medicine, University of California, San Francisco, San Francisco, California
Indoor and Outdoor Air Pollution

Brett M. Elicker, MD
Assistant Professor of Clinical Radiology, University of California, San Francisco, San Francisco, California
Radiographic Techniques

Armin Ernst, MD
Interventional Pulmonology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts
Ultrasonography

Peter F. Fedullo, MD
Professor of Medicine, and Director, Medical Intensive Care Unit, University of California, San Diego, San Diego, California
Pulmonary Thromboembolism

Matthew J. Fenton, PhD
Chief, Asthma, Allergy and Inflammation Branch, Division of Allergy, Immunology and Transplantation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, Maryland
Innate Immunity in the Lungs

Daniel Fertel, MD
Fellow, Division of Pulmonary, Allergy and Critical Care Medicine, Duke University Medical Center, Durham, North Carolina
Asthma

Hans G. Folkesson, PhD
Professor of Physiology and Pharmacology, Northeastern Ohio Universities Colleges of Medicine and Pharmacy, Rootstown, Ohio
Alveolar and Distal Airway Epithelial Fluid Transport

Rodney J. Folz, MD, PhD
University of Louisville School of Medicine; Professor of Medicine and Biochemistry and Molecular Biology, and Chief, Division of Pulmonary, Critical Care and Sleep Disorders Medicine, University of Louisville, Louisville, Kentucky
Pulmonary Complications of Stem Cell and Solid Organ Transplantation

Andrew P. Fontenot, MD
Henry N. Claman Associate Professor of Medicine, University of Colorado Denver, Denver, Colorado
Adaptive Immunity

Joe G. N. Garcia, MD
Lowell T. Coggeshall Professor of Medicine, Section of Pulmonary and Critical Care Medicine, Department of Medicine, University of Chicago Pritzker School of Medicine, Chicago, Illinois
Pulmonary Circulation and Regulation of Fluid Balance

Gerald F. Gebhart, PhD
Professor, and Director, Center for Pain Research, University of Pittsburgh School of Medicine, Pittsburgh, Pennsylvania
Chest Pain

Thomas J. Giordano, MD, PhD
Professor, Department of Pathology and Internal Medicine, University of Michigan Health System, Ann Arbor, Michigan
Benign Lung Tumors

Nicolas Girard, MD
Pilot Unit for Rare Malignant Thoracic Tumors, Department of Respiratory Medicine, Reference Center for Orphan Pulmonary Diseases, Louis Pradel Hospital, Lyon, France; Human Oncology and Pathogenesis Program, Memorial Sloan-Kettering Cancer Center, New York, New York
Lymphoma, Lymphoproliferative Diseases, and Other Primary Malignant Tumors

Mark T. Gladwin, MD
Pulmonary, Allergy and Critical Care Medicine, and Hemostasis and Vascular Biology Research Institute, University of Pittsburgh, Pittsburgh, Pennsylvania
Pulmonary Complications of Hematologic Disease

Michael B. Gotway, MD
Clinical Associate Professor, Diagnostic Radiology/Biomedical Imaging and Pulmonary/Critical Care Medicine, Department of Radiology, University of California, San Francisco, San Francisco, California; Scottsdale Medical Imaging, an affiliate of Southwest Diagnostic Imaging, Scottsdale, Arizona
Radiographic Techniques

James M. Greenberg, MD
Associate Professor, University of Cincinnati College of Medicine; Director, Division of Neonatology, Cincinnati Children's Hospital Research Foundation, Cincinnati, Ohio
Lung Growth and Development

David E. Griffith, MD
Professor of Medicine, University of Texas Health Science Center at Tyler, Tyler, Texas
Nontuberculous Mycobacterial Infections

Stephen Groshong, MD
Division of Pulmonary Sciences and Critical Care Medicine, Department of Medicine and Department of Pathology, University of Colorado Denver School of Medicine, National Jewish Health, Denver, Colorado
General Features of Non-Neoplastic Respiratory Pathology

Matthew J. Hegewald, MD, FCCP
Assistant Professor, University of Utah, Salt Lake City; Director of Pulmonary Function Laboratory, Intermountain Medical Center, Murray, Utah
Pulmonary Function Testing

Peter M. Henson, PhD, MD
Professor, Departments of Medicine, Immunology, Pharmacology and Pathology, University of Colorado Denver Health Sciences Center, Aurora; Professor, Program in Cell Biology, Department of Pediatrics, National Jewish Health, Denver, Colorado
Injury and Repair of the Lung

Nicholas S. Hill, MD
Professor of Medicine, Tufts University School of Medicine; Chief, Pulmonary, Critical Care and Sleep Division, Tufts Medical Center, Boston, Massachusetts
Acute Ventilatory Failure

Philip C. Hopewell, MD
Professor of Medicine, University of California, San Francisco; Director, Francis J. Curry National Tuberculosis Center, San Francisco General Hospital, San Francisco, California
Tuberculosis

Laurence Huang, MD, MAS
Professor of Medicine, and Assistant Director, Mentor Development Program, Clinical and Translational Science Institute, University of California, San Francisco; Chief, HIV/AIDS Chest Clinic, San Francisco General Hospital, San Francisco, California
Pulmonary Complications of Human Immunodeficiency Virus Infection

Yoshikazu Inoue, MD, PhD
Invited Associate Professor, Infection, Immunology and Oncology Cooperating Course, Osaka University Graduate School; Director, Department of Diffuse Lung Diseases and Respiratory Failure, Clinical Research Center, National Hospital Organization Kinki-Chuo Chest Medical Center, Sakai, Osaka, Japan
Lymphangioleiomyomatosis

Michael D. Iseman, MD
Professor of Medicine, University of Colorado School of Medicine; Physician, Division of Mycobacterial and Respiratory Infections, National Jewish Health, Denver, Colorado
Bronchiectasis

James E. Jackson, FRCR, FRCP
Honorary Senior Lecturer, Imperial College London, Hammersmith Hospital; Consultant Radiologist, Department of Radiology, Imperial College Healthcare NHS Trust, Hammersmith Hospital, London, United Kingdom
Pulmonary Arteriovenous Malformations and Other Vascular Abnormalities

Jeffrey R. Jacobson, MD
Assistant Professor of Medicine, Section of Pulmonary and Critical Care Medicine, Department of Medicine, University of Chicago Pritzker School of Medicine, Chicago, Illinois
Pulmonary Circulation and Regulation of Fluid Balance

James R. Jett, MD, FCCP
Professor of Medicine, Mayo Clinic, Rochester, Minnesota
Clinical Aspects of Lung Cancer

Demet Karnak, MD, FCCP
Professor, Chest Diseases Department, Ankara University School of Medicine, and Ankara University Hospital, Ankara, Turkey
Flexible Bronchoscopy

Midori Kato-Maeda, MD
Assistant Professor, University of California, San Francisco, San Francisco, California
Tuberculosis

Mani S. Kavuru, MD
Professor, Division of Pulmonary, Critical Care and Sleep Medicine, East Carolina University; Professor of Medicine, Pitt County Memorial Hospital, Greenville, North Carolina
Pulmonary Alveolar Proteinosis Syndrome

Talmadge E. King, Jr., MD
Julius R. Krevans Distinguished Professorship in Internal Medicine, Chair, Department of Medicine, University of California, San Francisco, San Francisco, California
Idiopathic Interstitial Pneumonias; Diffuse Alveolar Hemorrhage and Rare Infiltrative Disorders of the Lung

Michael R. Knowles, MD
Professor of Medicine, University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, North Carolina
Cystic Fibrosis

Kenneth S. Knox, MD
Associate Professor of Medicine, University of Arizona; Chief of Medicine, Southern Arizona Veterans Affairs Health Care System; Arizona Respiratory Center, Tucson, Arizona
Fungal Infections

Robert M. Kotloff, MD
Craig and Elaine Dobbin/Nancy P. Blumenthal Professor of Medicine, Pulmonary, Allergy, and Critical Care Division, and Chief, Section of Advanced Lung Disease and Lung Transplantation, University of Pennsylvania Medical Center, Philadelphia, Pennsylvania
Lung Transplantation

Monica Kraft, MD
Professor of Medicine, and Director, Duke Asthma, Allergy and Airway Center, Duke University Medical Center, Durham, North Carolina
Asthma

Elif Kupeli, MD
Staff in Pulmonary Diseases Department, Baskent University School of Medicine, Ankara, Turkey
Flexible Bronchoscopy

Stephen E. Lapinsky, MB, BCh, MSc, FRCPC
Associate Professor, Department of Medicine, University of Toronto; Site Director, Intensive Care Unit, Mount Sinai Hospital, Toronto, Ontario, Canada
The Lungs in Obstetric and Gynecologic Disease

Abigail R. Lara, MD
Instructor of Medicine, Department of Pulmonary Science and Critical Care Medicine, University of Colorado, Denver, Colorado
Hypersensitivity Pneumonitis

Stephen C. Lazarus, MD
Professor of Medicine, Interim Chief, Division of Pulmonary and Critical Care Medicine, Director, Training Program in Pulmonary and Critical Care Medicine, and Co-Director, Airway Clinical Research Center, University of California, San Francisco, San Francisco, California
Disorders of the Intrathoracic Airways

F. Eun-Hyung Lee, MD
Associate Professor, Division of Pulmonary and Critical Care, Department of Medicine, University of Rochester Medical Center, Rochester, New York
Viral Infections

Warren L. Lee, MD, PhD, FRCP(C)
Assistant Professor, Department of Medicine, University of Toronto; Attending Physician, Medical-Surgical Intensive Care Unit, St. Michael's Hospital, Toronto, Ontario, Canada
Acute Respiratory Distress Syndrome

Y. C. Gary Lee, MBChB, PhD, FRACP, FCCP
Winthrop Professor of Respiratory Medicine, School of Medicine and Pharmacology, University of Western Australia; Head of Pleural Unit, Lung Institute of Western Australia; Director of Pleural Services, Department of Respiratory Medicine, Sir Charles Gairdner Hospital, Perth, Australia
Pneumothorax, Chylothorax, Hemothorax, and Fibrothorax

Teofilo Lee-Chiong, MD
Professor of Medicine, National Jewish Health, and University of Colorado Denver School of Medicine, Denver, Colorado
Chest Pain

James F. Lewis, MD
Professor of Medicine and Physiology, Assistant Dean, Clinical Research, Schulich School of Medicine and Dentistry, University of Western Ontario, London, Ontario, Canada
Pulmonary Surfactant

Richard W. Light, MD
Professor of Medicine, Vanderbilt University, Nashville, Tennessee
Pleural Effusion; Pneumothorax, Chylothorax, Hemothorax, and Fibrothorax

Andrew H. Limper, MD
Professor of Medicine, Mayo Clinic College of Medicine; Chair, Pulmonary and Critical Care Medicine, Mayo Clinic, Rochester, Minnesota
Drug-Induced Pulmonary Disease

Robert Loddenkemper, MD
Professor of Medicine, Charité Universitätsmedizin Berlin; Former Medical Director and Chief of Department of Pneumology, HELIOS-Klinikum Emil von Behring, Lungenklinik Heckeshorn, Berlin, Germany
Pleuroscopy and Medical Thoracoscopy

John M. Luce, MD
Emeritus Professor of Medicine and Anesthesia, University of California, San Francisco; Member, Division of Pulmonary and Critical Care Medicine, San Francisco General Hospital, San Francisco, California
Care at the End of Life for Patients with Respiratory Failure

Njira Lugogo, MD
Instructor in Medicine, Duke University, Durham, North Carolina
Asthma

Andrew M. Luks, MD
Assistant Professor, University of Washington; Division of Pulmonary and Critical Care Medicine, Harborview Medical Center, Seattle, Washington
High Altitude

Charles-Edouard Luyt, MD, PhD
Service de Réanimation Médicale, Groupe Hospitalier Pitié-Salpêtrière, Paris, France
Ventilator-Associated Pneumonia

Roberto F. Machado, MD
Assistant Professor of Medicine, Section of Pulmonary and Critical Care Medicine, Department of Medicine, University of Chicago, Chicago, Illinois
Pulmonary Complications of Hematologic Disease

Neil R. MacIntyre, MD
Professor of Medicine, Duke University Medical Center, Durham, North Carolina
Principles of Mechanical Ventilation

Lisa A. Maier, MD, MSPH
Associate Professor, Division of Pulmonary Sciences and Critical Care Medicine, University of Colorado Denver School of Medicine; Head, Division of Environmental and Occupational Health Sciences, and Associate Professor of Medicine, Department of Medicine, National Jewish Health, Denver, Colorado
Evaluation of Respiratory Impairment and Disability

Fabien Maldonado, MD
Assistant Professor of Medicine, Mayo Clinic College of Medicine; Senior Associate Consultant, Mayo Clinic, Rochester, Minnesota
Drug-Induced Pulmonary Disease

Jean-Luc Malo, MD
Professor, Faculty of Medicine, Université de Montréal, and Sacré-Coeur Hospital, Montréal, Québec, Canada
Asthma in the Workplace and Occupational Asthma

Erica L. Martin, PhD
Post Doc, Dipartimento di Anestesiologia e Rianimazione, Università di Torino, Ospedale S. Giovanni Battista-Molinette, Torino, Italy
Hypoxemic Respiratory Failure

Thomas R. Martin, MD
Professor of Medicine, University of Washington; Chief of Medicine and Director, Primary and Specialty Medicine Service Line, Veterans Affairs Puget Sound Health Care System, Seattle, Washington
Innate Immunity in the Lungs; Pulmonary Edema and Acute Lung Injury

Robert J. Mason, MD
Cetalie & Marcel Weiss Chair in Pulmonary Medicine, Department of Medicine, National Jewish Health; Professor of Medicine, University of Colorado Denver Health Sciences Center, Denver, Colorado
Pulmonary Surfactant

Pierre P. Massion, MD
Associate Professor of Medicine, Department of Medicine, and Associate Professor of Cancer Biology, Department of Cancer Biology, Vanderbilt University School of Medicine; Attending Physician, Vanderbilt University Hospital; Attending Physician, and Section Chief, Pulmonary and Critical Care Medicine, Department of Veterans Affairs Medical Center, Nashville, Tennessee
Biology of Non-Small Cell Lung Cancer

Michael A. Matthay, MD
Professor, Medicine and Anesthesia, Senior Associate, Cardiovascular Research Institute, Associate Director, Intensive Care Unit, and Director, Critical Care Medicine Training, Department of Medicine, University of California, San Francisco, San Francisco, California
Alveolar and Distal Airway Epithelial Fluid Transport; Pulmonary Edema and Acute Lung Injury

Richard A. Matthay, MD
Boehringer Ingelheim Professor of Medicine, Pulmonary and Critical Care Medicine Section, Department of Medicine, Yale University School of Medicine, New Haven, Connecticut
Chest Pain

Annyce S. Mayer, MD, MSPH
Assistant Professor, Department of Preventive Medicine and Biometrics, University of Colorado Denver School of Medicine; Assistant Professor, Department of Medicine, National Jewish Health, Denver, Colorado
Evaluation of Respiratory Impairment and Disability

James McCarthy, MD, FRACP
Professor of Medicine, Queensland Institute for Medical Research, University of Queensland, Brisbane, Australia
Parasitic Lung Infections

F. Dennis McCool, MD
Professor of Medicine, Brown University, Providence; Chief, Pulmonary Critical Care Medicine, Memorial Hospital of Rhode Island, Pawtucket, Rhode, Island
The Respiratory System and Neuromuscular Diseases; The Lungs and Chest Wall Diseases

Francis X. McCormack, MD
Taylor Professor and Director, Division of Pulmonary, Critical Care and Sleep Medicine, Department of Internal Medicine, University of Cincinnati School of Medicine, Cincinnati, Ohio
Lymphangioleiomyomatosis

Dana McGlothlin, MD
Assistant Clinical Professor of Medicine, Associate Director, Pulmonary Hypertension Program, and Medical Director, Intensive Cardiac Care Unit, University of California, San Francisco, San Francisco, California
Cor Pulmonale

Atul C. Mehta, MB, BS, FACP, FCCP
Chief Medical Officer, Sheikh Khalifa Medical City, Abu Dhabi, United Arab Emirates
Flexible Bronchoscopy

Rosario Menéndez, MD
Servicio de Neumologia, Hospital Universitario La Fe, Valencia, Spain
Pyogenic Bacterial Pneumonia and Lung Abscess

Alison Morris, MD, MS
Assistant Professor of Medicine and Immunology, University of Pittsburgh, Pittsburgh, Pennsylvania
Pulmonary Complications of Human Immunodeficiency Virus Infection

Timothy A. Morris, MD
Professor of Medicine, Division of Pulmonary and Critical Care Medicine, University of California, San Diego, La Jolla, California
Pulmonary Thromboembolism

Lake D. Morrison, MD
Assistant Professor of Medicine, and Director, Interstitial Lung Disease Clinic, Duke University Medical Center, Durham, North Carolina
Idiopathic Interstitial Pneumonias

Marc Moss, MD
Roger S. Mitchell Professor of Medicine, and Head of Critical Care, Division of Pulmonary Sciences and Critical Care Medicine, University of Colorado Denver, Denver, Colorado
Injury and Repair of the Lung

Jill Murray, MBBCh, FFPath(SA)
Associate Professor, School of Public Health, Faculty of Health Sciences, University of the Witwatersrand; Head, Pathology Division, National Institute for Occupational Health, National Health Laboratory Service, Johannesburg, South Africa
Pneumoconioses and Other Mineral Dust-Related Diseases

John F. Murray, MD, FRCP, DSc (Hon)
Professor Emeritus, Department of Medicine, University of California, San Francisco, and San Francisco General Hospital, San Francisco, California
History and Physical Examination

Jeffrey L. Myers, MD
A. James French Professor and Director, Division of Anatomic Pathology, University of Michigan Health System, Ann Arbor, Michigan
Benign Lung Tumors

Jay A. Nadel, MD, DSc (Hon), DLaw (Hon)
Professor of Medicine and Physiology, Division of Pulmonary and Critical Care, and Cardiovascular Research Institute Investigator, University of California, San Francisco, San Francisco, California
Airway Epithelial Mucins and Mucous Hypersecretion

Koh Nakata, MD, PhD
Professor, Niigata University; Chairman, Bioscience Medical Research Center, Niigata University Medical and Dental Hospital, Niigata City, Niigata, Japan
Pulmonary Alveolar Proteinosis Syndrome

Thomas S. Neuman, MD
Emeritus Professor of Medicine, University of California, San Diego, La Jolla, California
Diving Medicine

Lee S. Newman, MD, MA
Professor, Department of Environmental and Occupational Health, and Department of Epidemiology, Colorado School of Public Health; Professor, Division of Allergy and Clinical Immunology, and Division of Pulmonary Science and Critical Care Medicine, Department of Medicine, School of Medicine, University of Colorado Denver; Staff Physician, University of Colorado Hospital, Aurora, Colorado
Sarcoidosis

Paul W. Noble, MD
Professor of Medicine, Duke University School of Medicine; Chief, Division of Pulmonary, Allergy and Critical Care Medicine, Duke University Medical Center, Durham, North Carolina
Idiopathic Interstitial Pneumonias

Marc Noppen, MD, PhD
Associate Professor, Free University of Brussels, VUB; Chief Executive Officer, and Head, Interventional Endoscopy Clinic, University Hospital UZ Brussel, Brussels, Belgium
Pleuroscopy and Medical Thoracoscopy

Thomas B. Nutman, MD
Head, Helminth Immunology Section, National Institutes of Health, Bethesda, Maryland
Parasitic Lung Infections

Thomas G. O'Riordan, MD, MRCPI
Senior Director, Clinical Research, Gilead Sciences Inc.; Clinical Associate Professor of Medicine, Division of Pulmonary and Critical Care Medicine, University of Washington, Seattle, Washington
Aerosol Deposition and Clearance

Allan I. Pack, MBChB, PhD
John Miclot Professor of Medicine, Director, Center for Sleep and Respiratory Neurobiology, and Chief, Division of Sleep Medicine, University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Sleep-Disordered Breathing

Peter D. Paré, MD, CM
Professor of Medicine, University of British Columbia; Principal Investigator, Jacob Churg Distinguished Researcher, James Hogg iCAPTURE Centre and Heart Lung Institute, St. Paul's Hospital, Vancouver, British Columbia, Canada
Respiratory System Mechanics and Energetics

David R. Park, MD
Associate Professor of Medicine, Division of Pulmonary and Critical Care Medicine, Harborview Medical Center, and University of Washington, Seattle, Washington
Tumors and Cysts of the Mediastinum; Pneumomediastinum and Mediastinitis

PREFACE TO THE FIFTH EDITION

As it has been from the beginning, the goal of this textbook is to be a well balanced, authoritative, and fully documented book that integrates the basic scientific principles with the practice of respiratory medicine for clinicians, trainees, students and educators. To accomplish this in a rapidly changing field, we have undertaken significant changes for the fifth edition. Chapters have been created to cover new topics, other chapters have been split into two to cover topics more thoroughly, and still other chapters have been merged to improve presentation of similar material. Key points distilled from each subject are now highlighted at the end of each chapter. Color photographs and illustrations have been incorporated into the chapters wherever possible. The locations of numerous instructional videos, which can be accessed at the textbook's website, are indicated by icons in the printed textbook. An active and regularly updated internet site is an integral part of the textbook, expanding, revising and supporting information from the printed pages.

We are mindful that we are trying to meet the educational needs of an increasingly global and sophisticated readership. There are 26 newly written chapters. These include chapters on genetics, asthma, particle deposition and clearance, innate immunity, lung injury and repair, pulmonary pathology, bronchoscopy (diagnostic and therapeutic), ultrasonography, pulmonary function testing, clinical exercise testing, respiratory impairment and disability, ventilator-associated pneumonia, lymphoma, occupational asthma, bioterrorism, nontuberculous mycobacterial disease, pulmonary vasculitis, sleep disorders, neuromuscular disease, lung transplantation, metastatic lung disease and the biology of non-small cell lung cancer. As for each edition, new authors have been recruited to provide new perspectives and our continuing authors have thoroughly updated their chapters. We are indebted and deeply appreciative of the hard work and dedication of all our authors, nearly half of whom are new to the textbook. Our international contributors, who represent 15 countries, now make up 25% of authors of the fifth edition.

We believe that this textbook remains an important resource for pulmonary physicians. From the time of its first publication in 1988, it retains the spirit of a comprehensive, well-referenced text created by internationally recognized authorities. Each chapter is meant to provide both a comprehensive overview and the authors' expert insights concerning the scientific-clinical foundations of the subject, on which the reader can integrate new knowledge as research progresses.

The online textbook and internet site will enhance the learning experience. Each figure in the printed edition is available from the internet site and can be readily downloaded into teaching presentations. Videos that illustrate procedures and important concepts not appreciated in static images are linked to several of the chapters. Pertinent review questions for each chapter can serve as a self-teaching module. Teaching cases prepared regularly by Dr. Michael Gotway present and explain important radiographic features of pulmonary disease. Literature updates that comment on recent articles should be of interest to the readership and, in addition, at the end of each chapter, links will direct the reader to recent articles and reviews. We aim to keep our online readers engaged and current and to give them reasons to visit the electronic textbook often.

We would like to thank our publisher Elsevier Inc. for their support and suggestions for improvement. We are very pleased with the layout of the book and the improved artwork. The publishing staff and copyeditors deserve special thanks and acknowledgment for their important contributions, particularly Dolores Meloni and Ann Ruzycka Anderson. Copyediting and print layout was skillfully performed by Berta Steiner and her staff at Bermedica Production, Ltd. We greatly appreciate the countless hours of work of authors, publishers, artists and copyeditors to bring this textbook to life. We encourage our readers to contribute also by providing feedback and suggestions for ongoing improvement.

PREFACE TO THE FIRST EDITION

The rapid growth of knowledge of basic scientific principles and their application to respiratory medicine has resulted in a proliferation of monographs and texts dealing with selected aspects of pulmonary science and clinical medicine, but no single work has provided a comprehensive description of all that is currently known. The *Textbook of Respiratory Medicine* is an attempt to provide a well-balanced, authoritative, and fully documented book that integrates scientific principles with the practice of respiratory medicine. The text is sufficiently detailed and referenced to serve as the definitive source for interested students, house officers, and practitioners, both pulmonary specialists and generalists. It is written by leading experts, to guarantee that the material is authoritative and contemporary.

To deal with such an enormous amount of material, we have divided the book into three major sections. This organization should help guide interested readers from the intricacies of basic science to their application at the bedside. We begin in Part I with Scientific Principles of Respiratory Medicine. As implied, this is where the reader will find detailed information about the anatomy and development of the respiratory tract, respiratory physiology, pharmacology and pathology, and defense mechanisms and immunology. A strong foundation in these basic sciences will make possible a rational and scientific approach to the more specialized clinical material included in the subsequent sections. Part II, Manifestations and Diagnosis of Respiratory Disease, contains four chapters on the cardinal signs and symptoms of respiratory disorders and ten chapters on diagnostic evaluation, ranging from the history and physical examination to the newest and most sophisticated imaging, applied physiologic, and invasive techniques. Discrete clinical disorders are included in Part III, Clinical Respiratory Medicine. There are sections on Infectious Diseases, Obstructive Diseases, Neoplasms, Disorders of the Pulmonary Circulation, Infiltrative and Interstitial Diseases, Environmental and Occupational Disorders, Disorders of the Pleura, Disorders of the Mediastinum, Disorders in the Control of Breathing, Respiratory Manifestations of Extrapulmonary Disorders, and Respiratory Failure. All but one of the sections dealing with a generic clinical problem begin with a chapter entitled "General Principles and Diagnostic Approach." New challenges to adult respiratory medicine have sprung up, and these are reflected in chapters on subjects such as cystic fibrosis (previously a disease only of childhood!), environmental and occupational diseases, disorders of breathing, and respiratory problems associated with unusual atmospheres (high altitude, diving). The book ends with a novel and important section on Prevention and Control.

Putting together a *Textbook* of this scope and magnitude is no easy task and involves making certain decisions that all readers may not agree with. For example, while trying to keep the length of the book as manageable as possible, we decided to permit some overlap of content. Thus, readers will find bronchodilators discussed in the chapter on airway pharmacology and again in the pertinent chapters on obstructive airway diseases. We have also welcomed differences of opinion among authors, provided the issues were clearly stated and the reasons for the author's position documented.

Our struggles were not as arduous as they might have been because we have had considerable help from many sources. First of all was the help from the 95 authors, who worked long and hard on their various contributions. The two editors worked in San Francisco, where they had the benefit of expert secretarial support from Ms. Dorothy Ladd and Mrs. Beth Cost. Special acknowledgment goes to Ms. Aja Lipavsky who, as editorial assistant, handled correspondence, proofing, permissions, and innumerable other details, and prepared the index. At W.B. Saunders in Philadelphia, the book was the brainchild of then-president John Hanley and was published with the guidance of J. Dereck Jeffers, William Lamsback, and the new president Lewis Reines. Production was supervised by Evelyn Weiman.

The long gestation of this book is over, parturition is near, and it will soon begin a life of its own. Like all expectant parents, we are concerned about how our offspring will make its way in the real world. We hope people will like it and find it useful.

INNERVATION

AIRSPACE MACROPHAGES, LYMPHATICS, LYMPHOID TISSUE, AND INNATE IMMUNITY

INTRODUCTION

The primary function of the lung is ventilation-perfusion matching such that gas exchange between alveolar air and alveolar capillary blood is efficient (Fig. 1-1). Therefore, this chapter emphasizes the gross, subgross, histologic, and ultrastructural determinants of ventilation-perfusion matching in the normal human lung. Secondary functions of the various cell types in the lung, particularly of alveolar type II and type I epithelial cells and capillary endothelial cells, also are considered.

GROSS AND SUBGROSS ORGANIZATION

The position of the lungs in the chest and in relationship to the heart is shown in Figure 1-2. Figure 1-2A shows a midfrontal section through the thorax of a frozen human cadaver. Figure 1-2B shows a posterior-anterior chest radiograph of a normal human at functional residual capacity (FRC). The two illustrations represent the extremes of the approaches to lung anatomy. The cadaver lung (see Fig. 1-2A) shows the gross anatomic arrangements and relationships. The main distortion is that the lungs are at low volume. The height of the lungs is only about 18 cm, which is well below FRC height (see Fig. 1-2B). The diaphragm is markedly elevated in Figure 1-2A, probably about 5 cm relative to its end-expiratory position in life. Another distortion is the abnormally wide pleural space. But that fixation shrinkage artifact serves as a useful reminder that the lung is not normally attached to the chest wall. In life, the separation between the parietal and the visceral pleuras is only several micrometers.[1,2] The chest radiograph (see Fig. 1-2B) shows that the height of the lung at FRC is approximately 24 cm, with the level of the bifurcation of the pulmonary artery about halfway up the lungs. The diaphragm is lower and flatter than in the cadaver. Conversely, the radiographic detail is only a shadow of dense structures.

In life, the lungs weigh 900 to 1000 g, of which nearly 40% to 50% is blood.[3,4] At end-expiration, the gas volume is about 2.5 L, whereas at maximal inspiration it may be 6 L. Thus, overall lung density varies from 0.30 g/mL at FRC to 0.14 g/mL at total lung capacity (TLC). But the density of the lung is not distributed uniformly, being about 1 g/mL near the hilum and 0.1 g/mL peripherally. If one likens each lung to a half cylinder, more than 50% of all the lung's alveoli are located in the outer 30% of the lung radius (hilum to chest wall). This is why the peripheral portion of the lung appears relatively empty in the chest radiograph (see Fig. 1-2). Variability in density also exists from top to bottom. In Figure 1-2, the blood vessels are more distended in the lower lung fields. The increasing distention of vessels from apex to base also illustrates the increase in vascular distending pressures at the rate of 1 cm H_2O/cm height down the lung.

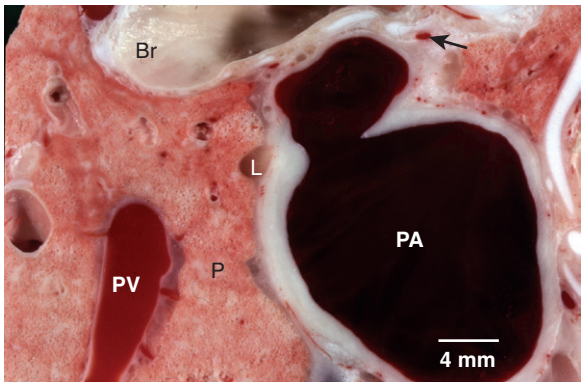

FIGURE 1-1 ■ Frozen block of lung tissue. Air is brought into the lung via the bronchus (Br). Pulmonary arterial (PA) blood is dark purple because it is poorly oxygenated. Gas exchange across the lung's parenchyma (P) results in oxygenated pulmonary venous (PV) blood, which is crimson. Also present in the peribronchovascular connective tissue are bronchial arteries (*arrow*) and lymphatics (L). (Frozen sheep lung, unstained.)

TABLE 1-1. Components of Normal Human Lung

Component	Volume or Mass (mL)	Thickness (μm)	Reference No.
Gas	2400		7
Tissue	900		3, 4
Blood	400		4
Lung	500		8
Support structures	250		5
Alveolar walls	250–300		5, 6
Epithelium	60–80	0.18	5, 6
Endothelium	50–70	0.10	5, 6
Interstitium	100–185	0.22	5, 6
Alveolar macrophages	55		6

The disposition of the various tissues that compose the lung is summarized in Table 1-1. An amazing point is how little tissue is involved in the architecture of the alveolar walls.[5,6] But this is as it should be, because the major physical problem of gas exchange is the slowness of oxygen diffusion through water.[7,8] Thus, the alveolar walls must be extremely thin. In fact, the thickness of the red blood cell forms a substantial portion of the air-blood diffusion pathway. Advantage was taken of this fact to separate the carbon monoxide diffusing capacity measurement into two components: the capillary blood volume and the membrane diffusing capacity.[9] (For a discussion of diffusing capacity, see Chapters 4 and 24.)

The lung has two well-defined interstitial connective tissue compartments arranged in series, as described by Hayek[10] (Fig. 1-3). These are the parenchymal (alveolar wall) interstitium and the loose binding (extra-alveolar) connective tissue (peribronchovascular sheaths, interlobular septa, and visceral pleura). The connective tissue fibrils (collagen, elastin, and reticulin) form a

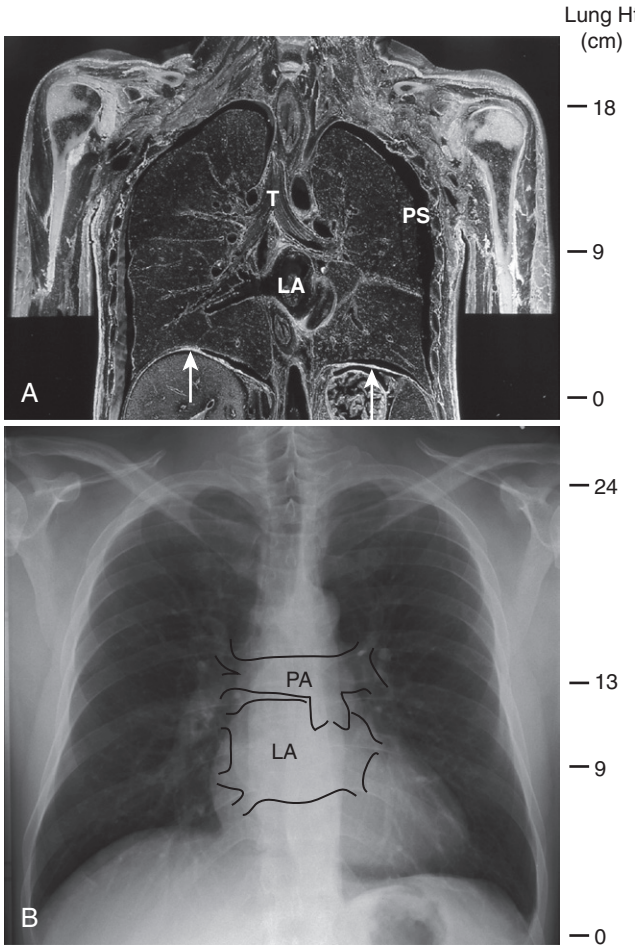

FIGURE 1-2 ■ Comparison views of lung position in the chest and relationship to the heart. **A,** Midfrontal section through the thorax of a frozen cadaver of a 35-year-old human. The cadaver was prepared by routine embalming procedures, stored horizontally for 3 months in 30% alcohol, and frozen in the horizontal position for 1 week at –20°C. Frontal sections were cut with a band saw. Because the cadaver was preserved in the horizontal position, the weight of the abdominal organs compressed the contents of the thoracic cavity. The domes of the diaphragm (*arrows*) are elevated about 5 cm relative to their end-expiratory position in life. Pleural space (PS) width is artifactually enlarged; normally in life, it is several micrometers in width. The trachea (T) is flanked on its left by the aortic arch and on its right by the azygos vein. The left pulmonary artery lies on the superior aspect of the left mainstem bronchus. Pulmonary veins from the right lung enter the left atrium (LA), which is located about 7 cm above the lung's base. These structures at the root of the lungs caused the esophagus to be cut twice as it follows a curved path behind them to reach the stomach. **B**, Chest roentgenogram of a normal human adult taken in the upright position at functional residual capacity. The lung height (cm) was measured from the costodiaphragmatic angle to the tubercle of the 1st rib. The main pulmonary artery (PA) and left atrium (LA) are outlined. The vascular structures, especially the pulmonary veins, are more easily seen near the base of the lung. This is partly because vascular distending pressures are greater near the bottom. The density of the lung is also graded, being higher at the bottom than the top and higher near the hilum than peripherally. (**A,** Reprinted with permission from Koritké JG, Sick H: Atlas of Sectional Human Anatomy. Vol 1: Head, Neck, Thorax. Baltimore: Urban and Schwarzenberg, 1983, p 83.)

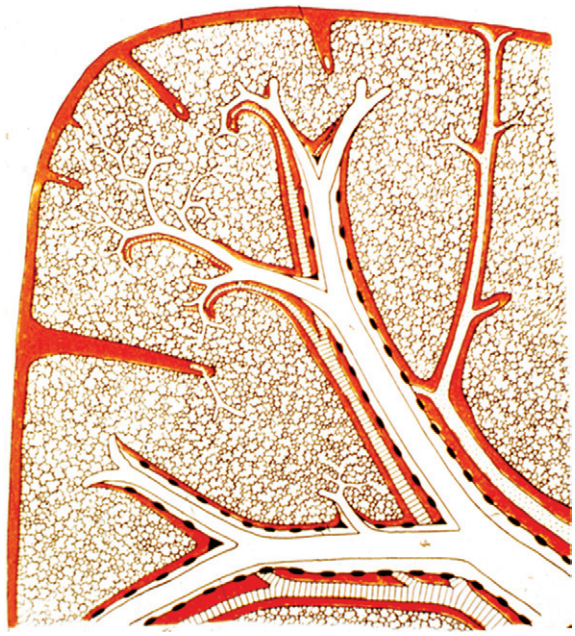

FIGURE 1-3 ■ General plan depicts the interstitial connective tissue compartments of the lung. All of the support structures (airways, blood vessels, interlobular septa, visceral pleura) are subsumed under the loose binding connective tissue. The alveolar walls' interstitium comprises the parenchymal interstitium. This organizational plan of the lung follows the general organization of all organs. (Reproduced with permission from Hayek H: The Human Lung. New York: Hafner, 1960, pp 298–314.)

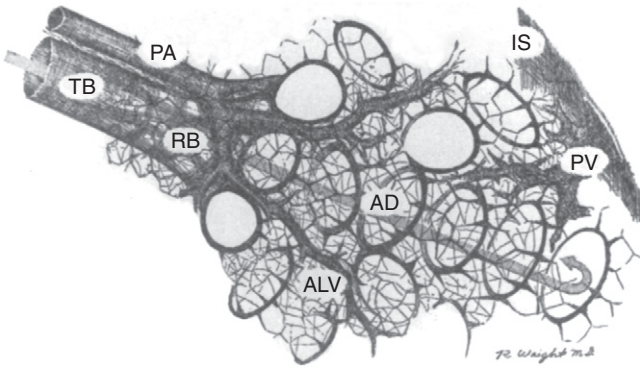

FIGURE 1-4 ■ A drawing of the connective tissue support of the normal human adult lung lobule demonstrates the exchange of fibers composing the "elastic continuum." AD, alveolar duct; ALV, alveolus; IS, interstitial space; PA, pulmonary artery; PV, pulmonary vein; RB, respiratory bronchiole; TB, terminal bronchiole. (Reprinted with permission from Wright RR: Elastic tissue of normal and emphysematous lungs. Am J Pathol 39:355–363, 1961.)

three-dimensional basket-like structure around the alveolar and airways (Fig. 1-4).[11] This basket-like arrangement allows the lung to expand in all directions without developing excessive tissue recoil. Because the connective tissue fibrils in the parenchymal interstitium are extensions of the coarser fibers in the loose-binding connective tissue, stresses imposed at the alveolar wall level during lung inflation are transmitted not only to adjacent alveoli, which abut each other, but also to surrounding

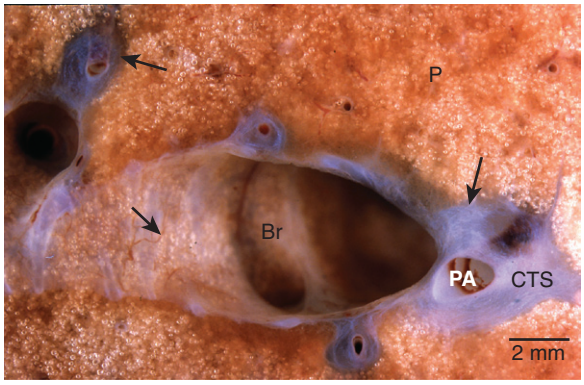

FIGURE 1-5 ■ Interstitial pulmonary edema cuffs (*arrows*) demonstrate the loose-binding (peribronchovascular) connective tissue spaces (CTS) that surround the bronchi (Br), pulmonary arteries (PA), and bronchial blood vessels (*arrowhead*). (Frozen sheep lung, unstained.)

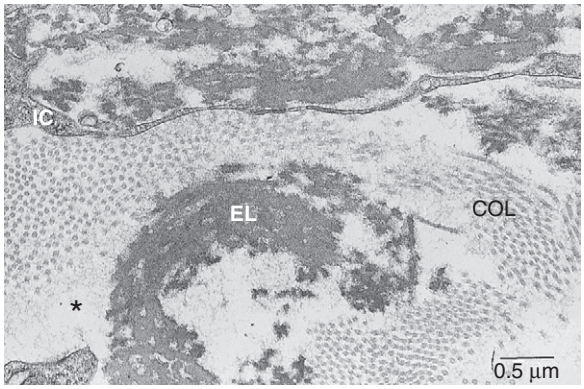

FIGURE 1-6 ■ The connective tissue compartment of the lung contains interstitial cells (IC), fibrils of collagen (COL), and elastin (EL). The bulk of the interstitium, however, is occupied by matrix constituents (*) such as glycosaminoglycans. (Human lung surgical specimen, transmission electron microscopy.)

alveolar ducts and bronchioles, and then to the loose-binding connective tissue supporting the whole lobule, and ultimately to the visceral pleural surface (see Fig. 1-3). These relations become more apparent in certain pathologic conditions. For example, in interstitial emphysema,[12] air enters the loose-binding connective tissue and dissects along the peribronchovascular sheaths to the hilum and along the lobular septa to the visceral pleura. The same separation occurs in pulmonary edema (Fig. 1-5).[13] (Further information about the pathophysiology of acute respiratory distress syndrome is presented in Chapter 90.)

The bulk of the interstitium is not the several varieties of interstitial cells (contractile and noncontractile interstitial cells,[14,15] mast cells, plasma cells, and occasional leukocytes) that reside in the connective tissue spaces of the lung. Nor is the bulk formed by laminin, collagens, elastin and reticulin fibrils, fibronectin, and tenascin (Fig. 1-6). Rather, the bulk of the interstitium is occupied by a matrix of proteoglycans (see Fig. 1-6).[16,17] Proteoglycans constitute a complex group of gigantic polysaccharide molecules (~30 different core proteins, with great diversity of glycosaminoglycan side chains) whose

entanglements impart a gel-like structure to the interstitium. That structural role, although essential, is not the sole role of these important molecules. A growing view is emerging of the lung's extracellular matrix components as regulators of lung physiology, such as determining epithelial cell phenotype; binding of and subsequent signaling by cytokines, chemokines, and growth factors; cell proliferation; migration; differentiation; and apoptosis.[18–25] In disease states, degradation products of extracellular matrix components may activate the Toll-like receptor pathways; thus, the degradation products may serve as endogenous sentinels of tissue damage and initiators of innate immune responses.[20,24–26] (Toll-like receptors are discussed further in the next section.)

AIRWAYS

The airways, forming the connection between the outside world and the terminal respiratory units, are of central importance to our understanding of lung function in health and disease. Intrapulmonary airways are divided into three major groups: bronchi (Fig. 1-7), membranous bronchioles (Fig. 1-8) and respiratory bronchioles/gas exchange ducts (Fig. 1-9). Bronchi, by definition, have cartilage in their wall. Respiratory bronchioles serve a dual function as airways and as part of the alveolar volume (gas exchange).

The anatomic dead space, as measured by the single-breath nitrogen dilution technique, measures principally the volume of the extrapulmonary (upper) airways (see Chapter 43) and the intrapulmonary bronchi.[27] The trachea and bronchi are cartilaginous. The membranous bronchioles (noncartilaginous airways of ~1 mm diameter or less), although exceedingly numerous, are short. They consist of about five branching generations and end at the terminal bronchioles. In contrast to the bronchi, the membranous bronchioles are tightly embedded in the connective tissue framework of the lung and therefore enlarge passively as lung volume increases.[28] Histologically, the bronchioles down to and including the terminal bronchioles ought to contribute about 25% to the anatomic dead space. In life, however, they contribute little because of gas phase diffusion and mechanical mixing in the distal airways resulting from the cardiac impulse. By definition, the respiratory bronchioles and alveolar ducts do not contribute to the anatomic dead space. The volume of the respiratory bronchiole-alveolar duct system is approximately one third of the total alveolar volume, and it is into this space that the fresh air ventilation enters during inspiration.

Most airway resistance resides in the upper airways and bronchi. Normally, smooth muscle tone in the large airways maintains partial constriction. Minimal airway diameter in the human lung, about 0.5 mm, is reached

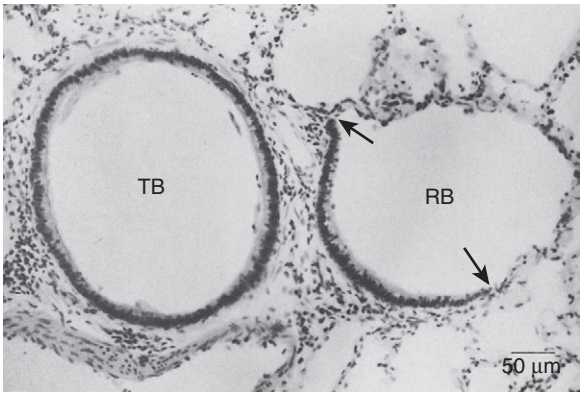

FIGURE 1-8 ■ Cross section of well-distended bronchioles. The wall of the terminal bronchiole (TB) is constructed of ciliated, cuboidal epithelium, thin discontinuous bands of smooth muscle, and submucosal connective tissue. In the respiratory bronchiole (RB), there is an abrupt transition (*arrows*) from cuboidal epithelium to alveolar epithelium. (Human lung surgical specimen, 10-µm-thick paraffin section, light microscopy.)

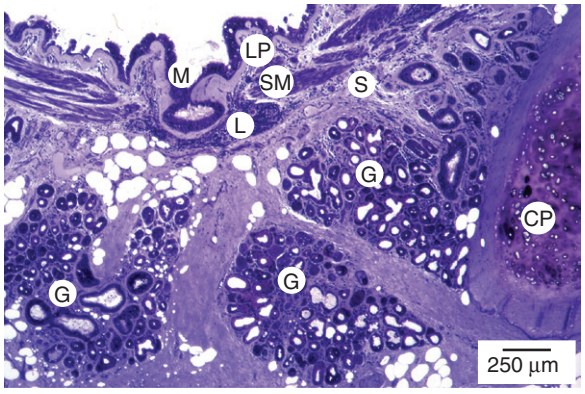

FIGURE 1-7 ■ The bronchial wall is composed of mucosa (M), lamina propria (LP), smooth muscle (SM), and submucosa (S). Seromucous glands (G) are located between the spiral bands of smooth muscle and cartilaginous plates (CP). Diffuse lymphoid tissue (L) has infiltrated the lamina propria and submucosa. (Human lung surgical specimen, right middle lobar bronchus, 2-µm-thick glycol methacrylate section, light microscopy.)

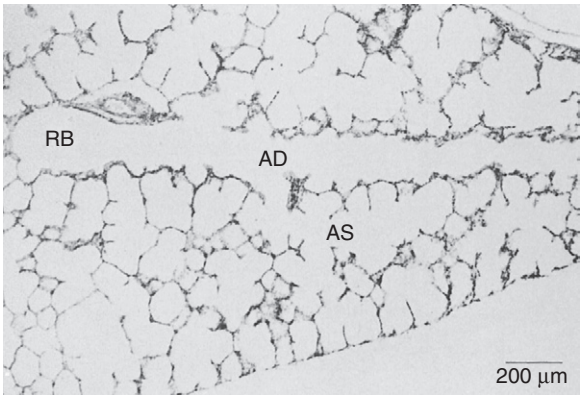

FIGURE 1-9 ■ Longitudinal section of a gas exchange duct shows that its diameter remains relatively constant along the respiratory bronchiole (RB) and alveolar duct (AD). Alveolar sacs (AS) communicate with the gas exchange duct. (Human lung surgical specimen, 10-µm-thick paraffin section, light microscopy.)

at the level of the terminal bronchioles; succeeding generations of exchange ducts (respiratory bronchioles and alveolar ducts) are of constant diameter (see Fig. 1-9).[29,30] The functional significance of centralized resistance is that the terminal respiratory units (the functional alveoli) within a lung subsegment are ventilated chiefly in proportion to their individual distensibilities (compliances) because most of their airway resistance is common. This is demonstrated normally by the finding that regional lung ventilation is dependent upon the initial volumes of the alveoli. Terminal respiratory units toward the top of the lung, which are more expanded at FRC, do not receive as great a share of the inspirate as do the terminal respiratory units near the bottom of the lung.

The balance between anatomic dead space volume, which ought to be as small as possible for efficient alveolar ventilation (dead space–to–tidal volume ratio), and airflow resistance, which means the airway diameter ought to be as large as possible for low work of breathing, requires a compromise. Normally, anatomic dead space is not maximal, nor is resistance minimal.

Cellular Complexity

The cellular complexity of the airways is indicated by the nearly 50 distinct cell types in the lung, at least 12 of which are epithelial cells on the airway surface.[31] Nearly half of the epithelial cells in the normal human airway are ciliated at all airway generations (Fig. 1-10) down to bronchioles (Fig. 1-11).[32] Cilia move the superficial liquid lining layer (see Fig. 1-11) continually toward the pharynx from deep within the lung. As the superficial lining liquid moves centripetally, the summed perimeter of the airways decreases markedly.[5] Mucins float on top of the liquid lining fluid (see Fig. 1-11). When cilia come in contact with mucins, they propel the mucins (together with deposited particulates) mouthward, promoting clearance of the particulates.

The presence of apical junctional complexes between airway epithelial cells (Fig. 1-12) has important functional implications for metabolically regulated secretion and absorption of electrolytes and water from the lining liquid. Apical junctional complexes consist of three elements: *zonula occludens* (tight junction), *zonula adherens*, and *macula adherens* (desmosome).[33] Tight junctions subserve two important functions: restriction of passive diffusion by blocking the lateral intercellular space and polarization of cellular functions (ion and water transport) between the apical and the basolateral membranes.[34] Polarization of chloride and sodium transport allows the airway epithelium to either secrete or absorb ions, followed by water movement.

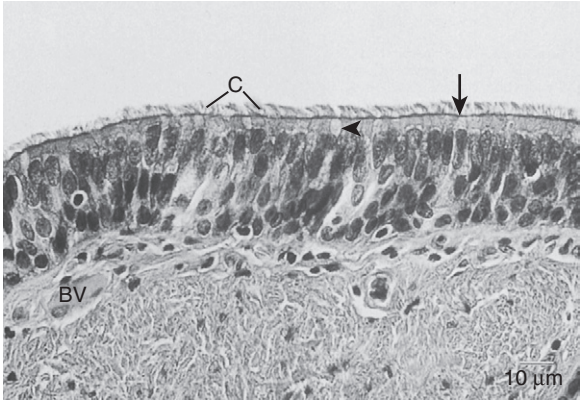

FIGURE 1-10 ■ The bronchial mucosa consists of pseudostratified, columnar epithelium with cilia (C) and goblet cells (*arrowhead*). The cilia, which form a thick carpet, move rhythmically and thereby propel liquid, mucus, cells, and debris centrally toward the pharynx. The dark band immediately beneath the cilia (*arrow*) is produced by the basal bodies. Under the electron microscope, basal bodies are recognized as modified centrioles (see Fig. 1-12). A bronchial blood vessel (BV) is located just beneath the mucosal layer. (Human lung surgical specimen, 10-µm-thick paraffin section, light microscopy.)

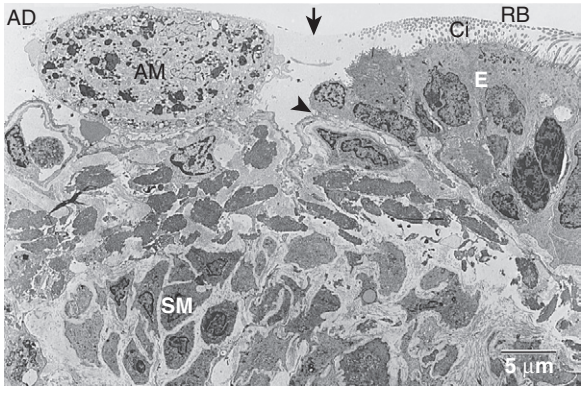

FIGURE 1-11 ■ The respiratory bronchiole (RB)-alveolar duct (AD) junction is demarcated by an abrupt transition (*arrowhead*) from low cuboidal epithelial cells (E) with cilia to squamous epithelial cells. Submerged in the lining liquid (*arrow*) are an alveolar macrophage (AM) and cilia (Ci). Airway smooth muscle cells (SM) extend to this level of the airway tree. (Human lung surgical specimen, transmission electron microscopy).

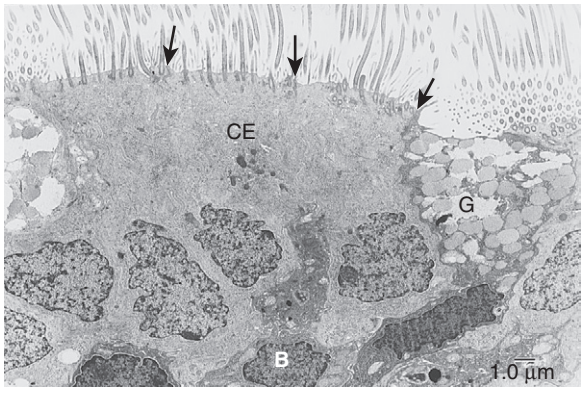

FIGURE 1-12 ■ Cells composing the bronchial epithelium are ciliated epithelial cells (CE), goblet cells (G), and basal cells (B). Goblet cells have abundant mucous granules in the cytoplasm and their apical surface is devoid of cilia. Basal cells, as their name indicates, are located along the abluminal portion of the lining epithelium, adjacent to the basal lamina. The *arrows* at the apical surface of the airway cells indicate the location of junctional complexes between contiguous epithelial cells. (Human lung surgical specimen, transmission electron microscopy.)

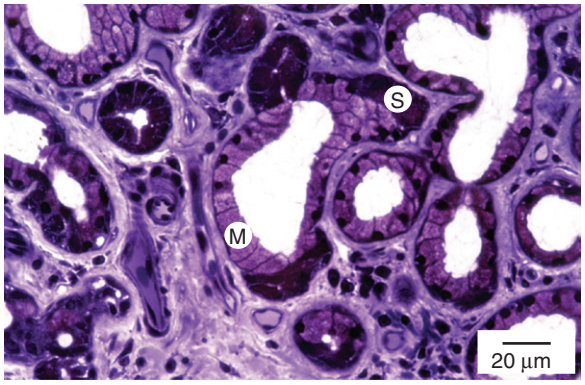

FIGURE 1-13 ■ High-power view shows the submucosal glands illustrated in Figure 1-7. These mixed, compound tubuloacinar glands contain mucus-secreting cells (M) and serous-secreting cells (S). The latter type form crescentic caps, or demilunes, over the ends of the acini. Mucous cells are the predominant glandular cell type.

TABLE 1-2. Airway Epithelial Cell and Glandular Epithelial Cell Products

MUCINS
MUC5AC
MUC5B
MUC7
RECEPTORS
TLRs (such as TLR1, 2, 3, 5, 6)
CHANNELS, TRANSPORTERS
CFTR
Connexins 26, 32, 40, 43
eNOS, iNOS
K^+ channels
Na^+ channels
Cl^- channels
Annexins
Muc 1
CC10 (Clara cells)
GLANDS
Neurotransmitters (e.g., cholinergic, adrenergic, peptidergic)
Inflammatory mediators (e.g., histamine, platelet-activating factor, eicosanoids)

CFTR, cystic fibrosis transmembrane regulator; eNOS, endothelial nitric oxide synthase; iNOS, inducible nitric oxide synthase; TLR, Toll-like receptors.

Trapping of foreign material, such as particulates or bacteria, is accomplished by mucins. Mucins are complex glycoproteins that form gels, exemplified by MUC5A. MUC5A is present in the lung of humans.[35,36] Other mucins (e.g., MUC5B, MUC7)[37,38] become expressed by airway epithelial cells in diseases, such a cystic fibrosis. In that disease, MUC5B is produced by airway epithelial cells.[39] Normally, MUC5B is produced by airway glandular cells[37] but its cell source is expanded in a variety of pulmonary diseases.

Glands are limited to the submucosa of the bronchi. Airway glands secrete water, electrolytes, and mucins into the lumen (Fig. 1-13; see also Fig. 1-7; Table 1-2). Studies of regulation of secretion in vivo and by explant culture systems in vitro have shown that release can be modulated by neurotransmitters, including cholinergic, adrenergic, and peptidergic transmitters,[40,41] and by inflammatory mediators such as histamine,[42] platelet-activating factor,[43] and eicosanoids.[44] Goblet cells, which are mucin-secreting epithelial cells, also are present at most airway levels (see Fig. 1-12). Goblet cells normally decrease in number peripherally and disappear at terminal bronchioles.[10,45] The disappearance of airway glands and goblet cells upstream of ciliated epithelial cells makes sense because that arrangement should minimize backflow of mucus into alveolar ducts and alveoli. Excessive mucin production results in airway obstruction by mucous plugs, especially in small airways. Mucin regulation is discussed in Chapter 11.

Lymphocytes are frequently seen intercalated between airway epithelial cells (Fig. 1-14; see also Fig. 1-10). These cytotoxic T lymphocytes undergo immunoglobulin A (IgA) class antibody responses.[46] T and B lymphocytes also accumulate in the lamina propria beneath the airway epithelium.[47]

Although most of inhaled foreign material and immunologic stimuli are carried up the airways by mucociliary action, some are cleared by the lymphatics (discussed at the end of this chapter). In addition, lymphoid tissue is located in the lungs. Patches are distributed along the tracheobronchial tree (see Fig. 1-7) and, to a lesser extent, along the blood vessels.[48,49] These patches apparently develop in response to antigenic stimulation because they are not present at birth and germ-free animals have little or no pulmonary lymphoid tissue.[48,49] Lymphocytes in these aggregates are principally B cells that express mainly IgA immunoglobulins.[47] The presence of lymphocytes along the airways provides a reminder that the respiratory system is constantly challenged by air-borne immunologic stimuli. The tracheobronchial lymphoid tissue, including bronchus-associated lymphoid tissue (BALT), appears to provide an important locus for both antibody-mediated and cell-mediated immune responses. Epithelial cells that line the airways and compose the airway glands are also important because of their expression of Toll-like receptors (TLRs; see Table 1-2), whose role is identification of pathogen-associated molecular patterns.[50] Activation of TLRs leads to downstream signaling cascades that are involved in mucin production, leukocyte recruitment, antimicrobial peptide production, wound repair, and vascular formation.[51-55]

Some of the other cells associated with the airways are smooth muscle cells, mast cells, basal cells, and Clara cells. Smooth muscle cells form circular bands around the airway epithelium as far peripherally as the respiratory bronchioles (see Fig. 1-7). Tone in the smooth muscle is altered by the autonomic nervous system and by mediators released from mast cells, inflammatory cells, and neuroendocrine cells. During normal breathing, slight tonic contraction of airway smooth

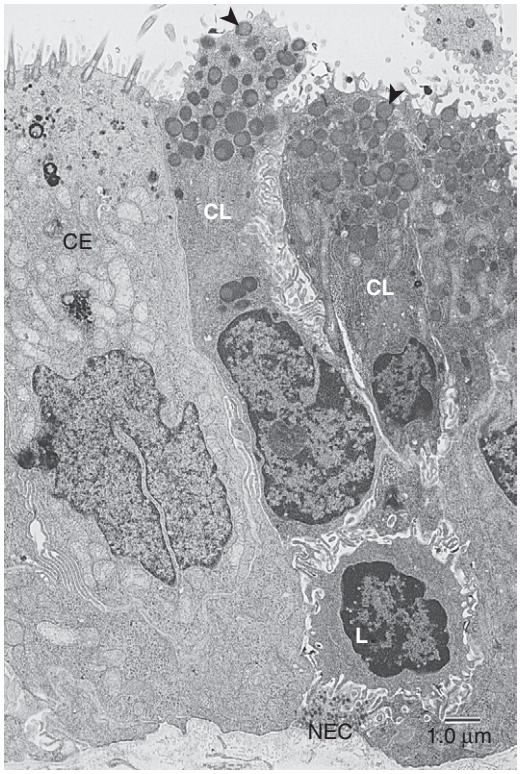

FIGURE 1-14 ■ The terminal airway epithelium consists mainly of ciliated epithelium (CE) and nonciliated, domed Clara cells (CL). Clara cells have the ultrastructural features of secretory cells; namely, they possess basally located rough endoplasmic reticulum, perinuclear Golgi apparatus, apically located smooth endoplasmic reticulum, and prominent membrane-bound granules (*arrowheads*). A lymphocyte (L) is intercalated among the epithelial cells. A small portion of a neuroendocrine cell (NEC) containing characteristic dense-cored vesicles is also visible at the base of the epithelial cells. (Human lung surgical specimen, transmission electron microscopy.)

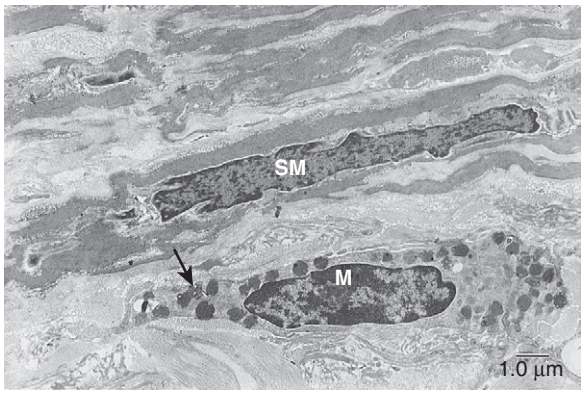

FIGURE 1-15 ■ Mast cell (M) located along an airway. The mast cell is adjacent to the airway smooth muscle cells (SM). Granules in mast cells demonstrate heterogeneous morphology, including whorled and scrolled contents (*arrow*). (Human lung surgical specimen, transmission electron microscopy.)

muscle cells and reflex contraction of the larger airways stiffen them against external compression, as may occur in forced expiration or coughing. The effector of these responses is the parasympathetic limb of the autonomic nervous system (vagus nerves). Excessive vagal stimulation results in severe contraction of airway smooth muscle and increases mucus secretion by submucosal glands, both of which limit airflow through conducting airways by decreasing airway lumen diameter.

Mast cells in the human lung contain membrane-bound secretory granules that are characteristically filled by scrolled, crystalline, or particulate inclusions (Fig. 1-15). These granules contain a host of inflammatory mediators, including histamine, proteoglycans, lysosomal enzymes, and metabolites of arachidonic acid.[56] Not only can these mediators induce bronchoconstriction, they can also stimulate mucous secretion and induce mucosal edema by increasing permeability of bronchial vessels. (For a discussion of specific airway diseases, see Section I, Chapters 38–42 and 44.)

Basal cells are located along the basal lamina of airways (see Fig. 1-12). These small epithelial cells have been classically thought to be precursor cells for other airway epithelial cells.[31,57] However, more recent experiments suggest that columnar secretory cells or Clara cells may also differentiate into ciliated epithelial cells following tissue injury.[58,59]

Clara cells are prominent in the terminal airways. Clara cells, interspersed among the ciliated epithelial cells, are nonciliated and have large apical granules (see Fig. 1-14).[60,61] They have at least four functions in the lung. One function is as progenitor cells for themselves and for ciliated epithelial cells.[62,63] Another function is xenobiotic metabolism that is effected by the cytochrome P-450 mono-oxygenase system.[64–67] A third function is secretion. Clara cells are a source of some of the surfactant apoproteins (SP-A, -B, and -D).[68–70] They also are a source of lipids, proteins (such as Clara cell 10kDa protein), glycoproteins, and modulators of inflammation (such as leukocyte protease inhibitor and trypsin-like protease).[71–73] A fourth function is fluid balance by influencing ion channels.[74,75]

Metabolic substrate is delivered to the trachea (and esophagus), main-stem bronchi and pulmonary vessels into the lung (see Fig. 1-5), as well as to the visceral pleura in humans by the bronchial (systemic) circulation.[45,76,77] Measurements of bronchial blood flow, by microsphere studies in animals, indicate that flow is 0.5% to 1.5% of cardiac output, predominantly to the large airways.[45,76,78–81] The bronchial capillaries form a network in the lamina propria, the submucosa, and external to the cartilage.[82] Venous blood from the trachea and large bronchi enters small bronchial veins, which drain into the azygos or hemiazygos veins. Thus, a substantial part of bronchial blood flow returns to the right side of the heart. Deeper in the lung, however, bronchial blood passes via short anastomotic vessels into the pulmonary venules, thus reaching the left side of the heart to contribute to the venous admixture. (The relationships among the bronchial, pulmonary, and systemic venous circulations are diagrammed in Figure 5-2.)

Bronchial Circulation

The bronchial circulation has enormous growth potential in contrast to the pulmonary circulation, which, after childhood, is unresponsive. In long-standing inflammatory and proliferative diseases, such as bronchiectasis or carcinoma, bronchial blood flow may be greatly increased.[76,83] Scar tissue and tumors larger than 1 mm in diameter receive their blood supply via the bronchial circulation.[84,85] The bronchial circulation is also the primary source of new vessels for repair of tissue after lung injury.

PULMONARY CIRCULATION

In humans, the pulmonary arterial circulation enters each lung at the hilum in a loose connective tissue sheath adjacent to the main bronchus (see Fig. 1-1). The pulmonary artery travels adjacent to and branches with each airway generation down to the level of the respiratory bronchiole (Fig. 1-16). The anatomic arrangements of the pulmonary arteries and the airways are a continual reminder of the relationship between perfusion and ventilation that determines the efficiency of normal lung function. Although the pulmonary veins also lie in loose connective tissue sheaths adjacent to the main-stem bronchus and pulmonary artery at the hilum, once inside the lung, they follow Miller's dictum that the veins will generally be found as far away from the airways as possible.[45] Peripherally, in the respiratory tissue, the pulmonary arteries branch out from the core of the terminal respiratory unit, whereas the veins occupy the surrounding connective tissue envelope (Fig. 1-17). Each small muscular pulmonary artery supplies a specific volume of respiratory tissue, whereas the veins drain portions of several such zones.

Considerable quantitative data about the pulmonary circulation are available for the human lung (Table 1-3).[86–88] Although most of the intrapulmonary blood volume is in the larger vessels down to approximately 500 μm diameter, nearly all of the surface area is in the smaller vessels. For example, the surface area of arterioles 20 to 500 μm diameter exceeds that of the larger vessels by a factor of two, and the maximal capillary surface area is 20 times that of all other vessels.

Because the vertical height of the lung at FRC is about 24 cm (see Fig. 1-2), the pressure within the pulmonary blood vessels varies by approximately 24 cm H_2O over the full height of the lung. Thus, if pulmonary arterial pressure is taken as 20 cm H_2O (15 mm Hg, 1.9 kPA)* at the level of the main pulmonary artery, which is about

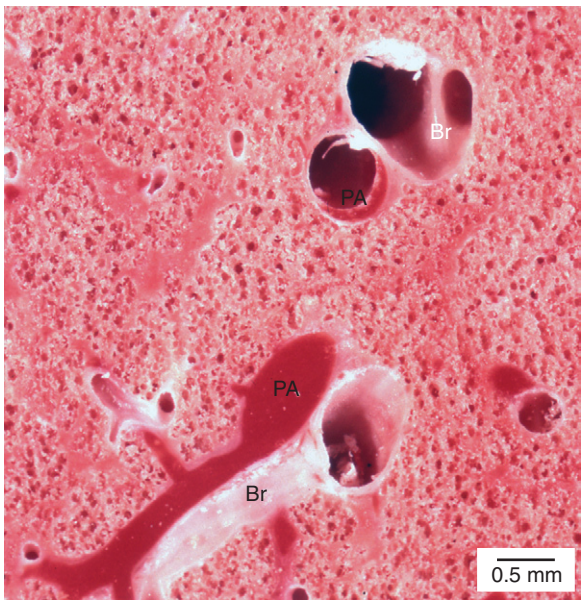

FIGURE 1-16 ■ Divisions of the pulmonary artery (PA) travel beside the bronchi (Br) out to the respiratory bronchioles. Thus, at all airway generations, there is an intimate relationship with the pulmonary arterial system. Note that the loose-binding (peribronchovascular) connective tissue sheaths are not distended, compared with the interstitial edema cuffs in Figure 1-5. (Frozen normal sheep lung, unstained.)

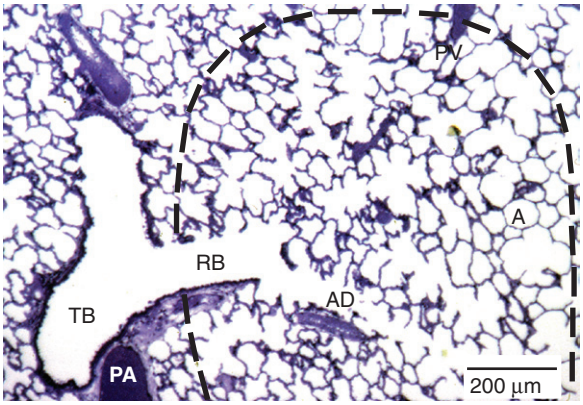

FIGURE 1-17 ■ The terminal respiratory unit (the physiologist's alveolus) consists of the alveoli (A) and alveolar ducts (AD) arising from a respiratory bronchiole (RB). Each unit is roughly spherical, as suggested by the *dashed outline*. Pulmonary venous vessels (PV) are peripherally located. TB identifies a terminal bronchiole. PA identifies a pulmonary artery. (Normal sheep lung, somewhat underinflated, 2-μm-thick glycol methacrylate section, light microscopy.)

TABLE 1-3. Quantitative Data on Intrapulmonary Blood Vessels in Humans

Vessel Class (with diameter)	Volume (mL)	Surface Area (m^2)	Reference No.
Arteries (>500 μm)	68	0.4	59
Arterioles (13–500 μm)	18	1.0	59
Capillaries (10 μm)	60–200	50–70	60
Venules (13–500 μm)	13	1.2	61
Veins (>500 μm)	58	0.1	61

*To convert from kPA to cm H_2O, multiply by 10.3; to mm Hg, multiply by 7.5.

halfway up the height of the lung, pressure in the pulmonary arteries near the top of the lung will be about 12 cm H_2O, whereas pressure in pulmonary arteries near the bottom will be about 36 cm H_2O. Pulmonary venous pressure, which is about 8 cm H_2O at the level of the pulmonary artery in midchest (left atrial pressure), would be −4 cm H_2O near the top of the lung and +20 cm H_2O at the bottom. In the normal lung, the blood volume is greater at the bottom because of increased luminal pressure, which expands those vessels and increases their volume. This effect of distention also decreases the contribution of the blood vessels at the bottom of the lung to total pulmonary vascular resistance.

Postnatally, the normal pulmonary circulation is a low-resistance circuit. The resistance is distributed somewhat differently, however, than in the systemic circulation. Although the pressure drop along the pulmonary capillaries is only a few centimeters of water (similar to the pressure drop in systemic capillaries), the pulmonary arterial and venous resistances are low, so a relatively larger fraction of the total pulmonary vascular resistance (35%–45%) resides in the alveolar capillaries at FRC.[89,90] (For further information about the pathophysiology of pulmonary circulation, see Chapter 4.)

Vasoactivity plays an important part in the local regulation of blood flow in relation to ventilation.[91,92] Because smooth muscle can be found in the pulmonary vessels on both the arterial and the venous side including pre- and postcapillary vessels,[93,94] any segment can contribute to active vasomotion.[95] In pathologic conditions, extension of vascular smooth muscle down to the capillary level may occur.[96,97]

Theoretically, gas exchange may occur through the thin wall of almost any pulmonary vessel. At normal alveolar oxygen tensions, however, little oxygen and carbon dioxide exchange occurs before the true capillaries.[98] Because of their small volume (see Table 1-3), pulmonary arterioles have rapid linear velocity of blood flow. As blood enters the vast alveolar wall capillary network, its velocity slows, averaging about 1000 μm/sec. Flow in the microcirculation is pulsatile because of the low arterial resistance.[99] Pulsations reach the microvascular bed from both the arterial and the venous sides. One sign of severe pulmonary hypertension is the disappearance of capillary pulsations.[100]

The capillary network is long and crosses several alveoli (Figs. 1-18 and 1-19) of the terminal respiratory unit before coalescing into venules. The vast extent of the capillary bed together with the length of the individual paths results in a reasonable transit time for red blood cells, during which gas exchange can occur. The anatomic estimate of approximately 0.5 to 1 second average transit time is essentially the same as that found by the carbon monoxide diffusing capacity method, in which one divides capillary blood volume by cardiac output to obtain mean capillary transit time.[101] In the normal lung, there is sufficient time for equilibrium between the oxygen and the carbon dioxide tensions in the alveoli and the erythrocytes in the pulmonary capillaries. Only under extreme stress (heavy exercise at low inspired oxygen tensions) or in severe restrictive lung disease are red blood cells predicted to pass through the microcirculation too fast too reach diffusion equilibrium.[102]

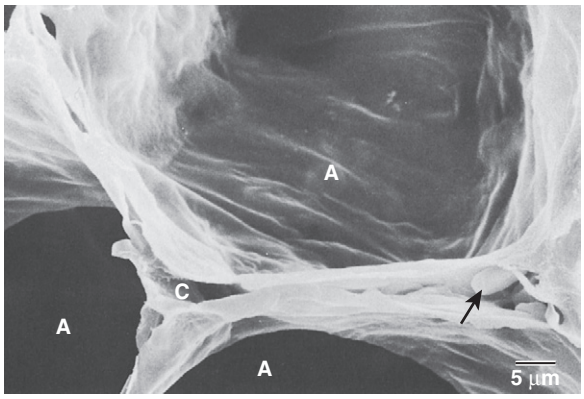

FIGURE 1-18 ■ An alveolar capillary (C) is split longitudinally along its path across three alveoli (A). The alveolar walls are flattened and the wall junctions are sharply curved because the lung is fixed in zone I conditions. Some red blood cells remain in the capillary at an alveolar corner (*arrow*). (Perfusion-fixed normal rat lung, P_{AW} = 30 cm H_2O; P_{PA} = 25 cm H_2O; P_{LA} = 6 cm H_2O; scanning electron microscopy.)

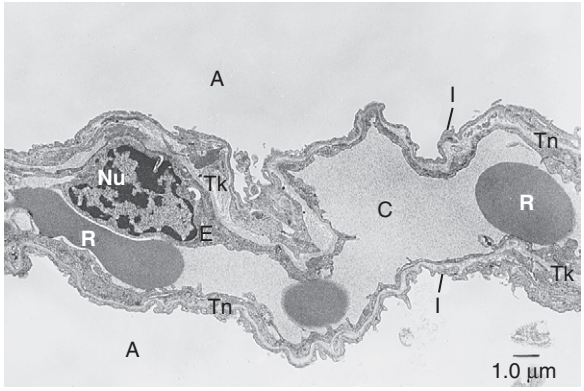

FIGURE 1-19 ■ The thick (Tk) and thin (Tn) sides of an alveolar capillary (C) change as the capillary crosses between alveoli (A). The basal laminae of the capillary endothelium and alveolar epithelium fuse in the thin regions. The nucleus (Nu) of an endothelial cell (E) is visible above a red blood cell (R). I, type I pneumonocyte. (Human lung surgical specimen, transmission electron microscopy.)

Normally, capillary blood volume is equal to or greater than stroke volume. Under normal resting conditions, the volume of blood in the pulmonary capillaries is well below its maximal capacity, however. Recruitment can increase this volume by a factor of about three. Thus, the normal capillary blood volume of 60 to 75 mL is one third of its capacity (200 mL) measured by quantitative histology.[5]

Anatomically, the pulmonary blood vessels can be divided into two groups in a manner similar to the connective tissue compartments. The vessels lying in the loose-binding connective tissue (peribronchovascular sheaths, interlobular septa) are extra-alveolar. Extra-alveolar vessels extend into the terminal respiratory units. Arteries as small as 100 μm in diameter have loose connective tissue sheaths. This is in contrast to the

bronchioles, which are tightly embedded in the lung framework from the membranous bronchioles (1 mm diameter) onward.

The blood vessels within the alveolar walls are embedded in the parenchymal connective tissue and are subject to whatever forces operate at the alveolar level. They are referred to as alveolar vessels in the sense that the effective hydrostatic pressure external to them is alveolar pressure. Not all of the alveolar vessels are capillaries, however. Small arterioles and venules, which bulge into the air spaces, may be affected by changes in alveolar pressure. Likewise, not all of the capillary bed is alveolar under all conditions.[103] The corner capillaries in the alveolar wall junctions are protected from the full effects of alveolar pressure by the curvature and alveolar air-liquid surface tension.[104] This may account for the fact that some blood flow through the lung occurs even under zone 1 condition, in which alveolar pressure exceeds both arterial and venous pressure.[105] One has to go several centimeters up into zone 1 to stop blood flow completely. (For a discussion of distribution of pulmonary blood flow and lung zones, see Chapter 4.)

An important question is whether the normal human lung contains connections between the pulmonary arteries and veins that permit some portion of pulmonary blood flow to bypass the capillary network. Such vessels may occur as congenital or pathologic developments.[106] In the normal lung, however, functioning short circuits probably do not exist. (Pathologic arteriovenous communications are discussed in Chapter 54.)

Pulmonary capillaries are lined by continuous (nonfenestrated) endothelial cells (see Fig. 1-19). These attenuated cells have an individual area of 1000 to 3000 μm^2 and an average volume of 600 μm^3.[107] These large, flat cells cover a surface area of about 130 m^2.[107] Other structural features of pulmonary capillary endothelial cells are the large number of plasmalemmal vesicles and small number of organelles (see Fig. 1-19). Despite having relatively few organelles, pulmonary capillary endothelial cells do have organelles involved in protein synthesis, such as endoplasmic reticulum, ribosomes and Golgi apparatus, and endocytosis (caveoli, multivesicular bodies, and lysosomes).[108] The endocytic apparatus appears to participate in receptor-mediated uptake and transport (transcytosis) of albumin, low density lipoproteins and thyroxin.[109–113] Another route for passage of solutes and water is between adjacent endothelial cells (transcellular transport). However, that passage route is restricted by specialized junctional complexes called tight junctions.[114,115]

Pulmonary Vascular Endothelial Cells

Specialized attributes of the pulmonary circulation's endothelial cells are the remarkable number of metabolic activities (Table 1-4). This is not to say that endothelial cells in other organs do not have similar activities. But the central position of the lung, through which the entire cardiac output passes, places extra responsibility and extra importance upon its endothelial cells.[116–118] For example, angiotensin I, bradykinin, and prostaglandin E_1 are almost completely inactivated in a single passage through the lungs. Pulmonary endothelial cells also express at least two subtypes of endothelin receptors (A and C).[119–121] Their expression coincides with rapid removal of endothelin, suggesting that the lung microcirculation participates in clearance of a potent vasoconstrictor peptide from the blood. Conversely, a potent vasodilator, nitric oxide, is generated locally in the lung, through expression of endothelial nitric oxide synthase.[122–128] A structural indication of a role for endothelial cells in regulation of vascular tone and reactivity is direct contacts between pulmonary endothelial cells in small arteries and veins and the surrounding smooth muscle cells. Such myoendothelial contacts had been described in the lungs of a number of small animals.[129–132] We have seen them in the human lung (Fig. 1-20). Although their functional importance is unknown, they may have some bearing on endothelial-dependent vasoactivity.[133]

In addition to gas exchange, the pulmonary circulation is involved in a number of other functions important to homeostasis. The pulmonary vascular bed serves as a capacitance reservoir between the right and the left sides of the heart. Sufficient blood resides in the pulmonary circulation to buffer changes in right ventricular output for two to three heartbeats. The lung is also a blood filter. The lung is likely to be frequently embolized by material from systemic vascular beds. For example, during intravascular coagulation or in processes involving platelet or neutrophil aggregation, the predominant site of sequestration is the lung. The main anatomic reason for this is that 75% of the total circulating blood

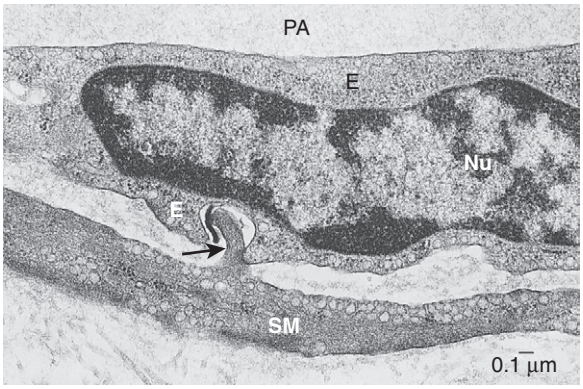

FIGURE 1-20 ■ A myoendothelial cell contact (*arrow*) is made between a pulmonary arteriolar (PA) endothelial cell (E) and a subjacent vascular smooth muscle cell (SM). The distribution and functional significance of such contacts is unknown. One potential role may be to facilitate delivery of endothelium-derived relaxing factor (EDRF) to smooth muscle cells. Nu, nucleus of the endothelial cell. (Human lung surgical specimen, transmission electron microscopy.)

volume is in the venous circuit, and the lung's microvascular bed is the first set of small vessels through which the venous blood flows. Moderate numbers of microemboli generally produce no detectable dysfunction because of the huge array of parallel pathways in the microcirculation. At most, microemboli temporarily block flow to a portion of or to an entire terminal respiratory unit. The fate of such emboli is not clear. Some are phagocytosed and removed into the lung tissue.[134] Some emboli can be degraded to small size, pass through into the systemic circulation, and be removed by the reticuloendothelial system. One example is the macroaggregated serum albumin used in lung-scanning procedures. (Further information about the pathophysiology of thromboembolic disorders is presented in Chapter 51.)

Endothelial cell phenotype in the lung is heterogeneous, with phenotypes that are site-specific. (reviewed by Garlanda and Dejana[135] and Gebb and Stevens[136]). A morphologic example of heterogeneity is the difference in lectin staining in the lung.[137] *Helix pomatia* binds to endothelial cells in pulmonary arteries, whereas *Griffonia simplicifolia* or *Glycine max* binds to endothelial cells in pulmonary microvessels in the rat lung. A functional example is endothelial nitric oxide protein localization, which is more evident in small pulmonary arterial vessels than in capillaries.[122–127] Presumably, the more evident localization reflects the functional role of nitric oxide in regulating pulmonary artery smooth muscle tone. Conversely, capillary endothelial cells appear to have more expression-activated leukocyte adhesion molecule message than arterial endothelial cells.[135,136] Greater expression by capillary endothelial cells may contribute to sequestration of leukocytes in the capillary bed during acute inflammatory reactions. Another endothelial cell function that is site-specific in the lung is Ca^{2+} transients that are induced by pressure elevations as little as 5 cm H_2O. The calcium transients occur in endothelial cells of pulmonary venular capillaries.[138] Moreover, Ca^{2+} oscillations occurred in a subset of endothelial cells. The oscillations are propagated to adjacent endothelial cells. Thus, the subset of Ca^{2+} oscillating cells are referred to as "pacemakers." Those findings indicate the presence of a sensitive endothelial response to pressure challenge in lung venular capillaries. The endothelial response may be relevant in the pathogenesis of pressure-induced lung microvascular injury.

TERMINAL RESPIRATORY UNITS

The "alveolus" of which the physician or pulmonary physiologist speaks is not the alveolus of the anatomist but what we have been referring to as the "terminal respiratory unit." The definition of *terminal respiratory unit* is all alveolar ducts, together with their accompanying alveoli, that stem from the most proximal (first) respiratory bronchiole (see Fig. 1-17). The terminal respiratory unit has both a structural and a functional existence and was first described by Hayek.[10] In the human lung, this unit contains approximately 100 alveolar ducts and 2000 alveoli. At FRC, the unit is approximately 5 mm in diameter, with a volume of 0.02 mL. In normal adult humans, there are about 150,000 such units in both lungs combined.[5] The acinus, an anatomic unit popular among pathologists, contains 10 to 12 terminal respiratory units.[139–141]

The functional definition of the terminal respiratory unit is that gas phase diffusion is so rapid that the partial pressures of oxygen and carbon dioxide are uniform throughout the unit. Diffusion is the name for a thermodynamic process by which molecules express their kinetic energy. Net diffusion occurs when there is a concentration difference of a substance between two volumes. Thus, oxygen in the alveolar duct gas will diffuse into the alveoli, because the incoming air has a higher oxygen concentration than the alveolar gas. Oxygen will also diffuse from the gas adjacent to the alveolar wall through the air-blood barrier into the red blood cells flowing in the capillaries (Fig. 1-21), where oxygen combines with hemoglobin. Carbon dioxide diffuses in the opposite direction. A key point in diffusion is that the process is much faster in the gas phase than in water. Thus, the terminal respiratory unit size is defined in part by the fact that gas molecules can diffuse and equilibrate anywhere within the unit more rapidly than they can diffuse through the membrane into the blood. The main problem is that the solubility of oxygen in water is low relative to its concentration in gas. Carbon dioxide is much more soluble in water, so it diffuses rapidly into the gas phase, even though the driving pressure for carbon dioxide diffusion is only one tenth that for oxygen entering the blood.

Demonstrating that diffusion is limiting in the normal lung is almost impossible, except during heavy exercise while breathing gas containing very low oxygen concentrations.[102] Even at that, it is not so much diffusion that is limiting, but the fact that the transit time of the red blood cells is reduced. Most disorders of alveolar-capillary block are really disorders of capillary blood volume and ventilation-perfusion inequalities.[142]

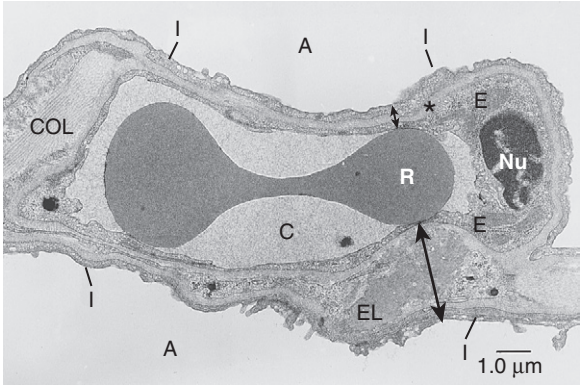

FIGURE 1-21 ■ Cross section of an alveolar wall shows the path for oxygen and carbon dioxide diffusion. The thin side of the alveolar wall barrier (*short double arrow*) consists of type I epithelium (I), interstitium (*) formed by the fused basal laminae of the epithelial and endothelial cells, capillary endothelium (E), plasma in the alveolar capillary (C), and finally, the cytoplasm of the red blood cell (R). The thick side of the gas exchange barrier (*long double arrow*) has an accumulation of elastin (EL), collagen (COL), and matrix that jointly separate the alveolar epithelium from the alveolar capillary endothelium. As long as the red blood cells are flowing, oxygen and carbon dioxide diffusion probably occur across both sides of the air:blood barrier. A, alveolus; Nu, nucleus of the capillary endothelial cell. (Human lung surgical specimen, transmission electron microscopy.)

All portions of the terminal respiratory unit participate in volume changes with breathing.[143,144] Thus, if a unit were to increase its volume from FRC, the alveolar gas that had been in the alveolar duct system would enter the expanding alveoli, together with a small portion of the fresh air. Most of the fresh air would remain in the alveolar duct system. This does not lead to any significant gradient of alveolar oxygen and carbon dioxide partial pressures because diffusion in the gas phase is so rapid that there would be equilibrium within a few milliseconds. But nondiffusible (suspended or particulate matter) would remain away from the alveolar walls and would be expelled in the subsequent expiration.[145] That explains why it is difficult to deposit particulates or aerosols on the alveolar walls and why large inspired volumes and breath-holding are important for obtaining efficient alveolar deposition.

The anatomic alveolus is not spherical. It is a complex geometric structure with flat walls and sharp curvatures at the junctions between adjacent walls (Fig. 1-22A). The most stable configuration is for three alveolar walls to join together, as in foams.[5] The resting volume of an alveolus is reached at minimal volume, which is 10% to 14% of TLC. When alveoli go below their resting volume, they must fold up because their walls have a finite mass

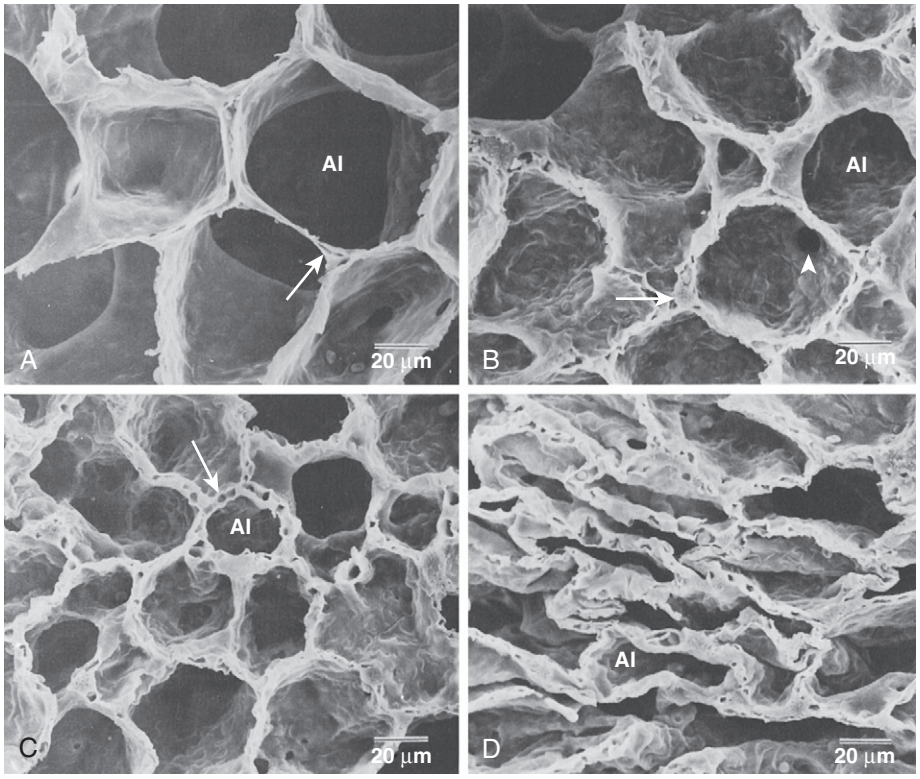

FIGURE 1-22 ■ Alveolar shape changes at representative points along the air deflation pressure-volume curve of the lung. The four micrographs are at the same magnification. The air deflation pressure points are as follows: **A,** 30 cm H_2O (total lung capacity; TLC); **B,** 8 cm H_2O (about 50% TLC); **C,** 4 cm H_2O (near functional residual capacity; FRC); and **D,** 0 cm H_2O (minimal volume). Vascular pressures are constant (P_{PA} = 25 cm H_2O and P_{LA} = 6 cm H_2O). Intrinsic alveolar shape (Al) is maintained from FRC to TLC (**C** through **A**). The alveolar walls are flat, and there is sharp curvature at the junctions between adjacent walls. Note the flat shape of the alveolar capillaries (*arrow*) at TLC (**A,** lung zone 1 conditions) compared with their round shape (*arrow*) at FRC (**C,** lung zone 3 conditions). The alveolar walls are folded and alveolar shape is distorted at minimal lung volume (**D**). The *arrow* in **B** identifies a type II pneumonocyte at an alveolar corner. (Perfusion-fixed normal rat lungs, scanning electron microscopy.)

(see Fig. 1-22D). Most of the work required to inflate the normal lung is expended across the air-liquid interface to overcome surface tension because the liquid-filled lung inflates at low pressure.[146]

The phenomenon of terminal respiratory unit, or alveolar stability, is confused because not only is air-liquid interfacial tension involved, but each flat alveolar wall is part of two alveoli and both must participate in any change. The phenomenon of atelectasis does not usually involve individual alveoli but rather relatively large units.[147]

The alveolar walls are composed predominantly of pulmonary capillaries. In the congested alveolar wall, the blood volume may be more than 75% of the total wall volume. Alveoli near the top of the lung show less filling of the capillaries than those at the bottom.[148,149] This affects regional diffusing capacity, which is dependent on the volume of red cells in the capillaries.

The transition from the cuboidal epithelium of the respiratory bronchiole to alveolar squamous epithelium is abrupt (see Fig. 1-11). Although Macklin[150] speculated that there is something special about the permeability of the bronchiole-alveolar epithelial junctions, no definitive difference has been demonstrated.[151] The controversy continues as to whether this region shows special permeability features.[152–154]

The pleomorphic nature of the alveolar epithelium and the light and electron microscopic structure of its constituent cells have been described many times and are only briefly summarized here. In normal mammals and other air-breathing species, including reptiles and amphibians, the alveolar epithelium is composed of small, cuboidal type II cells and large, flattened type I cells (Fig. 1-23). Type II cells outnumber type I cells (~15% vs. 8%–10% of total peripheral lung cells, respectively) but the type I cell accounts for about 90% to 95% of the alveolar surface area of the peripheral lung.[155] The two cell types have very different functions. In general, type II cells are specialized to be synthetic, secretory, and repair factories, whereas type I cells provide a large, thin cellular barrier specialized for gas exchange. Much more is known about the molecular functions of the type II cell than the type I cell. This is largely due to the availability of methods for isolating rodent and human type II cells in large numbers and high purity, allowing their molecular functions and responses to be studied in vitro.[156,157] Nonetheless, viable type I cells have also been isolated,[158,159] providing an opportunity to characterize their function more thoroughly.

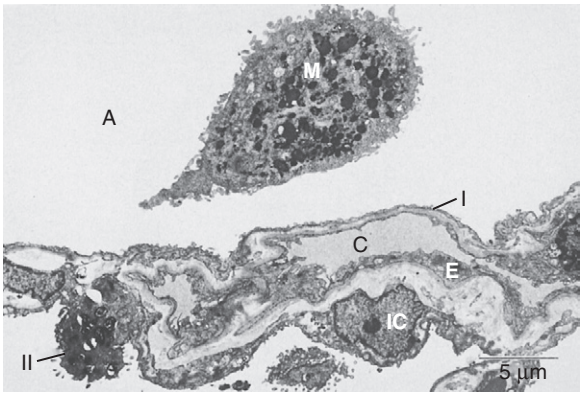

FIGURE 1-23 ■ The cells of the terminal respiratory unit are demonstrated in this micrograph. An alveolar macrophage (M) is located in an alveolus (A). These phagocytic cells are the air space scavengers; they are cleared either up the mucociliary escalator or into the interstitium. These cells can be activated to express and secrete cytokines, which may interact with other cells. Cells of the alveolar wall are the lining type I and II pneumonocytes (I and II, respectively) and the enclosed capillary (C), endothelial cells (E) and interstitial cells (IC). (Human lung surgical specimen, transmission electron microscopy.)

Type II Cell Structure

The typical (e.g., human, rodent) type II cell is a small (300 μm^3), cuboidal cell with short stubby apical microvilli (Fig. 1-24). Under normal conditions, type II cells attach via tight junctions to neighboring type I cells to form a relatively impermeable seal between alveolar air and connective tissue spaces. Although the cells express connexin proteins used to form gap junctions,[160] such junctions have not been consistently observed between type II and type I cells.

The distinguishing feature of a type II cell is its content of intracellular lamellar bodies, membrane-bound inclusions (diameter from <0.1–2.5 µm; mean, ~1 µm) composed of stacked layers of cell membrane–like material (see Fig. 1-24). These granules contain pulmonary surfactant and are composed of phospholipid species similar to those of lavaged surfactant.[161] The granules also contain various proteins, including surfactant proteins (SP) SP-A, SP-B, and SP-C but probably not SP-D, typical lysosomal enzymes, an H^+ transporter, a unique α-glucosidase, and other molecules.[162–164] The limiting membrane of the lamellar body contains an 180-kD ABC-type transporter likely to be involved in lipid transport and membrane movement.[165] Multivesicular bodies, organelles generally involved in endocytosis, are unusually abundant in type II cells, which also express the ABC-transporter membrane protein. Many types of studies indicate that multivesicular bodies are closely related to and participate in formation of lamellar bodies, probably by ferrying phospholipids, proteins, and other materials from synthetic sites within the cell, or after retrieval from alveoli. Kinetic studies suggest, for example, that SP-A in lamellar bodies is derived both directly from the intracellular synthetic pathway and from protein previously secreted by type II cells into alveoli.[166]

Lamellar bodies are secreted by classic mechanisms of calcium-dependent[167] membrane fusion and extrusion of the contents into the alveolar spaces, a process that has frequently been visualized microscopically. Type II cells also internalize and recycle surfactant lipids and proteins, but the cellular pathways are not well characterized in terms of participating organelles, signaling mechanisms, and general molecular regulation. Receptors have been tentatively identified that mediate reentry of surfactant proteins into type II cells, but there is not yet clear agreement about the nature and molecular characteristics of these molecules.

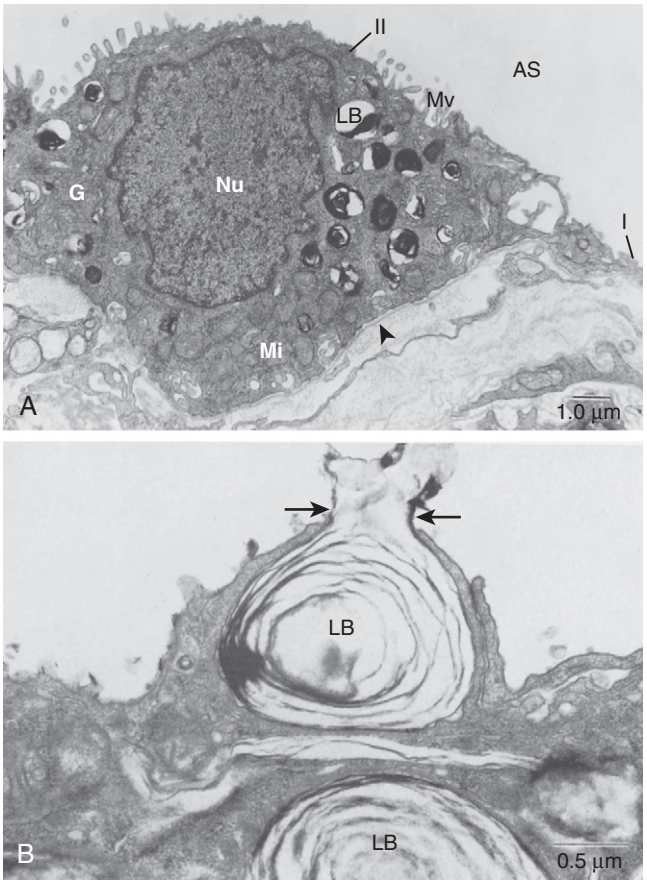

FIGURE 1-24 ■ **A,** Type II (or granular) pneumonocytes (II) are cuboidal epithelial cells that contain characteristic lamellar bodies (LB) in their cytoplasm and have stubby microvilli (Mv) that extend from the apical surface into the alveolar airspace (AS). Other prominent cytoplasmic organelles in type II pneumonocytes are mitochondria (Mi) and Golgi apparatus (G). Adjacent to the type II pneumonocyte is a process of a type I pneumonocyte (I). The abluminal surface of the epithelial cells rests on a continuous basal lamina (*arrowhead*). Nu, nucleus of a type II pneumonocyte. **B,** The apical region of a type II pneumonocyte has two lamellar bodies (LB), one of which has been fixed in the process of secretion by exocytosis (*arrows*). The lamellar osmiophilic bodies are believed to be the source of surface-active material (surfactant). Type II pneumonocytes are usually located in the alveolar corners (see Fig. 1-22B). (Human lung surgical specimen, transmission electron microscopy.)

Type II Cell Functions

The type II cell is the major synthesizing and secreting factory of the alveolar epithelium and implements epithelial repair via its ability to proliferate. The proteins reported to be produced by type II cells in vivo or in vitro are given in Table 1-5, a list that is undoubtedly incomplete. The general types of proteins produced by the type II cell include surfactant-associated proteins that affect surfactant recycling, adsorption of surfactant lipids to an air-liquid interface, and immunomodulatory functions; receptors for several growth factors and secretagogues; growth factors; enzymes; matrix proteins; epithelial mucins; and others. The presence in type II cells of various ion channels and transporters supports earlier evidence that type II cells are actively involved in fluid resorption and transepithelial water fluxes.[168] Type II cells have been reported to express some species of aquaporin (AQP-3, AQP-1),[169,170] water channels that may facilitate transepithelial fluid fluxes.

Some of the aforementioned proteins have been identified only in type II cells maintained in monolayer culture. The molecular behavior of type II cells in culture confounds interpretation of the source of this subgroup of proteins because, when isolated, the cells quickly change from a type II cell phenotype to a type I cell phenotype, as assessed by quantification of the messenger RNAs (mRNAs) of genes specific for either type II or type I cell phenotypes. This change in phenotype is well under way by 24 hours after the cells are isolated and plated and is typified by loss of SP-A, SP-B, and SP-C mRNAs and by induction of type I cell mRNAs, such as T1α, AQP-5, caveolin-1, and carboxypeptidase M.[171–178] Therefore, some of the proteins listed in Table 1-5 may belong in Table 1-6 (type I cell products). Verification of the cellular source of any protein therefore requires direct demonstration of the presence of that protein or its mRNA in cells in the intact lung.

Type II Cell Proliferation

Type II cells can proliferate and generate both new type II and new type I cells. The molecular signals required to initiate type II cell division are beginning to be identified. For example, several growth factors have been shown to trigger type II cell mitosis in vitro and in vivo. These include keratinocyte growth factor (FGF-7) and FGF-1, members of the fibroblast growth factor (FGF) family; hepatocyte growth factor (scatter factor); and heparin-binding epithelial growth factor (HB-EGF).[179–182] Type II cells therefore must express FGF receptors (R), of which there are several variants, as well as c-met, the receptor for hepatocyte growth factor. Activation of another receptor, EGF-R, which is expressed by airway epithelial cells, induces epithelial cell proliferation in sparse cultures; in dense cultures, contact inhibition occurs, cell division ceases, and the cells differentiate into goblet cells.[51] The downstream signaling events by which the ligand-activated receptors stimulate a mitotic event have not been well explored but are presumed to be similar to those in other cell types.

Type I Cell Structure

Scanning electron microscopic studies show that the morphology of a type I cell resembles that of a fried egg with a centrally placed nucleus and extensive, attenuated cytoplasmic processes that form a large surface area for gas exchange (see Fig. 1-22). The cytoplasmic processes of an individual cell may extend into several alveoli. The enormous surface area of these cells presents a logistical problem for transport of new proteins and other substances over long distances and most likely contributes to the vulnerability of the type I cell to injury.

Connexins 26, 32, 40, 43
Adducin
α1-antitrypsin
Cysteine transporter
eNOS, iNOS
K^+ channels
Na^+ channels
Annexins
Aquaporin-1 (debated)
Aquaporin-3 (human)
Surfactant phospholipids
Leukotriene C4
α_1-acid glycoprotein
5-lipoxygenase activating protein
Muc 1
CC10
Plasminogen activator inhibitor
Tissue factor (procoagulant)
Pneumocin
Lipocortin 1
Maclura pomifera binding proteins
ABC transporter ABCA3
Cl^-/HCO_3^- exchanger AE2

ANP, atrial natriuretic peptide; CC10, clara cell secretory protein: uteroglobulin; CFTR, cystic fibrosis transmembrane regulator; CGRP, calcitonin gene–related peptide; CTP, phosphocholine cytidyltransferase; EGF, epidermal growth fastor; eNOS, endothelial nitric oxide synthase; FGF, fibroblast growth factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; HDL, high-density lipoprotein; IFN-γ, interferon-γ; IL, interleukin; iNOS, inducible nitric oxide synthase; LAR-PTP, leukocyte common antigen–protein tyrosine phosphatase; MHC, major histocompatibility complex; PDGF, platelet-derived growth factor; PKCδ, protein kinase Cδ; -R, receptor; RAGE, receptor for advanced glycation end products; SP, surfactant protein; TGF-β, transforming growth factor-β; VEGF, vascular endothelial growth factor.

Type I cells contain many small, non–clathrin-coated vesicles, or caveolae, open either to the alveolar lumen or interstitium or detached from the surface as small intracytoplasmic vesicles.[183] The number of vesicles appears to be variable, an observation that may have physiologic significance. Immunohistochemistry shows that the vesicles contain caveolin-1 protein.[184] Likewise, biochemical analyses[185] show high concentrations of caveolin protein and mRNA in lung where it is expressed mainly by type I and vascular endothelial cells. Caveolin-1 is scaffolding protein that organizes specialized membrane phospholipids and proteins into vesicles. Caveolin-1 can bind free cholesterol and modulate the efflux of cholesterol from the cell when intracellular concentrations rise,[186] and in other cell systems, its expression is tightly linked to the availability of free cholesterol. Caveolae appear to sequester into the vesicles growth factor receptors, signaling molecules such as G proteins, Ca^{2+} receptors and pumps, and in endothelial cells, endothelial nitric oxide synthase. The general effect of sequestration of receptors and signaling molecules into caveolae is to maintain them in a functionally quiescent state.[187] Little is known about the general role of caveolae in type I cells and, although it has been repeatedly tested, evidence that the vesicles move materials across the cell by transcytosis is scanty.

Type I Cell Functions

Proteins known to be expressed by type I cells are listed in Table 1-6. Most are not expressed by type II cells. Two notable attributes are that many of the proteins are apical membrane proteins and the list is very short. Earlier lectin-binding and histochemical studies showed that the chemical nature of the type I cell apical membrane differs markedly from that of type II cells and this concept is confirmed by the identification of novel type I cell proteins. The general functions of some of these marker proteins are known,[188] although not necessarily in the context of type I cell biology.

The type I cell protein aquaporin-5 (AQP-5) is of particular interest. In vitro studies show that isolated rodent type I cells expressing this water channel have remarkable water permeability, the highest known to date.[159]

TABLE 1-6. Type I Alveolar Epithelial Cell Products

CP-M, carboxypeptidase M; eNaC, epithelial sodium channel; gp, glycoprotein; ICAM-1, intracellular adhesion molecule-1; IGFR-2, insulin-like growth factor receptor-2; INK4B, cyclin-dependent kinase 4 inhibitor 2B; RAGE, receptor for advanced glycation end products; VAMP-2, vesicle-associated membrane protein-2.

The cells also express epithelial Na^+ channels and membrane Na^+/K^+-ATPase.[189,190] These observations collectively imply that type I cells may play a major role in pulmonary water fluxes, although this has not yet been directly shown. AQP-5 may not be critical for certain functions related to fluid fluxes because null mutations in the murine AQP-5 gene do not interfere with clearance of edema fluid or fetal lung fluid at birth.[191] In type I cells, ICAM-1, regulated as a differentiation gene rather than by inflammatory mediators, is believed to facilitate alveolar macrophage activation and motility.[192] The physiologic function of type I cell carboxypeptidase M is not known but may be to activate or degrade substrates such as EGF, bradykinin, enkephalins, and other molecules as it does elsewhere.[193] Null mutations in the T1α gene interfere with development of normal alveoli in fetal mice and result in fatal respiratory failure within minutes after birth.[194]

Type I Cell Proliferation

Although it has not been directly tested and proven, type I cells are believed to be incapable of cell division, relying on type II cell progeny for normal turnover and replacement of injured cells.[195]

Relationship between Type II and Type I Cells In Vivo and In Vitro

Early studies demonstrated that, during postinjury repair, postmitotic progeny of type II cells differentiate into type I cells with normal morphology, a process that is also presumed to occur during the normal turnover of type I cells. The in vitro relationships are more complex. When cultured, highly purified type II cells, which are mitotically quiescent, rapidly cease expression of type II cell marker genes, such as SP-A, SP-B, and SP-C, and initiate expression of type I cell genes. If the cells are maintained in the presence of keratinocyte growth factor, in autologous serum, or with a cuboidal shape, type II cell gene expression is maintained and type I cell genes are suppressed. The cells can be manipulated to express either phenotype reversibly. Very little is known about the molecular regulation of either of these two phenotypes (i.e., sets of cell-specific genes) or about the molecular switch or switches that mediate the dramatic changes in expression patterns. Whether reversibility of phenotype (transdifferentiation of type I cells into type II cells) can occur in normal or injured lung in vivo is unknown.

INNERVATION

Innervation of the human lung consists of afferent and efferent pathways.[196–199] The sensory pathways originate in relation to the airway epithelium, submucosa, interalveolar septa, and smooth muscle. Fibers of this pathway include myelinated, slowly adapting stretch receptors (Hering-Breuer reflex) and irritant receptors but most are unmyelinated, slow-conducting C fibers located in the terminal respiratory units, either along the bronchioles or within the alveolar walls (Fig. 1-25). Much speculation has been made about the function of C fibers since Paintal first suggested that they played a role in sensing parenchymal connective tissue distortion, as during pulmonary vascular congestion and interstitial edema.[200–203] The afferent fibers travel in the vagus nerves and terminate in the vagal nuclei in the medulla oblongata.

Determination of the complete distribution of the mucosal sensory nerve endings has been hampered by the lack of dependable morphologic methods for the identification of intraepithelial sensory axons. Ultrastructural techniques have shown that axons, when found, resemble known sensory endings in other organs. The axons are small (<1 μm in diameter), electron-lucent, and contain microtubules and smooth endoplasmic reticulum.[204]

Submucosal sensory nerve endings, in contrast, are more reliably identifiable because the axon can be stained with methylene blue or silver nitrate. Furthermore, studies of axonal transport indicate that the peripheral processes of sensory ganglia project to the submucosa.[205] Ultrastructural observations of these fibers reveal axonal terminals containing numerous membra-

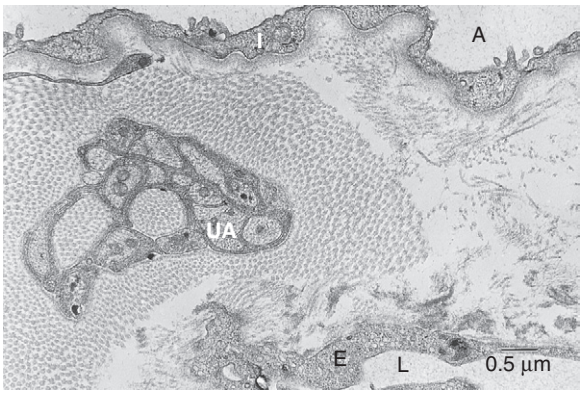

FIGURE 1-25 ■ Unmyelinated axons (UA) known as C-fibers are shown situated in the interstitium of a respiratory bronchiole, between a type I pneumonocyte (I) lining an alveolus (A) and an initial lymphatic (L). Although the presence of small clear vesicles is suggestive of cholinergic (autonomic) axons, unequivocal identification as either motor or sensory fibers is not possible in random thin sections. E, lymphatic endothelial cell. (Human lung surgical specimen, transmission electron microscopy.)

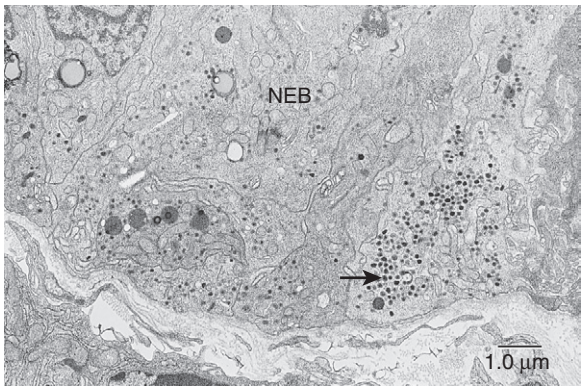

FIGURE 1-26 ■ Neuroepithelial body (NEB) located in a peripheral airway. Neuroepithelial bodies contain aggregates of neuroendocrine cells. A characteristic ultrastructural feature of neuroendocrine cells is the presence of small (0.1-0.3 μm in diameter) dense-cored vesicles in their cytoplasm (*arrow*). Each dense-cored vesicle is bounded by a unit membrane. (Human lung surgical specimen, transmission electron microscopy.)

nous inclusions and mitochondria, which are characteristic of mechanoreceptors.

The motor pathways reach the lung through the sympathetic and parasympathetic nervous systems. Preganglionic contributions to the sympathetic nerves arise from the upper four or five thoracic paravertebral ganglia, whereas the preganglionic parasympathetic nerves originate in the brain-stem motor nuclei associated with the vagus nerves. Postganglionic sympathetic nerve fibers terminate near airways, vascular smooth muscle cells, and submucosal glands. Postganglionic parasympathetic fibers extend from ganglia mainly located external to the smooth muscle and cartilage. Some submucosal ganglia exist, but they are generally smaller and have fewer neurons.

Mucosal motor nerve endings also exist.[206] Characteristic ultrastructural features are axonal profiles containing many small, agranular vesicles and few mitochondria. Unfortunately, the source and function of these axons is unknown. A goblet cell secretomotor role is doubtful because goblet cells in isolated epithelial strips do not secrete glycoproteins when bathed in drugs that mimic neurotransmitters.[207] Alternatively, a likely role may be release of mucus by direct response to mechanical and chemical signals. Another effector role of nerves in the lung is epithelial ion transport, a process that is stimulated by catecholamines,[208] acetylcholine,[209] and neuropeptides.[210] This role is further supported by the presence of α-adrenergic, β-adrenergic, and muscarinic receptors throughout the airway epithelium.[211]

Submucosal tracheal gland efferent nerve endings consist of cholinergic, adrenergic, and peptidergic axonal profiles.[212,213] Discrimination among these axonal types is partially aided by their ultrastructural appearance: cholinergic axons have small, agranular vesicles; adrenergic axons have small, dense-cored vesicles; peptidergic axons have many large, dense-cored vesicles. One must realize, however, that these descriptive definitions are not absolutely reliable.

Cholinergic, adrenergic, and peptidergic nerve endings are present around tracheal glands and do not show patterns of selective innervation density between serous and mucous cells.[211] Serous and mucous granule secretion is stimulated more by muscarinic than by adrenergic agents. Peptidergic agents, such as vasoactive intestinal peptide, have species-specific excitatory or inhibitory effects on glandular secretion.[214,215]

The lung also contains a component of the diffuse neuroendocrine system (APUD [amine uptake and decarboxylation] system).[216,217] This system is composed of single neuroendocrine cells and clusters of such cells, known as neuroepithelial bodies, distributed along the airway epithelium out to the region of alveolar ducts.[218–221] The neuroepithelial bodies are preferentially located at airway bifurcations. Pulmonary neuroendocrine cells are ultrastructurally characterized by dense-cored vesicles in their cytoplasm (Fig. 1-26). The dense-cored vesicles are considered to be the storage sites of amine hormones (serotonin, dopamine, norepinephrine) and peptide hormones (bombesin, calcitonin, leu-enkephalin).[222] Neurons are also associated with the airway epithelial and the neuroendocrine cells; they appear to be the storage sites for vasoactive intestinal peptide[222,223] and substance P.[224,225]

Despite the growing recognition that a diffuse neuroendocrine system is located in the lung, we do not understand its normal functional role, although one postulate is that these cells release hormones that affect smooth muscle. For example, hypercapnia and acute alveolar hypoxia in newborn rabbits cause the airway neuroendocrine cells to degranulate.[226,227] Thus, neuroendocrine cells may act as peripheral chemoreceptors.

AIRSPACE MACROPHAGES, LYMPHATICS, LYMPHOID TISSUE, AND INNATE IMMUNITY

The clearance of particulate matter impinging on the alveolar surfaces is dependent on the slow turnover and movement of the alveolar surface liquid, as well as on the phagocytic function of the macrophages and the clearance function of the pulmonary lymphatics.[228,229] The majority of the macrophages that reach the terminal airways (see Figs. 1-11 and 1-23) are expelled with the surface film as it is pulled up onto the mucociliary escalator. Some macrophages penetrate into the lung interstitium and can be seen as deposits of pigment within interstitial foci. Alveolar macrophages actively express and secrete cytokines, such as tumor necrosis factor-α and transforming growth factor-α.

Lymphatics of the lung have been subdivided into two principal groups based on their location: a superficial plexus and a deep plexus.[10,45,196,230] The superficial plexus is located in the connective tissue of the visceral pleura. This plexus is prominent in the human lung.[10,45,196] Lymphatics of the deep plexus are situated in the peribronchovascular connective tissue sheaths of the lung. Both plexuses are made up of initial and collecting lymphatics, and communications exist between the two plexuses.[10,45,153,196] Lymphatics in the deep plexus are distributed around the airways, extending peripherally to the respiratory bronchioles and next to branches of the pulmonary arteries and veins.[10,45,153,196] Lymphatics are not in the alveolar walls. Lymph is propelled centripetally toward the lung's hilum or pulmonary ligament to reach regional lymph nodes. In the human, pulmonary lymph flows to extrapulmonary lymph nodes located around the primary bronchi and trachea.[10,45,196]

KEY POINTS

- The primary function of the lung is ventilation-perfusion matching such that gas exchange between alveolar air and alveolar capillary blood is efficient.
- The anatomic arrangements of the pulmonary arteries beside the airways are a reminder of the relationship between perfusion and ventilation that determines the efficiency of normal lung function.
- The major physical problem of gas exchange is the slowness of oxygen diffusion through water. Thus, the alveolar walls must be extremely thin. Because of that thinness, the thickness of the red blood cell forms a substantial portion of the air-blood diffusion pathway.
- The airways form the connection between the outside world and the terminal respiratory units so the airways are central importance to our understanding of lung function in health and disease.
- Most airway resistance resides in the upper airways and bronchi.
- The cellular complexity of the airways is indicated by the nearly 50 distinct cell types in the lung, at least 12 of which are epithelial cells on the airway surface.
- Smooth muscle cells form circular bands around the airway epithelium as far peripherally as the respiratory bronchioles. Tone in the smooth muscle is altered by the autonomic nervous system and by mediators released from mast cells, inflammatory cells, and neuroendocrine cells.
- A relatively large fraction of the total pulmonary vascular resistance (35%–45%) resides in the alveolar capillaries at FRC.
- Because smooth muscle can be found in the pulmonary vessels on both the arterial and the venous side down to pre- and postcapillary vessels, any segment can contribute to active vasomotion and therefore pulmonary vascular resistance.
- Normally, capillary blood volume is equal to or greater than stroke volume. Thus, under normal resting conditions, the volume of blood in the pulmonary capillaries is well below its maximal capacity. Recruitment can increase capillary blood volume threefold.
- Specialized attributes of the pulmonary circulation's endothelial cells are the remarkable number of metabolic activities.
- Alveolar type II cells outnumber type I cells (~15% vs. 8%–10% of total peripheral lung cells, respectively) but the type I cell accounts for about 90% to 95% of the alveolar surface area of the peripheral lung.
- The type II cell is the major synthesizing and secreting factory of the alveolar epithelium and implements epithelial repair via its ability to proliferate.

- The type I cell may play a major role in pulmonary water flux, as well as activate or degrade vasoactive substrates.
- Sensory pathways in the lung originate in relation to the airway epithelium, submucosa, interalveolar septa, and smooth muscle.
- Motor pathways reach the lung through the sympathetic and parasympathetic nervous systems.
- The clearance of particulate matter impinging on the alveolar surfaces is dependent on the slow turnover and movement of the alveolar surface liquid, mucins, as well as on the phagocytic function of the macrophages and the clearance function of the pulmonary lymphatics.

Transcriptional Regulation of Lung Development

Summary

INTRODUCTION

Multicellular life requires the use of O_2 for the generation of high-energy compounds (e.g., adenosine triphosphate [ATP]) to sustain the metabolic activities of complex organisms. Because multicellular organisms depend on O_2, they have evolved systems for its efficient acquisition and distribution. A benchmark in the adaptation of vertebrates living on land was the development of a gas exchange system that provided a sufficient amount of O_2 to meet the metabolic requirements of cellular respiration. As organisms increased in size, the surface area required for adequate gas exchange became significantly larger; for example, the surface area of the adult human lung epithelium has been estimated to be 70 m^2.[1] The problem of generating such a large surface area in a confined space has been solved in the basic structure of the lung, where branched epithelial tubules conduct air to millions of alveoli that lie closely apposed to the lung microvasculature. The epithelium lining the surface of the lung is continuously exposed to biologic and chemical hazards, which has also necessitated the development of an innate defense system in the lung. Early embryologic experiments established that lung morphogenesis is critically dependent on reciprocal interactions between the lung endoderm and its surrounding splanchnic mesoderm, which supplies progenitors of endothelial cells, smooth muscle cells, mesothelial cells, and fibroblasts. As we discuss, these interactions are complex and highly regulated in time and space. Disruptions in the lung developmental program, be it for genetic or epigenetic reasons, can lead to compromised structure and function. A better understanding of the molecular mechanisms controlling lung development will optimize therapeutic strategies to treat the diseased or malformed lung. Several additional recent reviews are also available.[2-5]

STAGES OF LUNG DEVELOPMENT

Lung development has traditionally been divided into five stages that are primarily based on histologic appearance (Fig. 2-1). The basic branching pattern of the pulmonary tree and an associated vascular plexus is established during the **embryonic** and **pseudoglandular** stages. The epithelial branching program, which is under genetic control, is stereotyped and utilizes three geometrically distinct local modes of branching that occur in three different sequences.[6] The **embryonic stage** of human lung development begins with the emergence of the laryngotracheal groove from the floor of the foregut endoderm during the fourth week of gestation. A few days later, the caudal end of the primordium enlarges and bifurcates, giving rise to the left and right bronchial buds. These buds elongate caudally during the fifth week of gestation, when a second round of branching occurs, resulting in three secondary buds in the right lung and two in the left. These buds will become the primary lobes of the left and right lung. A third round of branching gives rise to bronchial tubules that will become the bronchopulmonary segments in the mature lung. Concurrent with these events in the distal region, the cranial portion of the primordium gives rise to the trachea and larynx, which separate from the esophagus by the end of this stage. The lung epithelium at this stage is tall columnar, and shows no morphologic evidence of differentiation (see Fig. 2-1A). At the molecular level, however, some aspects of epithelial differentiation have already begun; for example, the most distal epithelial

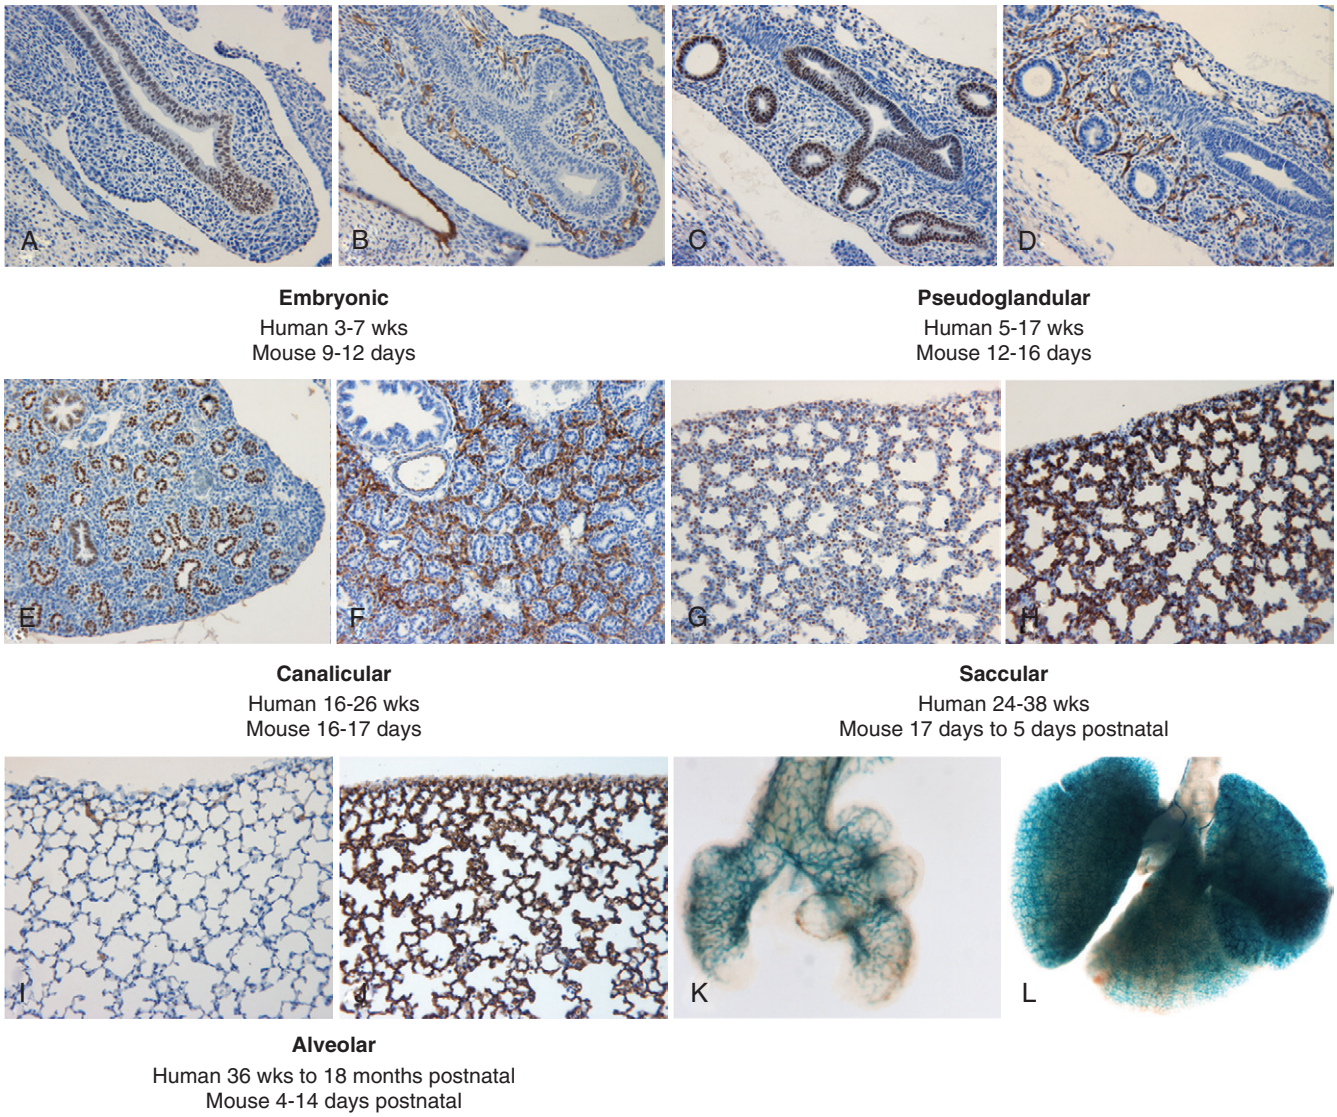

FIGURE 2-1 ■ Morphology of the stages of lung development. Mouse lungs from the indicated developmental stages were stained with antibodies against thyroid transcription factor 1 (TTF-1; **A, C, E, G, I**) to identify respiratory epithelial cells, or with antibodies against CD34 (**B, D, F, H, J**) to identify vascular cells. All images of sectioned lungs are at the same magnification. **K** and **L,** The lungs are from embryonic and saccular stage mice, respectively, in which the Tie2 promoter drives expression of the β-galactosidase transgene to histochemically mark endothelial cells. **A,** During the embryonic stage, the lung epithelium consists of apparently undifferentiated tall columnar cells. **B** and **K,** Vascular precursors are already present and form a plexus surrounding the epithelium. Dichotomous and lateral branching of the epithelium continues in the pseudoglandular stage (**C**) and the vasculature branches in parallel with the developing airways (**D**). Epithelial acini appear during the canalicular stage (**E**), and the vasculature becomes more abundant and closely apposed to the epithelium (**F**). **G,** Type I cell differentiation increases air space size during the saccular stage. **H** and **L,** The vasculature has continued to expand, fully investing the lung parenchyma. Fusion of the epithelial and endothelial basal laminae brings capillaries and type I epithelial cells into close association. **I,** The formation, lengthening, and thinning of secondary septae during the alveolar stage markedly increase the epithelial surface area. **J,** The capillaries, which until now have existed as a double septal network, have fused into one.

cells express mRNA for the lung-specific marker surfactant protein C (*Sftpc*).[7] The lung mesenchyme, which is derived from splanchnic mesoderm, is loosely organized at the beginning of this stage and lacks apparent vascular structures. In situ hybridization studies probing for the vascular endothelial cell growth factor (VEGF) receptor *Flk-1* have demonstrated, however, that vascular precursors are closely apposed to the distal epithelium at the time of bud induction.[8] These cells form a vascular plexus (see Fig. 2-1B and K) by a process termed "vasculogenesis," wherein vessels are formed de novo by the organization of vascular precursors. By the end of embryonic stage, pulmonary arteries and veins connect this plexus to the atria; the pulmonary arteries and veins grow into the lung by angiogenesis, with new branches arising from preexisting vessels.

Dichotomous and lateral branching of the lung epithelium continues during the **pseudoglandular stage**, which lasts from week 5 to week 17 of gestation. This results in the final pattern of the pulmonary tree,

which comprises 22 to 23 generations of bronchial tubules. Terminal bronchioles branch distally to give rise to the acinar tubules and buds that will eventually form pulmonary acini in the adult (see Fig. 2-1C). Morphologic differences in the epithelium are apparent. The proximal epithelium is initially populated by relatively undifferentiated columnar, glycogen-rich cells, but ciliated, nonciliated, goblet, mucous, basal, and neuroendocrine cells are identifiable by the end of this stage. Distal epithelial cells, which are the precursors of alveolar type II cells, are cuboidal-columnar and contain copious amounts of glycogen. Smooth muscle cells differentiate in the mesenchyme and surround the epithelium perpendicular to the long axis of the tubules; this proceeds in a proximal-to-distal manner. The pulmonary vasculature branches in parallel with the airway epithelium (see Fig. 2-1D), and pulmonary lymphatics initiate as buds from the veins.[9]

Patterning of the pulmonary tree is completed at the beginning of the **canalicular stage** (16–26 weeks; see Fig. 2-1E), and the cells constituting the proximal epithelium continue to differentiate as ciliated, nonciliated, and secretory cells. Among the latter are Clara cells, identifiable by the presence of the cell-specific Clara cell secretory protein (CCSP). Acinar tubules and buds, which are lined by cuboidal epithelial cells, expand and differentiate to form pulmonary acini consisting of respiratory bronchioles, alveolar ducts, and alveoli. Nascent type II cells containing increasing amounts of surfactant-associated proteins and phospholipids become prominent in the distal epithelium. Differentiation of squamous type I cells from type II cells begins. A dramatic expansion of the pulmonary capillary bed (vascular canals) in the lung parenchyma gives this stage its name (see Fig. 2-1F). These vessels surround the developing acini and come in direct contact with the epithelium, giving rise to the primordial air-blood barrier.

During the **saccular stage**, which persists from week 24 until term, the terminal acinar tubules in the lung periphery continue to branch and air space size increases. Alveolar type II cells undergo significant maturation, as evidenced by increased synthesis of surfactant proteins (SP-) A, B, C,[10] and D[11] as well as surfactant phospholipids.[12] Glycogen stores, which serve as a substrate for phospholipid synthesis,[13] decrease, while the number of lamellar bodies increases. Squamous type I cells continue to differentiate and constitute an increased proportion of the distal lung surface, thereby increasing the effective area for gas exchange (see Fig. 2-1G). Septal walls consist of a central connective tissue core with a capillary network on each side. Subsequent fusion of the basal laminae of the distal epithelium and endothelium brings capillaries into close association with type I cells, which decreases the diffusion distance between air spaces and capillaries to allow more efficient gas exchange (see Fig. 2-1H and L).

The transition from the canalicular to saccular stage of lung development marks the threshold of viability for preterm infants who have access to neonatal intensive care support.[14,15] Prior to 22 weeks' gestation, there is insufficient available surface area in the distal pulmonary tree to support safe, reliable oxygenation and ventilation, even when surfactant replacement therapy and sophisticated mechanical ventilation techniques are available. Survival at 23 weeks' gestation ranges from 15% to 30%. Mortality decreases with each additional week of gestation; by 25 weeks, survival exceeds 60%, although significant morbidity in the form of bronchopulmonary dysplasia (BPD) and neurodevelopmental compromise persist.[16]

As the threshold of viability is crossed, respiratory distress syndrome (RDS) becomes the primary source of morbidity and mortality for the preterm infant. RDS is a consequence of deficient surfactant production, leading to terminal airway atelectasis and epithelial injury. The subsequent capillary leak produces the hyaline membranes that are classically associated with this disease. Surfactant replacement therapy has dramatically improved RDS survival rates and reduced morbidity. Term infants affected by RDS typically have comorbid conditions such as maternal diabetes, which delay maturation of the surfactant production system.

Genetic mutations leading to SP-B deficiency result in a clinical presentation indistinguishable from the early stages of RDS. Affected infants, however, are typically full term and have only a transient response to surfactant replacement therapy, which leads to early neonatal death or the development of severe neonatal chronic lung disease. The only definitive treatment is lung transplantation. Lethal respiratory failure in a mouse model of SP-B deficiency can be reversed with targeted expression of an SP-B transgene, demonstrating potential for gene therapy.[17] Mutations of SP-C produce a spectrum of pulmonary disorders during infancy including pulmonary interstitial fibrosis.[18] As with SP-B deficiency, surfactant replacement therapy has little or no benefit, with lung transplantation as the only documented potential cure. Other genetic defects of the surfactant production system also lead to fatal surfactant deficiency in the neonate. Infants deficient in ABCA3, which transports surfactant phospholipids to lamellar bodies, have normal SP-B expression and unexplained lethal respiratory failure and death within 1 month of birth.[19]

The final stage of lung development is the **alveolar stage**, which lasts from week 36 of gestation through the first 18 months of postnatal life. As the name implies, the generation of true alveoli from terminal saccules occurs during this stage. Interstitial tissue in primary septae is reduced, while secondary septae markedly lengthen and thin (see Fig. 2-1I). Concomitant with these changes is the fusion of the double septal capillary network into one (see Fig. 2-1J). This remodeling requires an initial burst of interstitial fibroblast proliferation, which subsequently slows down and the cells synthesize increased amounts of collagen and elastin. Septation results in a marked increase in the number of alveoli from approximately 30 million at term to 300 million in the adult. Increased numbers of type II and type I cells accompany alveolar expansion, with type I cells now covering 97% of the alveolar surface area.[20]

BPD, which is typically restricted to infants born prior to 32 weeks' gestation, represents a particularly challenging complication. The condition is only associated

with preterm birth and is defined by a characteristic appearance on chest radiograph and persistent requirement for supplemental oxygen beyond 36 weeks postconception.[21] In the era of surfactant replacement therapy, BPD is distinguished by alveolar simplification due to the apparent arrest of alveolarization that occurs in utero during the third trimester.[22] Compromise of oxygenation and ventilation may worsen as infant somatic growth progresses and attendant metabolic demands outstrip pulmonary function. Respiratory morbidity is not restricted to infants born prior to 32 weeks' gestation. When compared with term infants, so-called late-preterm infants born between 32 and 37 weeks' gestation are more likely to require respiratory support, including positive-pressure ventilation after birth.[23] Given the dramatic increase in alveolar number during the late third trimester, it follows that late preterm infants may have a smaller margin of safety when making the transition to extrauterine life.

TISSUE INTERACTIONS AND LUNG DEVELOPMENT

A basic tenet of lung development is that it requires inductive interactions between the endodermal epithelium and the mesodermal mesenchyme. This is particularly evident in the embryonic and pseudoglandular stages, where it has been conclusively shown that lung epithelium must be associated with lung mesenchyme in order to survive[24] and branch.[25] The factors that drive branching morphogenesis are diffusible, because embryonic lung epithelium branches when separated from lung mesenchyme by a filter that prevents direct cell-cell contact, but allows diffusion of soluble factors.[26] Importantly, these experiments also showed that survival of lung mesenchyme is dependent on the presence of lung epithelium, underscoring that induction is reciprocal. The fate of the entire respiratory endoderm, from the trachea to the bud tips, however, is not fully committed during the embryonic stage. Reciprocal recombination experiments have shown that distal lung mesoderm can reprogram tracheal endoderm to branch and differentiate like lung,[27,28] and that tracheal mesoderm can reprogram lung endoderm to differentiate like trachea.[29,30]

Bronchopulmonary sequestration may represent an intriguing manifestation of aberrant pulmonary endoderm-mesoderm interaction. These masses of abnormal lung tissue, which may be contained within the lung or in an extrapulmonary location such as the abdomen, may be in direct communication with gastrointestinal tract structures suggesting ectopic induction of embryonic foregut. The histopathologic appearance of these lesions includes typical cellular components of pulmonary parenchyma along with inflammatory and fibrotic components (Fig. 2-2C).[31]

Normal lung function requires the precise alignment of the distal epithelium and the vasculature to meet the respiratory requirements of the developing organism. Certain lethal congenital malformations of the lung, such as alveolar capillary dysplasia (ACD), are due to a perturbation in the relationship between vascular and airway development. ACD is characterized by a paucity of alveolar capillaries, thickened pulmonary mesenchyme, and misalignment of the pulmonary veins, which reflect the reciprocal relationship required for airway and vascular development (see Fig. 2-2B). The alveolar simplification of BPD is also accompanied by a relative paucity of alveolar capillaries that is reminiscent of ACD. Evidence that VEGF-A, which is produced by lung epithelial cells, can reverse the alveolar defect further reinforces the concept of interdependent development of vascular and airway structures.[32]

MOLECULAR REGULATION OF LUNG DEVELOPMENT

Elucidation of the factors that regulate lung growth and development has been the focus of an intense research effort. This stems not only from a desire to understand the basis of pulmonary pathologies present at birth but also from the possibility that understanding how the lung develops will provide insight into how the lung repairs itself following injury or disease. Given the morphogenetic precision required to generate a lung that can function effectively in gas exchange, coupled with the fact that the lung contains over 40 differentiated cell types,[1] it is not surprising that the molecular regulation of lung development is proving to be very complex. Identifying the factors involved provides only part of the story. When, where, how much, and for how long these factors are expressed must also be considered. The fact that there is crosstalk between some of the identified pathways significantly increases the level of complexity.

Diffusible Mediators of Lung Development

Fibroblast Growth Factors and Fibroblast Growth Factor Receptors

In both humans and mice, the fibroblast growth factor (FGF) family comprises 22 structurally related molecules[33]; among these, FGF1, 2, 7, 9, 10, and 18 have been localized to the developing lung. FGFs bind and signal through high-affinity, ligand-dependent transmembrane receptors (FGF-Rs) that contain an intracellular tyrosine kinase domain. There are four FGF-Rs, all of which are expressed in the lung. Alternative mRNA splicing results in two isoforms each for FGF-R1, FGF-R2, and FGF-R3 that have distinct ligand specificities.[34] FGF-R activation is modulated by heparin or heparin sulfate.[35]

FGF1 and FGF2 are not critical for lung development, because the single deletion of either gene or the double ablation of both has no effect on lung development. FGF10 is an ideal candidate for mediating tissue interactions in the lung, because it is expressed in the mesenchyme, whereas its primary receptor, FGF-R2b, is expressed by epithelial cells. Ablation of either FGF10[36] or FGF-R2b[37] results in complete pulmonary agenesis caudal to the trachea. The basis for this phenotype

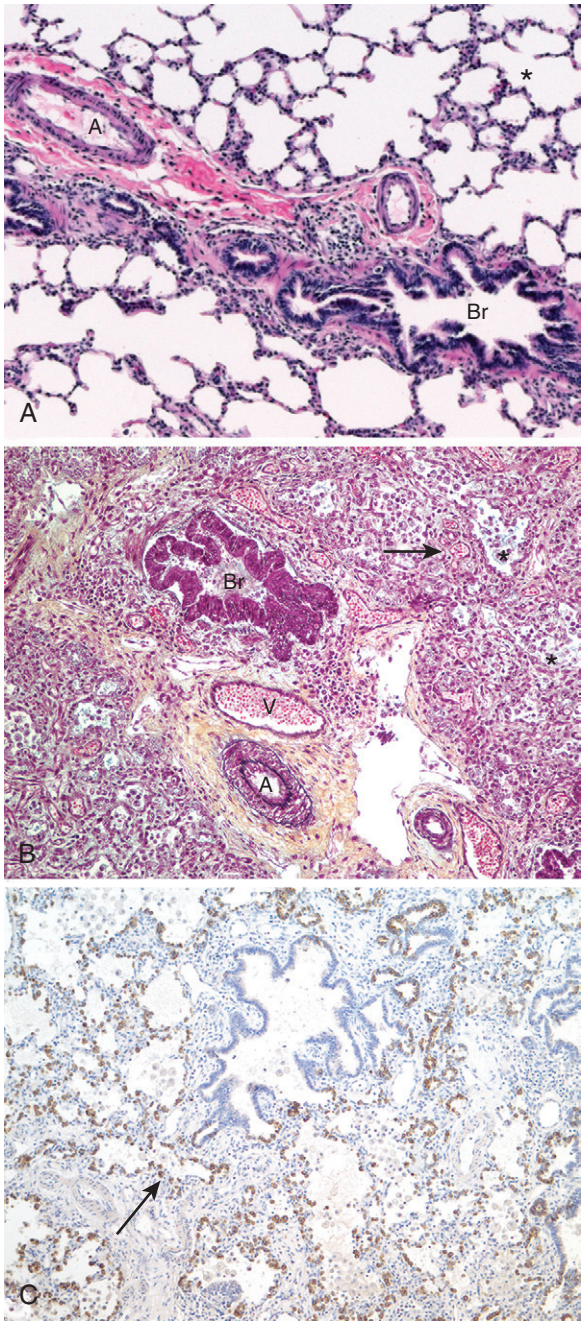

FIGURE 2-2 ■ Histopathologic features of alveolar capillary dysplasia and extralobar pulmonary sequestration. **A,** Section of normal lung stained with hematoxylin and eosin demonstrates a typical bronchovascular bundle incorporating a small bronchus (Br) and artery (A), without an accompanying vein. A typical alveolar network with abundant air spaces (*) is present. **B,** Pentachrome-stained section from a full-term newborn with alveolar capillary dysplasia. There is abundant mesenchyme separating rudimentary, dysplastic terminal airspaces (*). Alveolar capillaries (*arrow*) are sparse in number and distended. There is misalignment of the pulmonary vasculature. A pulmonary artery (A) with prominent muscularis and bronchus (Br) are accompanied by an anomalous pulmonary vein (V). The paucity of alveolar capillary structures accounts for the profound pulmonary hypertension in these patients. Original magnification ×10). **C,** Immunohistochemistry of extralobar pulmonary sequestration demonstrates expression of prosurfactant protein C in epithelium (brown-staining cells). The sequestration has the histologic appearance of primitive lung at the canalicular stage of development with an abundance of mesenchyme separating nascent air space structures (*arrow*). (**A–C,** Micrographs kindly provided by Dr. Susan Wert, Division of Pulmonary Biology, and Dr. Gail Deutsch, Division of Pathology, Cincinnati Children's Hospital Medical Center.)

comes from the ability of FGF10 to induce lung epithelial budding by chemoattraction[38,39]; in the absence of FGF10 primary bud formation cannot occur. Like FGF10, FGF9 acts as a mediator of reciprocal tissue interactions, because it is expressed in the epithelium and mesothelium, whereas its receptor, FGF-R2c, is found in the mesenchyme. FGF9 controls lung mesenchyme size by regulating cell proliferation.[40] The observation that the amount of available mesenchyme appears to control lung branching[24] is consistent with the result that the lungs of FGF9 null mice are severely hypoplastic, with decreased amounts of mesenchyme and reduced FGF10 expression.[41] The observation that FGF18 null mice exhibit reduced alveolar size resulting from reduced cell proliferation during the saccular stage[42] suggests a role for FGF18 in late lung development. FGF7 has been shown to markedly stimulate lung epithelial cell proliferation,[43] and pretreatment with FGF7 protects against lung injury, but by a mechanism more complex than increased cell proliferation.[44] Transgenic overexpression of FGF7 in the developing mouse lung results in lesions resembling cystic adenomatoid malformations[45]; examination of human congenital cystic adenomatoid malformations (CCAM), however, shows that FGF7 expression is actually decreased and FGF10 expression is unchanged.[46] FGF7 is a potent stimulator of surfactant protein gene expression and surfactant phospholipid synthesis in type II cells.[47,48] Although intraperitoneal

injection of neutralizing antibodies against FGF7 inhibits postnatal lung growth and alveolus formation,[49] mice with a targeted deletion of FGF7 have no apparent lung phenotype.[50] FGFs are also required during alveoligenesis, because mice with deletions of both FGF-R3 and FGF-R4 fail to form normal alveoli.[51]

The Sprouty (Spry) proteins, which antagonize FGF-R signaling, modulate the effects of FGFs in the developing lung. Transgenic misexpression of either Spry2[52] or Spry4[53] disrupts branching and causes lung hypoplasia. Although single deletion of either Spry2 or Spry4 has no effect on lung development, mice null for both genes have defects in multiple organs, including the lung.[54]

Retinoic Acid

Retinoic acid (RA), the active derivative of vitamin A, is essential for the normal development of many tissues, including the lung. Maternal vitamin A deficiency results in severe respiratory phenotypes in offspring, including tracheoesophageal fistula, lung hypoplasia, and lung agenesis.[55] RA signals through RAR and RXR nuclear receptors, both of which have α, β, and γ isoforms, and these are expressed in the lung from the outset of development. Mice with double deletions of RARα/RARβ or RARα/RXRβ show the same lung abnormalities as those seen in vitamin A–deficient embryos.[56] The mechanism by which RA controls lung morphogenesis is not fully resolved. Data from cultured early embryonic foreguts suggest that RA controls transforming growth factor-β (TGF-β) activity in the prospective lung field, which in turn controls the expression of FGF10, thereby affecting lung bud induction.[57] RA also influences perinatal alveolus formation in rodents,[58] which has led to its use clinically for the prevention of BPD.[59] The effect, however, is modest: about 15 infants must be treated to prevent 1 case of BPD.[60] The mechanism is not understood in detail, but is likely related to maintenance of alveolarization after preterm delivery, reducing the potential for alveolar simplification. The morphogenetic effects of RA have also led to investigation of its potential efficacy in inducing alveolar regeneration. RA has been shown to prevent and reverse emphysematous changes induced by elastase in rats[61] or by dexamethasone in mice.[62] Although studies of chronic obstructive pulmonary disease (COPD) patients treated with RA have not established a definitive clinical benefit, changes in some parameters of lung function suggest that further study may be warranted.[63]

Sonic Hedgehog

The hedgehog signaling pathway plays a important role in the development of multiple organs.[64] Sonic hedgehog (Shh) is expressed in the developing lung epithelium[65] and its primary receptor, Patched-1 (Ptc), is found in mesenchymal cells,[66] suggesting that Shh is part of a epithelial-mesenchymal inductive loop. Shh is initially expressed throughout the epithelium, but becomes restricted to subsets of cells from day E16.5 onward.[67] Shh null mice form lungs, indicating that Shh is not required for lung bud induction, but these lungs are severely hypoplastic,[68] suggesting that Shh is involved in regulating branching morphogenesis. Shh deletion profoundly affects lung growth and patterning, but the specification of epithelial cell types appears to be unaffected.[69] Because Shh serves as a survival factor for lung mesenchymal cells,[70] the lung hypoplasia seen in Shh null embryos may be due to a decrease in mesenchymal mass. Shh is also a negative regulator of FGF10, which is critical for lung bud induction.[69] Clinical syndromes with respiratory phenotypes that are consistent with disruption of Shh signaling include VACTERL (vertebral abnormalities, anal atresia, cardiac abnormalities, tracheoesophageal fistula and/or esophageal atresia, renal agenesis and dysplasia, and limb defects),[71] and Smith-Lemli-Opitz (SLO).[72] SLO is phenocopied by mutations in Δ-7-dehydrocholesterol reductase (DHCR7), which is involved in cholesterol synthesis[73]; cholesterol modification of Shh is required for effective signaling.[74]

Shh levels are modulated by binding to Ptc.[75] Shh up-regulates Ptc expression, and any Ptc in excess of that involved in signaling binds Shh and sequesters it, creating a negative feedback loop that restricts its spread. Another molecule regulating Shh levels is hedgehog-interacting protein 1 (HHIP1), a membrane-bound protein that binds all mammalian hedgehog proteins and, like Ptc, is up-regulated in response to Shh.[76] Targeted deletion of HHIP1 results in lung hypoplasia[77] that may be due to a loss of FGF10 expression at the prospective sites of bud formation as a result of increased Shh signaling.

Three GLI genes (1, 2, and 3) code for zinc finger transcription factors that are the principal effectors of hedgehog signaling. All three GLI genes are expressed in distinct but overlapping domains in lung mesenchyme, with expression being highest in the distal tips.[78,79] The analysis of compound mutant mice has demonstrated the complexity of how GLI genes affect lung development. Embryos expressing different combinations of GLI genes show a range of lung defects, the most striking of which is the absence of lungs, trachea, and esophagus in $GLI2^{-/-}$, $GLI3^{-/-}$ compound mutants.[80] The presence of a single GLI3 allele ($GLI2^{-/-}$, $GLI3^{+/-}$) is sufficient to allow formation of hypoplastic lungs in which the left and right lungs do not separate, and the embryos have tracheoesophageal fistula. The phenotype seen in GLI2/GLI3 double-null embryos is more severe than that seen in Shh-null animals; this suggests that the GLI genes may lie downstream in signaling pathways other than Shh, or that the other hedgehog proteins (Indian and Desert) may be active in the lung. Mutations in the human GLI3 gene cause Pallister-Hall and Greig syndromes, which affect development of several organ systems, including the lung.[81]

TGF-β Superfamily

The TGF-β superfamily comprises activins, inhibins, the bone morphogenetic proteins (BMPs), mullerian inhibiting substance, and TGF-β1, 2, and 3. TGF-β1 treatment of cultured embryonic lung explants[82] or misexpression

of TGF-β1 targeted to the lung in vivo[83] severely inhibit branching morphogenesis. This is likely due to the ability of TGF-β1 to inhibit FGF10 expression.[57] TGF-β1 signals through a heteromeric complex of type I (TGF-βrI) and type II (TGF-βrII) receptors, and exerts its effects on downstream target genes via the SMAD family of proteins.[84] Inhibition of TGF-βrII in cultured embryonic lungs increases lung branching,[85] as does attenuation of SMAD2/3,[86] underscoring the inhibitory nature of TGF-β1 on lung morphogenesis. TGF-β1–null mice show no apparent lung phenotype, although it should be noted that 50% of these mice die on E10.5, prior to the onset of lung development.[87] Most TGF-β2–null mice die shortly before or during birth with a wide range of developmental defects. The lungs of neonates have dilated conducting airways and collapsed terminal and respiratory bronchioles.[88] Deletion of TGF-β3 results in retarded development and differentiation of the lung epithelium, mesenchyme, and vasculature.[89] The fact that TGF-β3 appears to promote morphogenesis contrasts with the inhibitory function of TGF-β1, suggesting that these ligands affect distinct aspects of lung development.

Of the four BMPs expressed in the developing lung (BMP3, 4, 5, and 7), BMP4 has been the focus of the most studies. BMP4 is expressed in the ventral foregut mesenchyme prior to lung bud induction, and then is expressed in the distal epithelium and proximal mesenchyme after the lung has formed. In the mouse, epithelial expression declines in the distal epithelium prior to birth, but begins in the capillary endothelium. BMP4 expression is upregulated by FGFs in the epithelium and by Shh in the mesenchyme. Although the evidence to date suggests a role for BMP4 in modulating epithelial cell proliferation, determination of whether BMP4 supports or antagonizes proliferation has been controversial. Paradoxically, lung-targeted overexpression of either BMP4[66] or the BMP4 antagonists Noggin[90] or Gremlin[91] have the same effect of reducing cell proliferation and lung size. Specific deletion of BMP4 or BMPR1a from the distal lung epithelium results in reduced proliferation, increased apoptosis, and cystic morphogenesis.[92] These data support a model in which BMP4 produced by the distal epithelium acts in an autocrine manner to promote the proliferation and survival of undifferentiated progenitor cells in the distal lung epithelium.

Wnts and β-catenin

Members of the Wnt family of secreted glycoproteins are critically involved in cell fate determination, proliferation, survival, and motility in organogenesis. Wnt ligands bind their receptors to activate a pathway that ultimately stabilizes β-catenin, which then interacts with nuclear T-cell factor/lymphoid enhancer factor (TCF/LEF) transcription factors to modulate transcription of downstream target genes.[93] Wnts 1, 2a, 2b, 5a, 7b, and 11 are expressed in the lung. Deletion of both Wnt2a and 2b abrogates specification of lung progenitors in the foregut endoderm, resulting in lung agenesis.[93a] Inactivation of Wnt5a results in a foreshortened trachea, overexpanded distal airways, and retarded lung maturation.[94] Mice null for Wnt7b die at birth from respiratory failure; early mesenchymal cell proliferation is reduced, leading to lung hypoplasia, and defects in the smooth muscle layer around major pulmonary vessels results in hemorrhage.[95] Proximal-distal airway patterning and epithelial cell differentiation are disrupted when Wnt signaling is globally inhibited in the developing lung, either by targeted epithelial deletion of β-catenin[96] or by misexpression of the Wnt antagonist Dickkopf 1.[97] Constitutive activation of Wnt signaling in the developing lung epithelium with hyperactive β-catenin results in lungs that lack fully differentiated cell types.[98]

Platelet-Derived Growth Factor

The platelet-derived growth factor (PDGF) family consists of five different disulfide-linked dimers built up of four different polypeptide chains encoded by four different genes. PDGF-A, which homodimerizes with itself or heterodimerizes with PDGF-B, plays an important role in lung development. PDGF-A is expressed in distal lung epithelium, whereas its receptor, PDGFRα, is expressed in nearby mesenchymal cells, indicative of a paracrine signaling loop between the epithelium and the mesenchyme. Deletion of PDGF-A results in arrested alveolus formation and postnatal death.[99] The lungs lack the differentiated alveolar myofibroblasts that produce elastin, which is critical for alveolus formation.

VEGF

VEGF-A, C, and D are all found in the lung. The temporal and spatial expression of VEGF-A during lung development implies a central role in the maturation and organization of the pulmonary vascular network. VEGF-A is expressed in epithelial and mesenchymal compartments during the embryonic and pseudoglandular stages, becoming more restricted to the epithelium as development progresses into the canalicular stage.[8,100] VEGF-A exists as three isoforms (120, 164, and 188) that have distinct functions in vascular development.[101] Genetic studies in mice demonstrate the importance of local tissue concentrations of VEGF-A to effect appropriate vascular development and distal airway structures. Increased expression of VEGF164 in distal epithelium disrupts assembly of the vascular plexus and arrests airway branching without affecting endothelial cell proliferation or survival, indicating that crosstalk between the developing epithelium and vasculature is required for normal morphogenesis.[102] VEGF-A expression is controlled by multiple mediators, such as FGFs and Shh.[103]

Glucocorticoids

Glucocorticoids exert potent effects on a variety of different tissues, with a common theme that they induce the precocious appearance of normal developmental events. The effects of glucocorticoids on lung function have been a topic of intense interest since the observation that dexamethasone accelerates lung maturation in premature lambs.[104] Glucocorticoid receptors are

present on the developing pulmonary epithelium as airway branching progresses during the pseudoglandular stage of lung development. Epithelial expression persists through the saccular and alveolar stages, accompanied by the onset of expression within the mesenchymal compartment.[105] Exogenous glucocorticoids stimulate morphologic maturation and many aspects of surfactant phospholipid biosynthesis.[106] Targeted disruption of the glucocorticoid receptor in mice leads to respiratory distress and early neonatal death[107]; the lungs of these animals are atelectatic with blunted alveolarization. Although the number of type II cells is increased by 30%, the relative expression of SP-A and SP-C is decreased by 50%. The number of type I cells is decreased by 50%, as are the type I cell markers T1α and aquaporin 5, suggesting that glucocorticoids facilitate the differentiation of type II cells into type I cells.[108] Somewhat paradoxically, however, mice null for corticotropin-releasing hormone show deficits in septal thinning, air space formation, and content of SP-A and SP-B, but have no deficit in surfactant phospholipid biosynthesis.[109]

Given the broad distribution of pulmonary glucocorticoid receptors in the developing lung, it is not surprising that the therapeutic effects of glucocorticoid treatment are complex. Clinical experience suggests that glucocorticoids have contrasting biologic effects depending upon whether treatment is directed toward the fetal lung or the preterm neonatal lung. Women in preterm labor are routinely treated with glucocorticoids to reduce the incidence and severity of neonatal RDS.[110] Antenatal steroid treatment accelerates fetal lung maturation by inducing mesenchymal thinning and enhancing pulmonary function, presumably through stimulation of surfactant production. Morphometric studies in sheep suggest that antenatal steroid treatment may also induce some blunting of alveolarization[111]; these effects have been reversed in experimental animals by retinoic acid.[62] Glucocorticoid treatment has also been employed to treat preterm infants experiencing severe BPD. Although early studies and anecdotal reports suggested that steroid treatment could reverse the fibrosis and scarring associated with BPD and significantly improve pulmonary mechanics,[112] subsequent studies demonstrated no clear improvement in long-term pulmonary outcome and increased risk for neurodevelopmental impairment.[113]

Transcriptional Regulation of Lung Development

The diffusible molecules mediating tissue interactions in the developing lung initiate signaling cascades that lead to changes in gene expression. The diversity of cell types found in the lung, which all differentiate under tight spatial and temporal control, makes regulation of gene expression by transcription factors in the developing lung highly complex. Although no lung-specific transcription factors have yet been found, research has identified several transcription factors in addition to those described previously that are crucial to normal lung development.

Thyroid Transcription Factor 1

Thyroid transcription factor 1 (TTF-1; also known as Nkx2.1) is found in the presumptive respiratory region of the foregut endodermal epithelium before lung bud induction. TTF-1 is a homeodomain protein that is found in the forebrain, thyroid, and lung, where it interacts with multiple partners to influence several key aspects of development.[4] Mice null for TTF-1 have a tracheal-esophageal fistula, with main-stem bronchi connecting to hypoplastic, cystic lungs.[114] Whereas differentiation of the most proximal epithelium is somewhat preserved in TTF-1–null lungs, markers of distal epithelial differentiation, including the surfactant proteins, are completely lacking. Similarly, mutation in the human TTF-1 gene leads to thyroid dysfunction and respiratory failure.[115] The control of TTF-1 expression in lung development is not understood.

FOX Family

The FOX family of transcription factors contains more than 50 members, all of which share a winged helix DNA binding domain. FOXA1 and FOXA2 are closely related proteins found in the foregut endoderm and its derivatives. Their spatial and temporal expression patterns are similar in the lung. Mice lacking FOXA2 do not form endoderm and hence cannot form lungs[116]; targeted deletion of FOXA2 in lung epithelial cells, however, demonstrates that it is required for alveolarization and epithelial cell differentiation.[117] Deletion of FOXA1 in mice delays some aspects of sacculation and alveolarization pre- and perinatally, but these differences normalize by 2 weeks of age,[118] suggesting compensation by FOXA2. Deletion of both genes inhibited cell proliferation, branching morphogenesis, and epithelial cell differentiation,[119] indicating that FOXA1/2 play a central role in lung development.

FOXF1 is expressed in lung mesenchyme and controls genes involved in epithelial-mesenchymal interactions, because a haploinsufficiency results in defective branching, lobation, and epithelial differentiation.[120] FOXJ1 controls expression of left-right dynein, which is required for correct anchoring of basal bodies; deletion of FOXJ1 causes situs inversus, the loss of motile cilia in airway epithelial cells, sinusitis, and bronchiectasis.[121] Although these features are associated with Kartagener's syndrome in humans, no mutations in the *FOXJ1* gene have been directly linked to this disorder. FOXM1B is associated with proliferating cells in both the lung epithelium and mesenchyme, but mice null for FOXM1B only show decreased proliferation in the mesenchyme, which is accompanied by severe abnormalities in vascular development.[122] FOXP1 and FOXP2, which are known transcriptional repressors, are expressed in the lung epithelium; both genes are expressed distally, but only FOXP1 is expressed proximally. $FOXP2^{-/-}$ mice show impaired alveolarization, an effect exacerbated in compound mutant $FOXP2^{-/-}$, $FOXP1^{+/-}$ mice, which have hypoplastic lungs and die at birth. The basis for this neonatal lethality is not known, but is associated with decreased levels of N-myc and Hop and increased expres-

sion of T1α, all genes known to be critical regulators of lung development.[123]

GATA-6

GATA-6, a zinc finger transcription factor that is required for visceral endoderm differentiation,[124] is the only GATA family member expressed in the distal epithelium of the developing lung. Mice bearing a dominant-negative GATA-6/Engrailed fusion protein under control of the SP-C promoter show reduced numbers of proximal airway tubules. Lung epithelial cell differentiation is also affected, with these mice completely lacking detectable alveolar type I cells.[125] Loss of GATA-6 in the lung epithelium causes a loss of differentiation and the precocious appearance of bronchoalveolar stem cells that is the result of increased Wnt signaling.[126] GATA-6 regulates expression of Wnt7b, and also interacts with TTF-1 to control expression of SP-A, B, and C.[4]

SOX Family

Members of the SOX family of transcription factors, which contain a high mobility group (HMG) DNA binding domain, function as key regulators of cell fate and differentiation. Of the 20 known SOX proteins, SOX2, 4, 9, 11, and 17 are found in the developing lung. SOX2 is highly expressed in nonbranching epithelium but repressed by FGF10 in epithelial cells that are actively invading the surrounding mesenchyme,[127] suggesting that silencing of SOX2 is required for the epithelium to branch. Overexpression of SOX2 in lung epithelial cells inhibits lung branching by forcing the cells to prematurely commit to a differentiation program, thereby rendering the cells incompetent to respond to branching signals.[128] SOX9 is widely expressed in the embryonic lung epithelium throughout development. Whereas mice with a global deletion of SOX9 have significant skeletal and cartilage malformations, targeted deletion of SOX9 from the respiratory epithelium has no apparent effect.[129] SOX11 is also expressed throughout the developing lung epithelium, and mice null for SOX11 have significant lung hypoplasia.[130] SOX17 expression in the lung is dynamic, being first detected in the mesenchyme during the embryonic stage, then in the conducting airway epithelium during the canalicular stage. Because its misexpression in the distal epithelium disrupts branching and causes the ectopic expression of proximal airway markers, SOX17 is thought to play a key role in specifying differentiation of airway epithelial cells.[131,131a]

Summary

Beginning as a single outpocketing of the foregut, the human lung endoderm develops into an elaborate network of airways connected to alveoli that are intimately apposed to the microvasculature. The number of different cell types in the lung, combined with the morphogenetic specificity required to generate an organ capable of maintaining efficient gas exchange, makes the molecular regulation of lung development very complex. The number of soluble factors known to mediate tissue crosstalk in the developing lung continues to grow, and it is becoming increasingly evident that the importance of these factors is dependent on their temporal and spatial expression. Adding to this complexity is the influence of insoluble extracellular matrix molecules, which we have not discussed here. Not only does matrix provide structural integrity for the developing lung, but it also contributes crucial cell signaling functions and influences the availability of diffusible factors to neighboring cells. The list of transcription factors regulating gene expression relevant to lung growth and differentiation is also extensive. As the sheer number of transcription factors, signaling molecules, growth factors, matrix molecules, and related proteins continues to expand, it becomes possible to construct transcriptional and proteomic networks reflecting the molecular developmental "blueprint" required to make the transition from primitive endoderm to mature lung. Crucial pathways, nodes and intersections will undoubtedly become apparent and should serve as the basis for targeted therapeutic interventions to treat lung injury and disease. Those who treat pulmonary disorders will best serve their patients by understanding the molecular and developmental basis supporting their clinical care.

KEY POINTS

- The lung epithelium begins as two buds from foregut endoderm. Subsequent branching morphogenesis and alveolarization lead to a mature organ containing over 300 million alveoli.
- Development of the pulmonary vasculature mirrors epithelial morphogenesis.
- Lung development requires reciprocal interactions between the epithelium and the mesenchyme derived from splanchnic mesoderm.
- Tissue interactions are mediated by an array of diffusible signaling molecules. Variations in the temporal and spatial expression of these mediators add complexity to these interactions.
- Diverse classes of transcription factors that lie downstream of diffusible mediators further regulate morphogenesis and effect the differentiation of individual cell types.

THE PATH FORWARD

INTRODUCTION

There are two fundamental causes of most human diseases, genetic polymorphisms and environmental exposures. The first step in any investigation of the genetic causes of a disease or phenotype is to determine the relative importance of these two causes of the disorder. To begin this process, one must determine the heritability of the disease of interest. *Heritability* is defined as the estimated percentage of phenotypic variation that is due to genetic factors. Often, the first step is to determine if the trait, disease, or phenotype aggregates in families, but this will not prove that the trait of interest is genetic as traits can aggregate in families for purely environmental reasons, such as cigarette smoking, or because the prevalence of the trait is high, such as obesity. So the only direct way to determine whether a disease has a genetic cause is to measure heritability. Heritability can be estimated in twin studies, that is, a greater concordance of the phenotype between identical (monozygotic) twins than fraternal (dizygotic) twins. Such data provide evidence of significant heritability. For lung disorders, heritabilities range from 20% to 90% depending on the type of lung disease, the mode of inheritance, and the degree of environmental influence.

There are two primary types of genetic disorders: monogenic (due to a single gene) or complex (due to multiple genes). Monogenic disorders demonstrate high heritability, segregate in families in a predictable way, and are caused by a single major gene with less obvious environmental influence. The single gene usually has specific variation in the coding region of the gene that leads to an abnormal protein that causes an obvious clinical phenotype. Often the phenotype has multiple components, suggesting multiple effects of the gene. This is called pleotropy or one gene having many effects. There are currently over 10,000 monogenic disorders that have been identified and are characterized in Online Mendelian Inheritance in Man (OMIM) (http://www.ncbi.nlm.nih.gov/sites/entrez?db=omim). Linkage mapping and then positional cloning (described later) have been the primary means of their identification. With the completion of the Human Genome Project,

attention has been turned to trying to identify genes associated with complex genetic disorders initially using similar methods but now primarily with genetic association studies.

In contrast to monogenic disorders, complex genetic disorders are caused by multiple genes and multiple environmental exposures, with each gene having a much smaller effect than that seen in monogenic disorders. Because of the multiple gene-gene and gene-environment interactions, there is no obvious mendelian mode of inheritance for complex traits. The most common hypothesis for the genetic basis of common disease is the common disease/common variant hypothesis. This hypothesis suggests that key genetic determinants of common diseases have a relatively high allele frequency, that is, 5% to 40%, and modest effect sizes. Given the modest effect sizes (odds ratios on the order of 1.1–1.4), large sample sizes are necessary to identify the genetic variants associated with complex traits despite the high allele frequency expected in these disorders.

The dichotomy described previously is now beginning to be broken down as geneticists realize that the clinical phenotype of many monogenic disorders varies as a result of other genes and environmental exposures. As genes for complex traits begin to be identified, their role in monogenic disorders is also being elucidated.

Scope of the Problem

Some complex genetic disorders, such as age-related macular degeneration, are oligogenic, where a small number of genes, 3 to 5, explain the bulk of the clinical phenotype. However, for most complex traits, literally hundreds of genes with small effects are involved in disease causation and thus there are a series of challenges that have faced complex trait geneticists as we enter the genome era of medicine.

Initial problems relating to genotyping reliability and completeness that were present at the time of release of the initial sequence of the genome have been largely resolved, but many problems still remain. Because genetic association studies are the backbone of gene finding in complex traits, issues of sample size and population stratification (confounding by allele frequency differences in cases and controls, discussed later) remain problems for investigators. The ability to determine if genetic effects are real or not requires replication of results in independent populations, a process that is difficult with the presence of phenotypic heterogeneity across populations. With the move to testing of 500,000 to 1 million markers in whole genome association studies, the problem of multiple comparisons is a major issue, and ultimately putting 100 to 500 genes together in networks to model disease occurrence will require formidable bioinformatics capabilities. Finally, the ultimate challenge of finding the actual functional variants in putative disease genes is still a laborious process without a clear-cut methodology for success.

Potential Impact of Human Genetics

Genetics has the potential, because of its hypothesis-free nature, to identify novel mechanisms of disease pathobiology and, hence, to identify novel targets for a therapeutic intervention or disease prevention. In addition, genetics has the potential to predict specific subgroups of patients with different clinical course or response of their disease or differences in treatment. Finally, genetics has the potential to allow for early detection of susceptible individuals at risk of a specific disease phenotype or to allow avoidance of environmental factors that are known to cause the disease or to institute preventive therapy before disease develops. Of all of these applications, the predictive one is likely to be implemented first. But the application of each of these genetic insights is still just beginning to occur and it may take time for genetics to become routinely used at the bedside.

MOLECULAR CHARACTERIZATION OF GENETIC VARIATION

Molecular genetics is elegant in its simplicity. Just four base pairs (two purines [adenine and guanine] bind to two pyrimidines [thymine and cytosine]) code for 20 amino acids that form the molecular building blocks of complex proteins. However, the assemblage of inherited genes (genotypes), control mechanisms, resultant proteins, and posttranslational modifications has the capacity to create a complex panoply of unique biologic, physiologic, or visible traits of an organism (phenotypes). The relationship between these rather simple molecular characteristics and the vast array of complex phenotypes is, in part, explained by a number of seminal discoveries that were made more than 50 years ago.

Gregor Mendel[1] was the first to demonstrate that discrete traits could be inherited as separable factors (genes) in a mathematically predictable manner. Mendel's laws describe the relationship between genotype and phenotype and establish the concept that each gene has alternative forms (alleles). Charles Darwin[2] made the observation that evolution represents a series of environmentally responsive "genomic" upgrades, and Thomas Morgan[3] established the concept of linkage by using *Drosophila* to discover that genes were organized (and inherited) on individual chromosomes, that recombination or exchange of genetic material between maternal and paternal chromosomes occurred during meiosis, and that the frequency of recombination could be used to establish the relative distance between genes. However, it was not until 1944 that Avery, MacLeod, and McCarty while working with *Pneumococcus* discovered that DNA was the essential molecule that transmitted the genetic code.[4] The double-helix structure of DNA was discovered by Watson, Crick, Chargaff, Franklin, and Wilkins in 1953,[5] and over the next 50 years, genetics assumed a central role in understanding the biologic and physiologic differences between and among species and between states of health and states of disease. In

aggregate, these seminal discoveries led to a number of basic principles in molecular genetics that provide the basic mechanisms that link the four base pairs (adenine [A] binding to thymine [T] and guanine [G] binding to cytosine [C]) to health and disease.

Genomic Maps

Over the past several decades, genomic maps have evolved from karyotypes (microscopic visualization of chromosomes during metaphase) to restriction enzyme sites to genetic maps to maps with specific base pair sequence. In fact, to date, there are 15 vertebrates, 8 invertebrates, 7 protozoa, 42 plants, 17 fungi, and hundreds of bacteria and viruses that have been sequenced and are available on the National Center for Biotechnology Information (NCBI) website (www.ncbi.nlm.nih.gov). Not only have these genomic maps been critical to identifying which genes and sequence changes cause disease or enhance the risk of adverse outcomes, these species-specific maps have also led to a very clear understanding of molecular evolution and have provided essential tools to understand aspects of molecular biology. The construction of these genomic maps are based on the observation that the sequence of DNA is different from one organism to the next within the same species, and these allelic/sequence differences have been exploited to develop a number of commonly used DNA markers to create genomic maps (Table 3-1).

Genetic maps are based on the frequency of recombinant events defined as the exchange of genetic material between the maternal and the paternal chromosomes during meiosis. While Mendel's second law states that traits (or genes) are inherited independently, we now know that some genes do not segregate independently because they are on the same chromosome. Humans have 24 linkage groups, corresponding to the 22 autosomes, plus X and Y chromosomes. Genes on the same chromosome that are closer together are more likely to be inherited together (linked) than genes that are farther apart (may demonstrate independent assortment). In general, the greater the distance between genes on the same chromosome, the higher the recombination frequency (Fig. 3-1). Thus, the recombination frequency represents a measure of genetic linkage and is the fundamental event used to create a genetic linkage map. The unit of measurement for genetic linkage maps is the centimorgan (cM), with 1 cM equivalent to a recombination frequency of 1% (one recombinant event/100 meioses). While recombination frequencies vary across the chromosome, in general, at least for the human genome, a recombination frequency of 1% is equivalent to approximately 1 million base pairs. Genetic maps are constructed by identifying the number of recombinant events observed in parental meioses and are dependent on several factors: (1) the meioses observed; (2) the heterozygosity of the marker; (3) the physical distance between markers; and (4) the likelihood of recombination at that site. Genetic maps use a rather indirect method to estimate the order of genes and the relative distance between genes.

Genetic maps are routinely used in family-based linkage studies to identify the general location of genes that influence human traits and conditions. Highly polymorphic markers can be used as tags to identify regions of DNA that are associated with the occurrence of disease in families. These regions of DNA then serve as the targets to comprehensively interrogate the sequence of genes and their regulatory components. However, a

TABLE 3-1. Commonly Used DNA Markers

Restriction fragment length polymorphisms (RFLPs)—Presence or absence of a specific nucleotide sequence that can be cleaved by a restriction enzyme. These bacterial restriction enzymes fragment DNA only at sites that contain specific base pair sequences.

Variable number of tandem repeat polymorphisms (VNTRs)—Noncoding polymorphic base pair repeats in DNA (di-, tri-, and tetranucleotide repeats of CA or GT) that are present throughout the genome. At each site, the number of times a sequence is repeated may vary from one individual to the next.

Microsatellite polymorphism—Variable number of repetitions of a small number of base pairs within a sequence.

Single nucleotide polymorphisms (SNPs)—Individual point substitutions of a single nucleotide that do not change the length of the DNA sequence and occur throughout the genome (every several hundred base pairs).

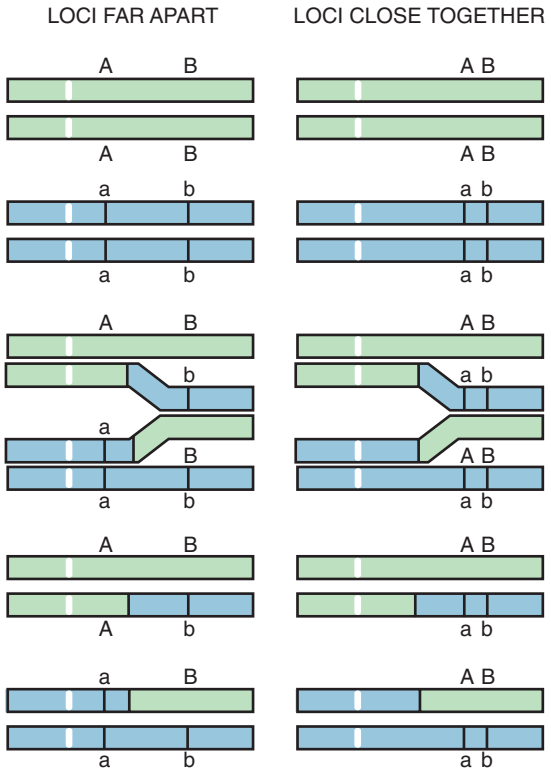

FIGURE 3-1 ■ Crossover between homologous chromosomes in meiosis. On the left is an example in which two loci are far apart on the chromosomes and so remain unlinked. On the right, the loci are relatively close to one another and so after recombination are more likely to remain together.

genetic linkage map should not be confused with a physical map of the genome since it is based on the rate of recombination, not the physical distance, between markers.

In contrast to a genetic map, a physical map describes the physical location of genes and the physical relationship between genes on each chromosome. Although the gene order from a genetic map and a physical map should theoretically be the same, the relative distance between genes may be quite different when comparing a genetic map (based on recombination frequency) with a physical map. The reason for this discrepancy is that some chromosomal regions, referred to as recombination hotspots, have much higher recombination frequencies than other regions. However, genetic maps provide a framework for the construction of physical maps.

While we typically think of physical maps as sequence-based, many years before sequence-based maps became available, investigators relied on lower resolution cytogenetic (chromosomal) and radiation hybrid maps. Cytogenetic maps are based on chromosomal banding patterns and have been used to locate genes in patients with chronic granulomatous disease, Duchenne's muscular dystrophy, and fragile X syndrome. Radiation hybrid maps, like genetic maps, estimate the physical distance between markers, but use breaks in DNA induced by radiation to determine the distance. By changing the dose of radiation, one can produce more (or less) resolved maps. Radiation hybrid maps have been extremely useful in ordering markers in a region when highly polymorphic markers were scarce.

Two major breakthroughs occurred during the early 2000s that has forever changed human genetics—the sequencing of the human genome[6,7] and the International HapMap Project[8] to identify the sequence specific differences and similarities between individuals. With the sequencing of the human genome, investigators for the first time had a detailed road map of the human genome that identified the genes, regulatory units, and noncoding sequence with a very high degree of resolution. Among the 3.2 billion base pairs in the human genome, less than 1% uniquely identifies each human being.[9] Single nucleotide polymorphisms (SNPs) are predicted to occur at least every 300 base pairs. While only 40% of these SNPs will result in amino acid changes, these SNPs provide the genetic diversity that underlies the variable susceptibility to environmental stimuli and the variable risk of disease development and progression.[9] By comparing the genetic sequences of different individuals, the HapMap Project was able to identify chromosomal regions where genetic variants were shared between individuals. While the initial HapMap project focused on four populations from African, Asian, and European ancestry, ongoing work is expanding these maps of shared genetic material.

In aggregate, the human DNA sequence and the shared genetic patterns between individuals have enabled geneticist to define the organization of genetic variants on chromosomes and the common inheritance of genetic variants. These developments have provided the polymorphic markers and the regions that are tagged to these markers that facilitate the identification of regions and genes. Consequently, real progress is now being made in identifying common genetic variations that contribute to complex diseases such as asthma,[10] age-related macular degeneration,[11] type 2 diabetes,[12] and prostate cancer.[13]

Comparative Genomics

Because DNA structure and protein functions are often conserved through evolution, the use of model organisms can enhance the efficiency of gene discovery and can provide insights into biologic responses to endogenous and exogenous forms of stress. Although genes present in humans oftentimes have counterparts in other species, the homology between gene and chromosomal structure across species does not necessarily lead to conserved protein function. However, the conservation of gene sequence and chromosomal structure in different organisms has resulted in accelerated gene discovery, insights into human biology, and a data-driven understanding of evolution. Despite this excitement, the field of comparative genomics is at a very early stage of development[14] and is dependent on evolving databases, like Gene Ontology functional classifications,[15] to facilitate these cross-species comparisons.

Comparative genomics is a powerful approach to search for disease-causing genes. Identifying similar regions of DNA associated with concordant phenotypes in multiple species enhances the confidence that a gene causing that disease resides in that locus. The overlapping DNA for concordant phenotypes between species can be used to substantially narrow the region of interest. Because there are approximately 340 known conserved segments between mice and humans,[16] a mouse region of interest associated with a trait can be used to narrow the human region of interest associated with a disease. In addition, the genomes of model organisms, such as mice, flies, worms, or yeast, can be manipulated through genetic engineering (resulting in deficiency or overexpression of a gene or controlled expression of a human allele) to further understand the function of a specific gene. For example, the discovery of the importance of the Toll-like receptors in innate immunity in mammals occurred as a direct result of the observation that a defective receptor in flies caused them to be much more susceptible to *Aspergillus fumigatus*.[17,18] The importance of this finding is clearly illustrated in the variations in the Toll-like receptors that alter the response to microbial pathogens[19] and modify the risk of developing a variety of diseases that are associated with innate immunity.[20] The ease with which we can observe and apply knowledge across model systems should be exploited so that we can efficiently understand the biologic and clinical importance of key regulatory genes.

Public Databases

If compiled in books, the data produced in defining the human genome would fill 200 volumes, each the size of a 1000-page phone book. Reading it would require 26

years working around the clock. While new tools are being developed to analyze, store, and present the data from genome maps and sequences, several databases presently exist that can be accessed through the Internet.

Important lessons can be learned from a detailed consideration of the characteristics of identified mutations in Mendelian diseases using online resources such as OMIM, the Human Gene Mutation Database (HGMD), and LocusLink.[21] For example, the data on the relative frequency of types of mutations underlying disease phenotypes indicate that mendelian disease genes most often have alterations in the normal protein-coding sequence. For general information on accessing sequence information, several available reviews provide details on available databases and searching strategies.[22] Table 3-2 gives the genetic variation–focused databases available on the Web. The NCBI is responsible for the final and reference assembly of the human genome (http://www.ncbi.nlm.nih.gov). Each DNA sequence is annotated with sequence features and other experimental data, including location of SNPs, expressed sequence tags, and clones. Up-to-date genetic sequence information can be obtained from Ensembl (http://www.ensembl.org), the University of California at Santa Cruz Genome Browser, and NCBI's GenBank. NCBI's Map Viewer provides a tool through which genetic maps and sequence data can be visualized and is linked to other tools such as Entrez, the integrated retrieval system providing access to numerous component databases (http://www.ncbi.nlm.nih.gov/Entrez/index.html). The database of Single Nucleotide Polymorphisms (dbSNP) at the NCBI allows the user to search for SNPs within a region of interest (http://www.ncbi.nlm.nih.gov/SNP).

GENETIC EPIDEMIOLOGY

Genetic Markers and Their Inheritance

The human genome is composed of approximately 3 billion base pairs. With the exception of identical twins, each human being has a unique DNA sequence. There are at least 10 million locations in the genome where DNA sequence varies between individuals. These locations are referred to as *polymorphic*, where there are at least two variants (also known as alleles) that occur with greater than 1% frequency. There are two commonly studied polymorphisms in human genetics; short tandem repeat (STR) markers (also known as microsatellites) and single nucleotide polymorphisms (SNPs). In general, STR markers are used for linkage and SNPs are used for genetic association studies, although technically, either marker can be used for both types of investigation.

STR markers are repeats of two, three, or four bases that are reasonably frequent in the genome. They tend to have multiple, common alleles that allow the transmission of specific regions on a chromosome to be followed accurately through a pedigree. They are not usually disease-susceptibility variants themselves, although they may be linked to such a variant.

There are approximately 12 million SNPs in the human genome. These are single base pair changes that result in allelic variation at a locus. So one could be c or g, and hence, all individuals are one or the other allele. These are the most common source of genetic variation used in genetic association studies. In addition to SNPs and STRs, insertions, deletions, and larger structural variations also occur commonly in the human genome.

Disorders that are monogenic typically have SNPs, insertions, or deletions within a single gene that result in a clear phenotype that segregates in families in a recognizable pattern. These patterns are clinically recognizable as definable Mendelian modes of inheritance (e.g., autosomal dominant, autosomal recessive, or x-linked dominant or recessive). Examples of monogenic disorders would be chronic obstructive pulmonary disease (COPD) due to severe alpha$_1$ antitrypsin deficiency, which results from mutations in the SERPIN A1 gene; or cystic fibrosis, which is the most common autosomal recessive disorder in white, which is due to mutations in the cystic fibrosis transmembrane conductance regulator gene (CFTR).

Linkage and Positional Cloning

Linkage analysis is a property of families and encompasses a group of genetic methods to analyze the distribution of DNA markers within families to determine whether there is a relationship between a particular region of the genome and a phenotype of interest. A requirement of linkage is to have family data, either extended pedigrees, trios, or affected sib pairs. The technique uses the concept of linkage disequilibrium or nonrandom assortment of alleles and the tendency of nearby genetic loci to be inherited together. When a mutation occurs on a particular chromosome, initially there is a large shared segment of DNA and hence linkage disequilibrium around it. With each subsequent generation, this region of linkage disequilibrium becomes smaller as a result of meiotic recombination. A basic approach in linkage analysis is to determine if alleles at two independent loci segregate together more often than one would

expect by random assortment or chance. This can be assessed by comparing the frequency of recombinant chromosomes in which a crossing over event has rearranged the parental chromosomes with the frequency of nonrecombinant chromosomes. When the loci are linked, parental chromosomes are more common than recombinant chromosomes. The strength of the linkage, expressed as the recombination fraction, is dependent on the genetic distance between loci. The more tightly linked the two loci are, the less likely it is to find recombinant chromosomes.

Linkage results are usually expressed as a LOD score, which is the result of a statistical test to determine if genetic loci are linked. LOD scores are log of the base 10 of the odds that the loci are linked and depend on study design. Linkage studies are usually based on STR or SNP markers distributed through the genome to search for susceptibility genes located anywhere on the genome. One of the tested markers will be close enough to demonstrate evidence of linkage. Typically, a genome-wide linkage scan requires about 400 STR markers that are equally spaced across the genome. LOD scores of 3 to 3.6 correspond to significant linkage. Linkage analysis was originally developed using a specific genetic model in which the allele frequency penetrance and mode of inheritance are specified. Positional cloning typically begins with genome-wide linkage studies, followed by fine mapping of linked regions with genetic association studies, either case-control or family-based, which are described later. Thus, the technique is ideal for classic Mendelian, monogenic disorders, but is less well adapted for complex traits, where these parameters are often not known. However, nonparametric methods have been widely used in complex traits, and this approach can be combined with genetic association within the linked region to identify disease susceptibility genes, particularly for asthma and Crohn's disease.[23–27]

Genetic Association and Candidate Genes

Zhang and Risch[28] have suggested that association studies can be a very powerful approach for finding genetic determinants of a complex disorder. Currently, genetic association studies are the most commonly used study designs to find disease genes in complex traits. These can be used in conjunction with linkage studies (positional cloning) or de novo with candidate genes or genome-wide association studies (GWAS). There are two basic types of study designs used for genetic association studies. These are the case-control study, and the family-based study.

Case-control studies are the most frequently performed type of genetic association studies because they are the easiest to do. In their simplest form, population-based genetic association studies are similar to epidemiologic case-control studies and involve identifying genetic markers with significant allele-frequency differences between individuals with the phenotype of interest (cases) and a set of unrelated control individuals.[29] A statistical association between genotypes at a marker locus and the phenotype can arise for three reasons: (1) the allele is the actual disease allele, (2) the allele being studied is in linkage disequilibrium with the true disease allele, and (3) a spurious association due to population stratification. Indeed, case-control genetic association studies have already contributed to identifying genes associated with complex disorders, as in the cases of apolipoprotein E-4 with late-onset Alzheimer's disease[30] and factor V gene with venous thrombosis.[31] Thus, performing valid case-control studies remains important in elucidating genetic risk factors for complex traits. Silverman and Palmer[32] have reviewed these factors that may adversely affect the results of any association study in complex diseases. They have recommended five key elements in the performance of valid case-control genetic association studies for complex diseases. These include (1) proper selection of gene polymorphisms, (2) accounting for population stratification, (3) assessment of Hardy-Weinberg equilibrium, (4) replication, and (5) adjustment for multiple comparisons.

Ideally, cases and control study subjects should be drawn from the same base population. Failure to do so will often result in biased selection that can adversely influence the results, often resulting in a spurious association. When subjects with different evolutionary histories and hence different genetic backgrounds are differentially selected to be cases and controls, this can cause spurious results, termed "population stratification." An approach useful in case-control studies to control this problem is to assess for population stratification in case and control groups by genotyping randomly distributed polymorphic markers.[33,34] Failure to demonstrate association to these random markers suggests that significant population stratification is not present, and case-control genetic association studies can likely be performed without significant risk of erroneous results due to population stratification. If population stratification is demonstrated between the case and the control populations, methods to detect significant disease gene associations have been developed based on correction for the degree of stratification.[34,35] A second major problem with case-control studies is that often too small sample size is used, often resulting in spurious association. Because of the small effect size seen in complex trait genetic association, sample size in the thousands is needed with replication to generate unequivocal results.

Family-based genetic association tests (FBAT) are based on the transmission disequilibrium test (TDT), which provides a test of linkage and association without bias from population stratification or admixture.[36,37] Parents and an individual offspring (child or proband) with the disease phenotype are recruited. Only trios with at least one heterozygous parent at the genetic marker of interest are used for testing. The test is predicated on hypothesizing that if a genetic locus is uninvolved in the phenotype of interest, one would expect the parents' allele at that locus to be transmitted equally (i.e., Mendelian, transmitted 50% of the time). However, if the locus is actually associated with disease, there will be over- (or under-) transmission of the allele at that

locus—and its transmission will differ significantly from the expected 50%.

Family-based association studies cost more than case-control studies because one has to recruit and genotype three people instead of two. In addition, not all diseases can utilized the family-based design because often parents have died and hence are not available for study. Despite these disadvantages, there are also powerful reasons to use trios if possible. First, unlike the case-control study, the family-based association study is immune to population stratification because you are using the parental genotype as the control. Second, within each trio, only one person (the subject) must be phenotyped. This is particularly useful when phenotyping is very expensive or invasive. Family-based testing also offers an important method of assessing genotyping quality, because data can be analyzed for mendelian errors.

Linkage disequilibrium with a gene or a region of a chromosome is very helpful in genetic association studies. When two SNPs are on separate chromosomes, they will segregate randomly (i.e., carrying the minor allele at SNP A does not affect your chances of carrying the minor allele at SNP B). If, conversely, the SNPs are in linkage disequilibrium, with little or no recombination between them, the genotype at SNP B can serve as a surrogate for SNP A. Thus, testing of all SNPs in a gene or a region of the genome is unnecessary. One need only select a subset of SNPs that will accurately capture the linkage disequilibrium pattern of the region of interest to be comprehensive. SNP selection in genetic association studies involves two major approaches: GWAS, in which 500,000 to 1 million SNPs are genotyped, or candidate gene studies, in which a single gene is genotyped.

Genome-Wide Association Studies

In GWAS, SNPs are selected to cover as much of the genome as possible. SNPs across all chromosomes and most genes are selected to assess association with a phenotype of interest. There are currently two companies Affymetrix and Illumina that have different SNP selection strategies and different chip chemistry for doing GWAS. Affymetrix has selected 1 million SNPs randomly distributed across the genome whereas Illumina has selected 500,000 haplotype-tagging SNPs, based on the HAPMAP project. Both platforms provide 80% coverage of common variants.

There are three major issues with GWAS as currently conceived. The first issue is cost. One can genotype an individual for about $500/subject with a per SNP cost of less than 1 cent. While this genotyping cost is reasonable, the large sample size required for these studies results in millions of dollars for a single case-control study. The second major issue in these studies is multiple comparisons; if one is doing over 500,000 separate statistical tests, then there needs to be a careful plan to deal with multiple comparisons; this usually involves replication in several other populations. Finally, one needs to be able to manipulate large amounts of data and strong bioinformatics is necessary for both computation and data storage.

Candidate Gene or Region-based Testing

There are three types of candidate gene studies. One can use this approach to follow up a region of linkage to determine which gene or genes in a region are responsible for the linkage signal. One can use this approach to follow up genes or SNPs of interest that are identified by GWAS. Finally, one can use known biology to direct the choice of specific candidate genes of interest for association testing. The number of SNPs studied depends on the number of genes or the region, the size of the genes, and the ultimate purpose of the study. Numbers of SNPs test can vary from simple replication of one or two SNPs previously identified to full sequencing of a region of interest to identify new variation and potentially functional SNPs and then their testing in a population. Cost and available genotyping platforms are all important determinants of SNP selection.

Gene by Environment Interaction

Because both genes and environmental exposures are known to cause complex traits, performing studies to test both factors in one study design is of great value. The study designs outlined previously, family-based or case-control, can be used to test both sets of variables. There are two major issues in these studies, accurate measurement of exposure and statistical power.

Much has been made of the difficulties of accurately measuring the environment as an exposure for genetic association studies. While some environmental factors such as diet are hard to measure accurately and require complex techniques, other exposures such as cigarette smoking can be measured with precision. Accurate measure of exposure will greatly enhance the ability of these studies to provide new insights into disease pathogenesis.

The second major issue in these types of studies is having a large enough sample size to have both exposed and unexposed among the case group to detect an effect. With allele frequencies that can be less than 10%, very large groups of subjects are necessary for these studies. At minimum, 1000 cases and 1000 controls will be needed even for allele frequencies of 30%. Finally, it will be difficult to replicate these types of studies because finding several studies with similar exposures measured in similar ways is often impossible.

EPIGENETICS

Epigenetics is the study of changes in gene transcription that are dependent on the molecules that bind to DNA, rather than the sequence of DNA.[38,39,39a] This includes both heritable changes in gene expression in the progeny of cells or of individuals and stable, long-term alterations in the transcriptional potential of a cell or tissue that are not necessarily heritable. Because epigenetic processes are highly interdependent and regulate gene expression in an age, state, cell-, and tissue-dependent manner,

TABLE 3-3. Known Epigenetic Mechanisms

DNA methylation—The methyl group is transferred from *S*-adenosylmethionine to the C-5 position of cytosine by a cytosine-methyltransferase. Hypermethylation of CpG motifs, particularly at promoter and enhancer sites, silence gene transcription. Alternatively, hypomethylation of these motifs enhances gene transcription.

Noncoding RNAs—Bind to DNA and interfere with transcription and posttranscriptional regulation of gene expression.

Histone modification—Histones, the building blocks of nucleosomes, undergo numerous posttranslational modifications (methylation, acetylation, or phosphorylation with >100 conserved, covalent modifications) that regulate chromatin structure and gene expression.

collectively, these mechanisms constitute a complex system of molecular controls that affects biologic processes and human diseases.

Whereas the fundamental mechanisms of epigenetics continue to evolve, it is recognized that epigenetic regulation of the genome results in a hierarchy of transcriptional switches that facilitate development and differentiation, normal tissue function, and the ability of the host to respond to stress.[38,39] There are three primary mechanisms that are known to govern gene expression (DNA methylation, noncoding RNAs, and histone modification) and may be inherited, independent of the sequence of DNA (Table 3-3). DNA methylation is controlled by cytosine-methyltransferase, which transfers the methyl group from *S*-adenosylmethionine to the C-5 position of cytosine. Hypermethylation of CpG motifs, particularly at promoter and enhancer sites, silences gene transcription. Alternatively, hypomethylation of these motifs enhances gene transcription. Noncoding RNAs bind to DNA and interfere with transcription and posttranscriptional regulation of gene expression. Histones, the building blocks of nucleosomes, undergo numerous posttranslational modifications (methylation, acetylation, or phosphorylation with > 100 conserved, covalent modifications) that affect chromatin structure and alter gene expression. In aggregate, these mechanisms serve to regulate the transcriptional activity of specific genes, at specific stages of development, and in response to specific forms of endogenous and exogenous stress. Importantly, these mechanisms are conserved in eukaryotic organisms, from yeast to humans.

Epigenetic mechanisms can have profound effects on cellular, tissue, and whole organism phenotype. Phenotypes that are known to be affected by epigenetic regulation include fundamental mechanisms such as stem cell differentiation[40] and inactivation of the X chromosome,[41] carcinogenesis[42] and cancer prognosis,[43] and even basic aspects of learning and memory.[44,45] Moreover, genomic imprinting (epigenetic mechanisms that lead to preferential expression of either the maternal or the paternal allele) has been shown to be the cause of rare genetic anomalies such as the Prader-Willi, Angelman's, Beckwith-Wiedemann, and Siover-Russell syndromes.

A convincing demonstration of the profound effect that epigenetic mechanisms can have on in vivo phenotypes is the coat color of the agouti mouse.[46] Transposable elements (retrotransposons and DNA transposons) constitute over 35% of the human genome and are normally silenced (epigenetically) by cytosine methylation within CpG dinucleotides of DNA. The yellow agouti mice harbor a transposable element in the *agouti* gene; expression of this gene results in a yellow mouse, lack of expression due to methylation results in a brown mouse. It has been shown that the concentration of methyl donors in the diet of pregnant agouti mice has transgenerational effects on coat color of the progeny due to altered expression of the *agouti* gene caused by methylation of the *agouti* promoter.[46] Genetically identical pups could be produced that were either preferentially yellow or brown depending on whether the pregnant mice were treated with a low-methylation or a high methylation diet (Fig. 3-2). While the yellow mice express the *agouti* gene, these mice undoubtedly express other genes that enhance their risk for obesity, diabetes, and cancer.

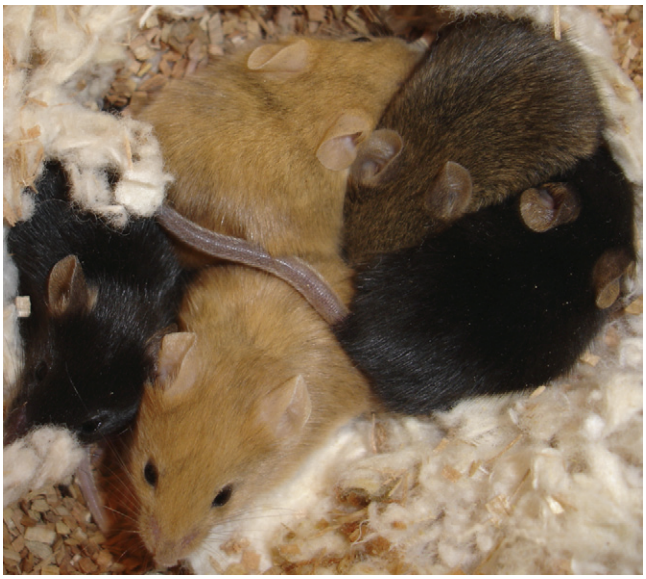

FIGURE 3-2 ■ Genetically identical agouti pups that are either preferentially yellow or brown depending on whether they were gestationally exposed to a low-methylation or a high-methylation diet.

Whereas epigenetic marks can be inherited, these potent regulators of transcription can also be modified throughout development[42] and by the environment.[47] For instance, whereas monozygotic twins are genetically identical, twin pairs often differ in phenotype (anthropomorphic features as well as disease outcomes). Global and locus-specific differences in DNA methylation and histone acetylation patterns indicate that early in life, monozygotic twins are epigenetically identical whereas older twin pairs have divergent epigenetic marks that are associated with differences in gene expression.[42] These findings suggest that various life events can alter epigenetic marks that may account, in part, for these phenotypic differences in twin pairs. Moreover, environmental endocrine disruptors (methoxychlor and vinclozolin)

have been shown to induce transgenerational effects on male fertility that occur as a result of DNA methylation.[47] In aggregate, these findings suggest that the epigenome can be reprogrammed, potentially affecting the risk, etiology, and treatment of various disease states.

The technology to measure epigenetic changes is continuing to evolve, and with the advent of pyrosequencing, it will soon be feasible to detect the epigenetic modifications of the entire genome during states of stress and disease. DNA methylation has been traditionally evaluated using methylation-sensitive restriction enzymes in conjunction with Southern blotting. However, this labor intensive approach has been largely replaced by bisulfite modification of DNA that deaminates unmethylated cytosines to uracils without affecting methylated cytosines. The cloned region of DNA is then amplified by polymerase chain reaction (PCR) and sequenced, with the unmethylated cytosine (that was converted to a uracil) being replaced by a thymine and the methylated cytosine amplifying as a cytosine. Methylation-specific polymerase chain reaction (MSP), a method that uses primers specific for methylated or unmethylated genomic DNA, is higher throughput but is unable to detect the exact pattern of DNA methylation. Thus, more global approaches, such as methylation-specific digital karyotyping,[48] array-based methylation hybridization, or methylated DNA immunoprecipitation coupled with either tiling arrays that include most of the human promoters or pyrosequencing are now being used. Functionally relevant methylation changes can be detected using demethylating agents with expression microarrays. However, the expression changes induced by demethylating agents could be caused by indirect effects of the drug.

High-quality antibodies have been used to detect known modifications in the amino acid residues of histones. While these antibodies can be used for Western blotting, they are more commonly used in a chromatin immunoprecipitation (ChIP) assay to measure the concentration of specific histone modifications at specific loci. ChIP can be used in conjunction with either microarrays (ChIP-chip) or pyrosequencing (ChIP-sequencing) to evaluate global changes in histone modifications. As the cost of sequencing decreases, these assays will become increasingly accessible.

Considering the importance of the environment in the development of lung disease, it is somewhat surprising that more attention has not been devoted to epigenetic mechanisms that lead to acute and chronic forms of lung disease. Epigenetic mechanisms (silencing of tumor suppressor genes) and patterns (hypomethylated DNA) have been associated with a number of tumors. In fact, it has recently been reported that the methylation pattern of six genes is associated with the development of lung cancer.[49] However, research is just beginning to emerge demonstrating the relevance of epigenetic changes and nonmalignant forms of lung disease. In humans, bronchial biopsies and alveolar macrophages have increased histone acetyltransferase (HAT) activity and reduced histone deacetylase (HDAC) activity in some diseases.[50–52] These consequent increases in histone acetylation enhance gene transcription and are thought to be important in the transcriptional regulation of inflammatory mediators in these airway diseases. In fact, steroid-treated asthmatics have reduced HAT and increased HDAC activity, presumably resulting in less airway inflammation.[52] In murine studies, methylation has been shown to alter the expression and activity of lineage-specific transcription factors that affect the maturation of naive T cells.[53–55] These results suggest that a hypomethylated state results in a Th1 phenotype whereas a hypermethylated state results in a Th2 phenotype. Because cigarette smoke, vitamin supplementation, and other environmental exposures can alter the epigenetic marks along the human genome, studying the importance of changes in DNA methylation, expression of noncoding RNAs, and structural changes in amino acid residues of histones should help us to understand the fundamental mechanisms associated with the etiology and progression of several types of lung disease.

Moreover, the epigenome can be modified by a variety of drugs. Compounds that alter DNA methylation and the amino acid residues on histones are most actively being investigated among patients with cancer. Two DNA methylation inhibitors, 5-aza-deoxycytidine and 5-azacytidine, have recently been approved by the U.S. Food and Drug Administration for the treatment of myelodysplastic syndrome, a preleukemic disease. Compounds that inhibit histone deacetylase (HDACi) have proapoptotic and antitumor properties and are undergoing phase I trials. Suberoylanilide hydroxamic acid, an HDACi, has been approved for the treatment of T cell cutaneous lymphoma. Interestingly trichostatin A, another HDACi, has been shown to decrease ovalbumin-induced allergic airway disease in a murine model of asthma.[56] As we begin to understand the role of epigenetic mechanisms in the development to lung disease, it will become much more obvious how we can modify these mechanisms therapeutically to reduce the burden of lung disease among our patients.

APPLICATION TO PULMONARY DISEASES

Asthma

Although there are more than 500 genetic association studies for asthma, most suffer from the methodologic problems discussed previously (Fig. 3-3). Most of the positive findings of these studies have not been adequately replicated. To date, there have been reports of positive associations between variants in over 100 genes and asthma phenotypes. Using the gene as the unit of replication (a liberal criterion), 54 associations have been replicated in at least two populations and 25 associations were "replicated" in at least six populations.[57] Replication is very loosely defined in this review. Space constraints do not allow us to cover all of these 79 genes but we review some genes of particular interest later. Candidate genes for association studies of asthma and/or its intermediate phenotypes have been selected on

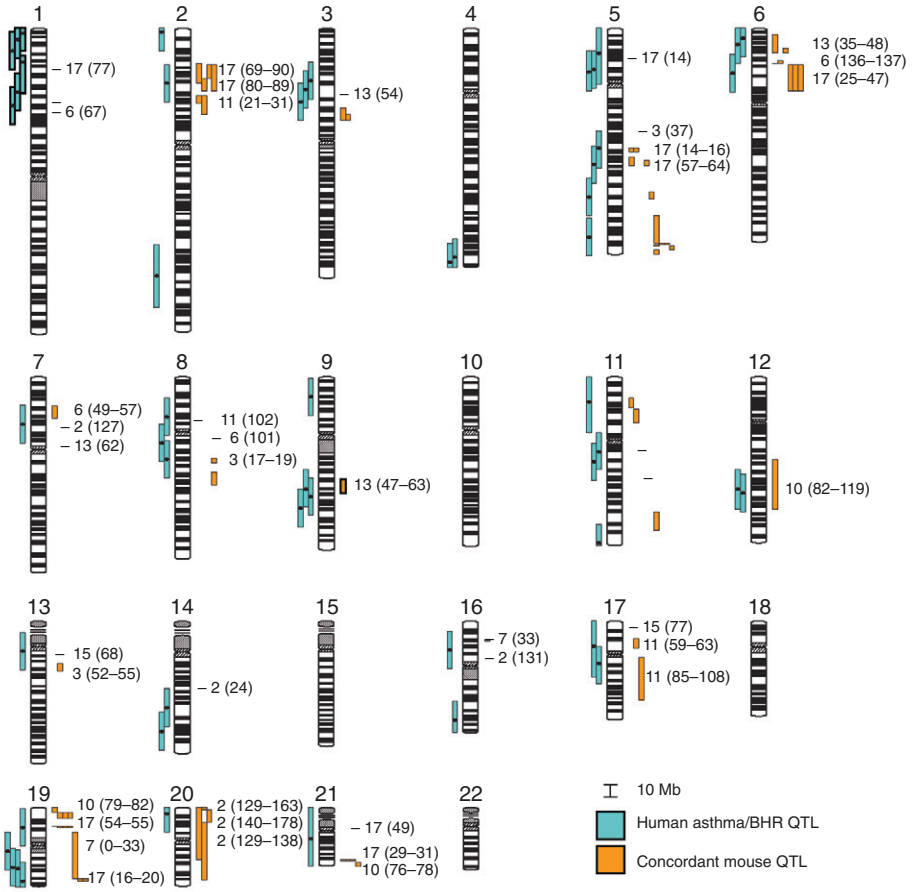

FIGURE 3-3 ■ Chromosome map of human QTLs for asthma and BHR and mouse concordant regions. The 95% confidence intervals (CIs) of human QTL are shown as *blue bars* to the left of their respective chromosome, with the peaks indicated by a *black line*. These data are also given in Table 3-1. Mouse asthma QTLs that are concordant to Human QTL are shown to the right of each chromosome with the mouse chromosome and the position given in parentheses. Chromosomes are drawn to scale, based on the length of each chromosome from the Human Genome Browser (www.ensembl.org/Homo_sapiens). As many of the human studies do not report CIs or names of the markers that flank the intervals, determining accurate CIs is difficult. Here (and in Table 3-1), we generated a conservative CI by including a region of 15 million base pairs both up and downstream of the peak. (From Stylianou IM, Singh J, Schwartz DA, Paigen B: Comparative genomics of asthma. In Postma DS, Weiss ST [eds]: Genetics of Asthma and Chronic Obstructive Pulmonary Disease. London: Taylor & Francis, 2006, pp 159–177, with permission.)

the basis of the results of genome-wide linkage analyses ("positional") and/or their biologic plausibility in asthma pathogenesis ("functional"). With regard to the 25 genes "replicated" in five or more association studies, careful review of these genes finds a substantial number of negative studies for all of them. The number of negative studies is likely biased toward the null because of publication bias.

Five potential asthma susceptibility genes have been identified using a positional cloning approach.[24-27,58] In all but one case,[58] significant linkage between a chromosomal region and asthma phenotypes was found in a genome-wide linkage analysis, and fine-mapping studies of linkage and association were then performed in the linked genomic region. Following fine-mapping studies, an association between variants in a specific gene and asthma phenotypes was identified in at least two populations. Using positional cloning, Laitinen and coworkers[27] identified a novel asthma susceptibility gene (G protein–coupled receptor for asthma susceptibility [*GPR154* also known as *NPSR1*]) on chromosome 7p. These investigators provided adequate functional data on *GPR154* by showing not only that the mouse orthologue of *GPR154* (GPRA) is up-regulated in murine lung after ovalbumin challenge in sensitized mice but also that, in humans, *GPR154* encodes protein isoforms that are produced in distinct patterns by bronchial epithelial cells and smooth muscle cells in asthmatic and healthy individuals. Four additional genes on chromosomes 6p21 (HLA-G),[58] 13q14 (PDH finger protein 11 [PHF11]),[25] 2q14 (dipeptidylpeptidase 10 [DPP10]), and 20p13 (disintegrin and metalloprotease 33 [ADAM 33])[26] have been identified by positional cloning as potential asthma-susceptibility genes. However, there is inadequate functional data for these seven genes, and linkage dysequilibrium (LD) with variants in adjacent genes could also explain the associations between these genes and asthma phenotypes. For example, several groups have tried to replicate the

association between ADAM33 and asthma phenotypes, with mixed results.[59–62] In summary, positional cloning has identified seven potential asthma-susceptibility genes. Results of functional studies and replication studies of these five genes suggest that GPR154 is most likely to influence asthma pathogenesis. None of these genes replicates in all populations, suggesting that there are likely multiple genetic determinants of asthma and none that appears to be universal.

Finally, to date, only one gene, *ORMDL3*, has been identified by GWAS.[10] This association finding has been confirmed by others.[63,64,64a] Most asthma GWAS are underpowered, hence pooling or meta-analysis may be the way forward to identify more genetic determinants.

Asthma genes are being identified at an increasing rapid pace, and it is likely that by 2015, many, if not most, of the genetic determinants of the disorder will be identified. However, it is likely to take a longer time frame to translate this basic research into clinically useful information that will benefit patients.

Chronic Obstructive Lung Disease

COPD is characterized by incompletely reversible airflow obstruction and excess mucous production in the airways. In the United States, COPD affects 16 million individuals, is the fourth leading cause of death, and the only one among the leading causes of death to be increasing in prevalence.[65] The role of genetic predisposition in the pathogenesis of COPD had been overlooked until very recently, and yet there are intriguing features in this disease to strongly suggest gene-environment interactions. First, the Framingham Study demonstrated that longitudinal decline in lung function is inherited with a heritability of approximately 20%, which increases substantially when the subjects were stratified according to smoking status.[66] Environmental exposures such as smoking and pollution have been implicated in the pathogenesis of COPD since the 1960s, yet "only" 10% to 20% of smokers develop COPD symptoms, further indicating that a susceptibility factor may exist in some individuals. Alpha$_1$-antitrypsin is a prototypical susceptibility gene that is associated with increased rates of COPD development in active smokers. Recent studies have also implicated alpha$_1$-antitrypsin in the decline in pulmonary function observed in passive smoke exposure and occupational exposures in susceptible individuals with severely or moderately decreased levels. Furthermore, although, traditionally, emphysema and chronic bronchitis are considered to be clinically distinct chronic obstructive diseases, in practice there is a substantial gray zone between "pure" irreversible airway obstruction (i.e., COPD) and "pure" reversible obstruction (i.e., asthma). Many physicians are therefore now suspecting that asthma and COPD may be sharing common characteristics and genetic background (the so-called Dutch hypothesis). However, genomic research in COPD is still in its early stages, and specific genes have yet to be conclusively identified.[67,67a] Initial linkage studies have singled out regions in chromosomes 2 and 4[68,69] and serpine2[70] that may be linked to COPD susceptibility.

Acute Respiratory Distress Syndrome

Acute lung injury (ALI) leading to acute respiratory distress syndrome (ARDS) is a common complication of systemic inflammation and sepsis, occurring in approximately 50% of such patients. The mortality of ARDS remains high at about 30% to 40%, despite recent advances in mechanical ventilation and patient management. The pathogenesis of ALI/ARDS is thought to derive from the effects of systemic inflammation, cytokine production, and oxidative damage. However, the sporadic (nonfamilial) nature of ARDS hampers genetic analysis of human subjects. Genetic analysis of inbred mouse strains first revealed that ALI susceptibility was strain dependent and, therefore may, in part, be genetically determined.[71] Human studies identified angiotensin-converting enzyme (ACE) as a candidate gene for ARDS susceptibility.[72] Subsequent animal studies verified the role of ACE in ARDS susceptibility and further showed that ACE2, an ACE isoform that metabolizes the ACE product angiotensin II, is protective against ARDS.[73] This was the first set of studies to conclusively show a link and a mechanism for genetic susceptibility and ARDS pathogenesis. A candidate gene approach utilizing preexisting gene expression profiles in animal models as well as human data was used by the Johns Hopkins Translational Respiratory Program.[74] A number of candidate genes, mostly from the inflammation and coagulation pathways, were identified: interleukin (IL) -1β, IL-6, tissue factor, plasminogen activator inhibitor 1, and chemokine receptors were the most abundantly up-regulated proteins. Surfactant protein B (SP-B) polymorphisms have also been associated with increased susceptibility to ARDS.[75] SP-B has not been used therapeutically in adults with ARDS; however, a recent study in infants and children with ARDS showed significant improvement in survival with a surfactant that contained SP-B.[76] It appears that proteins involved in inflammation and coagulation represent promising candidates for susceptibility testing in ALI/ARDS, but results are still quite preliminary.

Lung Cancer

Lung cancer is now the most common cause of cancer-related deaths in the United States, and yet no more than 100 years ago, lung cancer was quite rare. The rise in lung cancer incidence demonstrates the effects of changing environmental exposures on human disease. Inhalation of environmental carcinogens causes the vast majority of lung cancer cases. Cigarette smoke dominates this list. Since at least the 1950s, it has been recognized that cigarette smoking causes most lung cancer cases. However, only a minority of smokers develops lung cancer, again suggesting the role of susceptibility in lung cancer pathogenesis. Unfortunately, cigarette smoke contains more than 4000 chemicals, a fact that makes the search for a single susceptibility factor much more difficult. Investigators have focused on specific classes of tobacco compounds that are known carcinogens, such as the polycyclic aromatic hydrocarbons (PAH). These are nontoxic in themselves but are metabolized

in the body by enzymes such as CYP1A1 into DNA-binding diol-epoxides. Several studies from Japan have shown a significant association of high-activity CYP1A1 variants with the occurrence of lung cancer.[77] Conversely, the main PAH-detoxifying enzymes are the glutathione *S*-transferases GSTM1 and GSTP1. Polymorphisms in these enzymes that lead to reduced activity have also been linked to lung cancer susceptibility.[78] The carcinogenic effect of cigarette smoke is thought to rely upon DNA binding and mutations of tumor suppressor genes, such as P53. PAH and other smoke constituents like acrolein can bind to so-called mutational hotspots of the P53 gene and induced DNA damage.[79] Accordingly, the ability of the organism to correct and repair DNA damage is closely linked to cancer susceptibility.[80,81] For example, a recent analysis of a European cohort of 116 patients with lung cancer showed a significant association between SNPs in the DNA repair enzymes XRCCI and BRCA2 and exposure to urban pollution in the susceptibility to cancer.[82]

Genomic medicine not only is helpful in detecting genes associated with the development of lung cancer but also can be used to guide therapy[83] and to determine the prognosis of the patient.[84,85,85a] Indeed lung cancers can now be categorized based on their gene expression profile.[84–87a] Furthermore, somatic mutations in proto-oncogenes such as K-RAS, BRAF, and epidermal growth factor receptor (EGFR) have been identified that could potentially become targets of cancer drugs. Indeed, one of the most encouraging reports in lung cancer research was the recent finding that certain non–small cell lung cancers harbor mutations in the EGFR. These cell lines become malignant through EGFR-induced apoptosis inhibition, but simultaneously become extremely sensitive to EGFR tyrosine kinase inhibitors like gefitinib or erlotinib. This was an impressive accomplishment of genomic medicine that provided a seamless link between the pathogenesis of lung cancer, the prediction of treatment effect based on genetic cancer characteristics, and the successful application of treatment to patients with lung cancer.[85]

Interstitial Lung Disease

Interstitial lung disease (ILD) is thought to result from the aberrant response of reparatory mechanisms to repetitive environmental lung injury. Several environmental factors like cigarette smoke, wood and metal dust, asbestos, radiation, infections, and drugs have been implicated in the pathogenesis of ILD. Although a clear-cut genetic susceptibility factor to these environmental triggers is still lacking, there is nevertheless intriguing evidence suggesting that genetic susceptibility may play a role in environmental ILD. Genetic diseases such as Hermansky-Pudlak syndrome, Nieman-Pick disease, or dyskeratosis congenita are associated with the occurrence of ILD.[88] Furthermore, mutations in SP-C[89,90] and telomerase genes[91,92] have been found in familial and sporadic cases of ILD. Finally, familial cases of ILD have been described in the absence of a distinct clinical syndrome. Interestingly, cigarette smoke was a major risk factor in familial cases of ILD, suggesting that a host-environment interaction may underlie the genetic susceptibility to familial ILD.[93] Genomic analysis of mouse models of fibrotic lung disease (using bleomycin and radiation as environmental triggers) has identified distinct genetic loci of susceptibility[94] and identified specifically the major histocompatibility complex II antigen H2-Ea as a candidate gene. Genomic methods have been applied to familial ILD, cases as well and a putative candidate gene, ELMOD2, has been suggested.[95] The exact role of this gene in ILD pathogenesis is still speculative. Recently, a large database of over 200 familial ILD patients has been compiled and analyzed in a U.S. multicenter trial.[93] Preliminary linkage analysis of these patients shows regions of particular interest on chromosomes 10, 11, and 12. Further genetic analysis will hopefully identify distinct candidate genes in these regions. Later efforts will attempt to replicate the familial ILD findings in "sporadic" ILD cases. The goal is to identify the genes involved in the pathogenesis and susceptibility of those who develop ILD with the ultimate hope of effective treatment options.

THE PATH FORWARD

Although the Human Genome Project has successfully mapped the human genome and has developed innovative technology for genomic studies, we remain limited in how this information can be used to improve clinical medicine and public health. This limitation arises from the simple fact that genetics is not the sole determinant of health or disease. In fact, although an emerging consensus suggests that many of the complex and prevalent diseases that humans develop occur as a result of multiple biologically unique gene-gene and gene-environment interactions, even this conceptual framework is limited. The development of disease in humans, environmental and otherwise, is simply far more complex. Environmental exposures affect those that are vulnerable temporally (age), spatially (geographically), and by unique circumstance (comorbid disease, nutritional status, economic status, race, and genetics). Even this paradigm fails to address the complex interaction of endogenous and exogenous risks that ultimately interact to cause disease. Moreover, diseases are not usually single entities; rather, most diseases represent several or many specific pathophysiologic processes that can be fully understood only by focusing on the genetic and environmental contributions to etiology and pathogenesis. Environmental health research and genomic research are logical, even necessary, partners. Ultimately, the discoveries that are made in environmental genomics will lead to better diagnosis, treatment, and prevention of these common, complex human diseases.

KEY POINTS

- Heritability is the best way to determine if a disease has a genetic basis.
- Complex genetic disorders account for the majority of lung diseases and are caused by multiple genetic variations and multiple environmental factors.
- Model organisms can enhance the efficiency of gene discovery and can provide insights into biologic responses to endogenous and exogenous forms of stress.
- The human genome is composed of approximately 3 billion base pairs. There are approximately 12 million SNPs in the human genome.
- Linkage analysis is a property of families and encompasses a group of genetic methods to analyze the distribution of DNA markers within families to determine if there is a relationship between a particular region of the genome and a phenotype of interest.
- Genome wide association studies (GWAS) have emerged as the most commonly used study design to find disease genes in complex disorders.
- Epigenetics is the study of changes in gene transcription that are dependent on the molecules that bind to DNA, rather than the sequence of DNA. This includes both heritable changes in gene expression and stable, long-term alterations in the transcriptional potential of a cell or tissue that are not necessarily heritable.
- Asthma is a heritable disorder but the genetics are complex with almost every chromosome demonstrating linkage and over 100 genes found to be associated with the development of asthma.
- The role of genetic predisposition in the pathogenesis of COPD had been overlooked until very recently, and yet there are intriguing features in this disease to strongly suggest gene-environment interactions.
- Because only a minority of smokers develops lung cancer, genetic and epigenetic mechanisms need to be considered.
- ILD is caused by environmental and genetic factors. Mutations in SP-C and the telomerase genes have been shown to enhance the risk of developing this disorder.

GAS EXCHANGE
Causes of Hypoxemia
Blood-Gas Transport

INTRODUCTION

This first chapter in the section on respiratory physiology is devoted to the primary function of the lung: gas exchange. In addition, the principles of ventilation and blood flow that underlie gas exchange are reviewed. Although the lung has other functions, such as metabolizing some compounds, filtering unwanted materials from the circulation, and acting as a reservoir for blood, gas exchange is its chief function. Respiratory diseases frequently interfere with ventilation, blood flow, and gas exchange and may ultimately lead to respiratory failure and death.

VENTILATION

The anatomy of the airways and the alveolar region of the lung is discussed in Chapter 1. There we saw that the airways consist of a series of branching tubes that become narrower, shorter, and more numerous as they penetrate deeper into the lung. This process continues down to the terminal bronchioles, which are the smallest airways without alveoli. All these bronchi make up the *conducting airways.* Their function is to lead inspired gas to the gas-exchanging regions of the lung. Because the conducting airways contain no alveoli and therefore take no part in gas exchange, they constitute the *anatomic dead space.*

Each terminal bronchiole subtends a respiratory unit, or *acinus.* The terminal bronchioles divide into respiratory bronchioles that have occasional alveoli budding from their walls. Finally, we come to the alveolar ducts, structures that are completely lined with alveoli. This alveolated region of the lung where gas exchange occurs is known as the *respiratory zone.* The region distal to the terminal bronchioles is sometimes referred to as the *transitional and respiratory zone* because the nonalveolated regions of the respiratory bronchioles do not strictly have a respiratory function. The distance from the terminal bronchiole to the most distal alveolus is only about 5 mm, but the respiratory zone makes up most of the lung (its volume being some 2 to 3 L).

From a functional point of view, the morphology of the human airways was greatly clarified by the studies of Weibel.[1] He measured the number, length, width, and branching angles of the airways, and he proposed models that, although they are idealized, make pressure-flow and other analyses much more tractable.

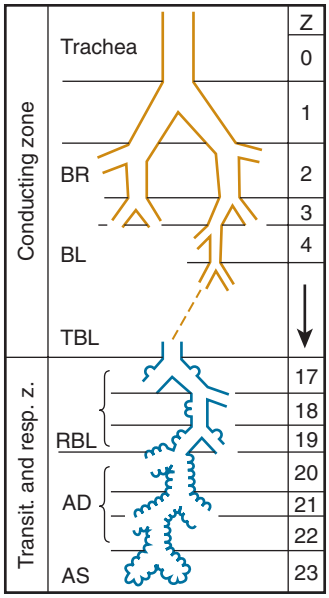

FIGURE 4-1 ■ Idealization of the human airways according to Weibel's model A. AD, alveolar duct; AS, alveolar sac; BL, bronchiole; BR, bronchus; RBL, respiratory bronchiole; TBL, terminal bronchiole; Z, airway generation. Note that the RBL, AD, and AS make up the transitional and respiratory zones. (Redrawn from Weibel ER: Morphometry of the Human Lung. Berlin: Springer-Verlag, 1963.)

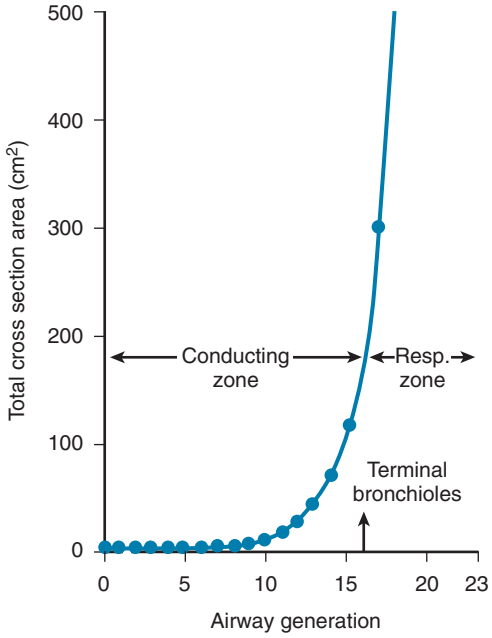

FIGURE 4-2 ■ Diagram showing the extremely rapid increase in total cross-sectional area of the airways in the respiratory (Resp.) zone as predicted from the Weibel model in Figure 4-1. (Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

The most commonly used Weibel model is the so-called model A, shown in Figure 4-1. Note that the first 16 generations (Z) make up the conducting airways ending in the terminal bronchioles. The next three generations constitute the respiratory bronchioles, in which the degree of alveolation steadily increases. This is the transitional zone. Finally, there are three generations of alveolar ducts and one generation of alveolar sacs. These last four generations constitute the true respiratory zone.

This idealized, dichotomously branching airway system is clearly an oversimplification. For example, in some regions of the human lung, there are far fewer than 23 generations from the trachea to the alveolar sacs, whereas other regions contain more generations. Some of the inadequacies of the model have been pointed out by Horsfield,[2] who has proposed other models, particularly of the most distal regions of the airways. In some respects, it makes more sense to begin counting at the terminal alveoli and work backward toward the origin. Such a system has been used to classify the tributaries of rivers.

However, the Weibel model has been of great value to respiratory physiology, and an example of its use is shown in Figure 4-2. Here the model clarifies the nature of gas flow in all generations of the airways in the lung. Figure 4-2 shows that, if the total cross-sectional area of the airways of each generation is calculated, there is relatively little change in area until we approach generation 16, that is, the terminal bronchioles. However, near this level, the cross-sectional area increases very rapidly. This has led some physiologists to suggest that the shape of the combined airways is similar to a trumpet or even a thumbtack!

The result of this rapid change in area is that the mode of gas flow changes in the region of the terminal bronchioles. Proximal to this point, flow is convective, or "bulk," that is, the sort of flow that occurs when beer is poured out of a pitcher. However, when the gas reaches the region approximating the level of the terminal bronchioles, its forward velocity decreases dramatically because of the very rapid increase in cross-sectional area. As a consequence, molecular diffusion begins to take over as the dominant mode of gas transport. Indeed, diffusion within the gas phase is the major mechanism of gas flow in the alveoli. Naturally, there is no sharp transition; flow changes gradually from primarily convective to primarily diffusive in the general vicinity of generation 16.

One implication of this change in mode of flow is that many aerosol particles penetrate to the region of the terminal bronchioles by convective flow, but they do not penetrate further because of their large mass and resulting low diffusion rate. Thus, sedimentation of these particles is heavy in the region of the terminal respiratory bronchioles. This is one reason why this region of the lung is particularly vulnerable to the effects of air pollutants.

Another implication of this dichotomously branching airway tree is that the greater the number of branch points, the greater is the potential for nonuniform distribution of airflow among the distal airways and alveoli. Thus, when experimental assessment of nonuniform flow is made, the greater the spatial resolution of the

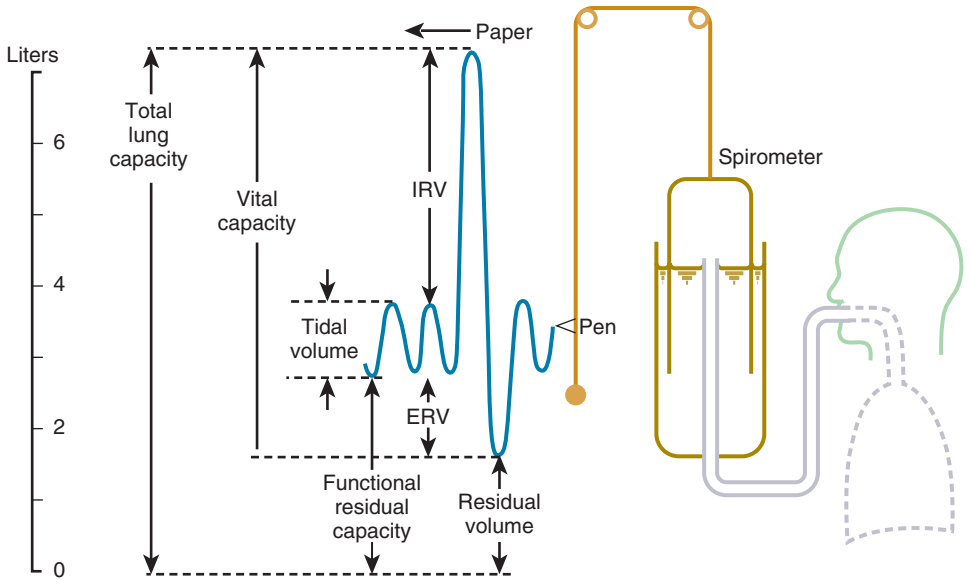

FIGURE 4-3 ■ Major divisions of lung volumes. Values are illustrative only; there is considerable normal variation. ERV, expiratory reserve volume; IRV, inspiratory reserve volume. (Modified from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

method, the greater will be the amount of nonuniformity detected. In addition, repeated, possibly minor, differences in flow distribution at each branch point will give rise to spatial correlation of flow. In other words, neighboring regions will tend to have more similar flows than regions located far apart, other factors being equal.

Lung Volumes

Figure 4-3 shows the major divisions of lung volume. *Total lung capacity* (TLC) is the volume of gas contained in the lungs at maximal inspiration. The *vital capacity* (VC) is the volume of gas that can be exhaled by a maximal expiration from total lung capacity. The volume remaining in the lung after maximal expiration is the *residual volume* (RV). *Tidal volume* (V_T) refers to the normal respiratory volume excursion. The lung volume at the end of a normal expiration is the *functional residual capacity* (FRC). The diagram also indicates the *inspiratory reserve volume* (IRV) and the *expiratory reserve volume* (ERV).

Functional Residual Capacity, Residual Volume, and Total Lung Capacity

These three volumes cannot be measured with a simple spirometer because there is no way of knowing the volume remaining in the lung after a maximal expiration (i.e., the residual volume). However, if the functional residual capacity is measured, the other two volumes can be derived by simple spirometry.

The functional residual capacity can be measured conveniently by helium dilution in a closed circuit. The subject is connected to a spirometer of known volume that contains a known concentration of helium (a very insoluble gas) and then rebreathes until the helium concentration in the spirometer and in the lungs is the same. The exhaled carbon dioxide is absorbed with soda lime, and oxygen is added to maintain a constant total volume. After equilibration, the total amount of helium is assumed to be unchanged because so little of it is removed by the blood because of its very low solubility. The functional residual capacity can then be derived from the following equation:

$$C_1 \times V_1 = C_2 \times (V_1 + V_2) \quad (1)$$

where C_1 and C_2 are the helium concentrations before and after equilibration, V_1 is the volume of the spirometer, and V_2 is the volume of the lung. If the subject is switched into the equipment when at functional residual capacity, V_2 gives that volume.

Another popular way of measuring the functional residual capacity is with a body plethysmograph. This is a large airtight box in which the subject sits. At the end of a normal expiration, a shutter closes the mouthpiece, and the subject is asked to make respiratory efforts. As the subject tries to inhale, the gas in the lungs expands, lung volume increases slightly, and the pressure in the box rises slightly because its gas volume decreases. Boyle's law (pressure times volume is constant at constant temperature) can then be used to calculate the change of volume of the plethysmograph. The equation is $P_1V_1 = P_2(V_1 - \Delta V)$, where P_1 and P_2 are the box pressures before and after the inspiratory effort, V_1 is the preinspiratory box volume, and ΔV is the change in the volume of the box (or lung). If mouth pressure is also measured during the respiratory efforts, Boyle's law can also be applied to the lung and functional residual capacity can be derived. The equation here is $P_3V_2 = P_4(V_2 + \Delta V)$, where P_3 and P_4 are the mouth pressures before and after the inspiratory effort, and V_2 is the functional resid-

ual capacity. Because this is the only unknown (ΔV was measured previously), V_2 can be calculated.

In patients with lung disease, the functional residual capacity measured by helium dilution may be substantially less than that measured by body plethysmography. The reason is that the body plethysmograph measures the total volume of gas in the lung, including any that is trapped behind closed airways, and that therefore does not communicate with the mouth. By contrast, the helium dilution method measures only communicating gas or ventilated lung volume. In young normal subjects these volumes are virtually identical, but they may be considerably different in patients with severe lung disease. Also in these patients, the volume that is obtained for functional residual capacity rises as the time for equilibration is increased because helium continues to penetrate into additional areas of poorly ventilated lung.

Total and Alveolar Ventilation

Total Ventilation

Total ventilation, also called minute ventilation, is the total volume of gas exhaled per minute. It is equal to the tidal volume times the respiratory frequency. The volume of inhaled air is slightly greater than the exhaled volume because more oxygen is inhaled than carbon dioxide is exhaled, but the difference is usually less than 1%.

Alveolar ventilation is the amount of fresh inspired air (non–dead space gas) that enters the alveoli per minute and is therefore available for gas exchange. Strictly, the alveolar ventilation is also measured during expiration, but the inhaled and exhaled volumes are almost the same.

Alveolar Ventilation

Because the tidal volume (V_T) is made up of the dead space volume (V_D) and the volume of gas entering (or coming from) the alveoli (V_A), the alveolar ventilation can be measured from the following equations:

$$V_T = V_D + V_A \tag{2}$$

Multiplying by respiratory frequency gives

$$\dot{V}_E = \dot{V}_D + \dot{V}_A \tag{3}$$

where $\dot{V}_A$ is the alveolar ventilation, and $\dot{V}_E$ and $\dot{V}_D$ are the expired total ventilation and dead space ventilation, respectively.

Therefore,

$$\dot{V}_A = \dot{V}_E - \dot{V}_D \tag{4}$$

A difficulty with this method is that the anatomic dead space is not easy to measure, although a value for it can be assumed with little error. One milliliter per pound of body weight is a common assumption.

Another way of measuring alveolar ventilation in normal subjects is to use the *alveolar ventilation equation,* which expresses mass conservation of carbon dioxide by defining carbon dioxide production $(\dot{V}_{CO_2})$ as the product of alveolar ventilation $(\dot{V}_A)$ and fractional alveolar concentration of carbon dioxide $(F_{A_{CO_2}})$. Because concentration is proportional to partial pressure, the relationship can be written as:

$$\dot{V}_{CO_2} = \dot{V}_A \times F_{A_{CO_2}} = \dot{V}_A \times P_{A_{CO_2}} / K \tag{5}$$

This can then be rearranged as follows:

$$\dot{V}_A = \frac{\dot{V}_{CO_2}}{P_{A_{CO_2}}} \times K \tag{6}$$

where $\dot{V}_{CO_2}$ is the volume of carbon dioxide exhaled per unit time, $P_{A_{CO_2}}$ is the alveolar P_{CO_2}, and K is a constant. In patients with normal lungs, the P_{CO_2} of alveolar gas and that of arterial blood are virtually identical. Therefore, the arterial P_{CO_2} can be used to determine alveolar ventilation from Equation 6. The equation then becomes

$$\dot{V}_A = \frac{\dot{V}_{CO_2}}{Pa_{CO_2}} \times K \tag{7}$$

This procedure is also often used in patients with lung disease, but the value then obtained is the "effective" alveolar ventilation. This is not the same as the alveolar ventilation as defined in Equation 4. Because patients with lung disease must increase their total ventilation to overcome the inefficiency of gas exchange caused by ventilation-perfusion inequality just to keep arterial P_{CO_2} normal, $\dot{V}_A$ from Equation 7 will be less than that from Equation 4.

Anatomic Dead Space

The anatomic dead space is the volume of the conducting airways. The normal value is in the range of 130 to 180 mL and depends on the size and posture of the subject. The value increases slightly with large inspirations because the radial traction exerted on the bronchi by the surrounding lung parenchyma increases their size. Anatomic dead space can be measured by Fowler's method,[3] in which a single breath of oxygen is inhaled and the concentration of nitrogen in the subsequent expiration is analyzed, as shown in Figure 4-4.

Physiologic Dead Space

Unlike anatomic dead space, which is determined by the anatomy of the airways, physiologic dead space is a functional measurement based on the ability of the lungs to eliminate carbon dioxide. It is defined by the Bohr equation:

$$\frac{V_D}{V_T} = \frac{P_{A_{CO_2}} - P_{E_{CO_2}}}{P_{A_{CO_2}}} \tag{8}$$

where A and E refer to alveolar and mixed expired gas, respectively. In subjects with normal lungs, the P_{CO_2} of alveolar gas and that of arterial blood are virtually the same, so that the equation is often written

$$\frac{V_D}{V_T} = \frac{Pa_{CO_2} - P_{E_{CO_2}}}{Pa_{CO_2}} \tag{9}$$

Physiologic dead space is very nearly the same as anatomic dead space when the lung is normal. However, in the presence of ventilation-perfusion inequality (i.e.,

when the ratio of local ventilation to local blood flow is *not* everywhere the same), physiologic dead space is increased, chiefly because of the ventilation going to lung units with abnormally high ventilation-perfusion ratios. Indeed, the physiologic dead space is often reported as one of the indices of the degree of mismatching of ventilation and blood flow within the lung.

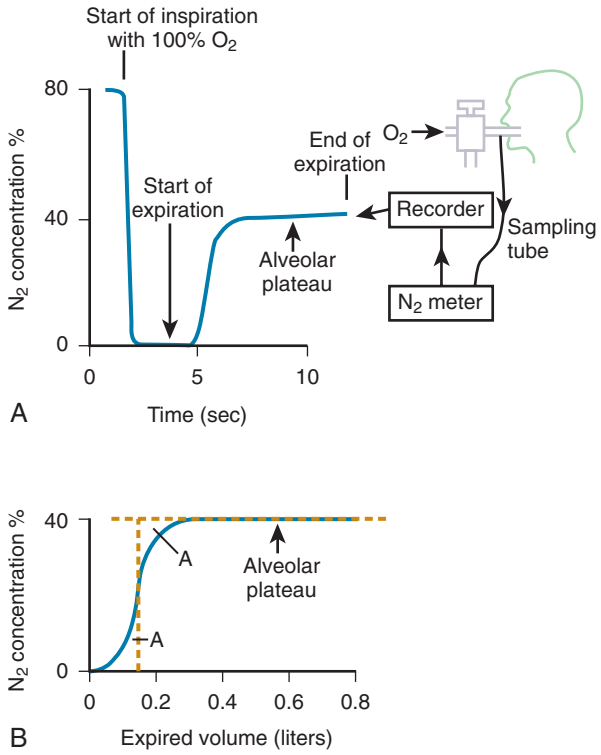

FIGURE 4-4 ■ Fowler's method of measuring the anatomic dead space with a rapid N_2 analyzer. **A** shows that, following a test inspiration of 100% O_2, the N_2 concentration rises during expiration to an almost level "plateau" representing pure alveolar gas. In **B**, N_2 concentration is plotted against expired volume, and the dead space is the volume up to the *vertical dashed line,* which makes the areas **A** and **B** equal. (Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

Inequality of Ventilation

Not all the alveoli are equally ventilated, even in the normal lung. There are several reasons for this, related both to gravitational (topographic) and to nongravitational influences on gas distribution.

Topographic Inequality

Regional differences in ventilation can be measured by having the patient inspire a radioactive gas such as xenon (^{133m}Xe). In one technique, the patient inhales a single breath of gas, and its concentration is detected by a radiation camera placed behind the chest. An additional measurement is made after the patient has rebreathed long enough to allow the xenon to equilibrate throughout the different regions of the lungs, thus reflecting regional lung volumes. By comparing the first and the second measurements, the ventilation per unit alveolar volume can be obtained.

Measurements in upright normal subjects show that the ventilation per unit volume of the lung is greatest near the base of the lung and becomes progressively smaller toward the apex. When the subject lies supine, this difference becomes much less, but the ventilation of the lowermost (posterior) lung exceeds that of the uppermost (anterior). In the lateral decubitus position, again, the dependent lung is better ventilated. The above results refer to an inspiration from functional residual capacity.

An explanation of this topographic inequality of ventilation is shown in Figure 4-5A, which depicts conditions at functional residual capacity.[4] Experimental studies show that the intrapleural pressure is less negative at the bottom than at the top of the lung. This pattern can be attributed to the weight of the lung, which requires a larger pressure below the lung than above it to balance the downward-acting weight forces. There are two consequences of this lower expanding pressure on the base of the lung. First, the resting volume of the alveoli is smaller, as shown by the pressure-volume curve. Second, the change in volume for a given change in intrapleural pressure is greater because the alveoli are operating on a steeper part of the pressure-volume curve. Thus, the ventilation (change in volume per unit resting

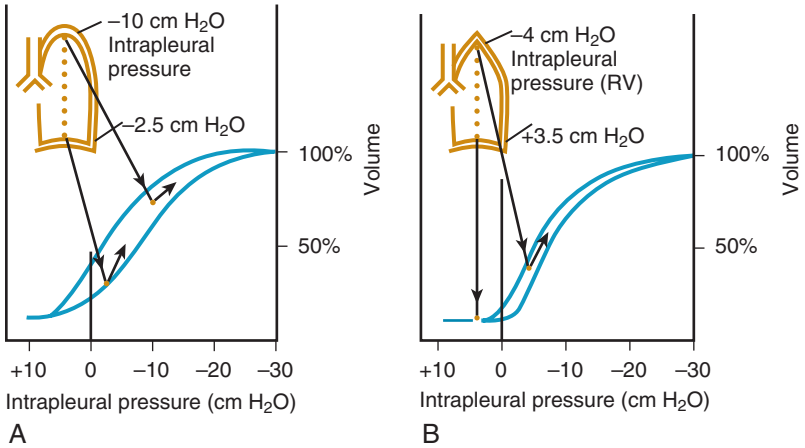

FIGURE 4-5 ■ The topographic inequality of ventilation down the lung. **A,** An inspiration from functional residual capacity. **B,** The situation at very low lung volumes (see text for details). (Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

volume) is greater at the base than the apex. However, if a normal subject makes a small inspiration from residual volume (rather than from functional residual capacity), an interesting change in the distribution of ventilation is seen. The major share of the ventilation goes to the apex of the upright lung, whereas the base is very poorly ventilated. Figure 4-5B shows why a different pattern is seen in this case. Now the intrapleural pressures are less negative, and the pressure at the base of the lung actually exceeds atmospheric pressure. For a small fall in intrapleural pressure, no gas will enter the extreme base of the lung, and only the apex will be ventilated. Thus the normal pattern of uneven ventilation is reversed in this early phase of inhalation.

Note that the explanations shown in Figure 4-5 are oversimplifications. They assume that the pressure-volume behavior of a portion of the lung is identical to that of the whole lung. However, this is not strictly true, because the regional distortion is opposed to some extent by the surrounding tissue. A more satisfying explanation is that both the topographic inequality of ventilation and the regional differences of intrapleural pressure are caused by distortion of the lung by its weight.[5] Such an explanation obviates making unwarranted assumptions about the local pressure-volume behavior of distorted lung.

More recently, xenon-enhanced computed tomography has been used to measure regional ventilation by determining the wash-in and washout rates of the radiodense, nonradioactive gas xenon measured in serial computed tomography scans.[6] Other techniques have been developed as well using hyperpolarized helium; they give similar results.[7]

Airway Closure

At residual volume, the compressed region of the lung at the base in Figure 4-5B does not have all its gas squeezed out because small airways, probably in the region of the respiratory bronchioles, close first and trap gas in the distal alveoli. This is known as *airway closure.* It occurs only at lung volumes below functional residual capacity in young normal subjects. However, this volume at which the basal airways close (*closing volume*) increases with age and may encroach on the functional residual capacity in older, apparently normal people. The reason for this increase is that the aging lung loses some of its elastic recoil and the intrapleural pressures therefore become less negative, thus approaching the situation shown in Figure 4-5B. Under these conditions, basal regions of the lung may be only intermittently ventilated, with resulting defective gas exchange. A similar situation frequently develops in patients with chronic obstructive pulmonary disease in whom lung elastic recoil may be reduced.

Nontopographic Inequality

In addition to the topographic inequality of ventilation caused by gravitational factors (see Fig. 4-5), nongravitational mechanisms also exist. This is proved by the fact that astronauts in space show uneven ventilation by both the single-breath and the multibreath nitrogen washout methods.[8,9] These methods are described in Chapter 24. Such findings have been confirmed by studies in which inspired gas is labeled by small particles. Such studies show considerable variability in ventilation at a given horizontal level.

Several factors are responsible for uneven ventilation in the distal, smaller regions of the lung. One of these is the existence of uneven time constants.[10] The time constant of a region of lung is given by the product of its resistance and compliance (analogous to the time constant in electrical circuits, which is the product of electrical resistance and capacitance). Lung units with different time constants inhale and exhale at different flow rates. Depending on the breathing frequency, a unit with a large time constant does not complete its filling before expiration begins and therefore is poorly ventilated. The faster the frequency, the greater the inequality of ventilation. In addition, a unit with a small time constant, which therefore fills rapidly, may receive a higher proportion of gas from the anatomic dead space, which reduces its alveolar ventilation.

Another cause of uneven ventilation in small lung units is the asymmetry of their structure, which can result in a greater penetration of gas by diffusion into the smaller units than into the larger.[11] The resulting somewhat complex behavior is known as diffusion- and convection-dependent inhomogeneity and may play an important role in lung disease.

A further possible reason for uneven ventilation at the level of small lung units is concentration gradients along the small airways. This is known as *series inequality.* Recall that inspired gas reaches approximately the region of the terminal or respiratory bronchioles by convective flow, but gas flow over the rest of the distance to the alveoli is accomplished principally by molecular diffusion within the airways. If there is abnormal dilation of an airway, the diffusion process may not be complete within the breathing cycle, and the distal alveoli will be less well ventilated than the proximal alveoli.

BLOOD FLOW

Blood flow is an equal partner with ventilation in the business of pulmonary gas exchange. This has not always been appreciated, partly because the process of ventilation is more obvious, especially in the dyspneic patient. In addition, the pulmonary circulation is relatively inaccessible, and this has impeded research. Much has been learned about the pulmonary circulation in the past few years, especially its metabolic functions. This topic overlaps with the pharmacology of pulmonary blood vessels, which is covered in Chapter 8. The anatomy of the pulmonary circulation is described in Chapters 1 and 6.

Pressures of the Pulmonary Circulation

The pressures in the pulmonary circulation are very low compared with those in the systemic circulation, and

this feature is responsible for much of its special behavior. The normal pressures in the human pulmonary artery are often given as about 25 mm Hg systolic, 8 mm Hg diastolic, and 15 mm Hg mean. Because the normal mean arterial pressure in the systemic circulation is about 100 mm Hg, the average arterial pressure is six times higher than that in the pulmonary circulation.

Pressure Inside Blood Vessels

Because the pulmonary artery pressure is so low, hydrostatic effects within the pulmonary circulation are very important. The adult upright human lung is some 30 cm high, giving a hydrostatic difference in pressure between the extreme apex and the base of 30 cm blood, which is equivalent to about 23 mm Hg. As a result, there are very substantial differences in pressure within the small pulmonary arteries and the capillaries between the top and bottom of the upright lung. This topic is discussed further in the section on the distribution of pulmonary blood flow.

Various techniques have been used to determine the pattern of pressure drop along the pulmonary blood vessels. These include measurement of the transudation pressure on the pleural surface of isolated lung, measurement of the pressure transient resulting from the injection of a slug of low- or high-viscosity blood into the pulmonary artery,[12] and direct puncture of different-sized vessels along with direct measurement of hydrostatic pressure.[13,14] The direct puncture measurements indicate that much of the normal pressure drop in the pulmonary circulation probably occurs in the pulmonary capillaries, and that the mean capillary pressure is approximately halfway between that in the pulmonary artery and that in the pulmonary vein (Fig. 4-6). It appears that the distribution of the pressure drop is consistent with the main function of the pulmonary circulation, which is to expose as large an area of blood as possible to the alveolar gas, while minimizing the work of the right heart.

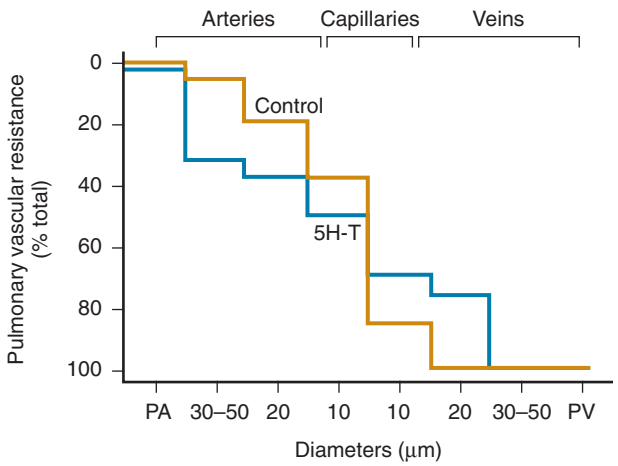

FIGURE 4-6 ■ Pressure drop along the pulmonary circulation as determined by direct puncture of vessels. The effects of 5-HT (5-hydroxytryptamine [serotonin]) are also shown. PA, pulmonary artery; PV, pulmonary vein. (Redrawn from Bhattacharya J, Nanjo S, Staub NC: Factors affecting lung microvascular pressure. Ann N Y Acad Sci 384:107–114, 1982.)

The distribution of pressure along the pulmonary blood vessels probably depends on lung volume. At low states of lung inflation, the resistance of the extra-alveolar vessels (see next section) increases, and more pressure drop occurs across the pulmonary arteries and veins. By contrast, there is evidence that, at very high states of lung inflation, the resistance of the capillary bed is increased, and therefore an additional pressure drop will occur in the capillaries.

The pressures in the pulmonary circulation are highly pulsatile; indeed, if we take the normal systolic and diastolic pressures in the main pulmonary artery as 25 and 8 mm Hg, respectively, this is one of the most pulsatile vascular pressures in the body. There is good evidence that the pulsatility of pressure, and therefore flow, extends to the pulmonary capillaries.[15]

Pressures Outside Blood Vessels

It is now known that some pulmonary blood vessels are exposed to alveolar pressure (or very nearly), whereas others are outside the influence of alveolar pressure but are very sensitive to the state of lung inflation. These two types of vessels are known as alveolar and extra-alveolar, respectively (Fig. 4-7).

The alveolar vessels are largely capillaries that course through the alveolar walls. The pressure to which they are exposed is very nearly alveolar pressure. However, it can be shown that, when the lung is expanded from a very low lung volume, this pressure falls several centimeters below alveolar pressure because of surface tension effects in the alveolar lining layer.[16] By contrast, during deflation from high lung volumes, the pericapillary pressure is very close to alveolar pressure.

The extra-alveolar vessels are not exposed to alveolar pressure. The caliber of these vessels is determined by the radial traction of the surrounding alveolar walls and therefore depends on lung volume. When the lung inflates, the caliber of these vessels increases; when the lung deflates, their caliber decreases because of the elastic tissue in their walls, and also because of a small amount of smooth muscle tone.

The small vessels (of approximately 30-μm diameter) in the corners of the alveolar walls behave in a manner that is intermediate between that of the capillaries and the extra-alveolar vessels. These corner vessels can certainly remain open when the capillaries are closed. Indeed, this is the normal appearance in zone 1 lung[17] (see later section on the distribution of blood flow). However, the shape and attachments of the corner vessels are very different from those of the larger extra-alveolar vessels, and it is unlikely that the pressure outside them varies in the same way as the lung expands.

The extra-alveolar vessels are surrounded by a potential perivascular space (see Fig. 1-5), which has an important role in the transport of extravascular fluid in the lung. The lymph vessels run in this space, although

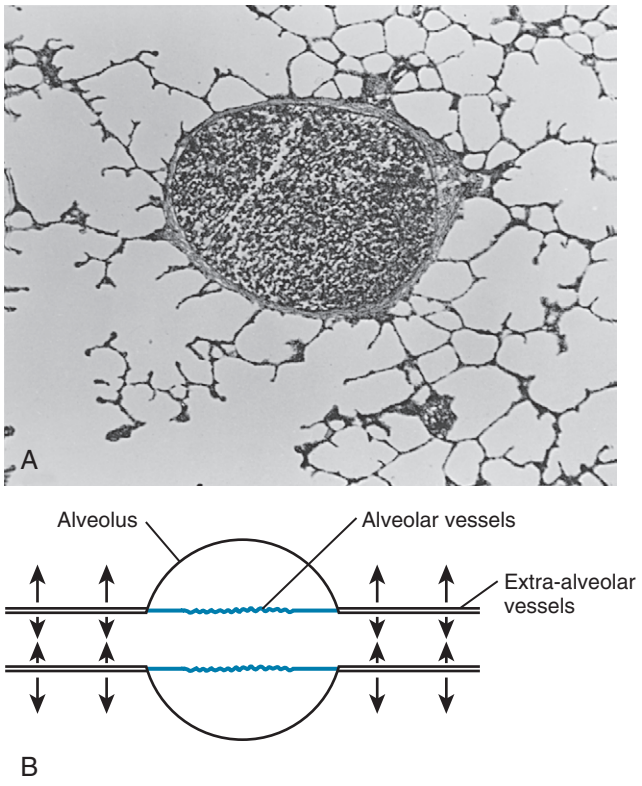

FIGURE 4-7 ■ **A,** Section of lung showing an extra-alveolar vessel (in this case, a small vein) surrounded by alveoli. Note the potential perivascular space. **B,** Diagram of alveolar and extra-alveolar vessels. The former are mainly the capillaries and are exposed to alveolar pressure. The latter have their lumina enlarged by the pull of radial traction (*outward-oriented arrows*) of the surrounding parenchyma. (Modified from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Williams & Wilkins, 2008.)

lymph can also traverse the space outside lymph vessels. One of the earliest histologic signs of interstitial pulmonary edema is "cuffing" of the perivascular space around the extra-alveolar vessels.[18,19]

A distinction should be drawn between the net pressure (sum of forces per unit area) pulling on the wall of an extra-alveolar vessel on the one hand, and the fluid hydrostatic pressure in the perivascular space on the other. The fluid hydrostatic pressure determines the movement of fluid into this region, and there is evidence that it is very low compared with the hydrostatic pressure in the interstitium of the alveolar wall. As a consequence, fluid that passes from the capillaries into the interstitial space of the alveolar wall eventually finds its way to the perivascular low-pressure region by virtue of the hydrostatic pressure gradient.[20] The pressure responsible for expanding extra-alveolar vessels may not be as low because of points of contact between the two sides of the potential perivascular space.

Pulmonary Vascular Resistance

Pulmonary vascular resistance is given by the following relationship:

$$\frac{\text{Pulmonary arterial pressure} - \text{pulmonary venous pressure}}{\text{Pulmonary blood flow}} \quad (10)$$

Because all three variables are pulsatile as a result of the heartbeat, mean values are generally used.

This definition is similar to that used for electrical resistance, which is the difference of voltage across a resistor divided by the current. However, whereas the resistance of an electrical resistor is independent of the voltage at both ends and the current, this is not the case for pulmonary vascular resistance. For example, an increase in either pulmonary arterial pressure or pulmonary venous pressure generally results in a decrease in pulmonary vascular resistance because capillary pressure rises, resulting in recruitment and distention (see later). Again, if pulmonary blood flow is increased (e.g., by raising pulmonary arterial pressure), pulmonary vascular resistance usually decreases.

It is important to appreciate that a single number for pulmonary vascular resistance is a very incomplete description of the pressure-flow properties of the pulmonary circulation. However, in practice, pulmonary vascular resistance is often a useful measurement because, although the normal value varies considerably, we often need to compare the normal lung with a markedly abnormal one in which the vascular resistance is greatly increased.

In practice, pulmonary venous pressure is difficult to measure, although an estimate can be obtained by wedging a catheter in a small pulmonary artery (the so-called pulmonary artery wedge pressure). Therefore, sometimes the ratio of pulmonary artery pressure to blood flow is reported, and the term *total pulmonary vascular resistance* is used for this.

Pressure-Flow Relations

If pulmonary blood flow is plotted against pulmonary arterial pressure, while pulmonary venous pressure, alveolar pressure, and intrapleural pressure are held constant (thus fixing lung volume), the slope of the line continually increases. This shows that pulmonary vascular resistance decreases as pressure is raised. Such measurements are best made on isolated lung preparations because of the near impossibility of changing one pressure at a time in the intact animal.

Figure 4-8 shows the changes in pulmonary vascular resistance in an isolated lung as *either* pulmonary arterial *or* pulmonary venous pressure is raised, all other pressures being held constant. Note that, as arterial pressure is increased, pulmonary vascular resistance falls. Of course, this is associated with an increase in blood flow. Note also that pulmonary vascular resistance decreases when venous pressure is raised (with pulmonary artery pressure held constant). In this case, pulmonary blood flow will fall.

The decreases in pulmonary vascular resistance shown in Figure 4-8 help to limit the work of the right heart under conditions of high pulmonary blood flow. For example, during exercise, both pulmonary arterial

and venous pressures rise. Although the normal pulmonary vascular resistance is remarkably small (the normal 5-L/min pulmonary blood flow is associated with an arterial-venous pressure difference of only about 10 mm Hg), the resistance falls to even lower values when the pulmonary arterial and venous pressures rise as during exercise.

Two mechanisms are responsible for the fall in pulmonary vascular resistance shown in Figure 4-8. These are *recruitment,* that is, opening up of previously closed blood vessels, and *distention,* that is, increase in caliber of vessels. Figure 4-9A shows experimental data from rapidly frozen dog lung preparations, indicating the importance of recruitment as the pulmonary artery pressure is raised from low values.[21] Note that the number of open capillaries per millimeter of length of alveolar wall increased from about 25 to over 50 as pulmonary artery pressure was raised from zero to less than 15 cm H_2O. Figure 4-9B shows data on the importance of distention of pulmonary capillaries.[17] Note that the mean width of the capillaries increased from about 3.5 to nearly 7 µm as the capillary pressure was increased to approximately 50 cm H_2O. Beyond that, there was very little change.

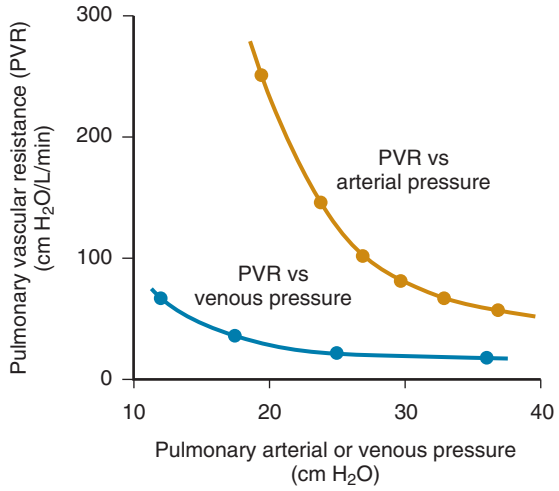

FIGURE 4-8 ■ Fall in pulmonary vascular resistance that occurred as the pulmonary arterial or venous pressure was raised in a canine lung preparation. When one pressure was changed, the other was held constant. (Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

The mechanism of recruitment of pulmonary capillaries is not fully understood. It has been suggested that, as the pulmonary arterial pressure is increased, the critical opening pressures of various arterioles are successively overcome. However, it has been shown that the variation in red blood cell concentration within areas supplied by single arterioles accounted completely for the variation between areas supplied by different arterioles.[21] This suggests that recruitment occurs at the capillary rather than the arterial level.

A possible mechanism of recruitment of pulmonary capillaries is based on the stochastic properties of a dense network of numerous interconnected capillary segments.[22] It can be shown in such a model that, if each capillary segment requires a very small critical pressure across it before flow begins, and the network contains a distribution of these critical pressures, recruitment can occur over a large range of arterial pressures. For example, in a network with as many elements as exist in the human pulmonary capillary bed,[1] a critical pressure of the order of only 0.02 cm H_2O for the individual segments could result in recruitment over a range of arterial pressures from 0 to 30 cm H_2O. Such a very small critical pressure could result from the intrinsic flow properties of blood, especially when the diameter of the red cells equals that of the capillary lumen.

The mechanism of distention of pulmonary capillaries is apparently simply the bulging of the capillary wall as

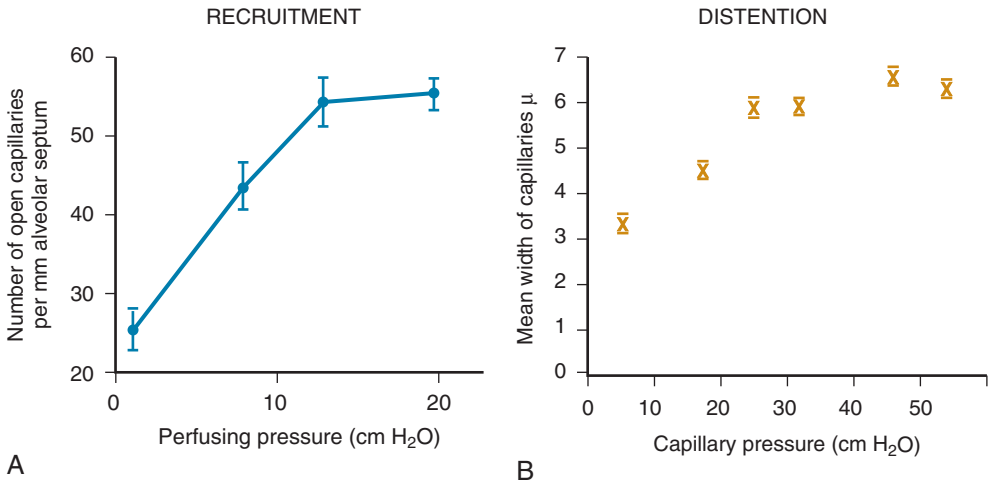

FIGURE 4-9 ■ **A,** Data showing recruitment of pulmonary capillaries as the pulmonary arterial pressure is raised. **B,** Data showing distention of pulmonary capillaries as their pressure is increased. (**A** redrawn from Warrell DA, Evans JW, Clarke RO, et al: Pattern of filling in the pulmonary capillary bed. J Appl Physiol 32:346–356, 1972. **B** redrawn from Glazier JB, Hughes JMB, Maloney JE, West JB: Measurements of capillary dimensions and blood volume in rapidly frozen lungs. J Appl Physiol 26:65–76, 1969.)

the transmural pressure of the capillaries is raised. As Figure 4-9B shows, the mean capillary diameter increases as capillary transmural pressure rises. Probably this behavior is caused by a change in shape of the capillaries rather than actual stretching of the capillary wall. There is evidence that the strength of the wall (at least on the thin side) comes from the type IV collagen in the basement membranes (see later), which has a high tensile strength and Young's modulus (i.e., is very stiff). It is unlikely that it stretches appreciably when the capillary transmural pressure rises to 30 cm H_2O. However, surface tension forces, and also longitudinal tension in the alveolar wall associated with lung inflation, tend to flatten the capillaries at low capillary transmural pressures, and this means that their diameter can increase when capillary pressure rises. Some photomicrographs of pulmonary capillaries with very high intracapillary pressures show remarkable bulging in rapidly frozen lung preparations.[17]

Recruitment and distention also provide mechanisms for increasing both the surface area of the lung microvasculature in contact with alveolar gas and the red cell transit time through the microvasculature, which may facilitate gas exchange.

Effect of Lung Volume

Lung volume has an important influence on pulmonary vascular resistance. Figure 4-10 shows that, as lung volume is increased from very low values, vascular resistance first decreases and then increases. The lung normally operates near the minimal value of vascular resistance, that is, functional residual capacity coincides with a low vascular resistance.

The increase in pulmonary vascular resistance at very low lung volume is caused by the decrease in caliber of the extra-alveolar vessels. Because these vessels are normally held open by the radial traction of the surrounding parenchyma, their caliber is least in the collapsed lung. Under these conditions, the presence of elastic tissue and smooth muscle with tone in the wall of these vessels may result in a measurable critical opening pressure of about 7 cm H_2O.[23] Also, at low lung volumes, vascular resistance is extremely sensitive to vasoconstrictor drugs, such as serotonin, which cause contraction of vascular smooth muscle.[24]

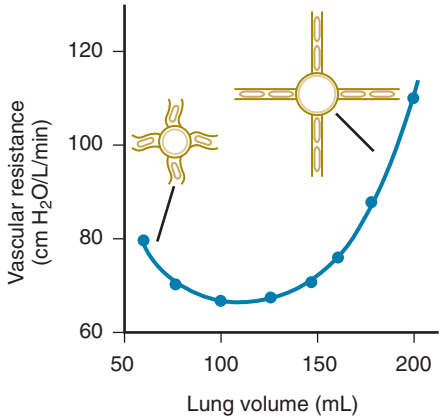

FIGURE 4-10 ■ Effect of changing lung volume on pulmonary vascular resistance. Data were taken from a canine lung preparation. (Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

Another factor that may contribute to the high pulmonary vascular resistance at low states of lung inflation is folding and distortion of pulmonary capillaries.[25,26] However, the possible importance of distortion of the pulmonary capillaries as a cause of the increase of vascular resistance at low lung volumes is still uncertain.

At high states of lung inflation, the increase in pulmonary vascular resistance is probably caused by narrowing of the pulmonary capillaries. An analogy is a piece of thin rubber tubing that narrows considerably when it is stretched across its diameter. This distortion increases the resistance to fluid moving through it. Direct measurements on rapidly frozen dog lungs show that the mean width of the capillaries is greatly decreased at high states of lung inflation.[17]

In considering the effects of lung inflation, a distinction should be made between "positive" and "negative" pressure inflation. The results shown in Figure 4-10 were found with negative-pressure inflation, that is, when the lung was expanded by reducing pleural pressure and the relationship between pulmonary arterial and alveolar pressures was held constant. If positive-pressure inflation is used (i.e., alveolar pressure is increased with respect to pulmonary arterial pressure), pulmonary vascular resistance increases even more at high states of lung inflation. The reason is that lung inflation is then associated with a decrease in the transmural pressure of the capillaries, and they are, in effect, squashed by the increased alveolar pressure. This is actually the case in normal subjects, for example, during inhalation to total lung capacity. Although alveolar pressure remains at atmospheric pressure at the end of inspiration (glottis open), pulmonary arterial and venous pressures fall along with intrapleural pressure. Thus, the net result is to decrease the transmural pressure across the pulmonary capillaries, and this is an additional contributing factor in the increase of pulmonary vascular resistance.

Other Factors

Various drugs affect pulmonary vascular resistance. In some instances, the effects depend on the species of animal. However, in general, serotonin, histamine, and norepinephrine cause contraction of pulmonary vascular smooth muscle and increase vascular resistance. These drugs are particularly effective as vasoconstrictors when the lung volume is small and the radial traction of surrounding parenchyma on the extra-alveolar vessels is weak. Drugs that often relax smooth muscle in the pulmonary circulation include acetylcholine and isoproterenol. However, normal pulmonary blood vessels have little resting tone, so the degree of potential relaxation is small.

The autonomic nervous system exercises a weak control on the pulmonary circulation. There is evidence that increased sympathetic tone can cause vasoconstric-

tion and stiffening of the walls of the larger pulmonary arteries. Both α- and β-adrenergic receptors are present.[27] Increased parasympathetic activity has a weak vasodilator action. As already indicated, any changes of vascular smooth muscle tone are much more effective at low states of lung inflation (when the extra-alveolar vessels are narrowed) or in the fetal state (when the amount of smooth muscle present is much greater than in the adult).

Pulmonary edema increases vascular resistance by a mechanism that is poorly understood. It may be that there are different mechanisms, depending on the type and stage of edema. Interstitial pulmonary edema causes marked cuffing of the perivascular spaces of the extra-alveolar vessels. Presumably this increases their vascular resistance,[28] because, as already indicated, these vessels rely on the radial traction of the surrounding parenchyma to hold them expanded. In addition, however, it may be that edema in the interstitium of the alveolar wall encroaches on the pulmonary capillaries to some extent, thus increasing their vascular resistance.[29] Hypoxic pulmonary vasoconstriction is discussed in a later section and in Chapter 6.

Distribution of Pulmonary Blood Flow

Just as for ventilation, blood flow is not partitioned equally to all alveoli, even in the normal lung. Both gravitational (topographic) and nongravitational factors affect the distribution of blood flow.

Normal Distribution

The topographic distribution of pulmonary blood flow can conveniently be measured using radioactive materials. In one technique, ^{133m}Xe is dissolved in saline and injected into a peripheral vein. When the xenon reaches the pulmonary capillaries, it evolves into the alveolar gas. If the subject undertakes a 15-second breath-holding period, the pattern of radioactivity within the lung can be measured using a gamma camera or similar device. This pattern reflects the regional distribution of blood flow. Subsequently, the distribution of alveolar volume is obtained by having the subject rebreathe radioactive xenon until the gas is evenly distributed. By combining the two measurements, the blood flow per unit alveolar volume of the lung can be obtained. The distribution of blood flow can also be measured with radioactive albumin macroaggregates, and with a variety of other radioactive gases, including ^{15}O-labeled carbon dioxide and ^{13}N. More recently, functional magnetic resonance imaging of the lung has been used to assess distribution of pulmonary blood flow.[30] This noninvasive technique does not expose subjects to radioactivity, can therefore be used repetitively, and shows great promise for the future.

In the normal upright human lung, pulmonary blood flow decreases approximately linearly with distance up the lung, reaching very low values at the apex.[31] If the subject lies supine, the rates of apical and basal blood flow become the same, but differences can be detected between the anterior (uppermost) and posterior (lowermost) regions of the lung. During exercise in the upright position, both apical and basal blood flow rates increase and the relative differences down the lung are reduced.

The factors responsible for the uneven topographic distribution of blood flow can be studied conveniently in isolated lung preparations. These studies show that, in the presence of normal vascular pressures, blood flow decreases approximately linearly up the lung[32] as it does in intact humans. However, if the pulmonary arterial pressure is reduced, blood flow rises only to the level at which pulmonary arterial and alveolar pressures are equal; above this point, no flow can be detected. If venous pressure is raised, some measurements show a more uniform distribution of blood flow in the region of the lung below the point at which pulmonary venous is equal to alveolar pressure.

Three-Zone Model for the Distribution of Blood Flow

Figure 4-11 shows a simple model that has proved to be useful in understanding the factors responsible for the topographic inequality of blood flow in the lung.[32] The lung is divided into three zones according to the relative magnitudes of the pulmonary arterial (Pa), alveolar (PA), and venous (Pv) pressures.

Zone 1 is that region of the lung above the level at which pulmonary arterial and alveolar pressures are equal; in other words, alveolar pressure exceeds arterial pressure in this region. Measurements in isolated lungs show that there is no blood flow in zone 1, the explanation being that the collapsible capillaries close because the pressure outside exceeds the pressure inside. Micrographs of rapidly frozen lung from zone 1 show that the

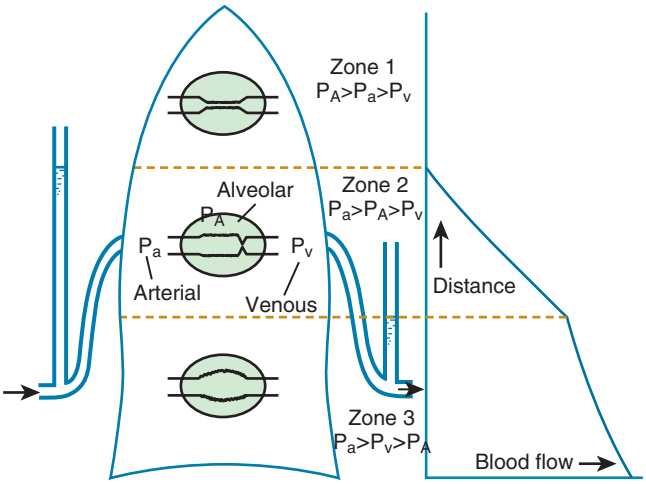

FIGURE 4-11 ■ Three-zone model designed to account for the uneven topographic distribution of blood flow in the lung. P_a, pulmonary arterial pressure; P_A, pulmonary alveolar pressure; P_v, pulmonary venous pressure. (Redrawn from West JB, Dollery CT, Naimark A: Distribution of blood flow in isolated lung: Relation to vascular and alveolar pressures. J Appl Physiol 19:713–724, 1964.)

capillaries have collapsed, although occasionally trapped red blood cells can be seen within them.[17]

The level to which blood rises can be influenced by the surface tension of the alveolar lining layer, as discussed earlier. If measurements are made on a lung immediately after it is inflated from a near-collapsed state, blood flow rises 3 or 4 cm above the level at which pulmonary arterial and alveolar pressures are equal.[16] This can be explained by the reduced surface tension, which lowers the pericapillary hydrostatic pressure.

Zone 2 is that part of the lung in which pulmonary arterial pressure exceeds alveolar pressure, but alveolar pressure exceeds venous pressure. Here the vessels behave as Starling resistors,[33] that is, as collapsible tubes surrounded by a pressure chamber. Under these conditions, flow is determined by the difference between arterial and alveolar pressures, rather than by the expected arterial-venous pressure difference. One way of looking at this is that the thin wall of the vessel offers no resistance to the collapsing pressure, so the pressure inside the tube at the downstream end is equal to chamber pressure. Thus, the pressure difference responsible for flow is perfusion minus chamber pressure.

This behavior has been variously referred to as the waterfall[33] or sluice[34] effect and can be demonstrated in rubber-tube models on the laboratory bench. However, it should be emphasized that the flow properties of capillaries are very different from those of the typical bench-top model. For example, the Reynolds number of the capillaries is very low, with the result that there is no instability as typically occurs in a rubber-tube model, which usually oscillates. Again, the capillaries contain a train of red blood cells that essentially fill the diameter of the small vessels. Thus these vessels cannot collapse in the same way as in a rubber-tube model. Nevertheless, operationally, the lung in zone 2 condition has essentially the same pressure-flow behavior as that of the laboratory Starling resistor.

The increase in blood flow down zone 2 can be explained by the hydrostatic increase in pulmonary arterial pressure down the zone, whereas the alveolar pressure remains constant. Thus the pressure difference determining flow increases linearly with distance.

Zone 3 is that part of the lung in which venous pressure exceeds alveolar pressure. Radioactive gas measurements show that blood flow increases down this zone, although in some preparations at least, the rate of increase is apparently less than in zone 2. Because the pressure difference responsible for flow is arterial minus venous pressure, and because these two pressures increase similarly with distance down the zone, it is not immediately apparent why blood flow increases down this zone. However, the transmural pressure of the capillaries increases, and because the vessels are distensible, their vascular resistance decreases down the zone. This appears to be the major factor responsible for the increase in blood flow down zone 3. Micrographs of rapidly frozen lung confirm the increase in caliber of the capillaries down zone 3.[17] However, it is also possible that there is some recruitment of capillaries that contributes to the increase in blood flow.

The Effect of Lung Volume on the Distribution of Blood Flow—Zone 4

In spite of its simplicity, the three-zone model of Figure 4-11, based on the effects of pulmonary arterial, alveolar, and venous pressures, accounts for many of the distributions seen in the normal lung. However, other factors play a role; one of these is lung volume. For example, under most circumstances, a zone of reduced blood flow, known as zone 4, is seen in the lowermost region of the upright human lung.[35] This zone becomes smaller as lung volume is increased, but careful measurements indicate that a small area of reduced blood flow is present at total lung capacity at the lung base. As lung volume is reduced, this region of reduced blood flow extends further and further up the lung so that, at functional residual capacity, blood flow decreases down the bottom half of the lung. At residual volume, the zone of reduced blood flow extends all the way up the lung, so that blood flow at the apex exceeds that at the base.[35]

These patterns cannot be explained by the interactions of the pulmonary arterial, venous, and alveolar pressures as in Figure 4-11. Instead, we have to take into account the contribution of the extra-alveolar vessels. As pointed out previously (see Fig. 4-10), the caliber of these vessels is determined by the degree of lung inflation; as lung volume is reduced, the vessels narrow. In the upright human lung, the alveoli are less well expanded at the base than at the apex because of distortion of the elastic lung caused by its weight (see Fig. 4-5). As a result, the extra-alveolar vessels are relatively narrow at the base, and their increased contribution to pulmonary vascular resistance results in the presence of a zone of reduced blood flow in that region. As overall lung volume is reduced, the contribution of the extra-alveolar vessels to the distribution of blood flow increases, and zone 4 extends further up the lung. At residual volume, the caliber of the extra-alveolar vessels is so small that they completely dominate the picture and determine the distribution of blood flow.

The role of the extra-alveolar vessels can be exaggerated by injecting vasoconstrictor drugs such as serotonin.[36] Under these conditions, zone 4 extends further up the lung. The opposite effect is seen if a vasodilator drug such as isoproterenol is infused into the pulmonary circulation.

The contribution of the extra-alveolar vessels increases in the presence of interstitial pulmonary edema, because this creates a cuff of fluid around the vessels and thereby narrows them. This is thought to be the cause of the increased pulmonary vascular resistance seen at the base of the human lung in conditions of interstitial pulmonary edema,[28] in which the distribution of blood flow often becomes inverted (e.g., in chronic mitral stenosis).[37] Under these conditions, the blood flow to the apex of the upright lung consistently exceeds the flow to the basal regions. However, the effects of interstitial edema on blood flow distribution are still not fully understood.

Increased Acceleration and Weightlessness. Because the topographic distribution of blood flow in the normal lung can be attributed to gravity, it is not

surprising that, during increased acceleration, the distribution of blood flow becomes more uneven.[38] For example, during exposure to +3*g* acceleration, that is, three times the normal acceleration experienced by someone in the upright posture, the upper half of the lung is completely unperfused. The amount of unperfused lung is approximately proportional to the *g* level.

By contrast, in astronauts during sustained microgravity in space, the distribution of blood flow becomes more uniform.[39] Because it is not possible to use radioactive gases in this environment, the inequality of blood flow has been determined indirectly from the size of the cardiogenic oscillations for P_{CO_2}. Cardiogenic oscillations are fluctuations in the concentrations of gases such as oxygen, carbon dioxide, and nitrogen during a single expiration caused by preferential emptying of different parts of the lung due to the movement of the heart. During hyperventilation, the P_{CO_2} was reduced in the alveolar gas, and during the breath-hold period, it then increased at a rate determined by the blood flow per unit of alveolar volume. It was found that there is a marked reduction in the inequality of blood flow during sustained microgravity compared with that observed in the upright posture before or after the flight. In particular, there is evidence that the topographic differences are essentially abolished. Interestingly, however, some inequality of pulmonary blood flow still remains, indicating that gravity-independent mechanisms are also present.

Nongravitational Factors Influencing the Distribution of Pulmonary Blood Flow. Although gravity is a major factor determining the uneven distribution of blood flow in the upright human lung, it is now clear that nongravitational factors also play an important role. There are several possible mechanisms. One is that there may be regional differences of vascular conductance, with some regions of the pulmonary vasculature having an intrinsically higher vascular resistance than others. This has been shown to be the case in isolated dog lungs,[40] and there is some evidence for higher blood flows in the dorsal-caudal than the ventral regions of the lung in both intact dogs and horses. Another possible factor is a difference in blood flow between the central and peripheral regions of the lung,[41] although this is controversial. Some measurements show differences in blood flow along the acinus, with the more distal regions of the acinus being less well perfused than the proximal regions.[42,43] Finally, as pointed out earlier, because of the complexity of the pulmonary circulation at the alveolar level, including the very large number of capillary segments, it is likely that there is inequality of blood flow at this level. Reference has already been made to the possibility of recruitment of pulmonary capillaries based on the stochastic properties of a dense network of numerous interconnected capillary segments.[22] There is also work suggesting that the distribution of pulmonary blood flow in small vessels may follow a fractal pattern.[44] The term *fractal* describes a branching pattern of both structure (blood vessels) and function (blood flow) that repeats itself with each generation. This means that any subsection of the vascular tree exhibits the same branching pattern as the entire tree. Were a picture of such a subsection to be enlarged, it would overlie and match the pattern of the whole tree. Just as mentioned for ventilation earlier, repeated branching of blood vessels with fractal properties has implications for how blood flow is distributed independently of gravitational influences. The greater the number of branch points, the greater is the likely inequality of perfusion among alveoli. This implies that the finer the spatial resolution of the method used to assess flow distribution, the greater is the likely amount of inequality detected.

Abnormal Patterns of Blood Flow

The normal distribution of pulmonary blood flow is frequently altered by lung and heart disease. Localized lung disease, such as fibrosis and cyst formation, usually causes a local reduction of flow. The same is true of pulmonary embolism, in which the local reduction in blood flow, as determined from a perfusion scan, is usually coupled with normal ventilation, and this pattern provides an important diagnostic clue. Bronchial carcinoma may reduce regional blood flow, and occasionally a small hilar lesion can cause a marked reduction of blood flow to one lung, presumably through compression of the main pulmonary artery. Generalized lung disease, such as chronic obstructive pulmonary disease and bronchial asthma, also frequently causes patchy inequality of blood flow. Sometimes, asthmatic patients whose disease is thought to be fairly well controlled show marked impairment of blood flow in some lung regions.

Heart disease frequently alters the distribution of blood flow, as might be expected from the factors responsible for the normal distribution (see Fig. 4-11). For example, patients with pulmonary hypertension or increased blood flow through left-to-right shunts usually show a more uniform distribution of blood flow.[45] Diseases in which pulmonary artery pressure is reduced, such as tetralogy of Fallot with oligemic lungs, are associated with reduced perfusion of the lung apices. Increased pulmonary venous pressure, as in mitral stenosis, initially causes a more uniform distribution than normal. However, in advanced disease, an inversion of the normal distribution of blood flow is frequently seen, with more perfusion to the upper than to the lower zones. The mechanism for this shift is not fully understood, but, as indicated earlier, perivascular edema causing an increased vascular resistance of the extra-alveolar vessels is thought to be a factor.

Active Control of the Pulmonary Circulation

The distribution of pulmonary blood flow and the pressure-flow relations of the pulmonary circulation are normally dominated by the passive effects of the hydrostatic pressure gradient described earlier. Thus, the roles of gravity, of variation in vascular lengths and diameters, and of recruitment and distention can account for much of the behavior of the normal circulation. The normal

adult pulmonary circulation has little smooth muscle in the walls of the vessels, and active control of vascular tone is weak. However, in conditions in which there is an increase in the amount of smooth muscle (e.g., in the fetal lung), in long-term residence at high altitude, or in prolonged pulmonary hypertension, the tone of the vascular smooth muscle plays a more significant role. *Nevertheless,* some active control of the circulation is seen in the normal lung, as described in the next section.

Hypoxia

One example of active control is hypoxic pulmonary vasoconstriction. This consists of contraction of smooth muscle in the walls of small blood vessels in a region of a lung with alveolar hypoxia. The precise mechanism of this response is still not known, but because it occurs in excised isolated lungs, it clearly does not depend on central nervous system connections. Furthermore, excised segments of pulmonary artery can be shown to constrict if their environment is made hypoxic, so it appears to be a local action of the hypoxia on the artery itself. It is also known that it is the P_{O_2} of the alveolar gas, not of the pulmonary arterial blood, that chiefly determines the response.[46] This can be proved by perfusing a lung with blood containing a high P_{O_2} while keeping the alveolar P_{O_2} low. Under these conditions, the response is well seen.

The stimulus-response curve of hypoxic pulmonary vasoconstriction is very nonlinear (Fig. 4-12). When the alveolar P_{O_2} is altered in the region above 100 mm Hg, little change in vascular resistance is seen. However, when the alveolar P_{O_2} is reduced to approximately 70 mm Hg, obvious vasoconstriction may occur, and at a very low P_{O_2} approaching that of mixed venous blood, the local blood flow may be almost abolished. The data shown in Figure 4-12 are from anesthetized cats.[47] However, there are species differences in the stimulus-response curves. For example, there is an almost linear reduction of blood flow between alveolar P_{O_2} values of 150 and 40 mm Hg in the coatimundi (a small South American mammal).[48] The preparation in which these measurements were made had the additional advantages that the chest was closed and the measurements were made in a very small region of lung. These conditions probably give better information on the role of the phenomenon in the local regulation of blood flow.

The major site of the vasoconstriction is in the small pulmonary arteries.[49] In the normal human lung, the small arteries have a meager amount of smooth muscle, and this tends to be uneven in its distribution. This may explain why in global alveolar hypoxia (e.g., at high altitude) there is evidence that the constriction is uneven. For example, alveolar hypoxia nearly doubles the dispersion of transit times through the pulmonary circulation of a lobe of dog lung,[50] and the distribution of India ink particles injected into the pulmonary circulation during alveolar hypoxia is more uneven than during normoxia.[51] This uneven vasoconstriction probably plays a role in the mechanism of high-altitude pulmonary edema[52] (see later).

The mechanisms of hypoxic pulmonary vasoconstriction are still not fully understood. Studies indicate that voltage-gated potassium channels in the smooth muscle cells are involved, leading to increased intracellular calcium ion concentrations.[53-56]

Endothelium-derived vasoactive substances play a role. Nitric oxide (NO) is an endothelium-derived relaxing factor for blood vessels. It is formed from L-arginine and is a final common pathway for a variety of biologic processes. NO activates soluble guanylate cyclase, which leads to smooth muscle relaxation through the synthesis of cyclic guanosine monophosphate. Inhibitors of NO

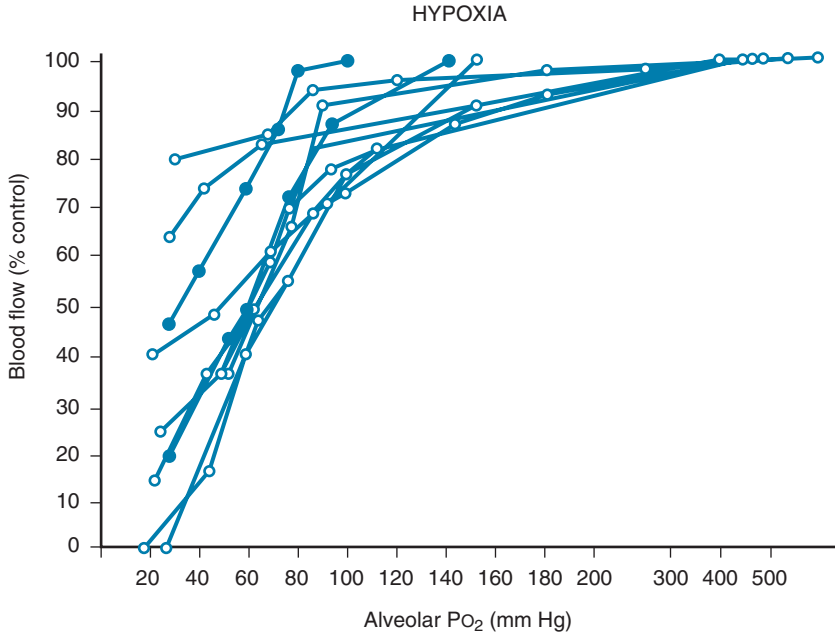

FIGURE 4-12 ■ Stimulus-response curves of hypoxic pulmonary vasoconstriction. The abscissa shows alveolar P_{O_2}. Data are derived from feline lung preparation. (Redrawn from Barer GR, Howard P, Shaw JW: Stimulus-response curves for the pulmonary vascular bed to hypoxia and hypercapnia. J Physiol [Lond] 211:139–155, 1970.)

synthesis augment hypoxic pulmonary vasoconstriction in animal preparations, and inhaled NO reduces hypoxic pulmonary vasoconstriction in humans.[57] The required inhaled concentration of NO is extremely low (about 20 parts per million), and the gas is very toxic at high concentrations.

Pulmonary vascular endothelial cells also release potent vasoconstrictor peptides, known as endothelins.[58] Their role in normal physiology and disease is still being evaluated.

Hypoxic pulmonary vasoconstriction has the effect of directing blood flow away from hypoxic regions of lung. Other things being equal, this reduces the amount of ventilation-perfusion inequality in a diseased lung and limits the depression of the arterial P_{O_2}. An example of this is seen in patients with asthma who are treated with certain bronchodilators. These sometimes cause a reduction in arterial P_{O_2} as a result of an increase in blood flow to poorly ventilated areas.[59,60] Whether this can be explained by the reversal of hypoxic pulmonary vasoconstriction is uncertain, but it seems a possible mechanism in some cases. In patients with severe chronic obstructive pulmonary disease, an elevated pulmonary artery pressure is frequently seen, and often this is exacerbated by a recent bronchial infection. Prolonged nocturnal treatment with oxygen has been shown to reduce the degree of pulmonary hypertension and to improve the prognosis in these patients. The mechanism of improvement is presumably a gradual inhibition by hyperoxia of increased smooth muscle tone originally caused by the hypoxia.

Residence at high altitude results in hypoxic pulmonary vasoconstriction, both in newcomers and in permanent residents. The increase in pulmonary artery pressure is especially marked during exercise. If 100% oxygen is given to normal subjects after they have been exposed to hypoxia for as little as 2 weeks, the pulmonary artery pressure does not immediately return to the normal level.[61] This suggests that some structural change in the pulmonary vessels has already occurred. There is considerable variation in the response of pulmonary artery pressure to alveolar hypoxia, leading some investigators to divide people into "responders" and "nonresponders."

The most important situation in which hypoxic pulmonary vasoconstriction occurs is in the perinatal period. During fetal life, pulmonary vascular resistance is very high, partly because of hypoxic vasoconstriction, and only some 15% of the cardiac output flows through the lungs. The rest bypasses the lungs via the ductus arteriosus. The vasoconstriction is particularly effective because of the abundance of smooth muscle in the pulmonary arteries. At birth, when the first few breaths oxygenate the alveoli, the vascular resistance falls dramatically because of relaxation of vascular smooth muscle, and pulmonary blood flow increases enormously. In this situation, the release of hypoxic vasoconstriction is critical in the transition from placental to air breathing, and it is this situation that is presumably responsible for the evolutionary pressure to maintain the phenomenon, which seems to be weak and variable in adult life.

Other Physiologic Substances

Many peptides and other substances can potentially alter the tone of muscular pulmonary blood vessels, although the roles of these substances under physiologic conditions are still being clarified.[62] They include angiotensin II, bradykinin, vasopressin, atrial natriuretic peptide, endothelin, somatostatin, products of both the cyclooxygenase and lipoxygenase arms of the arachidonic acid cascade, and calcitonin gene–related peptide. Some substances show species differences, and some evoke either vasoconstriction or vasodilation, depending on their concentration. Biogenic amines such as acetylcholine, histamine, serotonin, and norepinephrine also affect pulmonary vascular smooth muscle. Additional information about the pharmacology of the pulmonary blood vessels is provided in Chapter 8.

Damage to Pulmonary Capillaries by High Wall Stresses

It has become clear that the blood-gas barrier has a basic dilemma. On the one hand, the barrier has to be extremely thin to allow efficient gas exchange by passive diffusion (see Chapter 1). On the other hand, the blood-gas barrier must be immensely strong because of the large mechanical stresses that develop in the capillary wall when the pressure in the capillaries rises, or when the wall is stretched by inflating the lung to high volumes. There is evidence that the blood-gas barrier is just strong enough to withstand the highest stresses to which it is normally subjected. Unusually high capillary pressures or lung volumes result in ultrastructural damage or "stress failure" of the capillary wall, leading to a high-permeability type of pulmonary edema, or even pulmonary hemorrhage.

When the capillary transmural pressure is raised in animal preparations, disruption of the capillary endothelium, alveolar epithelium, or sometimes all layers of the capillary wall is seen. In the rabbit lung, the first changes occur at a transmural pressure of about 24 mm Hg, and the frequency of breaks increases as the pressure is raised.[63] Although at first sight these capillary pressures seem to be very high, there is now good evidence that the capillary pressure rises to the mid-30s (mm Hg) in the normal lung during heavy exercise.[64] This is largely secondary to the increase in left ventricular filling pressure, which has not been appreciated until recently.[65]

It can be shown that, at these increased capillary transmural pressures, the "hoop" or circumferential stresses in the capillary wall become extremely high. Indeed, they approach the breaking stress of collagen. The main reason for the very high stresses is the extreme thinness of the wall, which, in the human lung, is less than 0.3 μm in some places. It is now believed that the strength of the blood-gas barrier on the thin side comes from type IV collagen in the basement membranes.

Stress failure is the mechanism of several clinical conditions characterized by high-permeability pulmonary edema or hemorrhage.[66] Neurogenic pulmonary edema

has been shown to be associated with very high capillary pressures, the edema is of the high-permeability type, and ultrastructural damage to the capillaries has been demonstrated, consistent with stress failure. High-altitude pulmonary edema is apparently caused by uneven hypoxic pulmonary vasoconstriction (referred to earlier), which allows some of the capillaries to be exposed to high pressure.[67] Again, the edema is of the high-permeability type, and typical ultrastructural changes in the capillaries have been demonstrated in animal preparations.[68]

A particularly interesting condition is bleeding into the lungs in galloping racehorses. This is very common and is caused by the extremely high pulmonary capillary pressures, which approach 100 mm Hg. Direct evidence of stress failure of pulmonary capillaries has been shown in these animals.[69] In fact, it is probable that elite human athletes develop some ultrastructural changes in their blood-gas barrier during extreme exercise because significantly higher concentrations of red blood cells, total protein, and leukotriene B_4 are seen in their bronchoalveolar lavage fluid than in sedentary controls.[70] This only occurs at extremely high levels of exercise.[71] A similar group of athletes who exercised at submaximal levels for 1 hour showed no changes in the bronchoalveolar lavage fluid.[72]

Overinflation of the lung is known to increase the permeability of pulmonary capillaries, and stress failure is apparently the mechanism because it has been shown that, for the same capillary transmural pressure, the frequency of capillary wall damage is greatly increased at high lung volumes.[73] This is because some of the increased tension in the alveolar wall associated with lung inflation is transmitted to the capillary wall. This may be important in ventilator-induced pulmonary injury. Finally, conditions in which the basement membrane of the capillary wall is damaged are associated with alveolar bleeding because type IV collagen of the basement membranes is responsible for most of the strength of the capillaries. The best example is Goodpasture's syndrome.

Metabolic Functions of the Pulmonary Circulation

Although the primary purpose of the pulmonary circulation is to provide the lung with mixed venous blood so that oxygen can be added and carbon dioxide removed, the pulmonary circulation has other functions, particularly metabolism.

A number of vasoactive substances are metabolized by the lung.[74] Because it is the only organ whose microcirculation receives the whole cardiac output, the lung is uniquely suited to modifying blood-borne substances. Indeed, a substantial fraction of all the vascular endothelial cells in the body is located in the lung.

The only known example of biologic activation by passage through the pulmonary circulation is the conversion of the relatively inactive polypeptide angiotensin I to the potent vasoconstrictor angiotensin II.[75] The latter is up to 50 times more active than its precursor but is unaffected by passage through the lung. The conversion of angiotensin I is catalyzed by an enzyme, angiotensin I–converting enzyme, which is located in small pits (*caveolae intracellulares*) in the surface of the capillary endothelial cells.

A number of vasoactive substances are completely or partially inactivated during passage through the lung. Bradykinin is largely inactivated (up to 80%), and the enzyme responsible is angiotensin I–converting enzyme. The lung is the major site of inactivation of serotonin (5-hydroxytryptamine), not by enzymatic degradation, but by an uptake and storage process. Some of the serotonin may be transferred to platelets in the lung or stored in some other way and released during anaphylaxis. The prostaglandins E_1, E_2, and $F_{2\alpha}$ are also inactivated in the lung, which is a rich source of responsible enzymes. Norepinephrine is also taken up by the lung to some extent (up to 30%). Histamine appears not to be affected by the intact lung.[74]

Some vasoactive materials pass through the lung without significant gain or loss of activity. These include epinephrine, prostaglandins A_1 and A_2, angiotensin II, and vasopressin (also called antidiuretic hormone). Additional information on pulmonary vascular pharmacology can be found in Chapter 8.

Several vasoactive substances are normally synthesized or stored within the lung but may be released into the circulation in pathologic conditions. For example, in anaphylaxis, or during an asthma attack, histamine, bradykinin, prostaglandins, and "slow-reacting substance" are discharged into the circulation. Other conditions in which the lung may release potent chemicals include pulmonary embolism (see Chapter 51) and alveolar hypoxia.

There is also evidence that the lung plays a role in the clotting mechanism of blood under normal and abnormal conditions. For example, in the interstitium, there are large numbers of mast cells containing heparin. In addition, the lung is able to secrete special immunoglobulins, particularly immunoglobulin A, in bronchial mucus, which contribute to its defenses against infection. The synthesis of phospholipids such as dipalmitoylphosphatidylcholine, a component of pulmonary surfactant (see Chapter 9), is an important function of alveolar type II cells that prevents lung collapse. Surfactant turnover is rapid, and if the blood flow to a region of lung is obstructed (e.g., by an embolus), surfactant may become locally depleted with consequent atelectasis. Protein synthesis is also significant because collagen and elastin form the structural framework of the lung. Under abnormal conditions, proteases are apparently liberated from leukocytes or macrophages in the lung, causing breakdown of proteins and, possibly, emphysema (see Chapter 39). Another important activity is carbohydrate metabolism, especially the elaboration of the mucins and proteoglycans of bronchial mucus (see Chapter 11).

In addition to its metabolic functions, the lung has other functions apart from its primary gas-exchanging role. One is to act as a reservoir for blood. As stated previously, the lung has a remarkable ability to reduce

its pulmonary vascular resistance through the mechanisms of recruitment and distention as vascular pressures are raised. The same mechanisms allow the lung to increase its blood volume with relatively small rises in pulmonary arterial or venous pressures. This occurs, for example, when a subject lies down after standing. Blood then drains from the legs into the lung. The weightlessness that occurs when astronauts enter orbit also results in an increased pulmonary blood volume.

Another function of the lung is to filter blood. Small intravascular thrombi are removed from the circulation before they can reach the brain or other vital organs. There is also evidence that many white blood cells are sequestered by the lung, although the significance of this is not clear.

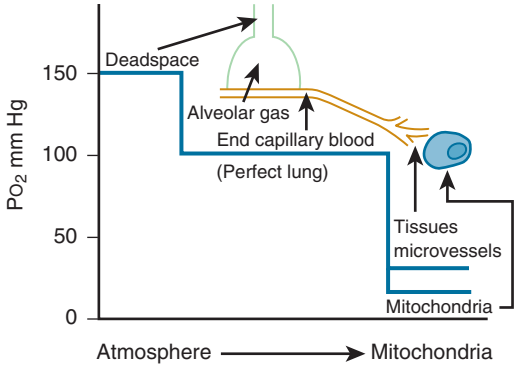

FIGURE 4-13 ■ Scheme of the oxygen partial pressures from air to tissues. This shows a hypothetically perfect situation. (Redrawn from West JB: Ventilation/Blood Flow and Gas Exchange [5th ed]. Oxford: Blackwell Scientific, 1990.)

GAS EXCHANGE

As we have seen, the primary function of the lungs is gas exchange, that is, to allow oxygen to move from the air into the blood, and to allow carbon dioxide to move out. It is now established that movement of gas across the blood-gas interface is by simple passive diffusion; the gases travel from an area of high to an area of low partial pressure. We have also seen that the structure of the lung is well suited to this mechanism of gas exchange. The blood-gas barrier is extremely thin (only 0.3 µm over much of its extent), and its area is between 50 and 100 m^2. Because Fick's law of diffusion states that the amount of gas that moves across a tissue sheet is proportional to the area but inversely proportional to the thickness, the blood-gas barrier is ideal for its gas-exchanging function.

An important concept in any discussion of gas exchange is partial pressure. The partial pressure of a gas is found by multiplying its concentration by the total pressure. For example, dry air has 20.9% oxygen. The P_{O_2} in dry air at sea level, where the barometric pressure is 760 mm Hg, is therefore (20.9/100) × 760 = 159 mm Hg. When air is inhaled into the upper airways, it is warmed and saturated with water vapor. The water vapor pressure at 37° C is 47 mm Hg. Under these conditions, the total dry gas pressure is only 760 − 47 = 713 mm Hg. The P_{O_2} of moist inspired air is therefore (20.9/100) × 713 = 149 mm Hg. In general, the relationship between the partial pressure (P) and fractional concentration (F) of a gas when water vapor is present is given by $P_X = F_X (P_B - P_{H_2O})$, where P_B stands for barometric pressure and X refers to the species of gas.

Figure 4-13 shows an overview of the oxygen cascade from the air that we breathe to the tissues where it is utilized. The solid line marked "perfect" represents an ideal situation that does not actually exist but does make a useful backdrop for purposes of discussion. One of the first surprises is that, by the time the oxygen has reached the alveoli, its partial pressure has fallen from about 150 to about 100 mm Hg. The reason for this apparent extravagance is that the P_{O_2} in the alveolar gas is determined by a balance between two factors. On the one hand, we have the essentially continuous addition of oxygen by the process of alveolar ventilation, and on the other the continuous removal of oxygen by the pulmonary blood flow. The net result is that the alveolar P_{O_2} settles out at about 100 mm Hg.

It might be argued that the process of ventilation is intermittent with each breath and not continuous. By the same token, pulmonary capillary blood flow is known to be pulsatile. However, the volume of gas in the lung at functional residual capacity is sufficiently large to damp out these oscillations, with the result that the alveolar P_{O_2} varies by only about 3 or 4 mm Hg with each breath, and less with each heartbeat. Thus, alveolar ventilation and capillary blood flow can be regarded as continuous processes from the point of view of gas exchange.

In an ideal lung (see Fig. 4-13), the effluent pulmonary venous blood (which becomes the systemic arterial blood) would have the same P_{O_2} as that of the alveolar gas, namely, about 100 mm Hg. This is very nearly the case in the normal lung. However, when the arterial blood reaches the peripheral tissues, a substantial fall in P_{O_2} occurs en route to the mitochondria. The movement of oxygen in the peripheral tissues is essentially by passive diffusion, and the mitochondrial P_{O_2} is certainly considerably lower than that in arterial or mixed venous blood. Indeed, the P_{O_2} in the mitochondria may vary considerably throughout the body, depending on the type of tissue and its oxygen uptake. Nevertheless, it is useful to bear in mind that the mitochondria are the targets for the oxygen transport system and that any fall in the arterial P_{O_2} caused, for example, by inefficient pulmonary gas exchange must be reflected in a reduced tissue P_{O_2}, other factors being equal.

For carbon dioxide, the process is reversed. There is essentially no carbon dioxide in the inspired air, and the alveolar P_{CO_2} is about 40 mm Hg. Under normal conditions, arterial and alveolar P_{CO_2} values are the same, whereas the P_{CO_2} of mixed venous blood is in the range of 45 to 47 mm Hg. The P_{CO_2} of the tissues is probably quite variable, depending, for example, on the state of metabolism. Nevertheless, any inefficiency of the lung for carbon dioxide removal tends to raise the P_{CO_2} of the tissues, other factors being equal.

Causes of Hypoxemia

Hypoxemia refers to a reduction in arterial P_{O_2} to below normal values. There are four major processes that can impair pulmonary gas exchange and cause hypoxemia when breathing room air at sea level: hypoventilation, diffusion limitation, shunt, and ventilation-perfusion inequality. These are now discussed in turn.

Hypoventilation

Hypoventilation is used here to refer to conditions in which alveolar ventilation is abnormally low in relation to oxygen uptake or carbon dioxide output. Alveolar ventilation is the volume of fresh inspired gas going to the alveoli (i.e., non–dead space ventilation), as mentioned earlier. As we shall see, hypoventilation always causes arterial hypoxemia (unless the patient is breathing an enriched oxygen mixture) and a raised arterial P_{CO_2}. It should be noted that other conditions (e.g., ventilation-perfusion inequality) can also result in carbon dioxide retention, and some physicians use the terms *hypoventilation* and *carbon dioxide retention* interchangeably. This confusing practice is not followed here.

We saw in the last section that the P_{O_2} of alveolar gas is determined by a balance between the rate of addition of oxygen by alveolar ventilation and the rate of removal by the pulmonary blood flow to satisfy the oxygen demands of the tissues. Hypoventilation occurs when the alveolar ventilation is reduced and the alveolar P_{O_2} therefore settles out at a lower level than normal. For the same reason, the alveolar P_{CO_2}, and therefore arterial P_{CO_2}, are also raised.

Causes of hypoventilation include depression of the respiratory center by drugs, such as morphine derivatives and barbiturates; diseases of the brain stem, such as encephalitis; abnormalities of the spinal cord conducting pathways, such as high cervical dislocation; anterior horn cell diseases, including poliomyelitis, affecting the phrenic nerves or supplying the intercostal muscles; diseases of nerves to respiratory muscles (e.g., Guillain-Barré syndrome); diseases of the myoneural junction, such as myasthenia gravis; diseases of the respiratory muscles themselves, such as progressive muscular dystrophy; thoracic cage abnormalities (e.g., crushed chest); upper airway obstruction (e.g., thymoma); hypoventilation associated with extreme obesity (pickwickian syndrome); and other miscellaneous causes, such as metabolic alkalosis and idiopathic states. For discussion of hypoventilation, see Chapter 78.

Note that, in all these conditions, the lungs are normal. Thus, this group can be clearly distinguished from those diseases in which the carbon dioxide retention is associated with chronic lung disease. In the latter conditions, the lungs are abnormal, and a major factor in the raised P_{CO_2} is the ventilation-perfusion inequality that causes gross inefficiency of pulmonary gas exchange.

The rise in alveolar P_{CO_2} as a result of hypoventilation can be calculated using the *alveolar ventilation equation* (see earlier section on "Alveolar Ventilation" for derivation):

$$\dot{V}_A = \frac{\dot{V}_{CO_2}}{P_{A_{CO_2}}} \times K \tag{6}$$

where K is a constant. This can be rearranged as follows:

$$P_{A_{CO_2}} = \frac{\dot{V}_{CO_2}}{\dot{V}_A} \times K \tag{11}$$

Because in normal lungs the alveolar ($P_{A_{CO_2}}$) and arterial (Pa_{CO_2}) P_{CO_2} are almost identical, we can write:

$$Pa_{CO_2} = \frac{\dot{V}_{CO_2}}{\dot{V}_A} \times K \tag{12}$$

This very important equation indicates that the level of P_{CO_2} in alveolar gas or arterial blood is inversely related to the alveolar ventilation. For example, if the alveolar ventilation is halved, the P_{CO_2} doubles. Note, however, that this is true only after a steady state has been reestablished and the carbon dioxide production rate is the same as before. In practice, if the alveolar ventilation of a patient is suddenly decreased (e.g., by changing the setting on a ventilator), the P_{CO_2} rises over a period of 10 to 20 minutes. The rise is rapid at first and then is more gradual as the body stores of CO_2 are gradually filled.[76]

The same principles as used for carbon dioxide can be applied to oxygen to understand the effect of hypoventilation on alveolar (and thus arterial) P_{O_2}. The corresponding mass conservation equation for oxygen is as follows:

$$\dot{V}_{O_2} = \dot{V}_I \times F_{I_{O_2}} - \dot{V}_A \times F_{A_{O_2}} \tag{13}$$

Here, $\dot{V}_I$ is inspired *alveolar* ventilation (sometimes written as $\dot{V}_{IA}$), while $\dot{V}_A$ is expired alveolar ventilation. Equation 13 expresses oxygen uptake as the difference between the amount of oxygen inhaled per minute (volume of inspired gas $[\dot{V}_I] \times$ fractional concentration of oxygen $[F_{I_{O_2}}]$) and that exhaled per minute (volume of alveolar ventilation $[\dot{V}_A] \times$ fractional concentration of oxygen in alveolar gas $[F_{A_{O_2}}]$). Normally, because a little more oxygen is taken up per minute than is carbon dioxide exhaled, $\dot{V}_I$ exceeds $\dot{V}_A$. However, this difference is usually no more than 1% of the ventilation, and clinically it can most often be ignored. If this is done, $\dot{V}_I$ may then be replaced by $\dot{V}_A$, and Equation 13 simplifies to

$$\dot{V}_{O_2} = \dot{V}_A \times (F_{I_{O_2}} - F_{A_{O_2}}) \; or$$
$$\dot{V}_{O_2} = \dot{V}_A \times \frac{(P_{I_{O_2}} - P_{A_{O_2}})}{K} \tag{14}$$

where $P_{I_{O_2}}$ is the partial pressure of oxygen in the inspired gas. Thus, as ventilation falls, $P_{A_{O_2}}$ must fall as well to maintain the rate of O_2 uptake necessary for metabolic function. Equations 11 (reexpressed as $\dot{V}_{CO_2} = \dot{V}_A \times P_{A_{CO_2}}/K$) and 14 can be usefully combined. If Equation 11 is divided by Equation 14, we get

$$\frac{\dot{V}_{CO_2}}{\dot{V}_{O_2}} = R = \frac{P_{A_{CO_2}}}{(P_{I_{O_2}} - P_{A_{O_2}})} \tag{15}$$

Here, R is the respiratory exchange ratio (volume of carbon dioxide exhaled/oxygen taken up in the same time). Both K and $\dot{V}_A$ cancel out when the division is performed. Rearranging this equation yields

$$P_{A_{O_2}} = P_{I_{O_2}} - \frac{P_{A_{CO_2}}}{R} \quad (16)$$

This is called the alveolar gas equation, and it uniquely relates alveolar P_{O_2} to P_{CO_2} for given values of inspired P_{O_2} and R. It is the basis of calculations of the alveolar-to-arterial P_{O_2} difference, a commonly used index of inefficiency of pulmonary gas exchange. Because we assumed that $\dot{V}_I = \dot{V}_A$ in deriving this equation, it is an approximation. It is possible to rigorously account for the difference between $\dot{V}_I$ and $\dot{V}_A$, and when this is done, the alveolar gas equation contains an additional term:

$$P_{A_{O_2}} = P_{I_{O_2}} - \frac{P_{A_{CO_2}}}{R} + \left[P_{A_{CO_2}} \times F_{I_{O_2}} \times \frac{(1-R)}{R} \right] \quad (17)$$

The term in brackets is the correction factor for the difference between inspired and expired volumes. It is generally small during air breathing (1 to 3 mm Hg) and can be ignored in most clinical settings.

As an example of the use of this equation, suppose that a patient with normal lungs takes an overdose of a barbiturate drug that depresses alveolar ventilation. The patient's alveolar P_{CO_2} might rise from 40 to 60 mm Hg (the actual value is determined by the alveolar ventilation equation). If the patient's respiratory exchange ratio is 1, the small correction factor disappears, and the alveolar P_{O_2} is given by

$$\begin{aligned} P_{A_{O_2}} &= P_{I_{O_2}} - \frac{P_{A_{CO_2}}}{R} \\ &= 149 - 60 \\ &= 89 \text{ mm Hg} \end{aligned}$$

Note that the alveolar P_{O_2} falls by 20 mm Hg; this is the same amount by which the P_{CO_2} rises. On the other hand, if R = 0.8, which is a more typical resting value, and we ignore the small correction factor in Equation 17, then

$$\begin{aligned} P_{A_{O_2}} &= 149 - 60/0.8 \\ &= 74 \text{ mm Hg} \end{aligned}$$

Note that in this case the P_{O_2} falls more than the P_{CO_2} rises.

Both examples emphasize that, in practical terms, the hypoxemia is generally of minor importance compared with the carbon dioxide retention and consequent respiratory acidosis. This is further illustrated in Figure 4-14, which shows calculated changes in gas exchange as a result of hypoventilation. Note that severe hypoventilation sufficient to double the P_{CO_2} from 40 to 80 mm Hg decreases the alveolar P_{O_2} from only, say, 100 to 50 or 60 mm Hg. Although the arterial P_{O_2} is likely to be a few millimeters of mercury lower than the alveolar value, the arterial oxygen saturation is approximately 80%. However, there is substantial respiratory acidosis with an arterial pH of about 7.2. This fact emphasizes again that the hypoxemia is usually not as important as the carbon dioxide retention and respiratory acidosis in pure hypoventilation.

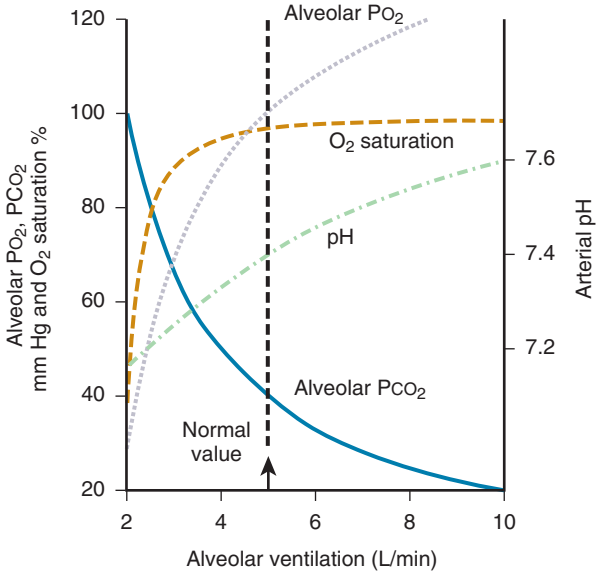

FIGURE 4-14 ■ Gas exchange during hypoventilation. Note the relatively large rise in P_{CO_2} and consequent fall in pH compared with the modest fall in arterial oxygen saturation. (Redrawn from West JB: Pulmonary Pathophysiology—The Essentials [7th ed]. Baltimore, Lippincott Williams & Wilkins, 2007.)

A feature of alveolar hypoventilation is that, although the arterial P_{CO_2} is always raised, the arterial P_{O_2} may be returned to normal very easily by giving supplementary oxygen. Suppose that the patient with barbiturate intoxication just discussed is given 30% oxygen to breathe. If we assume that the ventilation remains unchanged, it can be shown (from Equation 17) that the alveolar P_{O_2} rises from 74 to about 139 mm Hg. Thus, a relatively small increase in inspired P_{O_2} is very effective in eliminating the arterial hypoxemia of hypoventilation.

Diffusion Limitation

It is now generally believed that oxygen, carbon dioxide, and indeed all gases cross the blood-gas barrier by simple passive diffusion. Fick's law of diffusion states that the rate of transfer of a gas through a sheet of tissue is proportional to the tissue area (A) and the difference in partial pressure ($P_1 - P_2$) between the two sides, and is inversely proportional to the thickness (T):

$$\dot{V}gas = \frac{A}{T} \times D \times (P_1 - P_2) \quad (18)$$

As we have seen already, the area of the blood-gas barrier in the lung is enormous (50 to 100 m^2), and the thickness is less than 0.3 μm in some places, so the dimensions of the barrier are ideal for diffusion.

The rate of diffusion is also proportional to a constant, D, which depends on the properties of the tissue and the particular gas. The constant is proportional to the solubility (Sol) of the gas, and inversely proportional to the square root of the molecular weight (MW):

$$D \propto \frac{Sol}{\sqrt{MW}} \quad (19)$$

This means that, per mm Hg difference between capillary and alveolar partial pressures, carbon dioxide diffuses about 20 times more rapidly than oxygen through tissue sheets, because carbon dioxide has a much higher solubility (24:1 at 37° C), but the square roots of the molecular weights are not very different (1.17:1). Note that this calculation applies only to tissue sheets and not to the uptake of oxygen or output of carbon dioxide by the lung, wherein chemical reaction rates also play a role (see later discussion).

Oxygen Uptake along the Pulmonary Capillary

Figure 4-15 shows calculated changes in the P_{O_2} of the blood along the pulmonary capillary as oxygen is taken up under normal conditions. The calculation is based on Fick's law of diffusion (see Equation 18). One of the several assumptions is that the diffusion characteristics of the blood-gas barrier are uniform along the length of the capillary. The calculation is complicated by the fact that the change in the P_{O_2} of the capillary blood depends on the oxygen dissociation curve. This is not only nonlinear but is also influenced by the simultaneous elimination of carbon dioxide. The calculation is often known as the Bohr integration because it was first carried out in a simplified form by Christian Bohr.[77] Modern computations take into account reaction times of oxygen with hemoglobin and also reaction rates associated with carbon dioxide elimination (see later discussion). Such complicated calculations have only become feasible with the advent of the digital computer.[78]

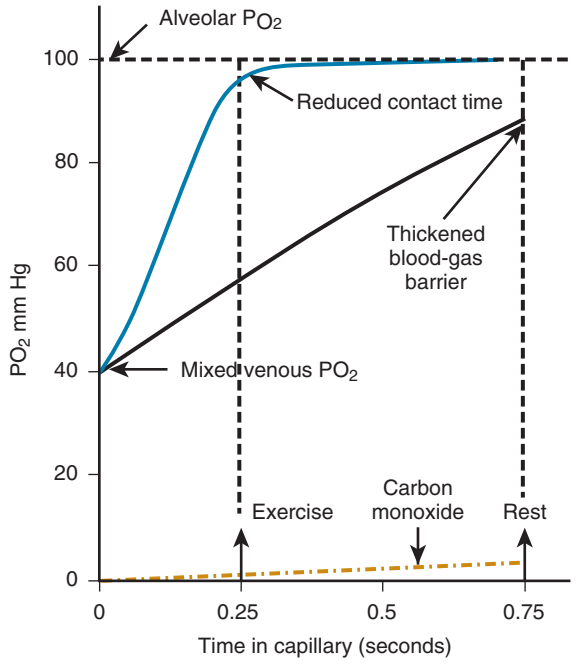

FIGURE 4-15 ■ Typical time courses for the change in P_{O_2} in the pulmonary capillary when diffusion is normal, when the contact time is reduced, and when the blood-gas barrier is abnormally thick. The time course for carbon monoxide uptake is also shown. (Redrawn from West JB: Pulmonary Pathophysiology—The Essentials [7th ed]. Baltimore: Lippincott Williams & Wilkins, 2007.)

Figure 4-15 shows that the time spent by the blood in the pulmonary capillary under normal resting conditions is about 0.75 second. This number is obtained by dividing the volume of blood in the pulmonary capillaries (about 75 mL) by the cardiac output (about 6 L/min).[79] The figure shows that the P_{O_2} of pulmonary capillary blood very nearly reaches that of alveolar gas after approximately a third of the available time in the capillary. This means that there is normally ample time for essentially complete oxygenation of the blood or, as it is sometimes said, the normal lung has substantial diffusion "reserves."

If the blood-gas barrier is thickened, the rate of transfer of oxygen across the barrier is reduced in accordance with Fick's law, and the rate of rise of P_{O_2} is slower, as shown in Figure 4-15. Under these circumstances, a P_{O_2} difference between alveolar gas and end-capillary blood may develop. This means that there is some diffusion limitation of oxygen transfer. It is important to appreciate that under most conditions oxygen transfer is perfusion limited, and only under unusual conditions such as severe interstitial lung disease is there some diffusion limitation.

It can be shown[80] that whether gas transfer is perfusion or diffusion limited depends on the ratio of D, the diffusive conductance of the blood-gas barrier, to the product of the slope of the oxygen-hemoglobin dissociation curve (commonly referred to as beta [β]) and the total pulmonary blood flow rate $(\dot{Q})$: $D/(\dot{Q}\beta)$.

It is clear that, for a gas such as oxygen, the slope of the blood dissociation curve is not a constant but depends on the P_{O_2} and also to a lesser extent on factors that shift the dissociation curve, such as pH, P_{CO_2}, temperature, and red cell 2,3-diphosphoglycerate concentration. Under hypoxic conditions, when the lung is operating on the lower, straighter part of the oxygen dissociation curve, the slope is sometimes assumed to be linear to simplify the analysis. Figure 4-16 shows the extent to which perfusion and diffusion limit the transfer of gas under various conditions.[80] Although the figure is based on a number of simplifying assumptions, it is conceptually valuable.

Note that the physiologically inert gases nitrogen and sulfur hexafluoride (*right-hand end of* Fig. 4-16) are completely perfusion limited in their transfer. (*Physiologically inert* means that, being carried in blood only in physical solution, their blood concentration is directly proportional to partial pressure; that is, they obey Henry's law of solubility.) The same perfusion limitation applies to oxygen in hyperoxia because, high on the dissociation curve, the value of β is very low so that $(D/\dot{Q}\beta)$ is very high and diffusion limitation is not seen. However, oxygen transfer under conditions of hypoxia can be partly diffusion limited because the lung is working low on the dissociation curve, where the slope (β) is much higher than normal. This is particularly the case for oxygen transfer during hypoxic exercise. Indeed,

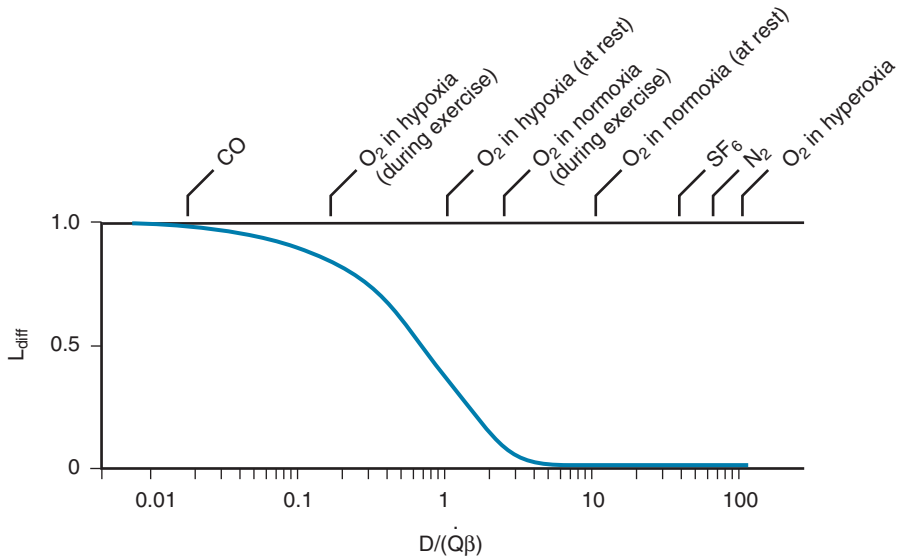

FIGURE 4-16 ■ Diffusion-limited transfer of various gases in the lung. Diffusion limitation (L_{diff}) is on a scale of 0 (no limitation) to 1 (complete limitation). See text for details. (Redrawn from Scheid P, Piiper J: Diffusion. *In* Crystal RG, West JB, Barnes PJ, Weibel ER [eds]: The Lung: Scientific Foundations [2nd ed]. New York: Raven Press, 1997.)

the most marked diffusion limitation that ever occurs in the normal lung is during maximal exercise at extreme high altitude in well-acclimatized subjects.[81,82] On the summit of Mount Everest, there is apparently diffusion limitation even at rest.

Figure 4-16 also shows that the transfer of carbon monoxide by the lung is markedly diffusion limited. This follows from the very steep slope of the dissociation curve of carbon monoxide with blood (that is, β is very large). Another way of looking at this is to say that the avidity of hemoglobin for carbon monoxide is so high that the partial pressure in the blood hardly rises along the pulmonary capillary (see Fig. 4-15). Under these conditions, it is intuitively clear that the amount of carbon monoxide that is taken up depends almost entirely on the diffusion properties of the blood-gas barrier.

Reaction Rates with Hemoglobin

When oxygen (or carbon monoxide) is added to blood, its combination with hemoglobin is quite fast, being close to completion in 0.2 second. Such reaction rates can be measured using special equipment in which reduced hemoglobin and dissolved oxygen are rapidly mixed and the rate of formation of oxyhemoglobin is measured photometrically. Although oxygenation occurs rapidly within the pulmonary capillary, even this rapid reaction significantly delays the loading of oxygen by the red cell.

The transfer of oxygen from the alveolar gas to its combination with hemoglobin in the red cell can therefore be regarded as occurring in two stages: (1) diffusion of oxygen through the blood-gas barrier, including the plasma and red cell interior; and (2) reaction of the oxygen with hemoglobin (Fig. 4-17A). Although at first sight these two processes are very different, it is possible to treat them mathematically in a similar way and to regard each as contributing its own "resistance" to the transfer of oxygen. Such an analysis was carried out by Roughton and Forster,[83] who showed that the following relationship exists:

$$\frac{1}{D_L} = \frac{1}{D_M} + \frac{1}{(\theta \times V_C)} \qquad (20)$$

where D_L refers to the diffusing capacity of the lung, D_M is the diffusing capacity of the membrane (which includes the plasma and red cell interior), θ is the rate of reaction of oxygen (or carbon monoxide) with hemoglobin (expressed per milliliter of blood), and V_C is the volume of blood in the pulmonary capillaries.

In the normal lung, the resistances offered by the membrane and blood reaction components are approximately equal. This means that, if the capillary blood volume is reduced by disease, the measured diffusing capacity of the lung is lowered. In fact, the equation can be used to separate the two components. To do this, the diffusing capacity is measured at both high and normal alveolar P_{O_2} values. Increasing the alveolar P_{O_2} reduces the value of θ for carbon monoxide because the carbon monoxide has to compete with a high pressure of oxygen for the hemoglobin. If the resulting measurements of $1/D_L$ are plotted against 1/θ, as shown in Figure 4-17B, the slope of the line is $1/V_C$, whereas the intercept on the vertical axis is $1/D_M$.

Diffusing Capacity

Carbon monoxide is usually the gas of choice for measuring the diffusion properties of the lung because, as Figure 4-16 shows, its transfer is almost entirely diffusion limited. It is true that part of the limitation has to do with the rate of reaction of carbon monoxide with hemoglobin (see Fig. 4-17A), but this is conveniently included in the measurement of diffusion properties. Although it

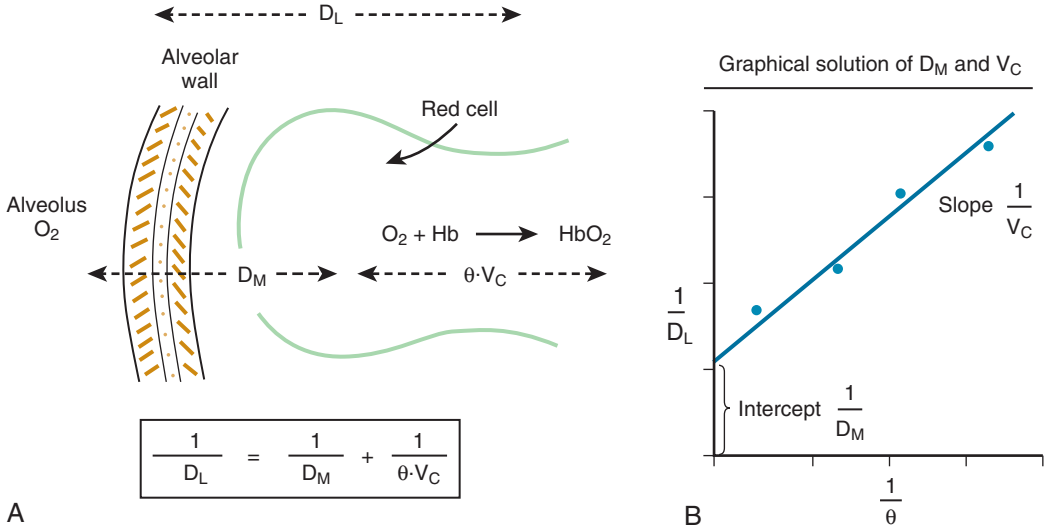

FIGURE 4-17 ■ **A,** The two components of the measured diffusing capacity (D_L) of the lung: that due to the diffusion process itself (D_M) and that attributable to the time taken for oxygen (or carbon monoxide) to react with hemoglobin (Hb) ($\theta \cdot V_C$). **B,** $1/D_L$ plotted against $1/\theta$ can be used to derive D_M and V_C.

could be argued that we are really more interested in oxygen and the effects of any diffusion limitation on this gas, oxygen uptake is typically perfusion limited under normoxic conditions (see Fig. 4-16) and partly perfusion and diffusion limited under hypoxic conditions. For this reason, measurements using oxygen are often difficult to interpret, although techniques utilizing isotopes of oxygen have been proposed.[80] However, for the measurement of diffusion properties in the pulmonary function laboratory, carbon monoxide is the best gas.

As indicated earlier, Fick's law states that the amount of gas transferred across a tissue sheet is proportional to the area, a diffusion constant, and the difference in partial pressure, and is inversely proportional to the thickness:

$$\dot{V}gas = \frac{A}{T} \times D \times (P_1 - P_2) \qquad (18)$$

The actual lung is so complex that it is not possible to determine the area and the thickness of the blood-gas barrier during life. Instead, the equation is written to combine the factors A, T, and D into one constant, D_L, as follows:

$$\dot{V}gas = D_L \times (P_1 - P_2) \qquad (21)$$

where D_L is called the diffusing capacity of the lung, and consequently includes the area, thickness, and diffusion properties of the tissue sheet, as well as the properties of the diffusing gas. Thus, the diffusing capacity for carbon monoxide is given by:

$$D_L = \frac{\dot{V}_{CO}}{(P_1 - P_2)} \qquad (22)$$

where P_1 and P_2 are the partial pressures of carbon monoxide in alveolar gas and capillary blood, respectively. Because the partial pressure of carbon monoxide in capillary blood is so small (see Fig. 4-15), it can generally be neglected. In this case, the equation becomes:

$$D_L = \frac{\dot{V}_{CO}}{P_{A_{CO}}} \qquad (23)$$

or, in words, the diffusing capacity of the lung for carbon monoxide is the volume of carbon monoxide transferred in milliliters per minute per millimeter of mercury of alveolar partial pressure of CO.

Some people, for example, cigarette smokers, have sufficient carboxyhemoglobin in their blood that the partial pressure of carbon monoxide in the pulmonary capillaries cannot be neglected. In this case, an estimate of the partial pressure of carbon monoxide in pulmonary capillary blood can be made using a rebreathing technique, and Equation 22 is then used to determine diffusing capacity.

Measurement. Several techniques are available for measuring the diffusing capacity of the lung for carbon monoxide. In the *single-breath method,* a single inspiration of a dilute mixture (about 0.3%) of carbon monoxide is made, and the rate of disappearance of carbon monoxide from the alveolar gas during a 10-second breath-hold is calculated. This is usually done by measuring the inspired and expired concentrations of carbon monoxide with an infrared analyzer. Alternatively, a respiratory mass spectrometer can be used if ^{18}O-labeled carbon monoxide is employed. At the end of the breath-holding period, a post–dead space sample of alveolar gas is obtained by discarding the first 750 mL of the expiration. The alveolar concentration of carbon monoxide is not constant during the breath-holding period, but allowance can be made, assuming that the disappearance of carbon monoxide follows an exponential law. Helium is also added to the inspired gas to give a measurement of lung volume by dilution. The appropriate equation is:

$$D_L = \frac{\dot{V}_A \times K}{t} \log_e \left[\frac{F_{I_{CO}} \times F_{A_{He}}}{F_{I_{He}} \times F_{A_{CO_2}}} \right] \quad (24)$$

where $\dot{V}_A$ is the alveolar volume in liters, t is breath-holding time in seconds, K is a constant, and the fractional concentrations of carbon monoxide and helium in inspired and expired gas are as indicated. Further details of this method, which requires considerable care for accurate results, can be found in more specialized texts.[84]

The diffusing capacity can also be measured using the *steady-state method.* The subject breathes a low concentration of carbon monoxide (about 0.1%) for 0.5 minute or so, until a steady state of gas exchange has been reached. The constant rate of disappearance of carbon monoxide from alveolar gas is then measured for a further short period, along with the alveolar concentration. This technique is better suited to measurements during exercise in which breath-holding becomes a problem. The normal value of the diffusing capacity for carbon monoxide depends on age, sex, and height (as is the case for most pulmonary function tests), and appropriate regression equations are available.[84]

Interpretation. As Figure 4-17A indicates, the uptake of carbon monoxide is determined by the diffusion properties of the blood-gas barrier (including plasma and red cell interior) and the rate of combination of carbon monoxide with blood. The *diffusion properties* of the alveolar membrane depend on its thickness and area. Thus, the diffusing capacity is reduced by diseases in which the thickness is increased, including diffuse interstitial pulmonary fibrosis, asbestosis, and sarcoidosis. It is also reduced when the area is decreased, for example, by pneumonectomy. The fall in diffusing capacity that occurs in emphysema may be caused by the loss of alveolar walls and capillaries, but unevenness of ventilation and diffusion may also play a role (see later discussion).

The *rate of combination* of carbon monoxide with blood is reduced whenever the number of red cells in the capillaries is reduced. This occurs in anemia and also in diseases that reduce the capillary blood volume, such as pulmonary embolism.

Figure 4-17B shows how it is possible to separate the membrane and blood components of the diffusing capacity by making measurements at high and normal values of alveolar P_{O_2}. However, this is only possible in subjects with nearly normal lungs. In many patients in whom the measured diffusing capacity is low, the interpretation is uncertain. The reason for this is the unevenness of ventilation and diffusion properties throughout the diseased lung. Such lungs tend to empty unevenly, with the result that the post–dead space sample of expired gas that is analyzed for carbon monoxide is not representative of the whole lung. Partly as a consequence of this, different methods of measuring diffusing capacity in patients with diseased lungs frequently give very different results. For this reason, the diffusing capacity is sometimes referred to as the *transfer factor* (especially in Europe) to emphasize that it is more a measure of the lung's overall ability to transfer gas into the blood than a specific test of diffusion characteristics. Nevertheless, the test gives considerable information in the nearly normal lung, and even in patients with severe disease, the results are empirically useful for assessing the severity and type of lung disease in the pulmonary function laboratory. (For a discussion of clinical tests, see Chapter 24.)

Shunt

Shunt refers to the entry of blood into the systemic arterial system without going through ventilated areas of lung. Even the normal cardiopulmonary system shows some depression of the arterial P_{O_2} as a result of this factor. For example, in the normal lung, some of the bronchial artery blood is collected by the pulmonary veins after it has perfused the bronchi. Because the oxygen concentration of this blood has been reduced, its addition to the normal end-capillary blood results in a reduction of arterial P_{O_2}. Another source is a small amount of coronary venous blood that drains directly into the cavity of the left ventricle through the thebesian veins. Of course, most of the coronary venous blood ends up in the coronary sinus, and only a minute fraction reaches the left ventricle directly. Such shunts depress arterial P_{O_2} only by about 1 to 2 mm Hg.

In patients with congenital heart disease, there may be a direct addition of venous blood to arterial blood across a defect between the right and left sides of the heart. Generally, this is associated with some increase in pressure on the right side; otherwise, the shunt is only from left to right. In lung disease, there may be gas-exchanging units that are completely unventilated because of airway obstruction, atelectasis, or alveolar filling with fluid or cells. The blood draining from these constitutes a shunt. It could be argued that such units are simply at the extreme end of the spectrum of ventilation-perfusion inequality (see next section), but the gas-exchange properties of unventilated units are so different (e.g., during oxygen breathing) that it is convenient to separate them.

When the shunt is caused by the addition of mixed venous blood (pulmonary arterial) to blood draining from the capillaries (pulmonary venous), it is possible to calculate the amount of shunt flow. This is done using a mixing equation. The total amount of oxygen delivered into the systemic circulation per minute is the total blood flow $(\dot{Q}_T)$ multiplied by the oxygen concentration in the systemic arterial blood (Ca_{O_2}), or $\dot{Q}_T \times Ca_{O_2}$. This must equal the sum of the amounts of oxygen in the shunted blood $(\dot{Q}_S \times C\bar{v}_{O_2})$ and the nonshunted or end-capillary blood $(\dot{Q}_T - \dot{Q}_S) \times Cc'_{O_2}$. Thus

$$\dot{Q}_T \times Ca_{O_2} = (\dot{Q}_S \times C\bar{v}_{O_2}) + (\dot{Q}_T - \dot{Q}_S) \times Cc'_{O_2} \quad (25)$$

Rearranging, this gives

$$\frac{\dot{Q}_S}{\dot{Q}_T} = \frac{(Cc'_{O_2} - Ca_{O_2})}{(Cc'_{O_2} - C\bar{v}_{O_2})} \quad (26)$$

The oxygen concentration of end-capillary blood is usually calculated from the alveolar P_{O_2} and the hemoglobin concentration, assuming 100% oxyhemoglobin saturation.

When the shunt is caused by blood that does not have the same oxygen concentration as mixed venous blood (e.g., bronchial venous blood), it is generally not possible to calculate its true magnitude. However, it is often useful to calculate an "as if" shunt, that is, what the shunt *would* be if the observed depression of arterial oxygen concentration were caused by the addition of mixed venous blood. An analogous procedure is frequently used to quantitate the degree of hypoxemia caused by ventilation-perfusion inequality, although it is clearly recognized in this case that there may be relatively little or even no blood flow to completely unventilated lung units.

An important diagnostic feature of a shunt is that the arterial P_{O_2} does not rise to the normal level (which in theory should be about 670 mm Hg) when the patient is given 100% oxygen to breathe. The reason for this is that the shunted blood that bypasses ventilated alveoli is never exposed to the higher alveolar P_{O_2}. Its addition to end-capillary blood, therefore, continues to depress the arterial P_{O_2}. Nevertheless, some elevation of the arterial P_{O_2} occurs because of the oxygen added to the capillary blood of the ventilated lung. Most of this added oxygen is in the dissolved form rather than attached to hemoglobin because the blood that is perfusing ventilated alveoli is normally nearly fully saturated.

The administration of 100% oxygen to a patient with a shunt is a very sensitive method of detecting small amounts of shunting. This is because when the arterial P_{O_2} is very high, a very small reduction of arterial oxygen concentration caused by the addition of the shunted blood causes a relatively large fall in P_{O_2}. This is directly attributable to the almost flat slope of the oxygen dissociation curve in this region.

A patient with a shunt usually does not have an increased P_{CO_2} in the arterial blood in spite of the fact that the shunted blood is rich in carbon dioxide. The reason is that the chemoreceptors sense any elevation of arterial P_{CO_2} and respond by increasing the ventilation. As a consequence, the P_{CO_2} of the unshunted blood is reduced by the hyperventilation until the arterial P_{CO_2} is back to normal. Indeed, in some patients with large shunts caused, for example, by cyanotic congenital heart disease, the arterial P_{CO_2} is low because the arterial hypoxemia increases the respiratory drive.

Ventilation-Perfusion Relationships

It has been known for many years that mismatching of ventilation and blood flow is the most common cause of hypoxemia in lung disease. More recently, the role of uneven ventilation and blood flow as a cause of carbon dioxide retention has also been appreciated. Early intimations of the importance of the subject go back to Krogh and Lindhard[85] and Haldane.[86] However, a very rapid advance in our understanding occurred in the late 1940s when Fenn and colleagues[87] and Riley and Cournand[88] introduced graphic analysis of gas exchange. This was an important advance because the interrelationships of ventilation, blood flow, and gas exchange depend on the oxygen and carbon dioxide dissociation curves that are not only nonlinear but interdependent, and direct solutions to the gas exchange equations that relate the ventilation-perfusion ratio to gas exchange (see below, Equations 28 and 29) are not possible.

A more recent phase began with the introduction of digital computer procedures to describe the oxygen and carbon dioxide dissociation curves.[89,90] These new procedures enabled investigators to answer questions about gas exchange that had been impossibly difficult prior to that time. The behavior of distributions of ventilation-perfusion ratios was analyzed,[91] and Wagner and his colleagues[92] introduced the multiple inert gas elimination technique, which allowed, for the first time, information about the dispersion, number of modes, and shape of the distributions of ventilation, of perfusion, and of their ratio to be obtained.

Gas Exchange in a Single Lung Unit

The P_{O_2}, P_{CO_2}, and P_{N_2} in any gas-exchanging unit of the lung are uniquely determined by three major factors: (1) the ventilation-perfusion ratio, (2) the composition of the inspired gas and the composition of the mixed venous blood, and (3) the slopes and positions of the relevant blood-gas dissociation curves.

Formally, the key role of the ventilation-perfusion ratio can be derived as follows. The amount of carbon dioxide exhaled into the air from alveolar gas per minute is given by a rearrangement of Equation 5:

$$\dot{V}_{CO_2} = \dot{V}_A \times P_{A_{CO_2}} / K \tag{5}$$

where $\dot{V}_{CO_2}$ is the carbon dioxide output, $\dot{V}_A$ is the alveolar ventilation, K is a constant, and there is no carbon dioxide in the inspired gas.

The amount of carbon dioxide lost into alveolar gas from capillary blood per minute is given by

$$\dot{V}_{CO_2} = \dot{Q}(C\bar{v}_{CO_2} - Cc'_{CO_2}) \tag{27}$$

where $\dot{Q}$ is blood flow, and $C\bar{v}_{CO_2}$ and Cc'_{CO_2} are the concentrations of carbon dioxide in mixed venous and end-capillary blood, respectively. Now, in a steady state, the amount of carbon dioxide lost from the alveoli and from the capillary blood must be the same. Therefore

$$\dot{V}_A \times P_{A_{CO_2}} \times K = \dot{Q}(C\bar{v}_{CO_2} - Cc'_{O_2}) \; or$$
$$\frac{\dot{V}_A}{\dot{Q}} = \frac{(C\bar{v}_{CO_2} - Cc'_{O_2})}{P_{A_{CO_2}}} \times K \tag{28}$$

Thus, the alveolar P_{CO_2} and the corresponding end-capillary CO_2 concentration (assuming end-capillary and alveolar P_{CO_2} are identical) are determined by (1) the ventilation-perfusion ratio, (2) the mixed venous CO_2 concentration, and (3) the carbon dioxide dissociation curve relating P_{CO_2} to carbon dioxide concentration.

Although this equation looks simple, its appearance is deceptive, because when the ventilation-perfusion ratio increases (for example), the alveolar P_{O_2} rises. This means that the oxygen saturation of the blood increases and therefore that the relationship between P_{CO_2} and carbon dioxide concentration is altered. Thus, the alveolar P_{O_2} is an implicit variable in the equation. In addition,

the relationship between P_{CO_2} and carbon dioxide concentration is nonlinear. This is the reason that it was only possible to solve the equation graphically until the introduction of numerical analysis by computer.

Just as, in the context of the alveolar ventilation equation (see "Hypoventilation" earlier), both oxygen and carbon dioxide exchange were able to be expressed in equations of similar form, it is possible to write an equation similar to Equation 28 for oxygen exchange based on the same principles as applied for carbon dioxide. Again, the approximation is made that inspired alveolar ventilation ($\dot{V}_I$) = expired alveolar ventilation ($\dot{V}_A$) to keep the equation simple, but as for the alveolar gas equation, the fact that $\dot{V}_I$ and $\dot{V}_A$ are generally not quite the same can formally be taken into account. Using this approximation, the equation for oxygen is

$$\frac{\dot{V}_A}{\dot{Q}} = K \times \frac{(Cc'_{O_2} - C\bar{v}_{O_2})}{(P_{I_{O_2}} - P_{A_{O_2}})} \qquad (29)$$

Just as for carbon dioxide, the alveolar and end-capillary P_{O_2} values are taken to be identical, implying diffusion equilibrium across the blood-gas barrier. It is seen that the determinants of alveolar P_{O_2} are threefold, as for carbon dioxide: (1) the ventilation-perfusion ratio, (2) inspired and mixed venous oxygen levels, and (3) the relationship between P_{O_2} and oxygen concentration (i.e., the oxygen dissociation curve).

Graphic analysis of these relationships is assisted by the use of the oxygen–carbon dioxide diagram, in which P_{O_2} is on the horizontal axis and P_{CO_2} on the vertical axis. This diagram has been used to solve many problems related to ventilation-perfusion relationships.[93] A simple introduction to the diagram is given elsewhere.[94] It shows the solutions to Equations 28 and 29 for each value of the ventilation-perfusion ratio from zero to infinity.

Figure 4-18 is an example of the use of the oxygen–carbon dioxide diagram to show how the P_{O_2} and P_{CO_2} of a lung unit alter as the ventilation-perfusion ratio is either decreased below or increased above the normal value. Note that for a given composition of inspired gas (I) and mixed venous blood ($\bar{v}$), the possible combinations of P_{O_2} and P_{CO_2} are constrained to a single line known as the ventilation-perfusion ratio line. Each point on that line uniquely corresponds to a value of the ventilation-perfusion ratio. Note also that, at the extremes of the spectrum of ventilation-perfusion ratios, the P_{O_2} and P_{CO_2} of end-capillary blood are those of mixed venous blood when the ventilation-perfusion ratio is zero, and the P_{O_2} and P_{CO_2} of alveolar gas are the same as those of inspired gas for a ventilation-perfusion ratio of infinity. In this diagram and in the rest of this section, we assume that there is complete diffusion equilibration between the P_{O_2} and P_{CO_2} of alveolar gas and end-capillary blood. This is a reasonable assumption unless there is marked thickening of the blood-gas barrier or one is considering a subject exercising in hypoxia.

Figure 4-19 shows the P_{O_2}, P_{CO_2}, and oxygen concentration of end-capillary blood of a lung unit as its ventilation-perfusion ratio is increased from extremely low to extremely high values. The lung is assumed to be breathing air, the P_{O_2} and P_{CO_2} of mixed venous blood are normal (40 and 45 mm Hg, respectively), and the hemoglobin concentration is 14.8 g/100 mL. The normal value of the ventilation-perfusion ratio is in the range of 0.8 to 1. Note that as the ratio is altered either above or below that value, the P_{O_2} changes rapidly. By contrast, the oxygen concentration increases little as the ventilation-perfusion ratio is raised above the normal value because the hemoglobin is already almost fully saturated. The P_{CO_2} falls considerably as the ventilation-perfusion ratio is raised, but rises relatively little at lower ventilation-perfusion ratio values. The quantitative information in this figure is consistent with the graphic analysis of Figure 4-18.

Pattern in the Normal Lung

Both ventilation and perfusion vary throughout the lung. It is thus instructive to look at the topographic inequality

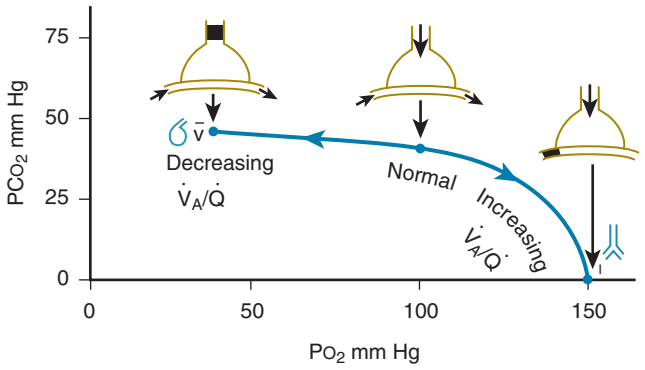

FIGURE 4-18 ■ Oxygen–carbon dioxide diagram shows how the P_{O_2} and P_{CO_2} of a lung unit alter as the ventilation-perfusion ratio ($\dot{V}_A/\dot{Q}$) is changed. I, inspired gas; $\bar{v}$, mixed venous blood. (Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

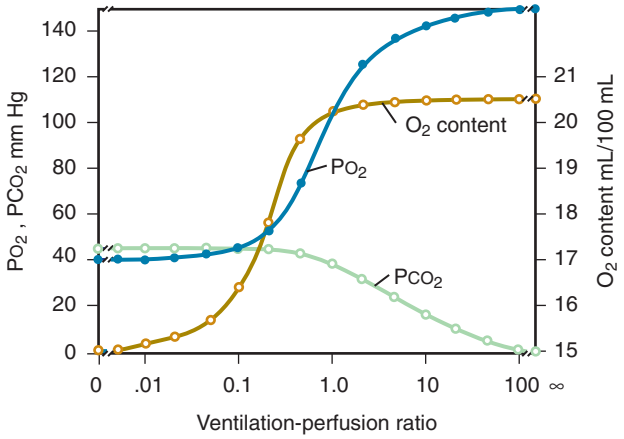

FIGURE 4-19 ■ Changes in P_{O_2}, P_{CO_2}, and end-capillary oxygen content in a lung unit are shown as its ventilation-perfusion ratio is altered. See text for assumptions. (Redrawn from West JB: State of the art: Ventilation-perfusion relationships. Am Rev Respir Dis 116:919–943, 1977.)

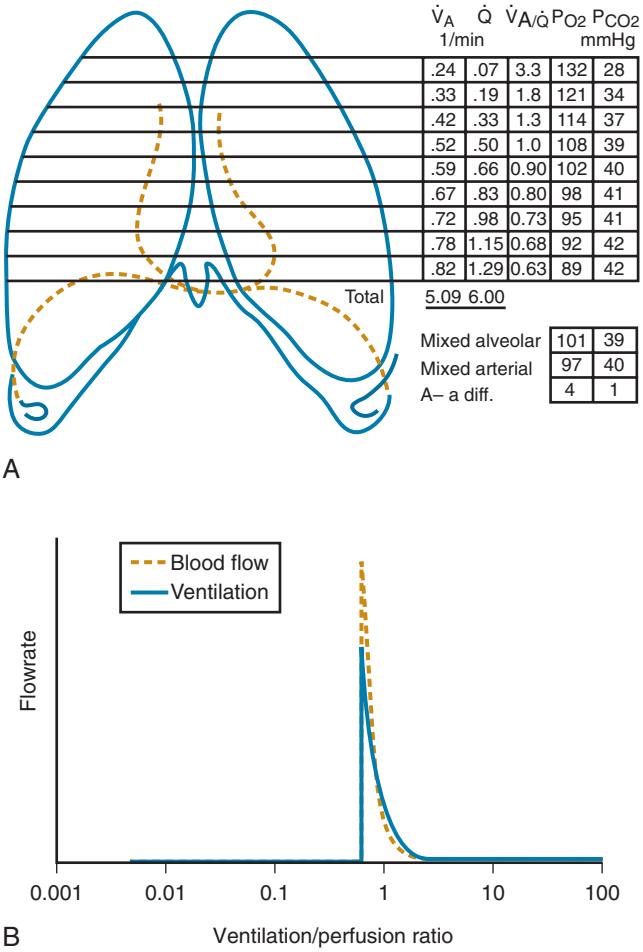

FIGURE 4-20 ■ **A,** Regional differences of gas exchange down the upright normal lung. The lung is divided into nine imaginary slices. $\dot{Q}$, blood flow; $\dot{V}_A$, gas flow. **B,** Topographic distribution of blood flow and ventilation taken from **A** are reexpressed as plots of blood flow and ventilation against ventilation-perfusion ratio. This transformation quantifies the distribution of ventilation-perfusion ratios. (**A** Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

of gas exchange that occurs in the normal upright lung as a result of ventilation-perfusion inequality. We saw previously that both ventilation and blood flow per unit volume decrease from the bottom to the top of the upright lung. However, the changes for blood flow are more marked than those for ventilation. As a consequence, the ventilation-perfusion ratio increases from low values at the base to high values at the apex of the normal upright lung (Fig. 4-20A).

Because the ventilation-perfusion ratio determines the gas exchange in any region (Equations 28 and 29), the corresponding pattern of variation in P_{O_2} and P_{CO_2} in the lung can be calculated. Normal composition of mixed venous blood is here assumed. Note that the P_{O_2} increases by some 40 mm Hg from base to apex, whereas the P_{CO_2} falls by about 14 mm Hg. The pH is high at the apex because the P_{CO_2} there is low (the base excess is the same throughout the lung). Very little of the total oxygen uptake occurs at the apex, principally because the blood flow there is very low.

Figure 4-20A also helps to explain why ventilation-perfusion inequality interferes with overall gas exchange. Note that the base of the lung has most of the blood flow, but the P_{O_2} and oxygen concentration of the end-capillary blood are lowest there. As a result, the effluent pulmonary venous blood (which becomes the systemic arterial blood) is loaded with moderately oxygenated blood from the base. The net result is a depression of the arterial P_{O_2} below that which would occur if ventilation and blood flow were uniformly distributed.

The same argument applies to carbon dioxide. In this case, the P_{CO_2} and carbon dioxide concentrations of the end-capillary blood are highest at the base, where the blood flow is greatest. As a result, the P_{CO_2} of arterial blood is elevated above that which would occur if there were no ventilation-perfusion inequality. In other words, a lung with mismatched ventilation and blood flow is inefficient at exchanging gas, be this oxygen or carbon dioxide. In fact, the inefficiency applies to any gas that is being transferred by the lung. The extent of the impairment of gas exchange caused by any given amount of ventilation-perfusion inequality depends on the solubility, or slope of the blood dissociation curve, of the gas. For example, in a lognormal distribution of ventilation-perfusion ratios, gases with medium solubility experience the greatest interference with pulmonary transfer.[95] In the normal lung, despite the degree of inequality due to gravity shown in Figure 4-20A, the overall effect on gas exchange is very small, reducing arterial P_{O_2} by only about 4 mm Hg (compared to that in a homogeneous lung).

The data in Figure 4-20A, showing values for ventilation, blood flow, and ventilation–blood flow ratio at all nine levels from apex to base, can usefully be considered as a frequency distribution of ventilation-perfusion ratios. This is accomplished by separately plotting ventilation and blood flow in each of the nine regions on the ordinate against the corresponding ventilation-perfusion ratio of each region. This is shown in Figure 4-20B. Such a distribution depicts succinctly the range of ventilation-perfusion ratios in the lung as a whole, and also shows the relative amounts of ventilation and blood flow associated with each. This narrow distribution should be compared to distributions in disease, which are discussed later in this chapter.

Traditional Assessment of Ventilation-Perfusion Inequality

A central question that has engaged the attention of physiologists and physicians for many years has been how best to assess the amount of ventilation-perfusion inequality. Ideally, we would like to know the actual distribution of ventilation-perfusion ratios (see next section), but the procedure required for this is too complicated for many clinical situations. Traditionally, we rely on measurements of P_{O_2} and P_{CO_2} in arterial blood and expired gas.

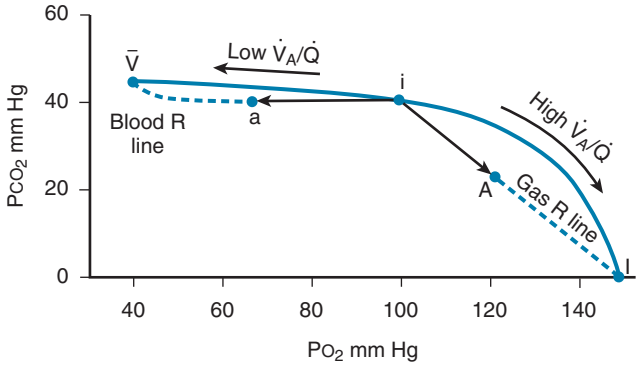

FIGURE 4-21 ■ Oxygen–carbon dioxide diagram showing the points for ideal gas (i), arterial blood (a), and alveolar gas (A). See text for details. $\dot{Q}$, blood flow; R lines, respiratory exchange ratio; $\dot{V}_A$, ventilation. (Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

The *arterial* P_{O_2} certainly gives some information about the degree of ventilation-perfusion inequality. In general, the lower the P_{O_2}, the more marked is the mismatching of ventilation and blood flow. The chief merit of this measurement is its simplicity, but a disadvantage is that its value is so sensitive to the overall ventilation and pulmonary blood flow.

We can quickly dismiss the *arterial* P_{CO_2}. This is so sensitive to the level of ventilation that it gives little information about the extent of the ventilation-perfusion inequality, though it should be added that the most common cause of an increased P_{CO_2} in chronic lung disease is mismatching of ventilation and blood flow.

Because of these limitations, the *alveolar-arterial* P_{O_2} difference is frequently measured and is more informative than the arterial P_{O_2} alone because it is less sensitive to the level of overall ventilation. To understand the significance of this measurement, we need to look in more detail at how gas exchange is altered by the imposition of ventilation-perfusion inequality.

Figure 4-21 shows an oxygen–carbon dioxide diagram with the same ventilation-perfusion line as that in Figure 4-18. Suppose initially that this lung has no ventilation-perfusion inequality. The P_{O_2} and P_{CO_2} of the alveolar gas and arterial blood would then be represented by point i, known as the ideal point. This is at the intersection of the gas and blood respiratory exchange ratio (R) lines; these are the lines that indicate the possible compositions of alveolar gas and arterial blood that are consistent with the overall respiratory exchange ratio (carbon dioxide output/oxygen uptake) of the whole lung. In other words, a lung in which R = 0.8 would have to have its mixed alveolar gas point (A) located somewhere on the line joining points i and I. A similar statement can be made for the arterial gas point (a).

What happens to the composition of mixed alveolar gas and arterial blood as ventilation-perfusion inequality is imposed on the lung? The answer is that both points diverge away from the ideal point (i), along the appropriate gas and blood R lines. The more extreme the degree of ventilation-perfusion inequality, the further the divergence. Moreover, the type of ventilation-perfusion inequality determines how much each point will move. For example, a distribution containing a large amount of ventilation to units with high ventilation-perfusion ratio especially moves point A down and to the right away from point i. By the same token, a distribution containing large amounts of blood flow to units with low ventilation-perfusion ratios predominantly moves point a leftward along the blood R line.

It is clear that the horizontal distance between points A and a (i.e., the mixed alveolar-arterial P_{O_2} difference) would be a useful measure of the degree of ventilation-perfusion inequality. Unfortunately, this index is impossible to obtain in most patients because A denotes the composition of *mixed* expired gas, excluding the anatomic dead space gas. In most diseased lungs, the alveoli empty sequentially, with poorly ventilated alveoli emptying last, so that a post–dead space sample is not representative of all mixed expired alveolar gas. In a few patients who have essentially uniform ventilation but uneven blood flow, this index can be used, and it is occasionally reported in patients with pulmonary embolism. In this instance, the P_{O_2} of end-tidal gas is taken to represent mixed expired alveolar gas.

Because the mixed expired alveolar P_{O_2} is usually impossible to obtain, a more useful index is the P_{O_2} difference between ideal alveolar gas and arterial blood, that is, the horizontal distance between points i and a. The ideal alveolar P_{O_2} is calculated from the alveolar gas equation:

$$P_{A_{O_2}} = P_{I_{O_2}} - \frac{P_{A_{CO_2}}}{R} + \left[P_{A_{CO_2}} \times F_{I_{O_2}} \times \frac{(1-R)}{R} \right] \qquad (17)$$

To use this equation, we assume that the P_{CO_2} of ideal alveolar gas is the same as the P_{CO_2} of arterial blood. The rationale for this is that the line along which point a moves (in Fig. 4-21) is so nearly horizontal that the value is close enough for clinical purposes. It is important to note that this ideal alveolar-arterial P_{O_2} difference is caused by units situated on the ventilation-perfusion ratio line between points i and $\bar{v}$, that is, units with abnormally low ventilation-perfusion ratios. This means that a diseased lung may have substantial ventilation-perfusion inequality but a nearly normal ideal alveolar-arterial P_{O_2} difference if most of the inequality is caused by units with abnormally high ventilation-perfusion ratios.

Physiologic shunt is another useful index of ventilation-perfusion inequality. It measures that movement of the arterial point away from the ideal point along the blood R line (see Fig. 4-21). It is therefore caused by blood flow to lung units with abnormally low ventilation-perfusion ratios. To calculate physiologic shunt, we pretend that all of the leftward movement of the arterial point a is caused by the addition of mixed venous blood $\bar{v}$ to ideal blood i. This is not so unreasonable as it might at first seem because units with very low ventilation-perfusion ratios put out blood that has essentially the same composition as that of mixed venous blood (see Figs. 4-18 and 4-19). The shunt equation is used in the following form:

$$\frac{\dot{Q}_{PS}}{\dot{Q}_T} = \frac{(Ci_{O_2} - Ca_{O_2})}{(Ci_{O_2} - C\bar{v}_{O_2})} \quad (30)$$

where $\dot{Q}_{PS}$ refers to physiologic shunt, $\dot{Q}_T$ refers to total blood flow through the lung, and Ci_{O_2}, Ca_{O_2}, and $C\bar{v}_{O_2}$, refer, respectively, to the oxygen concentrations of ideal, arterial, and mixed venous blood. The oxygen concentration of ideal blood is calculated from the ideal P_{O_2} and the oxygen dissociation curve. The normal value for *physiologic shunt* is less than 0.05.

The last traditional index to be discussed is *physiologic dead space* (also known as wasted ventilation). Whereas physiologic shunt reflects the amount of blood flow going to lung units with abnormally low ventilation-perfusion ratios, physiologic dead space is a measure of the amount of ventilation going to units with abnormally high ventilation-perfusion ratios. Thus the two indices provide measurements of both ends of the spectrum of ventilation-perfusion ratios.

To calculate physiologic dead space, we pretend that all the movement of the alveolar point A away from the ideal point i (see Fig. 4-21) is caused by the addition of inspired gas I to ideal gas. Again, this is not so unreasonable as it may first appear, because units with very high ventilation-perfusion ratios behave very much like point I (see Fig. 4-21). Because, as indicated earlier, it is usually impossible to obtain a pure sample of mixed expired gas, we generally collect mixed expired gas and measure its composition, E. The mixed expired gas contains a component from anatomic dead space, which therefore moves its composition further toward point I. The Bohr equation (Equation 9) is then used in the form

$$\frac{V_{D_{phys}}}{V_T} = \frac{(Pa_{CO_2} - P_{E_{CO_2}})}{Pa_{CO_2}} \quad (31)$$

where $V_{D_{phys}}$ is physiologic dead space, V_T is tidal volume, and $P_{E_{CO_2}}$ is mixed expired P_{CO_2}, and again we exploit the fact that the P_{CO_2} of ideal gas and that of arterial blood are virtually the same. The physiologic dead space/tidal volume ratio is sensitive to tidal volume because of the large contribution of anatomic dead space. The normal value for physiologic dead space is less than 0.3. (For applications of these principles in pulmonary function testing, see Chapter 24.)

Distributions of Ventilation-Perfusion Ratios

The analysis of ventilation-perfusion inequality briefly described in the last section is sometimes known as the *three-compartment model* because the lung is conceptually divided into an unventilated compartment (shunt), an unperfused compartment (dead space), and a compartment that is normally ventilated and perfused (ideal). This way of looking at the diseased lung, which was introduced by Riley and Cournand,[88] has proved to be of great clinical usefulness in assessing the effects of mismatching of ventilation and blood flow.

However, it was recognized many years ago that real lungs must contain some sort of distribution of ventilation-perfusion ratios and that a three-compartment model is therefore very remote from reality. The great difficulty of dealing with distributions of ventilation-perfusion ratios made progress very slow, although many clinical physiologists saw the measurement of distributions as an important goal.

The breakthrough came with the application of computer methods for analyzing the behavior of distributions, a very complex area because of the nonlinear and interdependent oxygen and carbon dioxide dissociation curves. With computer analysis, it was possible to make considerable advances in the understanding of the behavior of distributions of ventilation-perfusion ratios.[91] A key advance was the introduction of the multiple inert gas elimination technique, which allowed patterns of distributions to be recovered in patients with lung disease.[92]

Multiple Inert Gas Elimination Technique. The principles governing inert gas elimination by the lung are identical to those of O_2 and CO_2, and are dictated by equations corresponding to Equations 28 and 29. When an inert gas dissolved in saline is steadily infused into the peripheral venous circulation, it arrives at the lungs, and some of the gas will be exhaled. The proportion of gas that is eliminated by ventilation from the blood of a given lung unit depends only on the blood-gas partition coefficient of the gas (λ) and the ventilation-perfusion ratio $(\dot{V}_A/\dot{Q})$.[96,97] The relationship is given by the following equation:

$$\frac{Pc'}{P\bar{v}} = \frac{\lambda}{(\lambda + \dot{V}_A/\dot{Q})} \quad (32)$$

where Pc' and $P\bar{v}$ are the partial pressures of the gas in end-capillary blood and mixed venous blood, respectively. Equation 32 looks different from Equations 28 and 29 only because inert gases obey Henry's law, allowing concentration to be simply replaced by the product of solubility and partial pressure. This in turn permits the rearrangement of terms ending up with Equation 32. The ratio of end-capillary to mixed venous partial pressure is known as the *retention.* This equation is derived from exactly the same considerations of mass balance as applied to carbon dioxide in Equation 5.

In practice, a mixture of six gases (typically, sulfur hexafluoride, ethane, cyclopropane, isoflurane, ether, and acetone) is dissolved in saline and infused into a peripheral arm vein at the rate of about 3 mL/min until a steady state of gas exchange is achieved (about 10 to 20 minutes). Samples of mixed expired gas and arterial blood are then taken, and the gas concentrations in each are determined by gas chromatography. At the same time, cardiac output is obtained (e.g., by indicator dilution, echocardiography, or other method), and total ventilation is also measured. From these data, mixed venous concentrations of each inert gas can be calculated and retention determined. In patients who already have an indwelling pulmonary arterial catheter, a sample of mixed venous blood could be taken instead to directly measure mixed venous inert gas levels.

A graph is then constructed, as shown in Figure 4-22. The upper panel shows the data points of inert *gas retention* (arterial partial pressure divided by mixed venous partial pressure), which are joined for clarity by the broken line. Below this are the data points for *excretion*

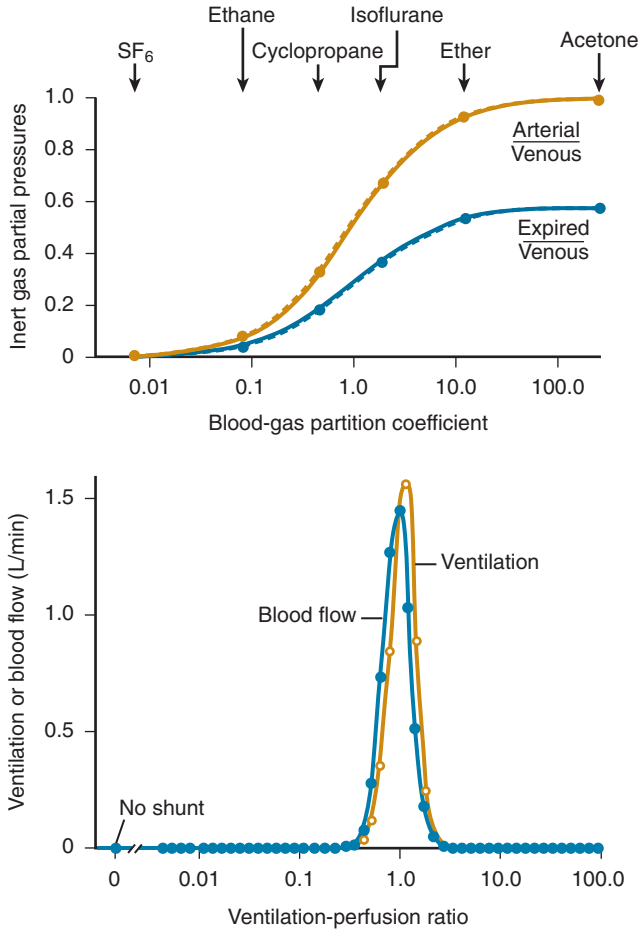

FIGURE 4-22 ■ Use of the multiple inert gas elimination technique to determine the distribution of ventilation-perfusion ratios in a 22-year-old normal subject. *Upper panel,* Data points for inert gas retention (*upper curve*) and excretion (*lower curve*). *Broken lines* join the points. The two *solid lines* show the values of retention and excretion for a lung with no ventilation-perfusion inequality. *Lower panel,* The recovered distribution of ventilation-perfusion ratios. SF_6, sulfur hexafluoride. (Redrawn from Wagner PD, Laravuso RB, Uhl RR, West JB: Continuous distributions of ventilation-perfusion ratios in normal subjects breathing air and 100% O2. J Clin Invest 54:53–68, 1974.)

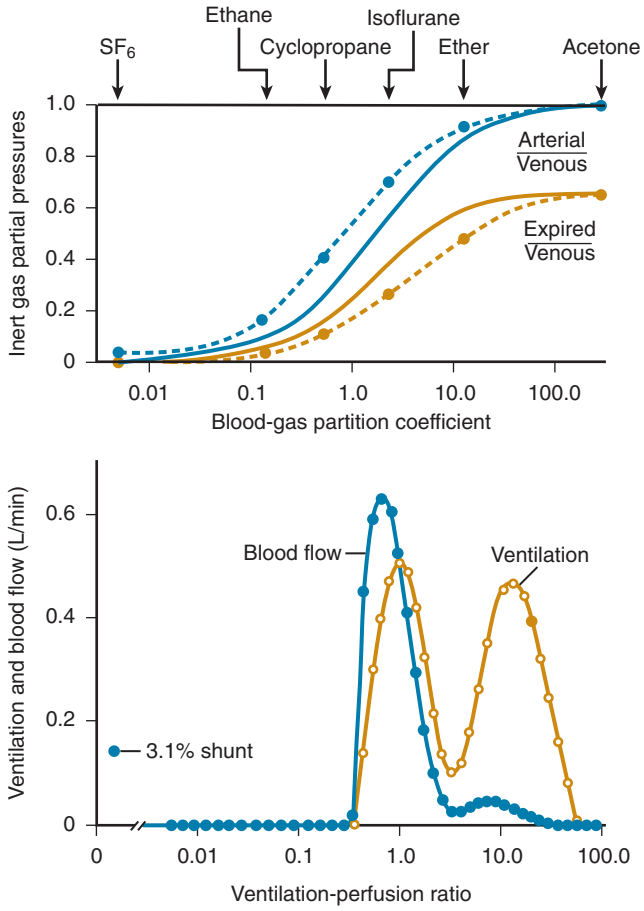

FIGURE 4-23 ■ Distribution of ventilation-perfusion ratios in a 60-year-old patient with chronic obstructive lung disease, predominantly emphysema. *Upper panel,* The retention and excretion solubility curves. *Lower panel,* The recovered distribution of ventilation-perfusion ratios. SF_6, sulfur hexafluoride. (Redrawn from Wagner PD, Dantzker DR, Dueck R, et al: Ventilation-perfusion inequality in chronic obstructive pulmonary disease. J Clin Invest 59:203–216, 1977.)

(mixed expired partial pressure divided by mixed venous partial pressure). Both are plotted against the partition coefficient. Again, the points are joined by a broken line. For comparison, the two solid lines show the values of retention and excretion for a lung with no ventilation-perfusion inequality but with the same overall ventilation and blood flow. The broken and solid lines are very close together in Figure 4-22, and the differences are more easily seen in Figure 4-23, where the lung is diseased.

These plots, called the retention-solubility and excretion-solubility curves, contain information about the distribution of ventilation-perfusion ratios in the lung. For example, if a lung contains units that are perfused but not ventilated (shunt), these particularly increase the retention of the least soluble gas, sulfur hexafluoride. Conversely, if the distribution contains large amounts of ventilation to lung units with very high ventilation-perfusion ratios, the excretion of the high-solubility gases is chiefly affected. The relationship between the distribution of ventilation-perfusion ratios and the retention-solubility and excretion-solubility curves can be expressed formally by a set of simultaneous linear equations.[98] These equations, one for each inert gas, simply reflect the principles of mass conservation and relate the ventilation-perfusion distribution (i.e., the paired set of gas-exchange unit blood flows and ventilations) to a measured set of inert gas retention and excretion values. The distribution of ventilation-perfusion ratios that is consistent with the pattern of inert gas retention and excretion is then determined using computer programs that solve these simultaneous equations.

The potential and limitations of this transformation have been explored in great detail.[98] The recovered distribution is not unique, but in most cases the range of possible distributions compatible with the data is small. No more than three modes of a distribution can be recovered, and only smooth distributions can be obtained. In

spite of these limitations, however, the technique gives much more information about patterns of distribution of ventilation-perfusion ratios in patients with lung disease than has previously been available.

Distribution in Normal Subjects. Figure 4-22 shows retention and excretion-solubility curves and the derived distribution of ventilation-perfusion ratios from a 22-year-old normal volunteer.[99] First, note that the retentions and excretions as indicated by the data points and broken lines in the upper panel are almost superimposed on the solid lines for a homogeneous lung. The recovered distribution (lower panel) is consistent with these data and shows that the plots of both ventilation and blood flow are narrow, spanning only one decade of ventilation-perfusion ratios (i.e., from a ventilation-perfusion ratio of about 0.3 to one 10 times higher, of about 3). In particular, there was essentially no ventilation or blood flow outside this range on the ventilation-perfusion ratio scale. Note also that there was no shunt, that is, blood flow to unventilated alveoli.

The absence of shunt was a consistent finding in all the normal subjects studied and was initially surprising. It should be pointed out that, first, this technique is very sensitive, in that a shunt of only 0.5% of the cardiac output approximately doubles the arterial concentration of sulfur hexafluoride. Apparently, young normal subjects are able to ventilate essentially all of their alveoli. Second, bronchial and thebesian shunts are not detected by the method.

In older normal subjects, increased dispersion of the distribution is found. This is consistent with the gradual fall in arterial P_{O_2} known to occur with aging.

Distributions in Lung Disease. Figure 4-23 shows a typical distribution of ventilation-perfusion ratios from a patient with chronic obstructive lung disease. The distribution is typical of the pattern seen in patients believed to have, predominantly, emphysema.[100] The upper panel shows that the measured retentions and excretions (dots, dashed lines) deviated greatly from those expected in a homogeneous lung with the same total ventilation and blood flow (solid lines). Consistent with this, the lower panel shows a broad bimodal distribution, with large amounts of ventilation to lung units with extremely high ventilation-perfusion ratios (alveolar dead space). Note the small shunt of 3.1%. The mild hypoxemia in this patient (arterial P_{O_2} of 63 mm Hg) is explained mostly by the slight displacement of the main mode of blood flow to the left of normal. Presumably the high ventilation-perfusion ratio mode reflects ventilation to lung units in which many capillaries have been destroyed by the emphysematous process, reducing their perfusion. Patients with acute pulmonary embolism often show a ventilation-perfusion ratio pattern similar to that in Figure 4-23. This is well explained by continuing ventilation in poorly perfused embolized regions. Sometimes, shunts are seen as well, possibly from scattered atelectasis, possibly from edema, and possibly from right-to-left shunting through a patent foramen ovale when right atrial pressure is elevated.

Patients with chronic obstructive lung disease whose predominant lesion is severe bronchitis generally show a different pattern. The main abnormality in the distribution is a large amount of blood flow going to lung units with very low ventilation-perfusion ratios, between 0.005 and 0.1. This explains the more severe hypoxemia in this type of patient, and is consistent with the large physiologic shunt that is usually found. Presumably, the low ventilation-perfusion ratios in some lung units are the result of partially blocked airways due to retained secretions and airway disease that reduces airway diameter. However, it is interesting that these patients generally do not show much shunting (blood flow to unventilated alveoli), and a possible explanation is collateral ventilation. It should be emphasized that the distributions found in severe chronic bronchitis show considerable variability.

A particularly interesting pattern of ventilation-perfusion ratios has been seen in some patients with asthma, even in remission.[101] Figure 4-24A shows an obvious bimodal appearance, with some 25% of the total blood flow going to lung units with ventilation-perfusion ratios in the region of 0.1. However, there was no blood flow to unventilated units. When this patient was given a β-adrenergic bronchodilator by aerosol, the distribution changed, as shown in Figure 4-24B. There was a marked increase in the amount of blood flow to low ventilation-perfusion ratio units, and this was associated with a corresponding decrease in arterial P_{O_2} from 81 to 70 mm Hg. However, the pattern was short lived; 5 minutes later, the distribution had returned to the pattern shown in Figure 4-24A, and the P_{O_2} was back to the prebronchodilator level. The bronchodilator effects of the drug on the airflow had a much longer duration.

Such a fall in arterial P_{O_2} is often seen in asthmatics after bronchodilator therapy even with improved airflow.[59,60] The reason for the redistribution of blood flow is probably that the blood vessels supplying the hypoxic low ventilation-perfusion ratio units dilate preferentially in response to the β-adrenergic agonists. Modern bronchodilators cause less hypoxemia than shown in Figure 4-24, and also less deterioration in the ventilation-perfusion ratio distribution.

It was surprising that this almost asymptomatic patient had as much ventilation-perfusion ratio inequality as shown in Figure 4-24. The extent of the abnormality of the distribution suggests that there were many more abnormalities in the lung, including obstruction of small airways, than were indicated by the patient's symptoms. One lung model consistent with the observed data is that about half of the small airways were totally occluded by mucous plugs (for a discussion of mucus hypersecretion, see Chapter 11) and/or airway wall edema, and that the ventilation of the lung subtended by them occurred through collateral channels. However, it should be emphasized that not all well-managed asthmatics show such abnormal distributions of ventilation-perfusion ratios. In some, the distribution is unimodal with little or no increase in dispersion. Importantly, the extent of ventilation-perfusion ratio inequality cannot be predicted from the impairment in spirometry. Patients with acute respiratory distress syndrome commonly show a full

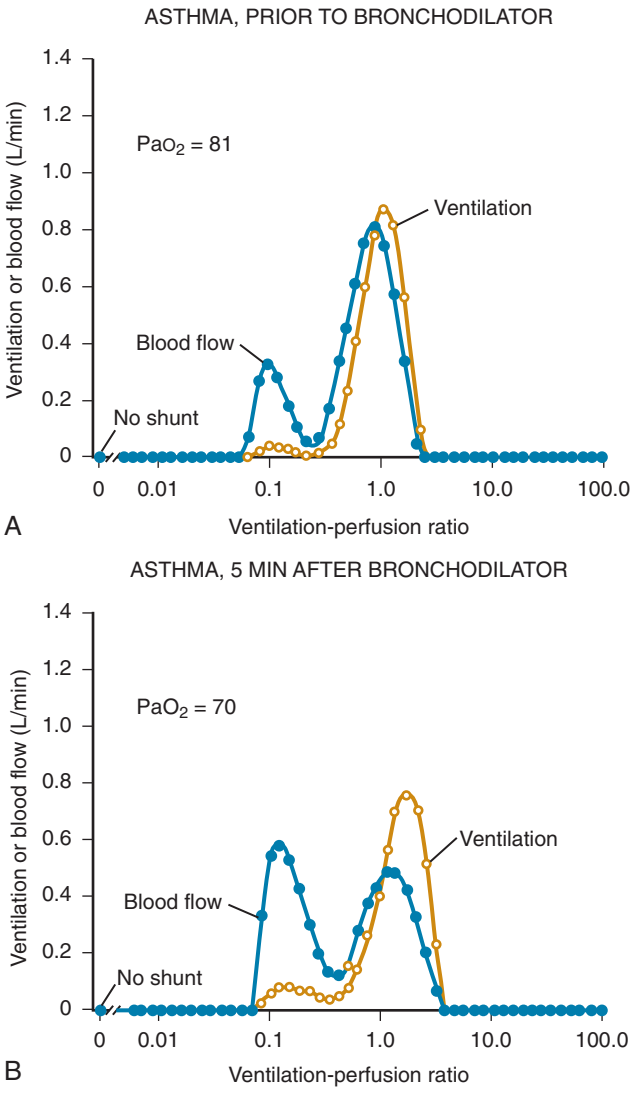

FIGURE 4-24 ■ Distribution of ventilation-perfusion ratios in a patient (DM) with asthma before **(A)** and after **(B)** the administration of isoproterenol by aerosol. (Redrawn from Wagner PD, Dantzker D, Iacovoni VE, et al: Ventilation-perfusion inequality in asymptomatic asthma. Am Rev Respir Dis 118:511–524, 1978.)

spectrum of ventilation-perfusion ratio abnormalities: especially shunt, but also low ventilation-perfusion ratio regions, areas of normal ventilation-perfusion ratio, high ventilation-perfusion ratio regions, and increased ventilation of unperfused lung.

Ventilation-Perfusion Inequality and Carbon Dioxide Retention

It is important to appreciate that ventilation-perfusion inequality interferes with the uptake and elimination of all gases by the lung (oxygen, carbon dioxide, carbon monoxide, and anesthetic gases). In other words, mismatching of ventilation and blood flow reduces the overall gas-exchange efficiency of the lung. There has been considerable confusion in this area, particularly about the role of ventilation-perfusion inequality in carbon dioxide retention.

Imagine a lung that is uniformly ventilated and perfused and that is transferring normal amounts of oxygen and carbon dioxide. Suppose that the matching of ventilation and blood flow is suddenly disturbed while everything else remains unchanged. What happens to gas exchange? It can be shown that the effect of this "pure" ventilation-perfusion inequality (i.e., with all other factors held constant) is to reduce both the oxygen uptake and carbon dioxide output of the lung.[91] The lung becomes less efficient as a gas exchanger for both gases, and therefore, mismatching of ventilation and blood flow must cause hypoxemia and hypercapnia (carbon dioxide retention), other things being equal.

In practice, however, patients with ventilation-perfusion inequality often have a normal arterial P_{CO_2}. The reason for this is that, whenever the chemoreceptors sense a rising P_{CO_2}, there is an increase in ventilatory drive. The consequent increase in ventilation to the alveoli usually effectively returns the arterial P_{CO_2} to normal. However, such patients can only maintain a normal P_{CO_2} at the expense of this increased ventilation to their alveoli. The ventilation in excess of what they would normally require is sometimes referred to as *wasted ventilation* and is necessary because the lung units with abnormally high ventilation-perfusion ratios contribute little to eliminating carbon dioxide. Such units are part of the alveolar (physiologic) dead space.

Patients with ventilation-perfusion ratio inequality that causes carbon dioxide retention are sometimes said to be "hypoventilating," but in fact they may actually be breathing more than normal. "Hypoventilation" in this setting is used by people who define the adequacy or inadequacy of alveolar ventilation by whether it maintains a normal arterial P_{CO_2}. Thus, hypoventilation in this context really simply means an increased arterial P_{CO_2}. "Alveolar ventilation" in this context does not refer to all the gas entering the lung alveoli but is related to "ideal alveolar" gas and excludes alveolar dead space gas. In this chapter, the term *alveolar* has been used to refer to all the gas in the lung, excluding the conducting airways that contain anatomic dead space. True hypoventilation was discussed in an earlier section when the relationship between alveolar ventilation and P_{CO_2} was examined.

Historically, it is easy to see how the term *hypoventilation* came to be applied so indiscriminately. When in the late 1950s it became possible to measure the P_{CO_2} of the arterial blood in the clinical setting, carbon dioxide retention was found to be a common and serious complication of chronic lung disease that could always be abolished by artificially increasing the ventilation. Thus, it was natural to say that these patients had an abnormally low ventilation, and the term *hypoventilation* had the advantage of keeping an important therapeutic option in the forefront.

However, far from having a reduced ventilation, most of these patients are moving far more air into their alveoli than normal subjects. Indeed, all patients with chronic lung disease and ventilation-perfusion inequality who have a *normal* arterial P_{CO_2} *must* have *increased* the ventilation to their alveoli, and this applies to most patients with carbon dioxide retention as well.

Although patients with mismatched ventilation and blood flow can usually maintain a normal arterial P_{CO_2} by increasing the ventilation to the alveoli, this is much less effective at increasing the arterial P_{O_2}. The reason for the different behavior of the two gases lies in the different shapes of the carbon dioxide and oxygen dissociation curves. The carbon dioxide dissociation curve is almost straight in the physiologic range, with the result that an increase in ventilation raises the carbon dioxide output of lung units with both high and low ventilation-perfusion ratios. By contrast, the nonlinearity of the oxygen dissociation curve means that only units with moderately low ventilation-perfusion ratios benefit appreciably from the increased ventilation. Those units that are very high on the flat portion of the dissociation curve (high ventilation-perfusion ratio) increase the oxygen concentration of their effluent blood very little. Furthermore, those units that have a very low ventilation-perfusion ratio continue to put out blood having an oxygen concentration close to that of mixed venous blood. The net result is that the mixed arterial P_{O_2} rises only modestly, and some hypoxemia always remains.

In summary, carbon dioxide retention can result from two clearly distinct mechanisms: pure hypoventilation, and ventilation-perfusion inequality. The latter is a common cause in clinical practice.

Effect of Changes in Cardiac Output on Gas Exchange in the Presence of Ventilation-Perfusion Inequality

In a lung with no ventilation-perfusion inequality, the cardiac output has no effect on arterial P_{O_2} or P_{CO_2}. This follows from Equations 5 and 14, which do not contain cardiac output. By contrast, these equations show that the level of total ventilation is very important.

However, in a lung with ventilation-perfusion inequality, cardiac output can have a major effect on arterial P_{O_2}, and this is important in some clinical settings. A reduction in cardiac output reduces the P_{O_2} of mixed venous blood, which in turn exaggerates the hypoxemia. This sometimes occurs in patients with myocardial infarction, in whom the reduction in arterial P_{O_2} seems to be out of proportion to the degree of ventilation-perfusion inequality because of the reduced cardiac output. The opposite is sometimes seen in patients with bronchial asthma, who may have unusually high cardiac outputs, especially when treated with some β-agonist drugs. The result is that the arterial P_{O_2} is higher than would be expected from the degree of ventilation-perfusion inequality. This important effect of cardiac output on gas exchange is often overlooked in the clinical setting.

Blood-Gas Transport

Oxygen

Oxygen is carried in the blood in two forms. A small amount is dissolved, but by far the most important component is in combination with hemoglobin.

Dissolved oxygen plays a small role in oxygen transport because its solubility is so low (0.003 mL O_2/100 mL blood/mm Hg). Thus, normal arterial blood with a P_{O_2} of about 100 mm Hg contains only 0.3 mL of dissolved oxygen per 100 mL, whereas about 20 mL is combined with hemoglobin.

Dissolved oxygen can become important under some conditions. The most common is when a patient is given 100% oxygen to breathe. This typically raises the alveolar P_{O_2} to over 600 mm Hg, with the result that, if the lungs are normal, the dissolved oxygen may increase from 0.3 to approximately 2 mL/100 mL blood. This dissolved oxygen then becomes a significant proportion of the normal arterial-venous oxygen concentration difference of about 5 mL O_2/100 mL blood.

Hemoglobin consists of heme, an iron-porphyrin compound, and a protein (globin) that has four polypeptide chains. There are two types of chains, alpha and beta, and differences in their amino acid sequences give rise to different types of human hemoglobin. The newborn infant has predominantly hemoglobin F (fetal), and this is gradually replaced over the first year or so of postnatal life. Hemoglobin S (sickle) has valine instead of glutamic acid in the beta chains. As a consequence, the affinity of hemoglobin for oxygen is reduced, and, in addition, the deoxygenated form tends to crystallize within the red cell. This causes the cell shape to change from biconcave to sickle, and the result is an increased fragility and likelihood of thrombus formation. Many abnormal hemoglobins with altered oxygen affinities have been described.

Methemoglobin is formed when the ferrous ion of normal hemoglobin A is oxidized to the ferric form. This can occur as a result of various drugs and chemicals, including nitrites, sulfonamides, and acetanilid. In one form of hereditary methemoglobinemia, there is a deficiency of the enzyme cytochrome b_5 reductase within the red cell. Methemoglobin is not useful for carrying oxygen, and, in addition, it increases the oxygen affinity of the remaining hemoglobin, thus impairing the unloading of oxygen to the tissues.

Blood is able to transport large amounts of oxygen because that molecule forms an easily reversible combination with hemoglobin (Hb) to give oxyhemoglobin (HbO_2):

$$O_2 + Hb \rightleftharpoons HbO_2 \tag{33}$$

The relationship between the partial pressure of oxygen and the number of binding sites of the hemoglobin that have oxygen attached is known as the *oxygen dissociation curve* (Fig. 4-25). Each gram of pure hemoglobin can combine with 1.39 mL of oxygen, and in normal blood with 15 g Hb/100 mL, the *oxygen capacity* (when all the binding sites are full) is 1.39 × 15, or about

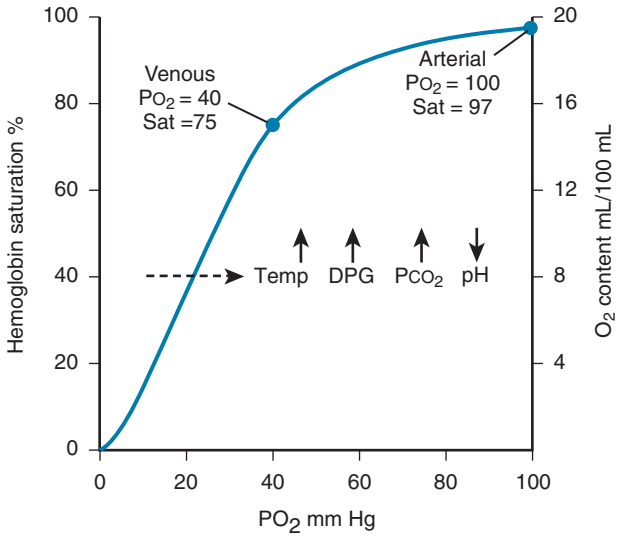

FIGURE 4-25 ■ Oxygen dissociation curve showing typical values for arterial and mixed venous blood. The curve is shifted to the right by increases of temperature, P_{CO_2}, 2,3-diphosphoglycerate (DPG), and H^+ concentration. Sat, saturation. (Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

20.8 mL O_2/100 mL of blood. The total *oxygen concentration* of a sample of blood, which includes the oxygen combined with hemoglobin and the dissolved oxygen, is given by

$$O_2 \text{ concentration} = (1.39 \times Hb) \times \frac{\% \text{ saturation}}{100} + (0.003 \times P_{O_2}) \quad (34)$$

where Hb is the hemoglobin concentration.

The characteristic shape of the oxygen dissociation curve has several advantages. The fact that the upper portion is almost flat means that a fall of 20 to 30 mm Hg in arterial P_{O_2} in a healthy subject with an initially normal value (e.g., about 100 mm Hg) causes only a minor reduction in arterial oxygen concentration. However, this also means that noninvasive monitoring of oxygen saturation by pulse oximetry will often fail to indicate substantial falls in arterial P_{O_2}. Another consequence of the flat upper part of the curve is that the diffusive loading of oxygen in the pulmonary capillary is hastened. This results from the large partial pressure difference between alveolar gas and capillary blood that continues to exist even when most of the oxygen has been loaded. The steep lower part of the oxygen dissociation curve means that considerable amounts of oxygen can be unloaded to the peripheral tissues with only a relatively small drop in capillary P_{O_2}. This maintains a large partial pressure difference between the blood and the tissues, which assists in the diffusion process.

Cyanosis refers to the blue color of skin and mucous membranes when the hemoglobin is desaturated. It is not a reliable sign of hypoxemia; if hypoxemia is suspected, the arterial P_{O_2} should be measured. Cyanosis depends on the amount of reduced hemoglobin present and therefore is often marked in patients with polycythemia but is difficult to detect in the presence of anemia. Various factors affect the position of the oxygen dissociation curve (see Fig. 4-25). It is shifted to the right by an increase of temperature, hydrogen ion concentration, P_{CO_2}, and concentration of 2,3-diphosphoglycerate in the red cell. A rightward shift indicates that the affinity of oxygen for hemoglobin is reduced. Most of the effect of the increased P_{CO_2} in reducing the oxygen affinity is due to the increased H^+ concentration. This is called the *Bohr effect,* and one consequence is that, as peripheral blood loads carbon dioxide, the unloading of oxygen is assisted.

2,3-Diphosphoglycerate is an end product of red cell metabolism.[102,103] Conditions in which its concentration is changed include chronic hypoxia, which tends to increase the concentration. The concentration falls in stored blood. A useful measure of the position of the dissociation curve is the P_{O_2} for 50% oxygen saturation; this is known as the P_{50}. The normal value for human blood is about 27 mm Hg.

Small amounts of carbon monoxide in the blood increase the affinity of the remaining oxygen for hemoglobin and therefore cause a leftward shift of the dissociation curve. As a result, the unloading of oxygen in the peripheral tissue is hampered. In addition, of course, the oxygen concentration of the blood is reduced because some of the hemoglobin is bound to carbon monoxide.

Carbon Dioxide

Carbon dioxide is transported in the blood in three forms: dissolved (about 5% of the total), as bicarbonate (about 90%), and in combination with proteins as carbamino compounds (about 5%). Dissolved carbon dioxide obeys Henry's law, and because carbon dioxide is some 24 times more soluble than oxygen in blood, dissolved carbon dioxide plays a much more significant role in its carriage compared to oxygen. For example, about 10% of the carbon dioxide that evolves into the alveolar gas from the mixed venous blood comes from the dissolved form.

Bicarbonate is formed in blood by the following hydration reaction:

$$CO_2 + H_2O \overset{CA}{\rightleftharpoons} H_2CO_3 \rightleftharpoons H^+ + HCO_3^- \quad (35)$$

The hydration of carbon dioxide to carbonic acid (and vice versa) is catalyzed by the enzyme carbonic anhydrase (CA), which is present in high concentrations in the red cells but is absent from the plasma (some carbonic anhydrase is apparently located on the surface of the endothelial cells of the pulmonary capillaries). Because the majority of the carbonic anhydrase is in the red cell, most of the hydration of carbon dioxide occurs there, and bicarbonate ion moves out of the red cell to be replaced by chloride ions to maintain electrical neutrality (chloride shift). Some of the hydrogen ions formed in the red cell are bound to hemoglobin, and because reduced hemoglobin is a better proton acceptor

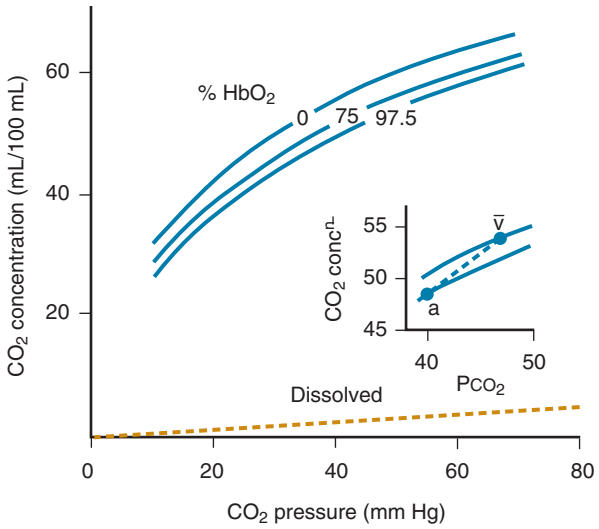

FIGURE 4-26 ■ Carbon dioxide dissociation curves for blood of different oxygen saturations (HbO_2). *Inset,* The "physiologic curve" between arterial (a) and mixed venous ($\bar{v}$) blood. (Redrawn from West JB: Respiratory Physiology—The Essentials [8th ed]. Baltimore: Lippincott Williams & Wilkins, 2008.)

than the oxygenated form, deoxygenated blood can carry more carbon dioxide for a given P_{CO_2} than oxygenated blood can (Fig. 4-26). This is known as the *Haldane effect.*

Carbamino compounds are formed when carbon dioxide combines with the terminal amine groups of blood proteins. The most important protein is the globin of hemoglobin. Reduced hemoglobin can bind more carbon dioxide than oxygenated hemoglobin, so the unloading of oxygen in peripheral capillaries facilitates the loading of carbon dioxide, whereas oxygenation has the opposite effect.

The carbon dioxide dissociation curve, that is, the relationship between P_{CO_2} and total carbon dioxide concentration, is shown in Figure 4-26. Note that the curve is much more linear in its working range than the oxygen dissociation curve (see Fig. 4-25) and also that, as we have seen, the lower the saturation of hemoglobin with oxygen, the larger the carbon dioxide concentration for a given P_{CO_2}.

The transport of carbon dioxide by the blood plays an important role in the acid-base status of the body. This topic is discussed at length in Chapter 7.

KEY POINTS

- The magnitudes of ventilation and perfusion, as well as their distribution, are key factors determining pulmonary gas exchange.
- Distribution of ventilation is predominantly affected by gravity in the normal lung, but intrinsic lung structure also plays a role.
- Distribution of perfusion is likewise mainly determined by gravity but intrinsic lung structure is also important.
- Distribution of ventilation-perfusion $(\dot{V}_A/\dot{Q})$ ratios is accordingly also nonuniform, the $\dot{V}_A/\dot{Q}$ ratio being generally higher in nondependent lung regions and lower in dependent lung regions.
- Regional alveolar P_{O_2} and P_{CO_2} are determined principally by the $\dot{V}_A/\dot{Q}$ ratio of each region. Secondary factors are the P_{O_2} and P_{CO_2} of inspired gas and mixed venous blood, and also the O_2 and CO_2 dissociation curves.
- Diffusion limitation is determined by the value of $D/\dot{Q}\beta$—the ratio of diffusing capacity (D) to the product of β (slope of the oxygen-hemoglobin dissociation curve) and $\dot{Q}$ (pulmonary blood flow). Its role in contributing to hypoxemia in lung disease is minor compared with $\dot{V}_A/\dot{Q}$ inequality.
- There are four causes of hypoxemia: hypoventilation, alveolar-capillary diffusion limitation, shunt, and $\dot{V}_A/\dot{Q}$.
- There are two principal causes of hypercapnia: hypoventilation and $\dot{V}_A/\dot{Q}$ inequality.
- $\dot{V}_A/\dot{Q}$ inequality is the most important cause of gas-exchange abnormalities in most lung diseases.

Oxygen Cost of Breathing

INTRODUCTION

Respiration, defined as the transport of oxygen from air to tissues and the transport of carbon dioxide from tissues to the air, is essential for survival. One major component of the process of respiration is *ventilation*, which involves the movement of oxygen from the ambient air to the alveoli and of carbon dioxide in the other direction. An understanding of respiratory system mechanics and energetics is essential in understanding normal ventilation and its disruption in disease.

This chapter reviews basic terminology, respiratory mechanics under static conditions, mechanics under dynamic conditions, and energetics, including measurements of the work of breathing. The chapter also highlights how physiologic principles can be applied to specific clinical problems.

TERMINOLOGY

Flow

Flow is defined as the volume of gas passing a fixed point per unit time. Flow is distinctly different from *gas velocity*, which is the distance moved by a gas molecule per unit time. At a constant flow, gas velocity will be greater in narrower tubes (Fig. 5-1). Flow is usually measured with a pneumotachograph, which consists of a tube with a known fixed resistance. Flow can be calculated by measuring the pressure drop across the resistor.

Volume

Volume is defined by the space occupied by a gas. The number of molecules of a gas contained in a fixed volume

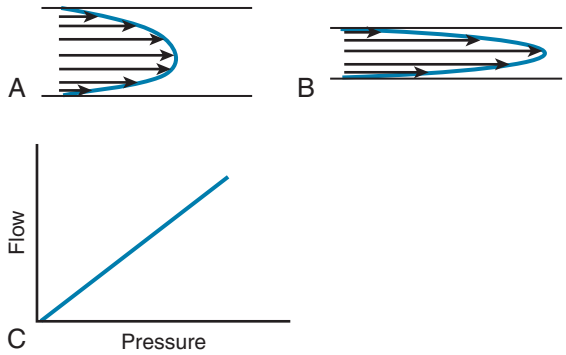

FIGURE 5-1 ■ Laminar flow through a tube. **A,** Schematic depiction of the spatial and velocity profiles of gas molecules within a laminar flow system. The velocity of the gas molecules is proportional to the length of *arrows*. For laminar flow, velocity is greatest in the center of the tube and least close to the edge. **B,** When tube diameter is reduced, the same gas flow rate will result in increased velocity of the individual gas molecules. **C,** During laminar flow, there is a linear relationship between pressure and flow.

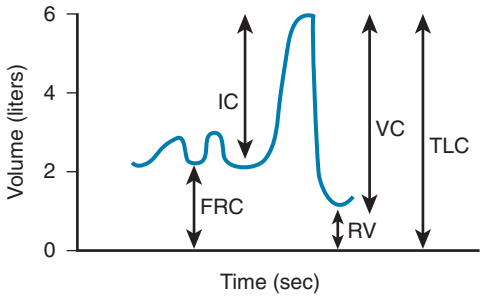

FIGURE 5-2 ■ Subdivisions of lung volume. Volume-time tracing of a subject taking two normal tidal breaths, inhaling to total lung capacity (TLC), and exhaling to residual volume (RV). Vital capacity (VC) and inspiratory capacity (IC) may be measured with a spirometer. The measurement of functional residual capacity (FRC), RV, and TLC requires a determination of intrathoracic gas volume by helium dilution, nitrogen washout, or plethysmography.

is influenced by temperature and pressure. For an ideal gas, the relationship between lung volume, pressure, temperature, and the number of molecules of gas is described by the combined gas law:

$$PV = nRT$$

where P is the absolute pressure of the gas, V is the volume, n is the number of moles of gas, R is the universal gas constant (8.3145 J/(mol K)), and T is the temperature in degrees Kelvin.

This equation summarizes earlier gas laws, including Boyle's law (PV = constant), Charles' law (V/T = constant), Gay-Lussac law (P/T = constant), and Avogadro's law (n/V = constant). The volume of a gas should thus increase as the number of molecules of gas increases, the temperature increases, or the applied pressure decreases. Although this equation theoretically applies only to an ideal or perfect gas, it is an adequate approximation for clinical purposes.

Lung volumes can be measured by a variety of techniques. The volume of gas entering and leaving the lung can be determined by a spirometer that measures volume displacement or by integrating flow over time using a pneumotachograph (flowmeter). Total gas volume in the lung can be measured using helium dilution or body plethysmography, and each of these techniques has advantages and disadvantages.[1] For the single-breath helium dilution technique, subjects inhale a fixed concentration of helium in a known volume; helium's low blood solubility allows it to be used as a tracer. The helium mixes with and is diluted by the gas already in the lung; the subject then exhales and the concentration of helium in the expired air is measured. The ratio of exhaled concentration to inhaled concentration allows calculation of the lung volume. The multiple-breath equilibrium technique is more reliable, although the concept is the same. With the multiple-breath technique, the patient breathes into a reservoir with a known helium concentration until the exhaled helium concentration reaches equilibrium. In general, helium dilution measurements tend to underestimate total lung volume, especially in patients with substantial airway obstruction who may have gas trapped in lung units that do not mix with inspired gas.

For the body plethysmography technique, subjects are completely enclosed in a gas-tight container. Lung volume can be calculated by comparing changes in alveolar pressure (measured at the mouth while the patient pants against an occluded mouthpiece) with changes in pressure in the container.[2] Body plethysmography may overestimate lung volumes, because it will include measurement of abdominal gas if that gas is compressed and decompressed during the panting maneuver.

Although not commonly used in clinical practice, lung volumes may also be measured using three-dimensional reconstructions of radiographic studies (chest roentgenography, computed tomography, or magnetic resonance imaging).[3–6] Changes in lung volumes can also be estimated using measurements of thoracic cage displacement with magnetometers or inductance plethysmography.[7,8]

The subdivisions of lung volumes are shown in Figure 5-2. Some of these subdivisions can be measured by spirometry alone (vital capacity, tidal volume), whereas others require use of helium dilution or plethysmography. *Total lung capacity* (TLC) is the lung volume at the end of a maximal inspiration. *Residual volume* (RV) is the volume at the end of a maximal expiratory effort. *Functional residual capacity* (FRC) refers to the volume in the lung at the end of a normal tidal exhalation, where there is relaxation of both inspiratory and expiratory muscles.

Pressure

The pressure of a gas is generated from the momentum of molecules colliding against a surface and is expressed as the force per unit area. Pressure, as opposed to force,

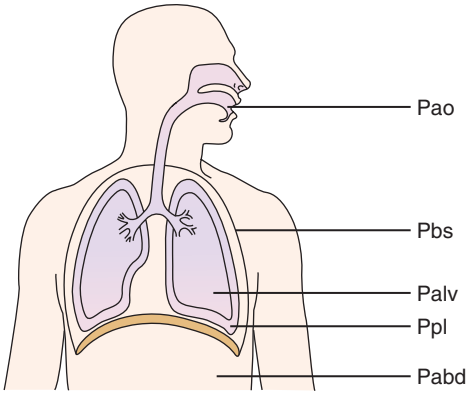

FIGURE 5-3 ■ Respiratory system pressures. Pao, pressure at airway opening; Pbs, pressure at body surface; Palv, pressure in alveolus; Ppl, pressure in pleural space; Pabd, pressure in abdomen. Transpulmonary pressure: Pao – Ppl; translung pressure: Palv – Ppl; transchest wall pressure: Ppl – Pbs; transrespiratory system pressure: Pao – Pbs; transdiaphragmatic pressure: Ppl – Pabd. Under static conditions, when the subject is not on assisted ventilation, Pao is equal to 0 (atmospheric pressure). However, Pao may be positive when the patient is receiving positive-pressure mechanical ventilation. Pbs is equivalent to atmospheric pressure unless the subject is in a negative pressure device such as an iron lung.

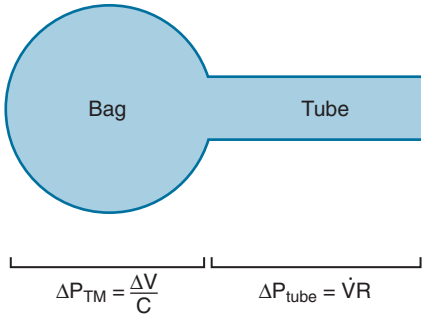

FIGURE 5-4 ■ Bag-and-tube analogy of the respiratory system, where ΔPtm = change in transmural pressure (inside – outside) of bag; ΔV = change in volume; C = compliance; $\dot{V}$ = flow; R = resistance; and ΔPtube = pressure difference from one end of the tube to the other.

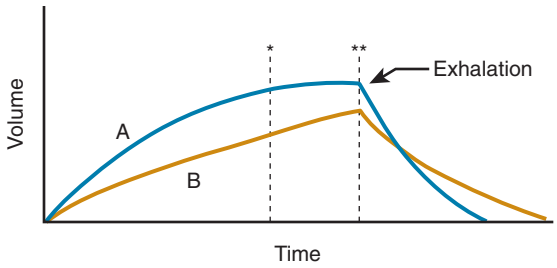

FIGURE 5-5 ■ Time constants. Shown are two units, one with a very short time constant, A, and one with a long time constant, B. Each is inflated under a constant pressure until point (**) and then exhalation is passive. At point **, unit A is completely filled, but unit B is not. Of note, decreasing inspiration time to point * will worsen heterogeneity in ventilation, when time constants are uneven.

is the same in all directions. Respiratory system pressures are usually reported relative to atmospheric pressure.

The pressures relevant to the respiratory system are shown in Figure 5-3. Pleural pressure can be measured directly, with a probe inserted directly into the pleural space. Esophageal pressure is usually used as a surrogate for pleural pressure because it is easier to measure using an air-filled balloon inserted into the esophagus.[9] The best place is in the middle third of the esophagus, approximately 35 to 45 cm from the nares.[10,11] Balloons placed in the proximal third can be affected by movement of the neck, and balloons placed in the distal third can record falsely high readings owing to compression by the heart. Absolute values of pressure may be difficult to interpret in the supine position owing to the weight of the mediastinum.

Compliance and Resistance

The respiratory system can be thought of as a combination of bags and tubes (Fig. 5-4). In its most simplistic form, the respiratory system can be compared with a single tube (representing the airways) attached to a single bag (representing the lung and chest wall).

As the pressure across the wall of a bag increases (called transmural pressure, or pressure inside minus pressure outside), the volume inside the bag increases until an equilibrium is reached (see Fig. 5-4). The ratio between the change in volume and the change in transmural pressure is the compliance of the bag. A large compliance indicates that volume changes markedly for every change in pressure. The inverse of compliance is elastance, with a greater value indicating a stiffer system.

In a tube, flow is proportional to the pressure difference between the two ends and inversely proportional to the resistance (flow = pressure difference/resistance) (see Fig. 5-4). Resistance, however, has a nonlinear relationship to diameter; reducing the diameter by half results in a 16-fold increase in resistance!

Time Constants

When a pressure is applied to a lung unit (Fig. 5-5), the time required to fill the unit is dependent on its compliance and resistance. That is, it will take longer to fill if resistance is high because the flow will be reduced. Similarly, it will take longer to fill the unit if compliance is high because it will require more volume. The product of the resistance and compliance (RC) of a lung unit is the time constant and represents the time required for the lung unit to fill to 63% of the final volume if a constant pressure is applied. Areas of the lung with small time constants (i.e., low resistance and/or low compliance) will fill more rapidly than areas with larger time constants.

The effect of variations in time constants of lung units is shown in Figure 5-5. This concept has clinical implications when there are heterogeneous time constants

between parallel lung units, as in patients with chronic airflow obstruction. As long as respiratory frequency is slow, all units will fill to their static equilibrium. However, if respiratory rate increases so that the inspiratory time becomes less than the time constant of some units, these units will receive less ventilation and contribute to ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch.

RESPIRATORY MECHANICS IN STATIC CONDITIONS

We first consider the lung during static conditions, during which measurements are made while the respiratory system is maintained at a fixed volume with no gas flow. Even under static or no-flow conditions, pressure gradients are still required to distend the respiratory system (analogous to the bag described previously). The energy used to distend the respiratory system (elastic work) during inhalation is stored as potential energy. Because of this stored energy, normal exhalation does not require work and is a passive process. This contrasts with resistive work (discussed later in this chapter), which cannot be stored as potential energy and is dissipated as heat.

The elastic work done against the respiratory system has both lung and chest wall components.

Elastic Recoil of the Lungs

If removed from the body, an isolated lung will deflate to a minimal volume containing only trapped gas, due to its elastic recoil. Because airways close before complete alveolar emptying, application of a negative pressure to the airway opening will not remove the trapped gas. Complete emptying of the trapped gas can be accomplished by exposing the isolated lung to a vacuum. The relationship between lung volume and transpulmonary pressure during inflation is shown in Figure 5-6. Lung compliance is fairly high at moderate lung volumes, but then decreases markedly near TLC. At this volume, very large increases in transmural pressure result in small changes in volume.

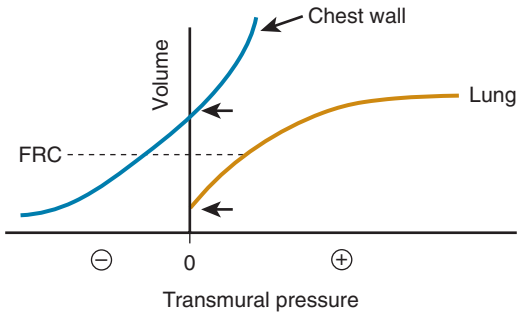

FIGURE 5-6 ■ Volume-pressure curves of lung and chest wall. The relationship between transmural (inside–outside) pressure of lung and relaxed chest wall volume are shown. At FRC, outward chest wall recoil is balanced by inward lung recoil. At FRC, transmural pressure for the lung = Pao – Ppl; because Ppl is negative, this yields a positive value. For the chest wall, transmural pressure = Ppl – Pbs, which yields a negative value. The static equilibrium of the chest wall is above FRC whereas that for the lung is below FRC (*arrows*).

Two major factors are responsible for the elastic recoil of the lung: (1) lung connective tissue and (2) surface tension related to the air-liquid interface of the alveolar surface.

Lung Connective Tissue

A network of connective tissue fibers provides the framework for the alveoli and structural integrity for the lung. The fibers are composed mostly of collagen and elastin. These fibers have different mechanical properties, which help to explain the shape of the pressure-volume curve of the lung.

Collagen fibers exhibit high tensile strength but are relatively noncompliant—they can be extended by only 2% of their length.[12] This contrasts with elastin, which has a lower tensile strength and is more compliant; elastin fibers can be stretched by as much as 130% of their length. Experiments using selective destruction of fibers by collagenase or elastase show that elastin fibers are the major contributors to the pressure-volume relationships at low lung volumes, whereas collagen is more important at higher volumes approaching TLC.[13,14] At low lung volumes, elastin fibers bear much of the stress and collagen fibers are curled and unstressed. As lung volume increases, collagen fibers uncurl and straighten and have a major stiffening effect on the lung. In other words, the major role of collagen is to limit overdistention of the lung, and the major role of elastin is to facilitate inflation while providing lung stability to maintain the configuration of internal structures.

Destruction of lung connective tissue, for instance from smoking-induced emphysema, can substantially increase lung compliance.[15] Contraction of smooth muscle in the airways and alveolar ducts may also affect elastic recoil, because contraction of smooth muscle reduces volume by exerting traction on the lung (similar to a drawstring).[16] The clinical importance of this effect in humans is unclear. Although contraction of airway smooth muscle in the peripheral lung units (small airways and alveolar ducts) changes lung compliance in several different animal species, there is little effect of contraction of lung smooth muscle on the shape of the pressure-volume curve in humans.[17-19]

Alveolar Surface Forces and Surfactant

When a lung is completely filled with water, compliance is much greater than when it is filled with air.[20] This suggests that the majority of lung elastic recoil is due to surface tension at the air-liquid interface lining the alveoli, rather than the recoil from elastin and collagen connective tissue fibers.

Because of intermolecular forces of attraction between molecules of liquids, the surface of an air-liquid interface is under tension (Fig. 5-7). That is, a molecule in the interior of a liquid is subjected to an equal force

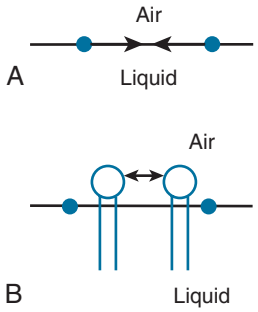

FIGURE 5-7 ■ Surface tension and surfactant. **A,** There is a force of attraction between water molecules at the surface (surface tension). **B,** Addition of surfactant reduces surface tension because charged molecules repel each other.

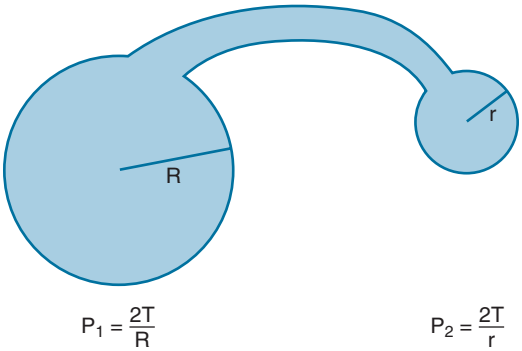

FIGURE 5-8 ■ Laplace's law. Consider two gas-filled fluid bubbles with equal surface tension (T) but differing radii, connected by a tube. Because of the smaller radius of curvature, P2 > P1, leading to gas flow from the smaller to the larger bubble.

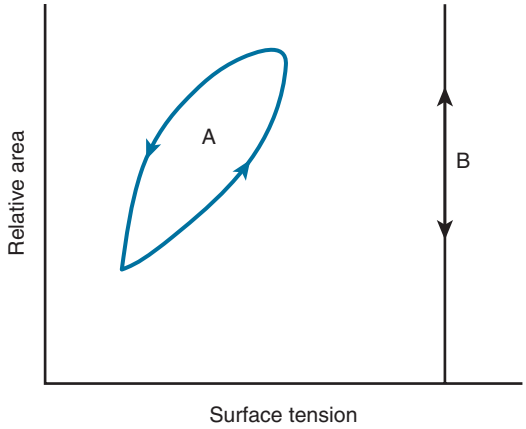

FIGURE 5-9 ■ Area–surface tension relationship. The surface area–tension relationship for lung washings containing surfactant is shown in the loop, A (with the *upward arrow* indicating inspiration and the *downward arrow* exhalation). As the area increases, surface tension increases. Also, the upward expansion and downward contraction demonstrate hysteresis of the area-tension relationship. This contrasts with the surface tension of water without surfactant, B, in which tension is greater but remains constant.

in all directions by other liquid molecules. However, the molecules at the surface are pulled toward each other and by molecules below the surface, and these forces (surface tension) cause a tendency for the surface to collapse.

Because of surface tension, a positive pressure must be present to prevent the collapse of a gas-filled bubble of liquid. The pressure of gas within a bubble is related to the surface tension (T) and the radius of curvature of the bubble (r) by the law of Laplace (P = 2T/r) (Fig. 5-8). The surface of the alveolus with an air-liquid interface can be likened to a bubble with a radius of approximately 0.1 mm at FRC. If the surface tension were similar to that of water (72 mN/m), the lungs would be very noncompliant and ventilation with transpulmonary pressures in the physiologic range (3-5 cm H_2O) would be impossible. Furthermore, the high surface tension would lead to alveolar instability and cause alveolar collapse. That is, smaller alveoli with smaller radii of curvature would, by the nature of the Laplace law, have higher alveolar pressures than larger alveoli with greater radii of curvature. Because gas travels from an area of higher pressure to one of lower pressure, smaller alveoli would tend to empty into larger alveoli, eventually resulting in one large air-filled alveolus with all other alveolar units collapsed.

A number of factors contribute to alveolar stability in normal lungs. First, the connective tissue scaffolding limits overdistention of alveoli. Second, alveoli are interconnected (alveolar interdependence) by common walls and structures. Therefore, if one alveolus began to collapse, it would stretch adjacent alveolar walls, creating a tethering effect on the collapsing unit. Third, surfactant has an important stabilizing effect.

Surfactant is a surface-active material secreted by type II alveolar epithelial cells.[21] Surfactant is composed predominantly of phospholipids such as phophatidyl choline, although other lipids, carbohydrates, and proteins are also present.[22] The phospholipids tend to aggregate at the air-liquid interface, with the hydrophobic ends (fatty acids) of the phospholipids projecting into the gas phase and the hydrophilic ends projecting into the alveolar-lining fluid. Because the hydrophilic ends are charged, the surfactant molecules tend to repel each other, thus reducing surface tension (see Fig. 5-7). Surfactant alters surface tension of alveolar-lining fluid, but does so in relation to the surface area (Fig. 5-9). That is, as surface area expands (e.g., during inhalation), surface tension increases, presumably because surfactant molecules are farther apart and exert less effect. Thus, in smaller alveoli (that have reduced surface area compared with larger alveoli), there is a greater reduction in surface tension, reducing gas pressure in these alveoli relative to larger alveoli. This stabilizes alveoli by helping to equalize pressures in alveoli of varying sizes (see Fig. 5-8).

In addition to surfactant lipids, there are four surfactant proteins (SP-A to -D). SP-B and SP-C are hydrophobic membrane proteins that enhance the spreading of surfactant over the alveolar surface and help to stabilize the lipid layer. SP-A and SP-D are involved in the innate immune response by binding to, and facilitating the phagocytosis of, bacteria and viruses.[23] Congenital deficiency of SP-B leads to progressive respiratory failure and

death in the first months of life.[24] Partial deficiency of SP-B has been associated with chronic interstitial lung disease in children,[25] whereas SP-C deficiency is associated with severe familial interstitial lung disease.[26]

Hysteresis and Stress Adaptation

When normal lungs are inflated and deflated slowly, the pressure-volume curves are not identical. During inflation of the lung, the pressure required at any given lung volume is greater than that during deflation (Fig. 5-10). The difference between the inflation and the deflation curves is due to hysteresis and stress adaptation.

Hysteresis refers to changes in mechanics measurements due to the volume-history of the lung and is caused by several factors. First, the effect of surfactant on surface tension is dependent on volume history (see Fig. 5-9). Surfactant has less effect on reducing surface tension during inspiration than during expiration. This is due to movement of surfactant molecules from below the surface of the fluid to the liquid surface during inhalation. Second, much higher pressures are required to open collapsed alveoli than are required to keep them open. In disease states characterized by collapse of alveoli (e.g., adult respiratory distress syndrome [ARDS]), significant hysteresis of the pressure volume curves can be seen[27] (see Fig. 5-10). This has clinical significance in patients with ARDS because higher inflation pressures are required to ventilate the lungs.

In contrast, *stress adaptation* refers to the time dependence of mechanics measurements. When lung tissue is stretched to a particular length, the tension required to maintain the length gradually diminishes due to time-dependent properties of surfactant and deformation of viscoelastic tissues of the lung. Therefore, after a sustained lung inflation, the pressure required to keep the lung at that volume will decrease.

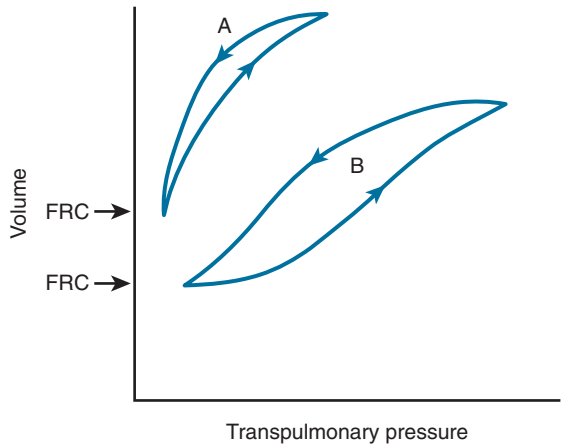

FIGURE 5-10 ■ Hysteresis in a normal lung and an acutely injured lung. In acute respiratory distress syndrome (ARDS), B, the lung is stiffer than the normal lung, A, and greater inflation pressure is required at any given lung volume. Furthermore, the degree of hystereis is much greater in ARDS lungs, with a greater separation of the volume-pressure curves on inspiration (*upward arrow*) and exhalation (*downward arrow*).

Recruitment Maneuvers in Acute Respiratory Distress Syndrome

ARDS is a disease characterized by surfactant dysfunction. The dysfunction of surfactant increases surface tension at the air-liquid interface of the alveoli, leading to collapse, intrapulmonary shunting, and hypoxemia.[28] Owing to alveolar collapse, hysteresis may be especially marked in patients with ARDS (see Fig. 5-10). The hysteresis and lung collapse necessitate high inflation pressures to ventilate the lungs, increasing work of breathing and potentially leading to barotrauma; low tidal volumes are used in ARDS to mitigate further lung injury.[29]

Because of this difference between opening and closing pressures, "recruitment maneuvers" have been used in ventilated patients with ARDS who remain hypoxemic despite moderate levels of externally applied positive end-expiratory pressure (PEEP).[30–32] A recruitment maneuver consists of a sustained inflation at a constant high pressure, which opens collapsed alveoli. Because closing pressures are much less than opening pressures, the alveoli stay open (at least temporarily) after the sustained inflation is ended, as long as the lung is not allowed to return to a very low volume (Fig. 5-11).

Elastic Recoil of the Chest Wall

The chest wall is made up of the rib cage laterally, the sternum anteriorly, the vertebral column posteriorly, and the diaphragm caudally. Movement of the chest wall by the muscles of ventilation generates pressure gradients between the alveoli and the surrounding air, enabling gas to be moved in and out of the lungs.

Respiratory Muscles

The diaphragm consists of two separate muscles joined by a central tendon. The crural diaphragm arises from the first three lumbar vertebrae and the medial and lateral arcuate ligaments. The costal diaphragm arises from the inner surfaces and upper margins of the lower six ribs and sternum. Both costal and crural fibers insert onto the central tendon. The phrenic nerve innervates the diaphragm, with costal fibers innervated from the 3rd and 4th cervical spinal segments, and crural fibers from the 4th and 5th segments. In normal subjects, the lower part of the rib cage encloses the upper part of the abdomen at FRC. In this area, the diaphragm is pushed against the lower rib cage (zone of apposition) with fibers arranged in a cranial-caudal direction (Fig. 5-12). Contraction of the diaphragm leads to a piston-like up-and-down motion of the diaphragm. Furthermore, diaphragm contraction leads to an increase in abdominal pressure, which pushes the rib cage upward and outward.[33,34]

In patients with substantial hyperinflation (e.g., emphysema), the position of the diaphragm is lower, with loss of the zone of apposition.[35] When the zone of apposition is lost, contraction of the diaphragm is less mechanically advantageous and can result in paradoxical inward movement of the lower rib cage during inhalation (Hoover's sign) and less piston-like motion of the

FIGURE 5-11 ■ Recruitment in ARDS. FIGURE 5-12 ■ Normal subject and patient with chronic obstructive pulmonary disease (COPD). **A,** In a normal subject, the lower part of the diaphragm lies next to the lower ribcage (zone of apposition). As indicated by the *arrows*, contraction of the diaphragm will pull the dome downward and push the lower rib cage upward and outward (due to increased abdominal pressure). **B,** In a patient with COPD and hyperinflation, there is loss of the zone of apposition. As indicated by the *arrow*, contraction of the diaphragm may lead to inward movement of the lower rib cage.

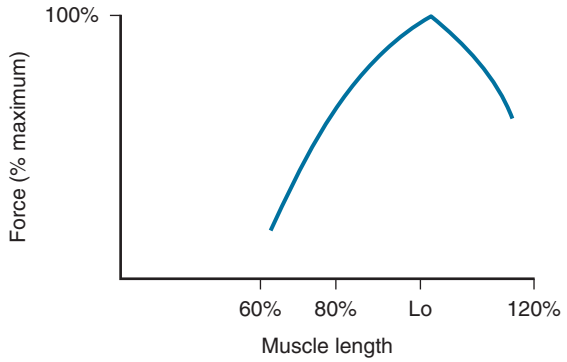

FIGURE 5-13 ■ Force-length characteristics of skeletal muscle. Skeletal muscle displays a characteristic force-length curve with a reduction in force generating capacity at lengths below or above optimal length (Lo).

diaphragm dome.[36] Furthermore, the length of the diaphragm is shortened, which creates a further mechanical disadvantage because the ability of the muscle to generate force is attenuated at shorter lengths (Fig. 5-13). However, in animals and humans, compensatory shortening of the diaphragm through loss of sarcomeres has been shown to mitigate these effects and help to improve the length-tension characteristics of the diaphragm.[37,38] The improved symptoms experienced by patients with COPD following lung volume reduction surgery may be related to increased length of the zone of apposition and improved mechanical function of the diaphragm.[39]

During inhalation, the rib cage moves laterally and anteriorly. The lateral movement and elevation of the ribs is akin to a "bucket-handle" motion, and the anterior motion of the sternum is akin to a "pump-handle" motion (Fig. 5-14). The muscles of the rib cage include the internal intercostal muscles, the external intercostal muscles, and the parasternal muscles. Internal intercostal muscles are used mainly for exhalation, while external muscles are used for inhalation.[40] The parasternal muscles are located next to the sternum; although they are part of the internal intercostal muscle layer, their major function is to raise the sternum during inhalation.[41]

Other muscles used in inhalation include the scalene muscles, which help to elevate the rib cage and prevent paradoxical inward movement of the upper rib cage with diaphragm displacement.[42] Under conditions of ventilatory stress, other muscles not normally used

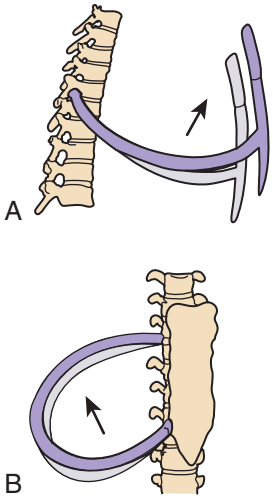

FIGURE 5-14 ■ Movement of rib cage during inspiration. Diagram indicating pump handle (**A**) and bucket-handle (**B**) rotations of the ribs. In both panels, the sternum and rib are shown before (*gray*) and after (*purple*) rib cage expansion. (From De Troyer A, Loring SH: Actions of the respiratory muscles. for respiration can be recruited. These include the sternocleidomastoid, pectoralis, trapezius, and muscles of the vertebral column. Contraction of the muscles in the abdominal wall can be used to aid exhalation.

Fatigue of Respiratory Muscles

Skeletal muscle fatigue refers to a reduction in the force-generating capacity of the muscles after excessive activity that is recoverable by rest. This should be differentiated from *respiratory muscle injury*, in which there is also loss of force-generating capacity. Injured muscles do not recover quickly with rest, but may experience slow recovery of function due to regeneration.[43]

Fatigue occurs when the rate of work required by the muscles exceeds the rate of energy supply. Usually, there is substantial reserve of the respiratory muscles such that fatigue does not occur. However, under conditions of excessive elastic or resistive load (either experimentally induced or due to disease states) and/or inadequate energy supply (e.g., during hypoxemia or cardiogenic shock), fatigue occurs and impairs respiratory muscle performance.[44,45] Recovery from fatigue usually requires more than 24 hours of rest.[46]

One measure of workload of the diaphragm is the pressure-time index. This is the product of the percentage of maximal pressure (i.e., transdiaphragmatic pressure/maximal transdiaphragmatic pressure) exerted by the muscle multiplied by the percentage of time spent during inspiration (inspiratory time/total time). In normal subjects, a value greater than 0.15 to 0.18, if sustained, will lead to fatigue and loss of force-generating capacity of the diaphragm.[47]

Central respiratory fatigue occurs when there is a reduction in central motor output to the muscles. Central fatigue can be identified when direct electrical stimulation of respiratory muscles increases muscle force generation as compared with a maximal voluntary effort.[48] This may represent an attempt to prevent damage to the muscles under conditions of inadequate energy supply. Central fatigue should be differentiated from peripheral fatigue, which represents failure at or past the level of the neuromuscular junction. With peripheral fatigue, a reduction in force generation occurs despite a constant electrical stimulation. Peripheral fatigue may occur because of transmission failure at the neuromuscular junction, reduced adenosine triphosphate (ATP), reduced calcium availability from the sarcoplasmic reticulum, or reduced calcium sensitivity of the myofilaments (caused by acidosis or increased inorganic phosphate).[49]

Respiratory Muscle Atrophy during Positive-Pressure Mechanical Ventilation

Although excessive loading of the respiratory muscles can lead to fatigue and a reduction in force generation, excessive unloading of the muscle may lead to muscle atrophy. Mechanical ventilation in paralyzed rats and baboons leads to diaphragmatic atrophy.[50,51] Furthermore, human studies in organ donors have shown significant diaphragm atrophy after 18 to 69 hours of diaphragmatic inactivity.[52] However, the clinical significance of disuse atrophy in ventilated patients is still unclear. Patients who are not paralyzed may still have substantial activation of respiratory muscles while receiving mechanical ventilation,[53,54] and this degree of stimulation may be adequate to prevent atrophy.[55–57] Furthermore, other potential causes of muscle weakness or injury in the intensive care unit include electrolyte disturbances, malnutrition, medications and toxins (e.g., alcohol, corticosteroids, aminoglycosides), sepsis-related cytokines, and inflammatory disorders (e.g., polymyositis), so that attributing muscle weakness to atrophy of muscle fibers in the clinical setting is difficult.

Chest Wall Compliance

The compliance of the chest wall can be determined by measuring changes in the transmural pressure across the thorax (pleural pressure minus body surface pressure) relative to change in volume. The volume-pressure curve of the relaxed chest wall is shown in Figure 5-6. In contrast to the lung, the resting volume of the relaxed chest wall is approximately 1 L above FRC. The difference between the resting volume of the lung and chest wall can be appreciated in patients with a pneuomothorax, in which the chest wall recoils outward and the lung recoils inward. When the chest wall is distended above this resting volume, the relaxed chest wall recoils inward, while it recoils outward at volumes below this. The compliance of the normal chest wall is approximately 200 mL/cm H_2O, but it becomes progressively stiffer at lower lung volumes and it is this stiffness in normal young subjects that predominantly determines RV.[58]

Factors such as ossification of costal cartilage, arthritis of costovertebral joints, skin eschars from burns, obesity, and abdominal distention may reduce chest wall compli-

ance. Chest wall compliance increases in the sitting position compared with the supine position, but the overall effect is usually modest.[59]

Integration of Lung and Chest Wall Mechanics

The chest wall and lung are juxtaposed, and in the absence of pleural disease (such as pneumothorax or pleural fibrosis), changes in chest wall volume are essentially identical to changes in lung volume (Fig. 5-15). Furthermore, the chest wall and lung are linked by the pleural pressure, with the transmural pressure (inside minus outside pressure) of the chest wall equal to

Pleural pressure – Body surface pressure

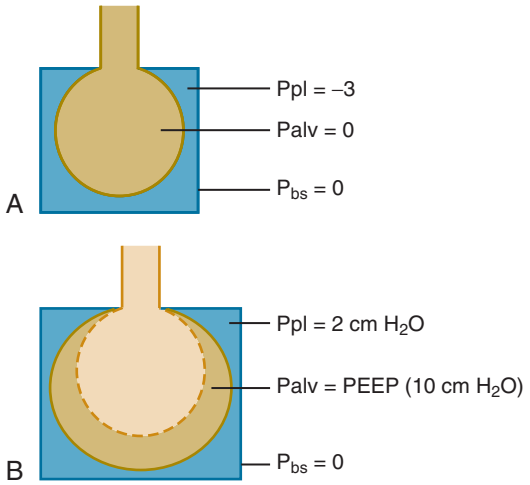

FIGURE 5-15 ■ Changes in pleural pressure with applied positive end-expiratory pressure (PEEP). **A,** Consider a lung at end-exhalation with no PEEP. **B,** With the application of PEEP, there is an increase in the volume of the respiratory system (lung and chest wall) and an increase in pleural pressure (Ppl). The magnitude of the increase in Ppl is dependent on the relative compliances of the lung and chest wall. Change in lung volume is the same as change in chest wall volume:

$$\Delta\text{Lung volume } (V_L) = \Delta\text{Chest wall volume } (V_{CW}).$$

Because compliance (C) = $\Delta V/\Delta$transmural pressure (ΔP):

$$C_L * \Delta P_L = C_{CW} * \Delta P_{CW}$$

Because $\Delta P_{CW} = \Delta Ppl$ and $\Delta P_L = PEEP - \Delta Ppl$:

$$C_L * (PEEP - \Delta Ppl) = C_{CW} * \Delta Ppl$$

Rearranging:

$$\Delta Ppl = PEEP * (C_L/(C_L + C_{CW}))$$

In other words, the percentage of PEEP transmitted to the pleural space is a function of the ratio of chest wall to lung compliance. If lung compliance (C_L) is low and chest wall compliance is high, very little of the PEEP will be transmitted to the pleural space and vice versa. In this example, the chest wall and lung compliances are equal and thus the increase in pleural pressure is equal to ½ (5 cm H_2O pressure) of the applied PEEP (10 H_2O pressure). Pleural pressure will increase from –3 cm to +2 cm H_2O pressure.

and that of the lung equal to

Alveolar pressure – Pleural pressure

An integration of lung and chest wall mechanics can be graphically represented by plotting the pleural pressure against the relaxed volumes of the lung and chest wall (Campbell diagram) (Fig. 5-16). These plots help to explain the determinants of the commonly measured static lung volumes.

At FRC (relaxation volume), the outward recoil pressure of the chest wall is balanced by the inward recoil of the lung. The pleural pressure at which this occurs is negative (approximately –3 to –4 cm H_2O) in normal subjects. Changes in the compliance of the lung or chest wall may change the relaxation volume (see Fig. 5-16). Increases in lung compliance (e.g., due to emphysema) will tend to shift the pressure-volume curve of the lung upward and to the left. If chest wall compliance remains constant, FRC will increase. In contrast, if lung compliance is reduced (e.g., due to pulmonary fibrosis), there will be shifting of the pressure-volume curve of the lung to the right, leading to a reduction in FRC. Similarly, changes in chest wall compliance can lead to increases or decreases in FRC.

FRC is believed to represent the balance of forces in a relaxed state of no muscle activation. However, FRC may not be completely passively determined. There appears to be a reduction in FRC with paralysis compared with the relaxed state, suggesting that inspiratory muscle tone of the rib cage muscles may contribute to FRC.[60]

With activation of inspiratory and expiratory muscles, the configuration of the chest wall changes. This is dem-

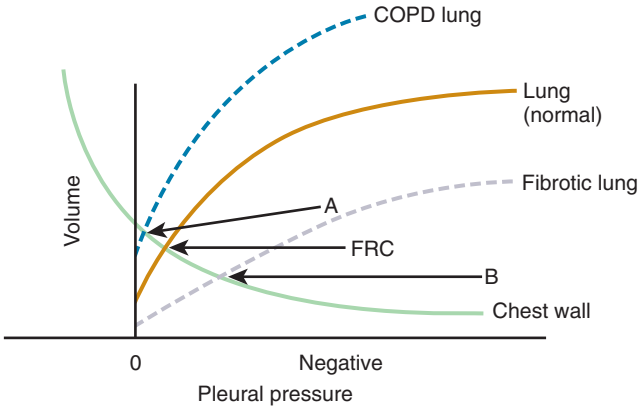

FIGURE 5-16 ■ Integration of lung and chest wall mechanics. Changes in lung and relaxed chest wall volumes as a function of pleural pressure (Campbell diagram). This is basically the same plot as in Figures 5-5 and 5-6 except that the x axis is simply Ppl rather than transmural pressure for the lung and chest wall. The point at which the two curves meet is the functional residual capacity (FRC) (lung recoil balanced by chest wall recoil). If lung compliance is increased (e.g., in COPD), the point at which the two curves meet (FRC) is greater (point A). In contrast, if lung compliance is reduced (e.g., in pulmonary fibrosis), the point at which the two curves meet is less (point B).

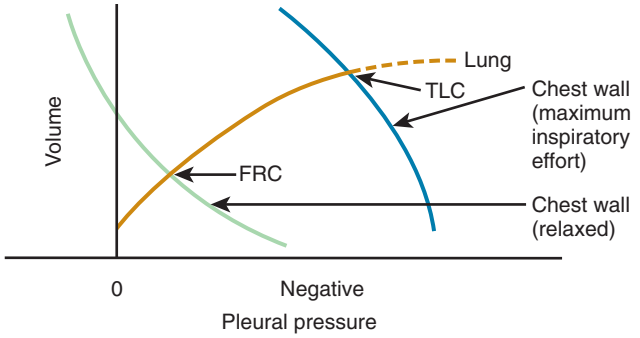

FIGURE 5-17 ■ Maximal inspiratory effort (Campbell diagram). With maximal inspiratory effort, the volume-pressure curve of the chest wall moves to the right. The point at which there is intersection of this curve and the lung volume-pressure curve is the total lung capacity (TLC).

onstrated in Figure 5-17. Activation of inspiratory muscles effectively shifts the pressure-volume curve of the chest wall, so that at any given pleural pressure, volume of the chest wall is increased relative to the relaxed state. The horizontal difference between the relaxed curve and the curve with inspiratory muscle activation represents the net pressure generated by the inspiratory muscles.

TLC is determined by the balance between inward lung recoil plus the inward chest wall recoil and the strength of the inspiratory muscles. However, in normal subjects, TLC is predominantly determined by the markedly increased stiffness of the lung at high lung volume, rather than the recoil of the chest wall or respiratory muscle strength.[61] In support of this concept, inspiratory muscle training in normal subjects increases strength substantially (55% increase in maximal inspiratory pressure) but results in a very modest change in TLC and VC (about 4%).[62] The situation in patients with neuromuscular disease is very different; in such individuals, reduced TLC is largely due to respiratory muscle weakness and can be improved to some extent by inspiratory muscle training.[63]

Activation of expiratory muscles shifts the volume-pressure curve of the chest wall in the other direction, and the degree of shift is a measure of the net pressure exerted by the expiratory muscles. In young subjects, RV is determined by the balance of static forces among the outward recoil of the chest wall, inward lung recoil (small component), and expiratory muscle strength.[61]

In older subjects or patients with obstructive lung disease, RV is not determined by this balance of forces, but is rather determined by airway closure. In such individuals, airway closure and trapping of gas occur during exhalation before a static balance is achieved.[61]

Calculation of Total Respiratory System Compliance from Lung and Chest Wall Compliance

The chest wall and lung act as capacitors in series, analogous to electrical capacitors. The relationship between total respiratory system compliance and lung–chest wall compliance is indicated by the following formula:

$$1/\text{Total compliance} = 1/\text{Lung compliance} + 1/\text{Chest wall compliance}$$

Alternatively, since elastance = 1/compliance,

$$\text{Total elastance} = \text{Elastance of lung} + \text{Elastance of chest wall}$$

As an example, in a supine paralyzed subject, lung compliance is approximately 150 mL/cm H_2O pressure and chest wall compliance is approximately 200 mL/cm H_2O pressure[64]; the calculated compliance of the respiratory system would thus be approximately:

$$1/(1/200 + 1/150) = 85.7 \text{ mL/cm } H_2O$$

Clinical Applications

The Impact of Positive End-Expiratory Pressure on Pleural Pressure

In patients receiving positive-pressure mechanical ventilation, pressure is usually applied at the end of exhalation to prevent alveolar collapse.[65] Some—but not all—of this PEEP is transmitted from the alveolar space to the pleural space (see Fig. 5-15). This is important because pericardial pressure will increase to a similar extent as pleural pressure. Increases in pericardial pressure reduce venous return and can lead to reduced cardiac output and hypotension.[66] Furthermore, PEEP will increase central venous pressure and pulmonary artery occlusion pressure to a magnitude similar to the increase in pleural pressure. If this is not taken into account, errors may be made when using these pressures to assess volume status.

The proportion of PEEP transmitted to the pleural space is dependent on the relationship between the compliances of the chest wall and the lung (see Fig. 5-15). When the compliances of the lung and chest wall are equal, 50% of the PEEP is transmitted to the pleural space. However, if lung compliance is much less than chest wall compliance (e.g., in a thin patient with severe ARDS), the pleural pressure will change minimally with PEEP. In contrast, if lung compliance is much greater than chest wall compliance (e.g., in a patient with emphysema and kyphoscoliosis), a much greater proportion of PEEP will be transmitted to the pleural space.

Plateau Pressures in Patients Receiving Positive-Pressure Mechanical Ventilation

In patients receiving positive-pressure mechanical ventilation, the plateau pressure is the distending pressure of the respiratory system at end inspiration when there is no flow. When possible, plateau pressures are limited to a maximum of 30 to 35 cm H_2O, because higher pressures can damage the lung through overdistention. This recommendation is based in part on animal studies that show that pressures below this range seem to protect the lungs from injury.[67] There is also a physiologic basis for this practice, because at TLC in a normal subject, the distending pressure across the lung (alveolar − pleural

pressure) is approximately 35 cm H_2O.[68] Therefore, limiting the plateau pressure to less than 35 cm H_2O should limit lung expansion to below TLC, and not overdistend the lung. Although controversial, some investigators have argued that in patients who have substantial heterogeneity of lung compliance (such as patients with ARDS), even plateau pressures below 30 to 35 cm H_2O might be harmful[69] because heterogeneity leads to opening of some alveoli while adjacent ones may remain closed, causing substantial shear stress even at modest airway pressures.[70]

A related issue is the clinical significance of the plateau pressure in patients with a stiff chest wall. The plateau pressure is usually used as a surrogate marker of transpulmonary pressure (pressure used to distend the lung), when it is actually a measure of transrespiratory system pressure. When lung compliance is much less than chest wall compliance, this is a reasonable assumption, because during mechanical ventilation, pleural pressure will not be substantially greater than body surface pressure. However, in conditions in which the chest wall is stiff (e.g., obesity, post–abdominal surgery) the plateau pressure may substantially overestimate the distending pressure of the lung, because pleural pressure may be much greater than body surface pressure. Under these conditions, tolerance of higher plateau pressure should be considered if there are problems with oxygenation. Indeed, some investigators have suggested that measurement of pleural pressure (with an esophageal balloon) could be useful in titrating mechanical ventilation in ARDS.[71]

THE RESPIRATORY SYSTEM IN DYNAMIC CONDITIONS

The work to distend the chest wall and lung during inhalation is stored as potential energy (elastic work). Work also must be done to overcome the inertia of the gas (which is negligible when breathing air at normal breathing frequency and atmospheric pressures) and nonelastic resistance (resistive work), which cannot be stored, but is dissipated as heat. Resistive work has two components that must be considered.

Resistive Work Due to Gas Flow through Airways

When gas flows through an airway, frictional and viscous forces cause energy loss and a pressure drop along the airway. The extent of this pressure drop is dependent on the resistance to gas flow, physical properties of the gas (e.g., density and viscosity), and the nature of flow (laminar versus turbulent).

Laminar versus Turbulent Flow

The least frictional drop occurs with pure laminar flow, in which gas molecules travel in a straight line. The velocity profile of the gas is parabolic, with the molecules closer to the wall traveling slower than molecules in the center of the airway (Fig. 5-18). When gas flow is laminar, the flow is proportional to the pressure gradient along the airway and inversely proportional to resistance.

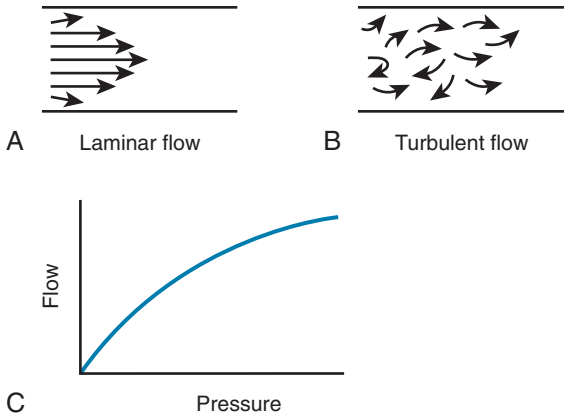

FIGURE 5-18 ■ Laminar versus turbulent flow. Schematic depiction of the spatial and velocity profiles of gas molecules within a laminar (**A**) and a turbulent (**B**) flow regime. The velocity of the gas molecules is proportional to the length of *arrows*. During turbulent flow, there is chaotic molecular movement between lamina that results in ever greater pressure being required to achieve incremental flow. **C,** Note the alinear pressure-flow relationship with turbulent flow.

$$\text{Flow} = \Delta P / R$$

For a straight airway under conditions of laminar flow, resistance of the tube is related to viscosity, length, and radius of the tube by the Poiseuille equation:

$$\text{Resistance} = 8 * \text{length} * \text{viscosity} / (\pi * \text{radius}^4)$$

Because of this relationship, flow through a tube is dramatically affected by even small changes in tube diameter, because resistance increases as the fourth power of the radius (i.e., reducing the radius by half causes a 16-fold increase in resistance).

When flow is turbulent, the orderly pattern of gas molecule movement is replaced with a haphazard pattern (see Fig. 5-18). Turbulent flow results in much greater pressure losses due to friction, with the pressure drop along the airway proportional to the square of flow (as opposed to a linear relationship in the case of laminar flow)[72]:

$$\Delta P = \text{constant} * \text{flow}^2$$

Because resistance is defined as the pressure gradient divided by the flow rate, the "resistance" for turbulent flow is not constant, but increases in proportion to flow.

In contrast to laminar flow, turbulent flow is inversely proportional to gas density, but is not affected by viscosity. The driving pressure required is proportional to the fifth power of the radius of the airway.

Reynold's Number

Reynold's number is a dimensionless coefficient that predicts whether flow through an unbranched airway will

be predominantly laminar, turbulent, or mixed. The equation is as follows:

$$Re = pdV/u$$

where p is the gas density, d is the diameter of the airway, V is the mean gas velocity, and u is the viscosity. In general, a value of Re of less than 2000 is associated with laminar flow, whereas a value greater than 4000 is associated with predominantly turbulent flow.[73] Intermediate values are associated with mixed flow patterns. Decreased airway radius or gas viscosity and increased gas density or gas velocity predispose to turbulent flow.

The cross-sectional diameter of the central airways (e.g., trachea) is much greater than the smaller peripheral airways (e.g., bronchioles). However, the entire cross-sectional area of the peripheral airways is much greater than that of the central airways. Therefore, as gas moves from the peripheral to the central airways during exhalation, the gas velocity increases as the airway diameter increases. This results in predominantly turbulent flow in the larger central airways (except at very low flow rates) and predominantly laminar flow in the periphery.

Clinical Effects of Heliox

Heliox is a mixture of oxygen and helium. Heliox has a density less than air and a viscosity greater than air. For instance, a mixture of 20% oxygen and 80% helium has a density of 0.33 relative to air and a viscosity of 1.08 relative to air.[73] Because gas density influences the resistance during turbulent flow, this gas mixture can be especially beneficial in patients who have upper airway narrowing (e.g., partial tracheal obstruction).[74] Substituting heliox for air or oxygen reduces gas density, lowering Reynold's number, and helps to convert turbulent to laminar flow. This reduces the pressure required to move gas through the airways and diminishes the work of breathing, unloading the respiratory muscles.

Heliox may be useful in patients with asthma or COPD, although this is controversial.[75,76,76a] The reason for a beneficial effect is unclear, because flow in the smaller bronchioles, which contribute most of the increased airways resistance in asthma, should be laminar rather than turbulent. Alternatively, the effectiveness of heliox in asthma might be related to narrowing of large central airways from secretions and conversion of flow from turbulent to laminar in larger airways.

Flow Limitation

In a normal subject, increasing expiratory effort will increase air flow until a threshold is reached. Once this effort threshold is exceeded, expiratory flow will not increase with a further increase in effort, resulting in flow limitation as opposed to pressure limitation[77] (Fig. 5-19). In contrast, patients with very poor effort or marked expiratory muscle weakness may be unable to generate high expiratory pressures, resulting in pressure limitation before flow limitation occurs. If flow were not relatively effort independent, measures such as forced expiratory volume in 1 second (FEV_1) would have little utility in monitoring patients.

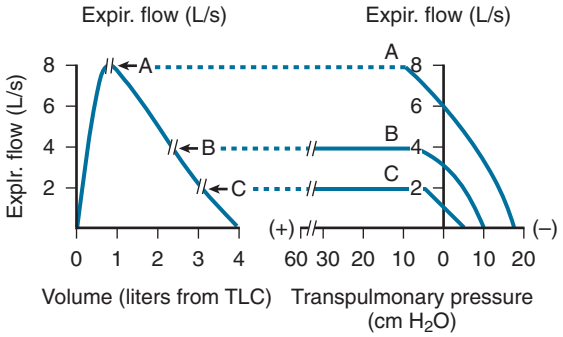

FIGURE 5-19 ■ Expiratory flow limitation. *Left,* The expiratory flow volume curve for a normal subject. Maximal flow rates are plotted against their corresponding volumes at A, B, and C and define the maximal expiratory flow-volume curve. *Right,* Three isovolume pressure-flow curves for the same subject. Once a threshold transpulmonary pressure is achieved, no increase in flow is seen. (From Hyatt RE: Forced expiration. *In* Macklem PT, Mead J [eds]: Handbook of Physiology. Section 3. The Respiratory System. Vol III: Mechanics of Breathing [part 1]. Bethesda, MD: American Physiological Society, 1986, pp 295–314.)

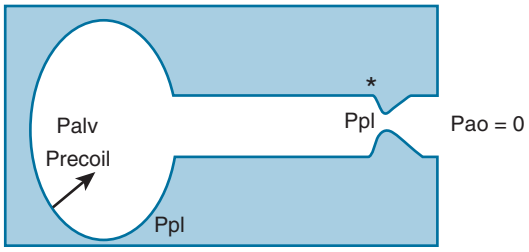

FIGURE 5-20 ■ Equal pressure point theory. At the equal pressure point (EPP; *), pressure inside the tube is equal to the pressure outside the tube (pleural pressure) due to pressure drop related to flow resistive losses from alveolus to *. Downstream (mouthward) from the EPP, the airway is compressed. Once an EPP develops, increasing expiratory effort, although increasing the alveolar pressure, simply increases the downstream compression and causes no increase in flow.

The concept of expiratory flow limitation is important, and the reason that flow is limited is because of the properties of the airways. For simplicity, the airways are often likened to a rigid tube, but in reality, the airways are partially collapsible. During inhalation, pleural pressure is negative, and the intrathoracic airways tend to be pulled open. During active exhalation, pleural pressure becomes positive, increasing pressure around the intrathoracic airways and predisposing to their collapse.

Several theories have been developed to explain the limitation of flow at less than maximal effort.

Equal Pressure Point Theory (Fig. 5-20). Consider the respiratory system depicted as a bag (lung) inside a box (chest wall) connected by a tube that extends through the box (intrathoracic airway). The pressure inside of the lung is equal to the pleural pressure (created by expiratory muscle activation) plus the recoil pressure of the lung. As air travels down the airway, pressure in

the airway will decrease, predominantly due to frictional losses. A point is eventually reached where the pleural pressure in the box is equivalent to the pressure inside the tube, termed the equal pressure point (EPP).[78,79] Downstream (mouthward) of this EPP, the pressure outside the airway exceeds the pressure within the airway, and the airway tends to collapse. Further increases in effort increase pleural pressure, but this simply causes greater narrowing of the airway downstream of the EPP, so that flow remains constant. Under these conditions, the airway acts as a Starling resistor; flow is now not proportional to the difference between alveolar and mouth pressure, but rather is proportional to the difference between alveolar pressure and pressure at the EPP. In this case, the pressures downstream from the EPP have no effect on expiratory flow.

This concept can be mathematically expressed as follows:

Because:

$$\text{Alveolar pressure} = \text{Pleural pressure} + \text{Elastic recoil pressure of the lung}$$

and

$$\text{Pressure at EPP} = \text{Pleural pressure}$$

and

$$\text{Driving pressure for flow} = \text{Alveolar pressure} - \text{Pressure at EPP}$$

therefore

$$\begin{aligned}\text{Driving pressure} &= (\text{Pleural pressure} \\ &\quad + \text{Lung recoil pressure}) \\ &\quad - \text{Pleural pressure} \\ &= \text{Lung recoil pressure}\end{aligned}$$

Therefore, further increases in effort will increase alveolar and EPP pressure equally, resulting in no difference in driving pressure and airflow.

The Bernoulli Effect and Wave Speed Theory. The Bernoulli effect provides an alternative explanation for flow limitation.[80] As gas flows through a tube, the lateral pressure exerted by the gas is less than the pressure driving flow by an amount proportional to the velocity of the gas. If the tube is collapsible, as gas velocity increases, there is a tendency for the tube to collapse, leading to a reduction in airflow.

The wave speed theory is yet another explanation for expiratory flow limitation.[81] When fluid is pushed through a collapsible tube, a pressure wave is propagated along the wall of the tube. The speed of this pressure wave is dependent on the characteristics of the tube and the density of the gas rather than the driving pressure. The velocity of the gas in the tube cannot exceed the velocity of the pressure wave, and thus the velocity of this wave represents a "speed limit" for the gas in the tube.

Interestingly, the maximal flow of gas derived using the Bernoulli effect and wave speed theory are identical, as shown by the following formula:

$$\text{Maximal flow} = A * \sqrt{((A * / \text{gas density}) * dP/dA)}$$

where A represents the cross-sectional area of the airway wall and dP/dA represents the slope of the relationship between changes in transmural pressure of the tube and changes in tube area. Therefore, maximal flow should increase if the tube area increases, gas density decreases, or tube stiffness increases.

The EPP mechanism might be more important at lower lung volumes and flows, while the Bernouilli and wave speed effects might predominate at higher volumes and flows.[82]

Other Resistive Work

Besides of the elastic work done by the respiratory muscles on the lung and chest wall, an additional component of work is expended to overcome what is sometimes called "tissue resistance." This is energy required to distort the lung and chest wall during inhalation and is dissipated as heat.

The breakdown of the various components of the total resistive work is shown Table 5-1.

Auto-PEEP during Positive-Pressure Ventilation of COPD

An appreciation of the dynamics of the respiratory system aids in understanding clinical scenarios, such as patients with COPD who are treated with positive-pressure ventilation for respiratory failure.[83] Because lung resistance and compliance are increased in these patients, their lungs contain individual lung units with long time constants, and there may be insufficient time for the lungs to completely empty at the end of exhalation. Heterogeneity of time constants will result in heterogeneity of emptying times. If insufficient time is allowed for complete emptying of lung units, the result will be a positive mean alveolar pressure in the alveolus at the end of exhalation. This has been termed "auto-PEEP" or "intrinsic PEEP."

PEEPs have a number of adverse consequences. First, the positive pressure at end-exhalation increases intratho-

TABLE 5-1. Components of Respiratory System Resistance

	Mouth/Pharynx	Large Airways	Small Airways	Lung Tissue	Chest Wall	Total
Resistance (cm H_2O L/s)	0.5	0.5	0.2	0.2	1.2	2.6
% of resistance	19	19	8	8	46	100

racic pressure and can reduce venous return, causing hypotension.[66] Second, the high end-expiratory alveolar pressure acts as an inspiratory threshold load. That is, in order to generate a negative pressure that is great enough to trigger the ventilator and initiate inspiratory flow, the inspiratory respiratory muscles must exert adequate pressure to counteract the auto-PEEP pressure and reduce alveolar pressure to a subatmospheric value.[84] Third, high auto-PEEP may lead to inspiratory efforts that are ineffective in triggering the ventilator if the respiratory muscles cannot reduce alveolar pressure to less than the applied PEEP[85] (Fig. 5-21). This may lead to patient ventilator dyssnchrony and discomfort. Fourth, auto-PEEP and the consequent hyperinflation of the lung at end-exhalation place the inspiratory muscles at a mechanical disadvantage,[36] which can lead to failure of weaning from mechanical ventilation.

Auto-PEEP is treated by increasing the applied PEEP from the ventilator, which may improve patient-ventilator synchrony.[86] Increasing applied PEEP will not reduce expiratory flow if the applied PEEP is less than the level of auto-PEEP, because these patients are usually flow- rather than pressure-limited. However, increasing the applied PEEP will decrease inspiratory muscle work and facilitate ventilator triggering.

The end-expiratory occlusion method is commonly used to measure auto-PEEP (Fig. 5-22) (static auto-PEEP). The expiratory line in the ventilator is occluded at the end of an exhalation.[87] If auto-PEEP is present, airway pressure will increase until a plateau is reached (usually 4-5 seconds). This value represents an "average" measure of auto-PEEP after redistribution of volume from some alveoli to others depending on regional compliance (pendelluft). Pendelluft is the transient movement of gas from one lung unit to another.

Alternatively, auto-PEEP may be measured under dynamic conditions (dynamic auto-PEEP) when the patient is spontaneously breathing.[87] This can be done by inserting an esophageal balloon to measure pleural pressure and measuring the reduction in pleural pressure necessary to initiate inspiratory flow. Dynamic auto-PEEP is usually less than that measured under static conditions, because it reflects the region of the lung with the least amount of auto-PEEP, as opposed to the average amount of auto-PEEP.

Auto-PEEP is not limited to mechanical ventilation. Spontaneously breathing patients who have COPD can develop positive end-expiratory alveolar pressure, especially when they increase their inspiratory rate during exertion, a phenomenon that has been termed "dynamic hyperinflation." This increases work of breathing (see later) and contributes to exercise limitation in these patients.

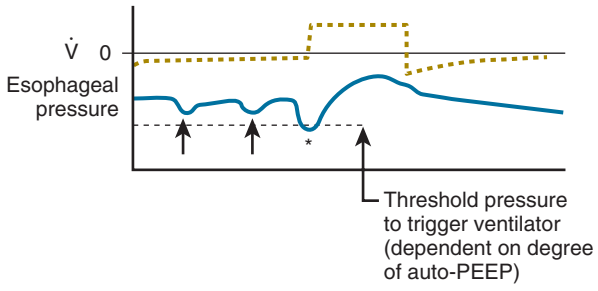

FIGURE 5-21 ■ Failure to trigger the ventilator in a COPD patient. Graph of flow (V̇) and esophageal pressure over time in a patient with COPD and auto-PEEP receiving positive-pressure mechanical ventilation. The patient has made two attempts (↑) at triggering inspiration but could not, due to the positive end-expiratory alveolar pressure. When pleural pressure is sufficiently negative to exceed the ventilator's threshold (*dotted line*), this triggers the ventilator (*) and a breath is provided. Note the failure of expiratory flow to reach 0 prior to a triggered breath.

Measurement of Static Compliance and Resistance during Mechanical Ventilation

In the intensive care unit, measurement of respiratory system compliance and resistance can be helpful in assessing the timing for weaning from mechanical ventilation or determining the reasons for failure of a spontaneous breathing trial. Normal respiratory system compliance in a supine subject is approximately 100 cm H_2O/mL. A markedly decreased compliance should prompt a search for causes of reduced lung (e.g., edema) and/or chest wall compliance (abdominal distention) that might be potentially reversible. Similarly, a markedly increased resistance should prompt a search for reversible causes, including bronchospasm, or partial endotracheal tube obstruction from kinking or secretions.

Calculation of compliance and resistance should be performed with a square wave flow pattern after an inspiratory pause. Patients need to be relaxed or paralyzed to obtain accurate measurements. If respiratory efforts are present, airway pressures may not reflect transmural pressures across the respiratory system, but rather may reflect pleural pressures.

Consider a paralyzed sedated patient treated with positive-pressure mechanical ventilation in the assist-control mode. The changes in flow, volume, and pressure over time are shown in Figure 5-23. Assume a constant inspiratory flow rate (1 L/sec) and a tidal volume of 500 mL (0.5 sec inspiratory time). Because flow is constant, volume increases linearly over time. Peak pressure is 40 cm H_2O, plateau pressure is 35 cm H_2O, and PEEP is set at 5 cm H_2O.

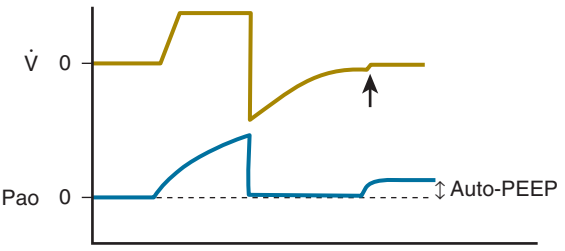

FIGURE 5-22 ■ Measurement of auto-PEEP while on a ventilator. Flow (V̇) and airway pressure (Pao) over time. *Arrow* represents the point at which the expiratory line is occluded, leading to an increase in measured pressure that represents the degree of auto-PEEP.

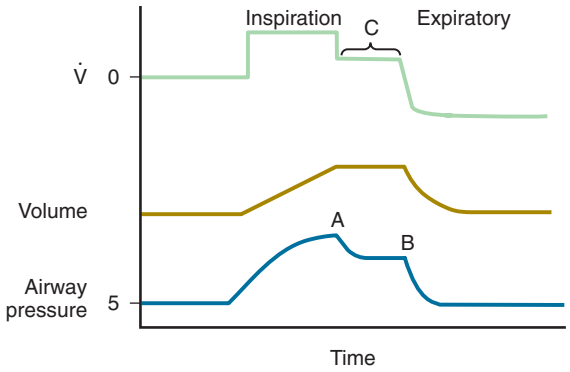

FIGURE 5-23 ■ Ventilator mechanics. **A,** Peak pressure (40 cm H_2O). **B,** Plateau pressure (35 cm H_2O). **C,** Inspiratory pause.

Using the bag and tube analogy of the respiratory system (see Fig. 5-4), the components of pressure required are as follows:

$$\begin{aligned}\text{Total pressure} = {} & \text{Pressure to distend respiratory system} \\ & + \text{Pressure to maintain gas flow} \\ & + \text{Inertial pressure losses}\end{aligned}$$

Because the inertial component can be ignored at the respiratory rates commonly used:

$$\begin{aligned}\text{Total pressure} = {} & \text{Pressure to distend respiratory system} \\ & + \text{Pressure to maintain gas flow} \\ = {} & \Delta\text{Volume}/\text{compliance} + \text{Flow} * \text{resistance}\end{aligned}$$

The difference between plateau pressure (measured during an inspiratory hold) and PEEP represents the pressure required to distend the respiratory system at 0 flow.

Therefore,

$$\begin{aligned}\text{Plateau pressure} - \text{PEEP} = {} & \Delta\text{Volume}/\text{compliance} \\ & + \text{Flow} * \text{resistance}\end{aligned}$$

Because flow = 0, rearranging the equation yields:

$$\text{Compliance} = \Delta\text{Volume}/(\text{Plateau pressure} - \text{PEEP}) \quad (1)$$

The difference between peak pressure (A) and plateau pressure (B) represents the pressure required to overcome resistance of the respiratory system (this predominantly represents flow resistance, but also includes contributions from tissue resistance, stress relaxation, and pendelluft) and the pressure required to distend the respiratory system.

Therefore,

$$\begin{aligned}\text{Peak pressure} - \text{PEEP} = {} & \Delta\text{Volume}/\text{compliance} \\ & + \text{Flow} * \text{resistance}\end{aligned} \quad (2)$$

Rearranging Equations 1 and 2:

$$\text{Peak pressure} - \text{Plateau pressure} = \text{Flow} * \text{resistance}$$

Because flow is known:

$$\text{Resistance} = (\text{Peak pressure} - \text{Plateau pressure})/\text{Flow}$$

Going back to our patient:

$$\text{Compliance} = 500\ \text{mL}/(30\ \text{cm}\ H_2O) = 16.7\ \text{mL/cm}\ H_2O$$
$$\text{Resistance} = 40 - 35\ \text{cm}\ H_2O/1\ \text{L/s} = 5\ \text{cm}\ H_2O/\text{L/s}$$

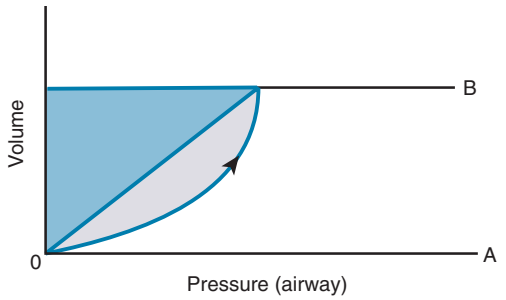

FIGURE 5-24 ■ Work of breathing during mechanical ventilation. Consider a paralyzed patient receiving one tidal breath while on positive-pressure mechanical ventilation (point A to point B). The *diagonal blue line* represents the volume-pressure curve of the static respiratory system; the *shaded dark blue area* to the left of this line thus represents the elastic work done during the inflation. This work can be stored as potential energy and can be used during exhalation. The *gray shaded area* to the right of the line represents the resistive work done.

In other words, the patient's compliance is severely reduced, suggesting an extremely stiff respiratory system. However, the resistance is relatively low.

ENERGETICS AND WORK OF BREATHING

When a force is applied to an object over a distance, energy is required; the work done is equal to:

$$\text{Work} = \text{force} * \text{distance}$$

Similarly, because pressure is force over an area and volume is an area multiplied by a distance, work in a fluid system may be defined as the integral of applied pressure over a change in volume:

$$\text{Work} = \int \text{PdV}$$

During inspiration, work must be performed to distend the respiratory system (elastic work) which is stored as potential energy. Also, nonelastic work must be done to generate flow through the airways (to overcome resistance to gas flow), to deform the lung and chest wall (to overcome tissue resistance), and to accelerate gas (to generate the inertial component). This work cannot be stored as potential energy and is dissipated as heat. The inertial component is minimal and is usually ignored in measuring total work.

Measuring Work of Breathing Done by a Positive-Pressure Ventilator in a Paralyzed Patient

Consider a paralyzed patient receiving positive-pressure mechanical ventilation, such that the entire work of breathing is performed by the ventilator (Fig. 5-24). On a volume-pressure plot, pressure applied to the airway will track to the right of the static volume-pressure curve of the respiratory system, because additional pressure is

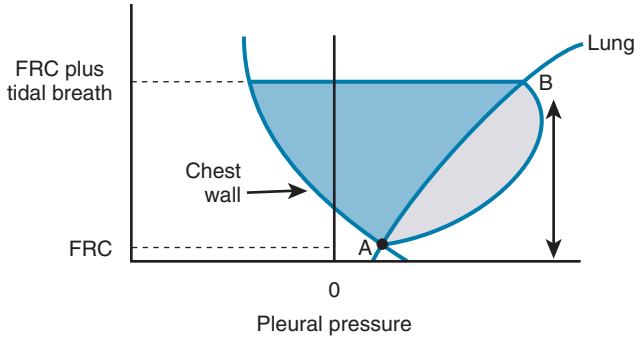

FIGURE 5-25 ■ Work of breathing during spontaneous breathing (Campbell diagram). A portion (from FRC to FRC plus tidal volume) of the volume-pleural pressure (VP) curves of the lung and relaxed chest wall are shown. Consider a patient taking a spontaneous breath from FRC (point A) with a volume equal to the height of the *double-headed arrow* (point B). In order to overcome elastic forces of the lung and chest wall, the inspiratory muscles must exert a force equal to the horizontal distance between the chest wall and lung VP curves. Thus, the entire elastic work done will be equal to the *blue shaded area*. Furthermore, resistive work must also be done, necessitating the inspiratory muscles to generate an even greater negative pleural pressure. This is indicated by the *gray shaded area*. The total work done will be the sum of both areas.

required to overcome resistive forces. The *blue shaded area* represents the elastic work done by the ventilator during one inhalation, while the *gray shaded area* represents the resistive work that was expended to generate flow and overcome tissue resistance. With exhalation, the stored elastic energy can be used to deflate the lungs, so that exhalation is normally a passive process. Increases in resistance or decreases in compliance can markedly increase the work of breathing.

Measuring Work of Breathing in a Spontaneously Breathing Patient

In a spontaneously breathing patient, work is performed by the inspiratory muscles rather than a ventilator. Graphing the pressure-volume characteristics of the lung and chest wall against pleural pressure is useful in illustrating the work performed by the inspiratory muscles (Fig. 5-25). During inspiration, pleural pressure decreases to expand the lungs (see Fig. 5-25A and B). The distance between the two curves at any given lung volume represents the pressure the inspiratory muscles must exert to overcome elastic forces of the lung and chest wall. The *blue shaded area* thus represents the elastic work of breathing against the lung and chest wall. To overcome the resistive forces, additional pressure and work are required, as indicated by the *gray shaded area*.

Under normal conditions, exhalation is passive, because the stored potential energy from elastic work is more than sufficient to overcome resistive work. However, in the presence of severe airflow obstruction (e.g., an asthma attack), resistive work may exceed this stored energy, requiring active generation of force by expiratory muscles and additional work for exhalation.

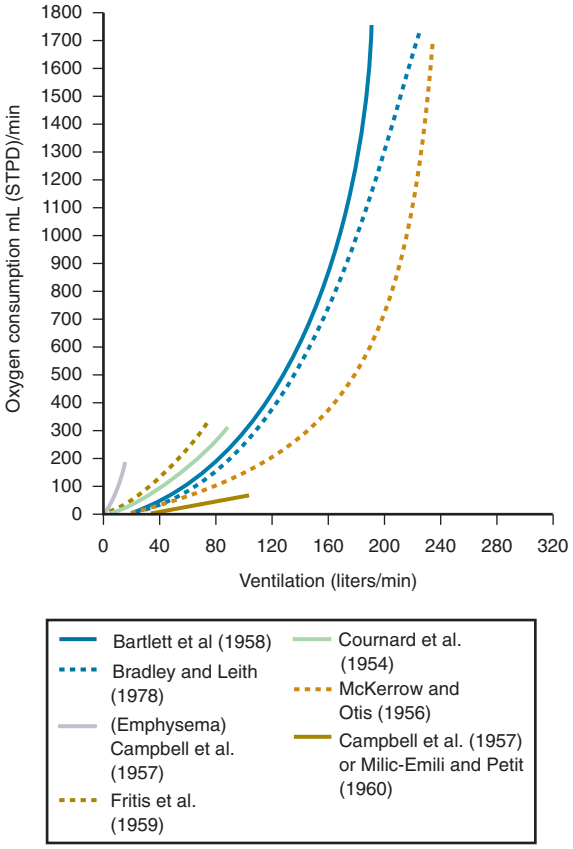

FIGURE 5-26 ■ Oxygen cost of breathing. Oxygen cost of breathing at varying levels of ventilation. Note the variability among studies and the steeper slope in patients with emphysema. (From Roussos C, Zakynthinos S: Respiratory muscle energetics. In Roussos C [ed]: The Thorax [Part A]. New York: Marcel Dekker, 1995, pp 681–749.)

Oxygen Cost of Breathing

The oxygen cost of breathing (V_{O_2} resp) is an indicator of the total amount of energy required by the respiratory muscles for ventilation. At rest, the oxygen cost of breathing is low, 0.25 to 0.5 mL/L of ventilation, or 1% to 2% of total body oxygen consumption. However, at maximal exercise in normal subjects, the oxygen cost of breathing represents approximately 10% to 15% of total oxygen consumption.[88] The oxygen cost of breathing can increase markedly as minute ventilation increases (Fig. 5-26).

Patients with COPD have an increased oxygen cost of breathing as a function of ventilation (see Fig. 5-26). This may be related to a combination of increased work of breathing and decreased efficiency due to dynamic hyperinflation. Dynamic hyperinflation is an increase in end-expiratory lung volume that occurs when patients with airflow obstruction develop auto-PEEP due to the long time constants for gas distribution in the lungs and increased respiratory rate.[89]

In addition, tonic inspiratory muscle activity at end-expiration contributes to dynamic hyperinflation. Although this dynamic increase in lung volume can have a beneficial effect by dilating intraparenchymal airways

to decrease the resistive work, the end-expiratory alveolar pressure acts as an inspiratory threshold load, which increases the work of breathing. Furthermore, the mechanical efficiency of the inspiratory muscles is compromised by hyperinflation because the zone of diaphragmatic apposition is reduced and the inspiratory muscles are shorter than the optimal length for force generation. The efficiency of breathing (defined as the ratio between the rate of mechanical work accomplished and the rate of energy consumed) may be further diminished if postural or other stabilizing muscles (trunk, neck, shoulder) need to be recruited.

KEY POINTS

- An understanding of the mechanical properties of the lung and chest wall under static and dynamic conditions is important for appreciating the determinants of lung volumes and expiratory flows under normal and pathological conditions.
- Under conditions of laminar flow, flow is directly proportional to the pressure difference along the path of flow. Under conditions of turbulent flow, flow is directly proportional to the square root of the pressure difference.
- The majority of the elastic recoil of the lung is due to surface forces generated by fluid lining the alveoli.
- The unique properties of surfactant help to stabilize alveoli at low lung volumes and prevent their collapse.
- At FRC (relaxation volume), the outward recoil pressure of the chest wall is balanced by the inward recoil of the lung. TLC is determined by the balance between the maximal inspiratory pressure generated by the respiratory muscles and the opposing pressure generated by the inward recoil of the lungs and chest wall. In young subjects, RV is determined by the balance of pressure generated by the expiratory muscles and the opposing pressures generated by the outward recoil of the chest wall and inward of the lungs (normally a small component). In older subjects or patients with obstructive lung disease, RV is not determined by this balance of forces, but is rather determined by airway closure.
- In patients with airflow obstruction who are treated with positive-pressure ventilation, dynamic hyperinflation (auto-PEEP) can lead to hemodynamic compromise, increased work of breathing, an inspiratory threshold load, mechanical inefficiency of the diaphragm, and patient-ventilator asynchrony.

Strategies to Reverse Permeability and Restore Barrier Integrity

PULMONARY VASCULAR GENOMICS

INTRODUCTION

The pulmonary circulation, which is interposed between the right and left ventricles, has the following functions: (1) to deliver the entire cardiac output under low pressure from the right ventricle to the pulmonary microvessels and, in that process, to exchange carbon dioxide for oxygen across the alveolar-capillary membrane; (2) to act as a source of production, release, and processing of humoral mediators; and (3) to serve as a barrier to the exchange of fluid and solutes and thus maintain lung fluid balance. The morphology of the pulmonary circulation is ideally adapted for these functions. Nearly the entire cardiac output is brought into contact with alveolar gas at the 1- to 2-μm-thick alveolar-capillary membrane for about 0.75 to 1 second. This juxtaposition of capillaries with alveoli provides the vast surface area needed for effective gas exchange: well over 100 m^2 (more than one half the area of a singles tennis court). The structural arrangement is such that the distance through which oxygen and carbon dioxide must diffuse between gas and blood is about one tenth of the distance of diffusion in peripheral tissues. (Additional information about the anatomy of the pulmonary circulation is found in Chapter 1, and about the physiologic factors that govern the distribution of blood flow and ventilation in Chapter 4.)

As indicated, the pulmonary circulation has important functions in addition to its role in gas exchange. The microvessels exchange solutes and water, and the mechanisms regulating the balance of fluid and solutes in extravascular spaces of the lung are critical in the understanding of the pathophysiology of pulmonary edema (see later in this chapter and in Chapter 55). The pulmonary vascular endothelium, the monolayer of cells that line all vessels, is a multidimensional tissue whose specialized functions include direct lung vascular barrier regulation, participation in inflammatory responses, and the processing of mediators before they are delivered to the systemic circulation.

PULMONARY HEMODYNAMICS

Thorough, in-depth reviews of hemodynamic aspects of the pulmonary circulation have been written by Fishman,[1] Dawson,[2] Hughes and Morrell,[3] and Gao and Raj.[4] The effect of gravity on the distribution of blood flow in the lungs and the influence this has on gas exchange is fully discussed in Chapter 4 of this book.

Pulmonary Vascular Pressures

Pressure and flow are highly pulsatile throughout the pulmonary circulation. The pressure pulsatility decreases across the pulmonary circuit, but the pulsatile nature of the flow persists on the venous side.[1] Pulmonary arterial pressure (P_{PA}) is normally approximately 25/9 mm Hg and is roughly one fifth the value of systemic arterial pressure. Because P_{PA} is low, hydrostatic pressure differences due to gravity result in substantial differences in vascular pressure from the top to the bottom of the lung. If the pulmonary artery is considered to be a column of blood approximately 25 cm high, P_{PA} will be 25 cm H_2O (or 18 mm Hg) higher at the bottom of the lung than at the top. This pressure difference results in a nonuniform distribution of blood flow, as discussed subsequently in the section on "Distribution of Pulmonary Blood Flow."

P_{PA} is measured by inserting a cardiac catheter or a balloon-tipped flotation catheter into the pulmonary artery.[2] Inflating the balloon leads to advancement ("floating") of the catheter (Fig. 6-1) until it "wedges" and occludes a peripheral pulmonary artery. With the balloon inflated, the pressure measured in the tip of the catheter is called the *pulmonary artery wedge pressure* (P_{PW}).[5] This procedure effectively extends the static fluid within the catheter lumen into the vascular bed, and the measured pressure is thus at the site where this extended column next joins a vessel in which blood is flowing. The wedge pressure (normally 5 to 10 mm Hg) is an estimate of the vascular pressure at the point of confluence of pulmonary veins and hence reflects left atrial pressure (P_{LA}).

Changes in pressure distal to the confluence of the pulmonary veins, such as that induced by constriction of the pulmonary venules, can alter the relationship between P_{LA} and P_{PW}. Also, the precise location of the tip of the catheter in the lung influences the measurement of P_{PW} (Fig. 6-2). Zone 1 is the region of the lung defined by West (see Fig. 4-11) in which alveolar pressure (Palv) > P_{PA} > pulmonary venous pressure (P_{PV}), and therefore there is minimal blood flow through the alveolar vessels. Zone 2 is where P_{PA} > Palv > P_{PV}, and therefore flow increases linearly descending into the lung. Positioning the catheter in the upper lung (in zone 1 or 2) results in a P_{PW} different from P_{LA} because higher alveolar pressures occlude the fluid column. Under these conditions, P_{PW} provides an incorrect measurement of pulmonary vascular outflow pressure. A catheter wedged in zone 3, where P_{PA} > P_{PV} > Palv, provides an accurate measurement of P_{LA}.

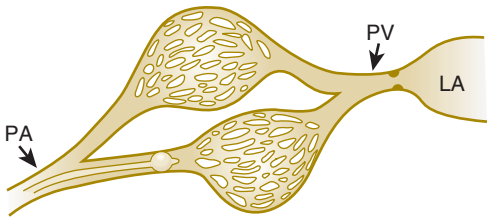

FIGURE 6-1 ■ Method of determining pulmonary wedge pressure. By placing a catheter through the right heart and pulmonary artery (PA) and occluding a small pulmonary artery with a balloon (*circle*), the static fluid column within the catheter is functionally extended from the catheter tip through the capillaries and into pulmonary veins (PV). The pressure measured is at the confluence of veins, where flow is again present. Because the pressure drop from a large vein to the left atrium (LA) is small, wedge pressure is a reflection of left atrial pressure except when (1) there is a change in downstream resistance, indicated by constriction (*solid semicircles*) proximal to the LA or (2) the catheter is in an artery perfusing a capillary bed where alveolar pressure exceeds PV pressure (i.e., zone 1 or 2). In the latter case, when the balloon is inflated, pressure within the capillary bed falls toward PV pressure, capillaries are compressed, and the fluid column interrupted, and wedge pressure will no longer reflect left atrial pressure (see Fig. 6-2).

Pulmonary Vascular Resistance

Pulonary vascular resistance (PVR) is calculated by the following equation:

$$PVR = \frac{\overline{P_{PA}} - \overline{P_{LA}}}{\dot{Q}_T} \quad (1)$$

where $\dot{Q}_T$ is pulmonary blood flow, $\overline{P_{PA}}$ is mean pulmonary artery (inflow) pressure, and $\overline{P_{LA}}$ mean left atrial (outflow) pressure, which is often estimated by mean P_{PW} ($\overline{P_{PW}}$) PVR is expressed in units of mm Hg/L/min, or in dynes/sec/cm^5 (to convert units to dynes/sec/cm^5, PVR in mm Hg/L/min is multiplied by 1332). The normal

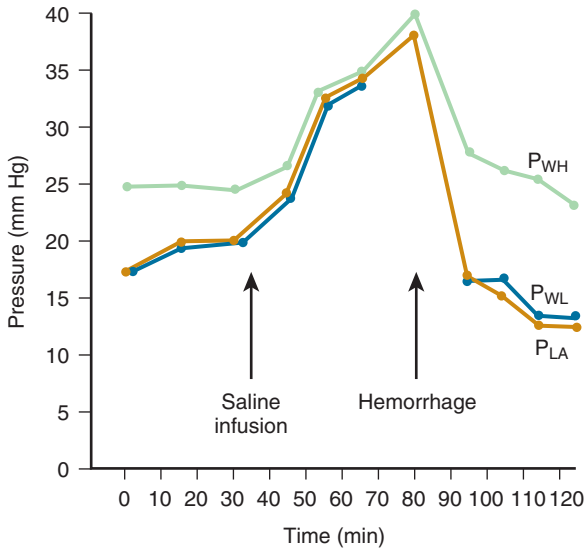

FIGURE 6-2 ■ Illustration of the influence of catheter position on wedge pressure measurement. When the catheter is wedged in a low position (i.e., zone 3), wedge pressure (P_{WL}) reflects left atrial pressure (P_{LA}). When the catheter is wedged in a high position (P_{WH}), however, the pressure does not reflect left atrial pressure, because when the catheter is wedged, pulmonary capillary pressure falls toward pulmonary venous pressure, which is less than alveolar pressure (i.e., zone 2), and the capillary bed is compressed. With a saline infusion, pulmonary venous pressure rises, capillaries open (i.e., zone 3), and P_{WH} is equal to P_{LA}. Hemorrhage again lowers pulmonary venous pressure, and again P_{WH} is greater than P_{LA}. (Redrawn from Todd TR, Baile EM, Hogg JC: Pulmonary arterial wedge pressure in hemorrhagic shock. Am Rev Respir Dis 118:613–616, 1978.)

PVR value is about 0.1 mm Hg/L/min, or 100 dynes/sec/cm^5. This value is approximately one tenth the value of systemic vascular resistance.

The use of Equation 1 (from Ohm's law) is complicated by the fact that resistance is not independent of PPA or PLA. As an example, if both PPA and PLA were elevated to such a degree that the pressure difference remained unchanged, PVR would nevertheless decrease because of distention of vessels by higher intravascular pressures. Thus, inferences regarding resistance changes in the vasculature require consideration of multiple mechanical factors that affect vascular resistance, including not only vascular pressures but also lung volume and inflation pressure. PVR is a function of lung volume because inflation distends some vessels and compresses others, as described later in the discussion of alveolar and extra-alveolar vessels.

PVR can also be potentially modeled by Poiseuille's equation, which describes for laminar flow the relationship of resistance (R) of a tube to the tube's physical characteristics and viscosity of perfusing fluid:

$$R = \frac{8}{\pi} \cdot \frac{l}{r^4} \cdot \eta \qquad (2)$$

where l is the length of the tube, r is the radius of the tube, and η is the viscosity of the perfusion fluid. It is evident from this equation that the critical determinant of PVR is the tube's radius, because resistance is proportional to l/r^4. Although this suggests that a 50% decrease in the tube radius, which might be encountered with constriction of a vessel, increases resistance 16-fold, this derived relationship may be excessively robust.

Ohm's law and the Poiseuille equation, although useful in describing the resistance properties of pulmonary vessels, have limitations that must be considered when changes in the calculated PVR value are interpreted. Blood flow is pulsatile, blood vessels are complex distensible branching tubes (not rigid cylinders), and blood-formed elements in the plasma constitute a nonhomogeneous fluid. These characteristics are not accounted for in either equation. Nevertheless, the ratio of pulmonary perfusion pressure to blood flow under strictly controlled conditions is a useful measure of pulmonary vasomotor tone. Its usefulness depends on knowledge of levels of intravascular pressure, pulmonary blood volume, and lung volume.

Vascular Resistance Profile

The vascular resistance profile in the pulmonary circuit has been estimated by the use of micropipettes to measure the pressure drop across the pulmonary circulation.[6] In zone 3 conditions, where vascular resistance is not influenced by alveolar pressure, most of the resistance lies in pulmonary microvessels with nearly half of the total in alveolar capillaries (Fig. 6-3). These results indicate that the diameters of small pulmonary arteries and capillaries account for the greater part of pressure drop across the pulmonary vascular bed. This finding is in striking contrast to the systemic circulation, in which the greatest pressure drop occurs in arterioles.

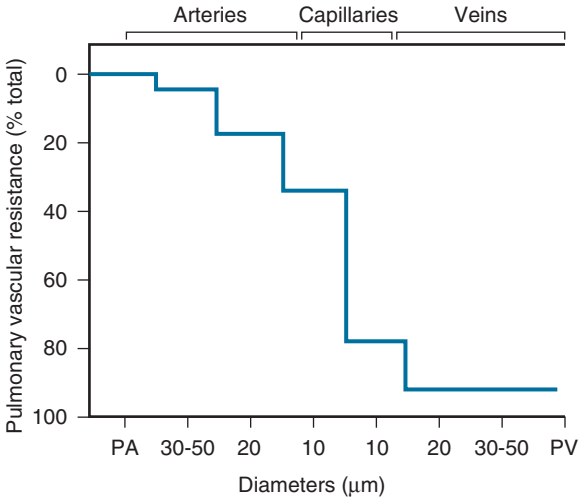

FIGURE 6-3 ■ Distribution of vascular resistance as determined by micropuncture measurement of pressures. Unlike the situation in the systemic circulation, most of the vascular resistance in the pulmonary circuit is in the capillaries. Measurements were made in subpleural vessels of isolated dog lung under zone 3 conditions. (Redrawn from Bhattacharya J, Staub NC: Direct measurement of microvascular pressures in isolated perfused dog lung. Science 210:327–328, 1980.)

Other investigators have used indirect approaches to measure the distribution of vascular resistance, such as observing vascular pressures after rapid vascular occlusion or injection with a low-viscosity bolus.[1] These techniques localize vascular resistance sites in relation to sites of vascular volume or compliance. Vascular occlusion experiments have localized nearly half of the vascular resistance within a central compartment that also includes 75% of the vascular compliance.[7] Because these compartments are defined functionally rather than anatomically, the central compartment may include small arteries and veins in addition to capillaries. Models of this type are particularly useful in identifying sites of vascular action of neural humoral mediators. Hypoxia primarily constricts arteries, as does sympathetic stimulation and serotonin, whereas histamine primarily constricts veins, and catecholamines increase both arterial and venous resistance.[2]

Functional Description of Pulmonary Vessels

The diameter of any vessel is determined by the transmural pressure difference, defined as the pressure difference acting across the vessel wall; that is, intraluminal (or intravascular) pressure (Piv) minus perivascular (or interstitial hydrostatic) pressure (Pi). The transmural pressure difference (Piv – Pi) is important in determining the diameter of pulmonary vessels because of the distensible nature of the pulmonary vascular bed. An increase in intraluminal pressure (e.g., secondary to increased left atrial pressure) increases transmural pressure and thus dilates pulmonary vessels. A decrease in perivascular pressure also dilates pulmonary vessels.

The intrapulmonary vascular tree is subdivided into three major types of vessels that are defined by the

pressures around the vessel: *extra-alveolar, alveolar,* and *corner vessels.*[1] The definitions of these three types of vessels are based on functional rather than anatomic descriptions, but in general, extra-alveolar vessels are considered to be pre- and postcapillary vessels in series with alveolar vessels, which are the capillaries.

Extra-Alveolar Vessels. Extra-alveolar vessels are defined as the intrapulmonary vessels affected by intrapleural pressure and *not* by alveolar pressure changes. The extra-alveolar vessels in the lung parenchyma are surrounded by collagen fibers, lymphatic vessels, and loose areolar tissue and include arteries, veins, venules, and arterioles. These vessels are affected by changes in pleural pressure and the closely related interstitial fluid pressure. Both pressures are the result of lung inflation and the recoil force generated by elastin in lung tissue. The pressure in the perivascular interstitial space surrounding the large pulmonary arteries or veins is somewhat more negative than the pleural pressure and becomes more so when the lung is inflated.[8] Changes in pleural or interstitial pressure have marked effects on the vascular caliber of extra-alveolar vessels. A decrease in the pleural pressure such as that occurring at high lung volumes passively dilates these vessels, whereas an increase in pleural pressure, such as that occurring at low lung volumes compresses the vessels.

Alveolar Vessels. These vessels are the capillaries within the interalveolar septa, which are surrounded by alveoli and are subjected to alveolar pressure and *not* to pleural pressure: thus, an increase in alveolar pressure compresses these vessels. The perivascular tissue of the septa consists of the extracellular matrix, whose constituents include fibronectin, laminin, heparan sulfate, and collagen fibrils. As the lung expands, the alveolar wall, which is pleated at functional residual capacity, unfolds,[9] and connective tissue elements in the wall change their conformation. Because of the surface tension of the layer of surfactant at the air-liquid interface, the actual pericapillary pressure is normally slightly less than the alveolar pressure,[10] but is always higher than the pressure around extra-alveolar vessels.[1]

Corner Vessels. These vessels are capillaries embedded in the thick alveolar-capillary septum between three alveoli or within pleats in alveolar walls.[9] Corner vessels are distinguishable from capillaries in the thin septum (the alveolar vessels), and hence are not subject only to changes in alveolar pressure. Alveolar vessels are compressed by increases in the alveolar pressure, whereas the corner vessels remain patent.[11] Corner vessels bypass the alveoli, and allow septal tissue to remain perfused in the presence of increases in alveolar pressure.

Mechanical Effects on Pulmonary Vascular Resistance

Transmural Pressure. The importance of transmural pressure is highlighted by the experiments described in Figures 6-4 and 6-5. At a controlled P_{LA} (see Fig. 6-4), increases in P_{PA} cause a decrease in PVR, but the effect is progressively less as P_{LA} is raised.[12] This indicates that the vessels are nearly maximally dilated at high levels of

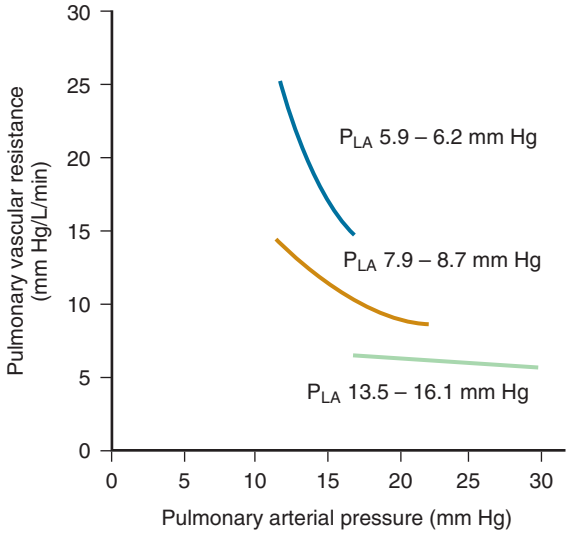

FIGURE 6-4 ■ Pulmonary vascular resistance depends on pulmonary arterial pressure. As pulmonary arterial pressure increases as a result of increasing flow, vessels are distended and resistance falls. This effect is diminished at higher left atrial pressures (P_{LA}) because the vascular bed is near maximal distention. (Data from Borst HG, McGregor M, Whittenberger JL, Berglund E: Influence of pulmonary arterial and left atrial pressures on pulmonary vascular resistance. Circ Res 4:393–399, 1956.)

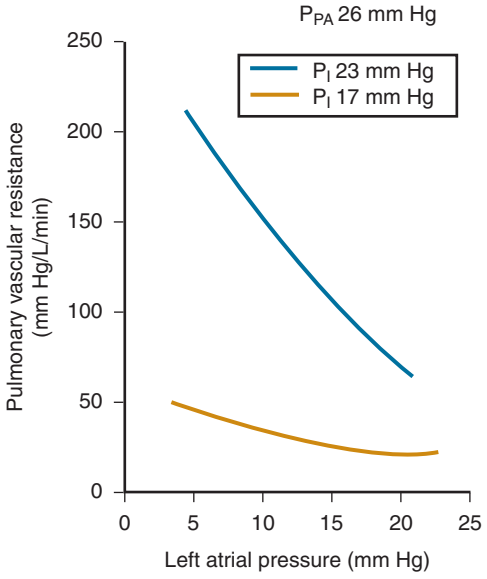

FIGURE 6-5 ■ Increases in left atrial pressure decrease pulmonary vascular resistance. In an isolated lung lobe, pulmonary artery pressure was held constant (P_{PA} = 26 mm Hg), the alveolar pressure was increased to either 23 or 17 mm Hg, pleural pressure was zero, and left atrial pressure varied. Pulmonary vascular resistance drops as left atrial pressure increases because the higher transmural pressure dilates vessels. The curves are for two different levels of lung inflation pressure. At higher inflation pressures (P_I) and lung volumes, vascular resistance is increased at all levels of left atrial pressure because alveolar vessels are stretched and compressed (see Fig. 6-6). (Data from Roos A, Thomas LJ Jr, Nagel EL, Prommas DC: Pulmonary vascular resistance as determined by lung inflation and vascular pressures. J Appl Physiol 16:77–84, 1961.)

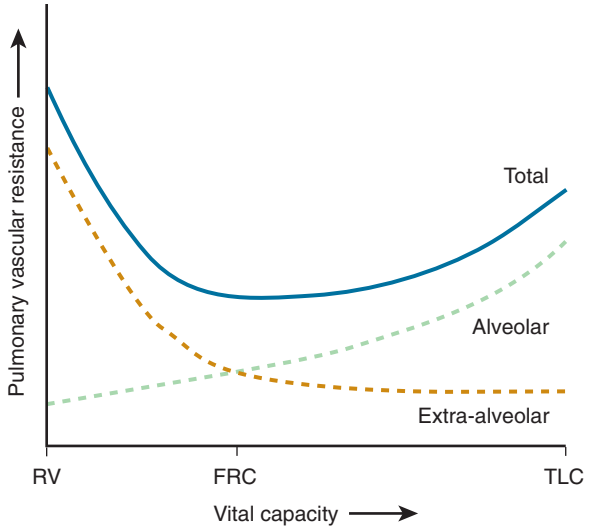

FIGURE 6-6 ■ Pulmonary vascular resistance increases as lung volume is decreased from functional residual capacity (FRC) to residual volume (RV) because of the influence of rising intrapleural pressure on extra-alveolar vessels. Resistance also increases with lung inflation from FRC to total lung capacity (TLC) because of stretched and flattened alveolar vessels. (Redrawn from Murray JF: The Normal Lung [2nd ed]. Philadelphia: WB Saunders, 1986.)

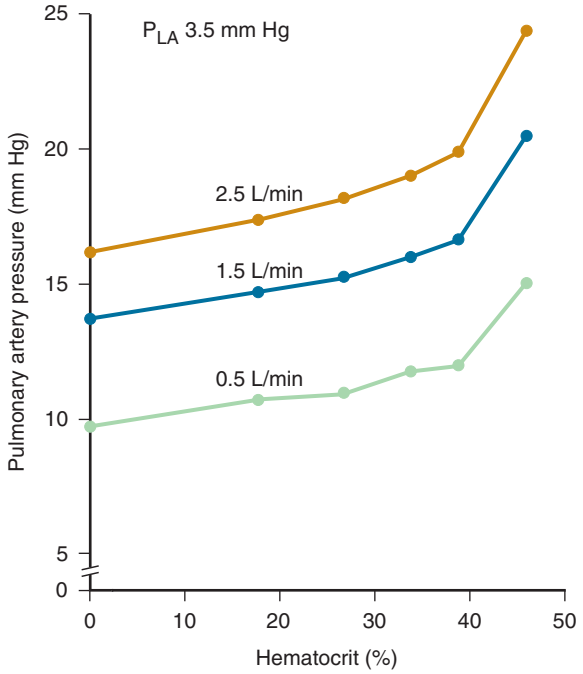

FIGURE 6-7 ■ Effect of hematocrit on pulmonary artery pressure at three levels of blood flow (0.5, 1.5, and 2.5 L/min are depicted). Left atrial pressure (P_{LA}) was held constant at 3.5 mm Hg. As hematocrit is increased at constant levels of pulmonary flow, pulmonary artery pressure increases, reflecting the higher vascular resistance caused by increased blood viscosity. (Redrawn from Murray JF, Karp RB, Nadel JA: Viscosity effects on pressure-flow relations and vascular resistance in dogs' lungs. J Appl Physiol 27:336–341, 1969.)

P_{LA} and that, once this occurs, additional increases in transmural pressure brought on by elevating P_{PA} do not produce further marked decreases in PVR. A similar phenomenon is demonstrated in Figure 6-5, where P_{LA} is increased at two different levels of transpulmonary pressure (23 and 17 mm Hg) while P_{PA} is held constant throughout. As P_{LA} is increased, PVR decreases because transmural pressure increases and vessels are progressively distended.[13] At a constant P_{PA} and P_{LA}, PVR is increased at the higher level of transpulmonary pressure because alveolar vessels are compressed by high alveolar pressures.

Lung Volume. A change in lung volume has opposite effects on the caliber of alveolar and extra-alveolar vessels, as shown in Figure 6-6. During lung inflation from residual volume to total lung capacity, resistance of alveolar vessels progressively increases, whereas resistance of extra-alveolar vessels progressively decreases. Alveolar vessels are compressed and elongated as lung volume increases. In contrast, interstitial pressure surrounding extra-alveolar vessels decreases, and the increased transmural pressure causes a decrease in resistance of these vessels. Corner vessels are also subjected to this same interstitial pressure and thus show a decreased resistance with lung inflation. Because the resistances of alveolar and extra-alveolar vessels are in series, the resistances add and the change in PVR forms a "U"-shaped curve, with the nadir of the curve operating at approximately functional residual capacity, the usual end-expiratory lung volume.

Viscosity. The viscosity term (η) of Poiseuille's formula (Equation 2) predicts that an increase in blood viscosity produces a proportional increase in PVR. The primary factor determining viscosity of the blood is the hematocrit.[14] Viscosity is also a function of the deformability of red blood cells in pulmonary microvessels and the viscosity of plasma. Figure 6-7 shows the effects of changes in the hematocrit on pulmonary arterial pressure at three levels of blood flow. After each level of blood flow, it is evident that blood hematocrit values over 40% cause increases in P_{PA} and PVR.

Pulmonary Vascular Compliance

Pulmonary Vascular Pressure-Volume Curve

The pulmonary vasculature is a highly compliant circuit, and pulmonary blood volume normally constitutes about 10% of total blood volume. The distribution of blood volume among the arterial, capillary, and venous volumes, however, varies among species, and depends on techniques of measurement and whether the arteries, capillaries, and veins are defined functionally or anatomically. Human capillary blood volume has been functionally estimated[15] to be approximately 75 mL, or about 10% to 20% of total pulmonary blood volume, but estimates in animals have generally shown a higher proportion of pulmonary blood volume within the capillaries[2]; for example, by morphologic methods, between 60 and 200 mL, or one third of total pulmonary blood volume, has been localized in capillaries.[16]

The pressure-volume curve of the pulmonary vasculature is linear at low levels of pulmonary perfusion pressure, with small changes in volume resulting in small changes in pressure, but becomes nonlinear at higher pressures, at which small changes in volume cause large pressure changes. Pulmonary vascular compliance is defined as $\Delta V/\Delta P$, where ΔV is the change in pulmonary vascular volume and ΔP is the change in transmural pressure. Microvessels are usually identified as the primary site of vascular compliance,[17] although others have postulated that larger pulmonary vessels may contribute to the compliance.

Changes in Vascular Compliance

Pulmonary vascular compliance is regulated by alterations in sympathetic nerve activity; compliance decreases with sympathetic activation.[18] The pulmonary circulation serves as a vascular reservoir that responds to sympathetic stimulation by increasing left atrial filling pressure and increasing cardiac output. Pulmonary vascular compliance can also be influenced by changes in lung volume secondary to alterations in intrapleural pressure. Because a substantial fraction of blood volume is localized in large pulmonary arteries and veins, which are largely extra-alveolar vessels, lung inflation increases transmural pressure, passively enlarges these vessels, and thereby increases blood volume within the pulmonary circuit. Reduction in lung volume has the opposite effect of reducing pulmonary blood volume within the pulmonary circuit.

Pulmonary Perfusion

Distention and Recruitment

Pulmonary microvessels can be recruited (i.e., new vessels are "brought into play" in the microcirculation) or already-perfused vessels can be distended (i.e., vessels dilate as a result of increased transmural pressure). The question of which process occurs in response to increasing the pulmonary capillary pressure—or more importantly, which is the dominant process under a particular circumstance—is unresolved. (See also Fig. 4-9 and related discussion.) There are regional differences in the relative importance of recruitment and distention of pulmonary vessels. Alveolar vessels in the upper lung regions (zone 1) are more likely to be recruited when transmural pressure rises, because vessels are normally collapsed in this region; both recruitment and distention occur in zone 2 conditions because of the uneven perfusion in this region; and distention is likely to predominate in zone 3 vessels when transmural pressure rises, because this lung region is more uniformly perfused than other regions.

Distribution of Pulmonary Blood Flow

Because of gravity and the prevailing low pulmonary artery perfusion pressure, the regional distribution of blood flow within the lung varies considerably. The factors that govern intrapulmonary blood flow were largely defined during the 1960s in a series of elegant experiments by West and coworkers, which are described in detail in Chapter 4. The model that unites all these factors (see Fig. 4-11) subdivides the lung into three perfusion zones depending on the relationships among mean P_{PA}, mean P_{PV}, and P_{alv}.

Zone 1 is the region of the lung in which $P_{alv} > P_{PA} > P_{PV}$ and, in theory, there is no blood flow because alveolar vessels are collapsed; in reality, however, blood flow persists to some extent because pericapillary pressure in zone 1 is slightly lower than P_{alv}; because corner vessels are not subject to changes in P_{alv}; and because of the pulsatile nature of pulmonary capillary pressure, with intermittent bursts of flow occurring during systole.

Zone 2 is the region of the lung in which $P_{PA} > P_{alv} > P_{PV}$. Accordingly, blood flow begins just below the level of lung where $P_{PA} = P_{alv}$ and progressively increases, moving linearly downward from there; pulmonary perfusion in zone 2 is determined by the $P_{PA} - P_{alv}$ difference, rather than the conventional arterial minus *venous* pressure difference.

Zone 3 is the more dependent region of the lung in which $P_{PA} > P_{PV} > P_{alv}$. As conditions move downward, even though P_{PA} and P_{PV} increase by the same amount, perfusion increases within the zone because the increasing intravascular pressures progressively dilate vessels, which lowers regional vascular resistance and causes blood flow to steadily increase. The preponderance of blood flow in zone 3 in comparison with the other zones favors gas exchange because other factors (also described in Chapter 4) cause ventilation to be preferentially distributed to this region.

To describe conditions in the most dependent portion of the lung, zone 4 was added to account for the factors that decrease regional perfusion from the peak observed in zone 3. Blood flow in zone 4 is not determined by the relationships among P_{PA}, P_{PV}, and P_{alv}, but by lung volume and other local conditions at the base of the lung that affect the caliber of blood vessels, which are fully described in Chapter 4.

Because of the prevailing intravascular pressures, there is no zone 1 in the lung of healthy humans under ordinary conditions, even when upright (see Fig. 56-2). Most of the normal lung functions in zone 3 conditions, and only the uppermost region is in zone 2. However, a decrease in intravascular pressures, as in hemorrhagic shock, or an increase in intra-alveolar pressure, as with mechanical ventilation—especially with positive end-expiratory pressure—expands zone 2 and possibly creates zone 1. Variations to the zone-gravity model have been proposed by Hlastala and Glenny[19]; they continue to emphasize the role of gravity in determining blood flow distribution, but their conceptual framework incorporates additional concepts of fractal vascular trees and perfusion heterogeneity, and suggests that the structure of the pulmonary vascular system is an additional critical factor in determining regional blood flow.

Mechanical Stress and Strain

The pulsatile nature of blood pressure and flow exposes blood vessels to constant hemodynamic forces in the form of cyclic stretch and shear stress. The endothelium converts these mechanical stimuli to intracellular signals that affect cellular functions, including proliferation, migration, remodeling, apoptosis, and permeability, as well as gene expression. The cytoskeleton is the key structural framework for the endothelial cells to transmit mechanical forces between its luminal, abluminal, and junctional surfaces to its interior, including the cytoplasm, nucleus, and focal adhesion sites. Changes in mechanical stress activate multiple sensing mechanisms and signaling networks in endothelial cells, resulting in physiologic and pathologic functional responses.

Shear Stress

The flow of blood parallel to the vessel surface produces fluid shear stress from the friction of blood against the vessel wall. Endothelial cells are the primary vascular cells exposed to shear stress from laminar blood flow. The response of endothelial cells to physiologic levels of shear stress serves a number of regulatory functions, including vascular remodeling via the production of growth-promoting and growth-inhibiting substances; the modulation of hemostasis and thrombosis through the secretion of procoagulant, anticoagulant, and fibrinolytic agents; inflammation through the expression of chemotactic and adhesion molecules on membrane surfaces; and vascular smooth muscle cell contraction through the release of vasodilators and vasoconstrictors.[20] Endothelial cell perfusion at the physiologic shear rate of 10 dynes/cm^2 has been associated with barrier enhancement (see later discussion and Fig. 6-15), suggesting that shear stress is important in normal barrier maintainance.[21] Furthermore, disruption or unsteady blood flow at atherosclerosis-prone regions of blood vessels can impair these functions, leading to proatherogenic and/or prothrombotic states. Endothelial cells use multiple sensors for shear stress, including membrane receptors such as integrins, vascular endothelial growth factor receptor-2, ion channels, and platelet endothelial cell adhesion molecule-1.[22] These sensors can interact with each other and transactivate multiple signaling pathways,[23] including p38 and p42/44 mitogen-activated protein kinase, tyrosine kinase, and focal adhesion kinase, leading to differential gene expression,[20] as well as rapid actin cytoskeletal rearrangement as evidenced by flow-directed reorientation of the endothelium.[24]

Shear stress also serves a protective role by reducing endothelial cell turnover through inhibition of cell proliferation and suppression of apoptosis via activation of both p53 and the PI3K-Akt survival pathway, and nitric oxide production. The variability of vessel properties along with the pulsatile nature of blood flow results in temporal and spatial variations of shear stress on the vessel wall. In the straight part of the vessel, blood flows undisturbed with a mean shear rate of 10 to 70 dynes/cm^2. However, blood flow patterns in the bends and bifurcations are disturbed with eddies in which peak shear rates can exceed 100 dynes/cm^2. Thus, the nature of blood flow has varying effects on the endothelium depending on the microenvironment of the vasculature.[25]

Cyclic Stretch

Another important mechanical force generated in the lung circulation either by circulating blood, which results in the rhythmic, pulsatile distention of the arterial wall, or by tidal breathing, is cyclic stretch (CS). Blood pressure is the major determinant of vessel stretch, although arterial wall distention normally does not exceed 10% to 12% stretch.[26–28] Similar to shear stress, cyclic stretch induces reorientation of the endothelium, but transverse to the direction of strain.[26,29] Cultured endothelial cells stretched at 5% CS for 2 hours activate Rac signaling[30] and induce redistribution of actin[26] and cortactin[30] (an actin-binding protein) toward the cell periphery. Furthermore, in comparison to static conditions, physiologic stretch induces desensitization to edemagenic agents, as evidenced by the reduction of thrombin-induced paracellular gap formation.[26,30] In contrast, excessive distention of 18% CS induces Rho activation and increased sensitivity to edemagenic agonists.[26,29]

Long-term cyclic stretch increases the content of signaling and contractile proteins, including Rho GTPase, myosin light chains, myosin light chain kinase, ZIP kinase, PAR1, caldesmon, and hsp27, suggesting regulation at both the translational and posttranslational levels.[26,31] Chronic increased blood pressure activates vascular cell proliferation, collagen, and fibronectin synthesis, which results in thickening of the vascular wall leading to hypertension-induced vascular remodeling. Clinically, acute lung overdistention caused by mechanical ventilation at high tidal volumes can also induce remodeling of extracellular matrix constituents such as collagen, elastin, proteoglycans, glycosaminoglycans, and matrix metalloproteinases.[32] This reorganization, in part, influences cellular responses to mechanical stress via increased inflammatory cytokine production, macrophage activation, acute inflammation, and barrier dysfunction resulting in pulmonary edema. Reduction in tidal volume causes less extracellular matrix disorganization[32] and has improved patient mortality from ventilator-induced lung injury.[33]

Pulmonary Vascular Response to Hypoxia

Response Elements

Alveolar hypoxia, an alveolar P_{O_2} of less than 70 mm Hg, typically elicits pulmonary vasoconstriction. In general, experiments with isolated lungs, perfused in either the forward or reverse direction and ventilated with a variety of gas mixtures, have shown that the most important stimulus for vasoconstriction is alveolar hypoxia, as opposed to the P_{O_2} of pulmonary arterial blood.[2] The basis of increased resistance is constriction of small precapillary vessels.[34] Although smaller arteries constrict,

larger arteries dilate in response to elevated pressures,[34,35] and pulmonary veins do not constrict.[35] The vasoconstrictor response to hypoxia is unique to lungs in that local exposure of systemic vessels to hypoxia results in vasodilation. Hypoxic pulmonary vasoconstriction serves a regulatory function in matching perfusion to ventilation by redirecting perfusion away from poorly oxygenated (i.e., hypoxic) regions of the lung. Alveolar hypoxia in a lung segment causes significant diversion of blood flow to the normoxic lung.

Neurohumoral signals generated during hypoxia have been invoked to explain the response, but the basis of the constriction still remains unknown (recently reviewed by Stenmark and colleagues[36]). A major limitation in understanding the mechanisms has been the inability to obtain smooth muscle cells of microvessels of pulmonary arteries, the primary sites of contraction during hypoxia, which retain their contractile phenotype. Because the hypoxic pulmonary vasoconstrictor response occurs in isolated-perfused lungs and in isolated small (<300 μm) pulmonary arteries,[37] it is unlikely that it is directly the result of nerve stimulation. However, local activation of peptidergic nerves and axon reflexes cannot be discounted. Studies over the years have failed to identify blood-borne or released mediators to account for the hypoxic vasoconstriction response. Mediators such as catecholamines, histamine, serotonin, angiotensin II, thromboxane, leukotrienes C_4 and D_4, endothelin, and platelet-activating factor do not appear to be primarily responsible for hypoxic vasoconstriction,[2] although they can modulate the magnitude of the hypoxic response by influencing the basal pulmonary vasomotor tone. There exists the possibility that there may be a complex interplay between these mediators or that an unidentified chemical mediator is responsible. Several candidates have been now identified by genomic strategies.[38]

Chronic exposure to hypoxia increases the muscular content of small arteries, which are normally devoid of smooth muscle. People native to high altitude in the Andes have been shown to have increased muscularization of arteries as small as 20 μm,[39] which suggests differential responsiveness to growth factors such as platelet-derived growth factor that induce vascular smooth muscle cell proliferation. Not all high-altitude natives have shown this increase in muscularization, nor do all animals that live at high altitudes, which indicates a differential response to growth factors or differences in their release, neither of which is dependent simply on long-term residence at high altitude. Both cellular influences, which involve vascular smooth muscle cells, endothelial cells, and fibroblasts, and molecular mechanisms, such as release of vascular endothelial growth factor, are responsible for the pulmonary vascular remodeling seen during hypoxia.[40]

The increase in PVR induced by hypoxia is augmented by increases in plasma hydrogen ion concentration and in partial pressure of carbon dioxide, but only as it affects pH.[41] Intracellular mechanisms activated by hypoxia may also be activated by intracellular hydrogen ion concentration. The increased hydrogen ion concentration in pulmonary vascular smooth muscle cells resulting from hypoxia or elevated carbon dioxide is an important intracellular signal mediating the interaction between actin and myosin filaments and thus vascular tone.

Cyclooxygenase inhibitors (e.g., indomethacin) augment the hypoxic pulmonary vasoconstrictor response. Inhibition of the cyclooxygenase cascade, which prevents prostacyclin generation, is a likely basis of indomethacin-induced augmentation of vasoconstriction. An increase in left atrial pressure and in blood volume can prevent the hypoxia-induced pulmonary vasoconstriction, which indicates that transmural pressure changes influence the response.

A significant factor with the potential of influencing the hypoxic pulmonary vasoconstrictor response is nitric oxide (NO). Vasodilation of pulmonary artery rings in response to acetylcholine was found to depend on an intact endothelium that releases NO.[42] Antagonists of endothelium-dependent relaxation potentiated the hypoxic pulmonary vasoconstriction.[43] Pulmonary vascular endothelial cells activated by hypoxia may not release NO to the same extent as systemic vessels; thus, absence of the moderating influence of NO could lead to hypoxia-induced pulmonary vasoconstriction. Therefore, the magnitude of hypoxic pulmonary vasoconstriction is related to the concomitant generation of NO.

There are other endothelium-derived relaxing factors (besides NO), because not all endothelium-dependent vascular smooth muscle relaxation can be fully prevented by inhibitors of the L-arginine–NO generating pathway. Endothelium-derived hyperpolarizing factor (EDHF) is the likely mediator of endothelium-derived relaxation that cannot be attributed to NO.[44] EDHF mediates its vasodilator effect by causing the Ca^{2+}-dependent K^+ channels to open, leading to hyperpolarization.[45] However, the role of EDHF in the control of basal pulmonary vasomotor vasoconstriction in general and in hypoxic pulmonary vasoconstriction in particular is not yet known.

A constricting factor, the peptide endothelin, is released by both systemic and pulmonary endothelial cells by hypoxia.[46] Because removal of the endothelium from isolated pulmonary artery strips abolishes hypoxia-induced vasoconstriction,[46] this peptide may be involved in hypoxic pulmonary vasoconstriction. However, these experiments were made with arteries larger than those generally considered to be responsible for hypoxic pulmonary vasoconstriction.

Because the search for a chemical mediator has been unsuccessful, investigators have proposed mechanisms whereby hypoxia has a direct effect on vascular smooth muscle cells. This has led to the redox theory, which postulates that the proximal mitochondria electron transport chain serves as an oxygen-sensing unit that decreases production of reactive oxygen species in response to hypoxia, resulting in a decrease in superoxide or H_2O_2, thereby inhibiting the K^+ channel that elicits membrane depolarization.[47] This in turn leads to opening of a Ca^{2+} channel and influx of Ca^{2+}-mediating contraction of pulmonary arterial smooth muscle.[47] Because metabolic inhibitors enhance hypoxic vasoconstriction,

hypoxia-induced decrease in oxidative phosphorylation has also been suggested as a possible mechanism.[48] Evidence of energy failure has not been found except at such low oxygen levels that vessels actually dilate rather than constrict.[49] However, it is likely that changes in oxidative phosphorylation may be a sensing and signal transduction mechanism that activates the inhibition of K^+ channels.[48]

Vasoconstriction is likely mediated by an increase in intracellular calcium ion concentration ($[Ca^{2+}]_i$) in smooth muscle cells, the "Ca^{2+} hypothesis."[50] The increased $[Ca^{2+}]_i$ combines with the Ca^{2+}-binding protein calmodulin to activate the enzyme myosin light chain kinase (MLCK), resulting in the phosphorylation of myosin and contraction. Ca^{2+} channel blockers inhibited and Ca^{2+} channel agonists enhanced the hypoxia-induced constriction of pulmonary vessels.[51] At the same time, hypoxia augments RhoA- and Rho kinase–mediated Ca^{2+} sensitization, resulting in increased RhoA and Rho kinase activity with consequent dephosphorylation of myosin light chain phosphatase and further increased myosin light chain phosphorylation effecting contraction.[52] The importance of Rho kinase signaling in this context is suggested by the attenuation of hypoxia-induced pulmonary vasoconstriction in mice treated with a Rho kinase inhibitor.[53] Ca^{2+} influx may occur in response to membrane depolarization induced by hypoxia,[54] with resulting increased Ca^{2+} permeability, release of intracellular stores of Ca^{2+}, or both. It is not clear how hypoxia causes depolarization of pulmonary vascular smooth muscle membrane or whether this leads to the influx of Ca^{2+} via voltage-gated channels responsible for activating pulmonary vascular smooth muscle contractility.

Neural Regulation of Pulmonary Vascular Resistance

Adrenergic and cholinergic efferent nerves are present in pulmonary arteries and veins in all mammals in which innervation has been examined. However, there is considerable variation in the distribution and amount of innervation. Innervation of the pulmonary vasculature is typically less than that of the systemic arterial vessels. The concentration of fibers is greatest in large vessels and at branch points and decreases in smaller vessels.[55] α-Adrenergic receptors predominate in the pulmonary vascular bed, particularly in the fetal circulation, where there is high basal vasomotor tone and greater reactivity to α-adrenergic stimulation. Stimulation of α-adrenergic receptors mediates the constriction of pulmonary vessels, whereas β-adrenergic receptors mediate dilation. Stimulation of the sympathetic nerve efferents characteristically produces pulmonary vasoconstriction and decreased distensibility of pulmonary vessels.[56] α-Adrenergic mechanisms probably contribute little to normal adult pulmonary vasomotor tone. Blockade of the α-adrenergic receptors with receptor antagonists modifies neither baseline pulmonary vasomotor tone nor the response to hypoxia. Because pulmonary vessels are normally in a dilated state, β-adrenergic responses are not evident. However, β-adrenergic blockade enhances the vasoconstrictor response to catecholamines, which stimulate both α- and β-receptors, and increases in tone augment responses to β-adrenergic agents.[57]

There is limited understanding of the functional significance of sympathetic and parasympathetic innervation of pulmonary vessels. It is unclear why the pulmonary vascular bed is so richly innervated and yet stimulation of these nerves produces relatively small changes in vasomotor tone in the adult lung. One possibility is that neural mechanisms balance the distribution of vascular resistance and compliance in the pulmonary vascular bed and thereby finely regulate regional and total pulmonary perfusion.[1] It is also possible that vasodilator influences (i.e., NO, EDHF, and prostacyclin [PGI_2]) normally predominate and thus mask the constrictor effect of sympathetic stimulation.

Humoral Regulation of Pulmonary Vascular Resistance

Numerous pulmonary vasoconstrictor mediators, as reviewed by Barnes and Liu,[58] have been identified. These include norepinephrine (a stimulator of α-adrenergic receptors), angiotensin II, histamine, endothelin, serotonin, thromboxane, leukotrienes C_4 and D_4, and platelet-activating factor.[1] These mediators bind to their receptors on pulmonary vascular smooth muscle cells and induce pulmonary vascular smooth muscle contraction by activation of second messenger pathways. As in the peripheral circulation, changes in pulmonary vasomotor tone induced by these constrictors are regulated by NO.[59]

Various pulmonary vasodilator substances have also been identified. These include acetylcholine, which mediates its effects in part by NO release; bradykinin, which has heterogeneous responses with direct as well as NO-dependent actions; PGI_2; and prostaglandin E_1.[59,60] It is important to note that the magnitude of the effects of both pulmonary vasoconstrictors and vasodilators is dependent on the species and initial baseline pulmonary vasomotor tone. The latter is particularly important because pulmonary vasoconstrictors such as platelet-activating factor induce constriction in the pulmonary vascular bed when it has low basal tone, whereas they are potent dilators during elevated pulmonary vascular tone.[60] The basis for this divergent effect is unclear but may reflect differential activation of second messenger pathways in pulmonary vascular smooth muscle cells in the basal state in comparison with conditions of increased tone.

In addition to angiotensin II, however, the role of the renin-angiotensin system in pulmonary vascular regulation is now well recognized. Angiotensin II, a key component of the renin-angiotensin system, is generated primarily by angiotensin-converting enzyme (ACE) from angiotensin I, and its effects are mediated through angiotensin type I (AT-1) and type II (AT-2) receptors, both of which are expressed in the normal lung.[61] The pulmonary endothelium represents a major site of ACE

expression and angiotensin II production.[62] Notably, ACE2 is a homologue of ACE expressed in the lung that inactivates angiotensin II, leading to the downstream generation of angiotensin-(1-7), which acts through AT-2 receptors to induce vasodilation, serving as a counterbalance to the vasoconstrictive effects of angiotensin II through AT-1 receptors. Although components of the renin-angiotensin system have been implicated in a variety of lung diseases, including pulmonary hypertension and fibrotic lung diseases, the system has been most strongly linked to the pathophysiology of pulmonary vascular leak syndromes. For example, ACE2 serves as the receptor for the coronavirus responsible for severe acute respiratory syndrome (SARS), first identified in 2003.[63] The significant mortality rate from SARS—greater than 50% in patients older than 65—is largely attributable to the subsequent development of acute respiratory distress syndrome (ARDS), which is characterized by profound lung vascular leak.[64] ACE and AT-2 have been found to serve a protective role in ARDS, whereas ACE2, angiotensin II, and AT-1 appear to mediate lung edema and injury associated with ARDS.[65]

LUNG FLUID AND SOLUTE EXCHANGE

Pulmonary edema is defined as the accumulation of water in the lungs' extravascular spaces. It occurs in a sequential process, first developing in the hilar region of the lungs followed by fluid filling of the interstitial compartment. Finally, fluid enters the alveoli in an all-or-nothing manner.[66] When associated with alveolar flooding, pulmonary edema becomes a cataclysmic event that results in impaired gas exchange and arterial hypoxemia. The healthy lung consists of about 80% water, as measured gravimetrically. The characteristics of fluid exchange between the vascular space and interstitium of lungs have been reviewed by Taylor and Parker[67] and Staub,[66] and factors regulating pulmonary vascular endothelial permeability have been reviewed by Dudek and Garcia[68] and more recently by Mehta and Malik.[69]

Pathogenesis of Pulmonary Edema

Sites of Fluid Accumulation

In addition to the longitudinal gradient in the interstitial fluid pressure from the alveolar septum to the lung hilum (as discussed in a later section and illustrated in Fig. 6-13), there are vertical pressure gradients within the pulmonary circulation. The vertical gradients are the result of differences in hydrostatic pressure in pulmonary microvessels at different lung heights, vertical pleural fluid pressure, and regional lung volume. A greater capillary hydrostatic pressure in the dependent lung regions favors edema formation in these regions. Although it is predicted from this that there should be greater lung water content in the dependent lungs, no such vertical gradient has been found by either measurement of extravascular lung water content or morphometric determinations of the interstitial space.[70,71] Because the gradient of alveolar-septal fluid pressure to small vessel adventitial pressure is greater in the lung apex than in the lung base, there is likely to be greater accumulation of fluid in the extravascular space of the upper lung than in the dependent lung, even though the fluid filtration rate is greater in the dependent lung region.[67]

Fluid that cannot be cleared by the lymphatic channels accumulates in the connective tissue surrounding smaller vessels and bronchioles.[72] The fluid migrates down the interstitial fluid pressure gradient to interstitial spaces around larger vessels and airways. If lymphatics in the connective tissue sheaths are unable to remove the excess fluid, undrained fluid becomes compartmentalized and forms perivascular cuffs.[73] After an increase in the interstitial fluid volume from 35% to 50%, individual alveoli begin to flood in an all-or-nothing manner.[72] Initially, the distribution of alveolar flooding is patchy, but this is followed by rapid flooding.

The exact route by which fluid moves into the alveoli is not known. Fluid movement may involve bulk flow through large epithelial pores or channels or may be the result of increased transport through intercellular pathways in respiratory epithelium of terminal bronchioles,[72] with the possibility of epithelial detachment from the underlying matrix resulting in movement of fluid directly into the alveoli.[74]

Mechanisms of Pulmonary Edema

Increased Pulmonary Capillary Pressure. The relationship between left atrial pressure and the rate of formation of pulmonary edema is shown in Figure 6-8. For

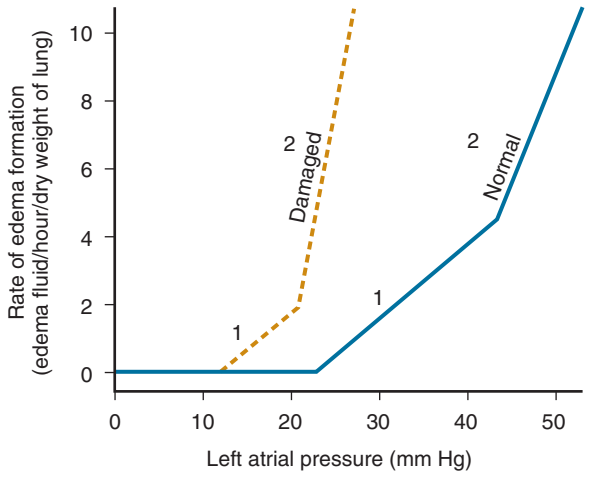

FIGURE 6-8 ■ Graph showing the rate of edema formation as a function of left atrial pressure. In the normal lung (*solid line*), edema does not form until left atrial pressure exceeds 20 to 25 mm Hg. Above this pressure, edema forms slowly at first (1), and then more rapidly (2) at higher pressures. If the endothelium is damaged (*dashed line*) or if plasma colloid osmotic pressure is reduced, then edema begins to form at lower left atrial pressures. (Redrawn from Guyton AC, Lindsay AW: Effect of elevated left atrial pressure and decreased plasma protein concentration in the development of pulmonary edema. Circ Res 7:649–653, 1959.)

left atrial pressures up to 20 to 25 mm Hg, water content does not increase in the normal lung.[75] The water content begins to increase only when the pulmonary capillary pressure reaches a critical value. Fluid accumulation in the lung is minimized by "safety factors" that are activated below this critical capillary pressure.[67] The pulmonary extravascular water content increases progressively as a result of the inability of these safety factors to reduce fluid filtration rate after capillary hydrostatic pressure increases above the critical value. The primary safety factors (discussed later) are the increase in lymph flow, decrease in interstitial colloid osmotic pressure, increase in interstitial hydrostatic pressure, and decrease in albumin exclusion volume. These changes serve to minimize the increase in the extravascular lung water content when left atrial pressure is increased.

Decreased Plasma Oncotic Pressure. A decrease in the plasma protein concentration, such as in hypoalbuminemia, reduces the intravascular absorptive pressure and thus increases the net transcapillary filtration pressure. In this case, the critical capillary pressure at which lungs begin to gain water decreases in direct proportion to the reduction in plasma oncotic pressure (see Fig. 6-8).[67]

Increased Lung Vascular Permeability. Two general pathways allow movement and flow of fluid, macromolecules, and leukocytes into the interstitium and subsequently into the alveolar air spaces to produce clinically significant pulmonary edema during inflammatory lung processes. The transcellular pathway utilizes a tyrosine kinase–dependent, gp60-mediated transcytotic albumin route whose regulation and function are unclear, but that may serve to uncouple protein and fluid permeability.[76] However, there is general consensus that the primary mode of fluid and transendothelial leukocyte trafficking occurs by the paracellular pathway,[68] as shown by electron microscopy studies that demonstrate the formation of paracellular gaps at sites of active inflammation within the vasculature.[77]

The mechanisms mediating alterations in pulmonary vascular endothelial permeability occurring as a result of a variety of mechanical stress factors, inflammatory mediators, and activated neutrophil products (such as reactive oxygen species, proteases, and cationic peptides) have been discussed earlier. The critical functional definition of increased lung vascular permeability is the extravasation of protein-rich fluid into the interstitial space and ultimately into the alveolar space,[72] resulting in fulminant pulmonary edema. In high-permeability pulmonary edema, the alveolar fluid protein concentration approximates the plasma protein concentration, whereas in hydrostatic edema (i.e., edema resulting from increase in the pulmonary capillary hydrostatic pressure), the ratio of alveolar fluid to plasma protein concentration is usually less than 0.6.[67] The increase in lung vascular permeability shifts the relationship between left atrial pressure and pulmonary extravascular water content to the left (see Fig. 6-8).

Lymphatic Insufficiency. The lymphatic vessels are capable of removing excess extravascular fluid because of their effectiveness as pumps. Lymphatic propulsion is determined by the intrinsic contractility of lymphatic vessels, by inspiration and expiration, and by lymphatic valves, which account for the unidirectional lymph flow.[72] Lymphatics, however, have a limited capacity to increase lymph flow, as shown in Figure 6-9. Beyond their critical capacity, the lymph flow does not increase in direct proportion to the increase in interstitial fluid volume and may actually decrease because of compression of the lymphatic channels.[78] The extent to which lymphatic insufficiency serves as an important mechanism of fluid accumulation in the lung is not clear. Some studies have indicated that surgical removal of the lymphatics predisposes the lung to edema, although the increase in water content is usually transient.[79]

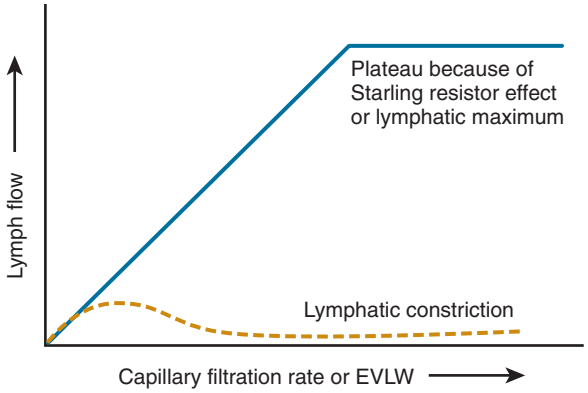

FIGURE 6-9 ■ Graph showing the relationship between capillary filtration rate and lymph flow in the normal lung (*solid line*) and with increased lymphatic resistance (*dashed line*). In a normal lung, the lymph flow plateau is reached because of pressure effects of the increase in interstitial fluid volume (Starling resistor effect), as well as attainment of maximum lymph flow, whereas with lymphatic constriction or obstruction the capillary fluid filtration rate continues, but without a concomitant increase in lymph flow. (Redrawn from Malik AB: Mechanisms of neurogenic pulmonary edema. Circ Res 57:1–20, 1985.)

Safety Factors in Lung Fluid Homeostasis. The safety factors that were mentioned in the discussion of increased pulmonary capillary pressure become operative when fluid begins to accumulate in the interstitial space. A decrease in the exclusion volume for albumin (or an increase in its actual volume of distribution) merits particular attention because it is important in decreasing the interstitial protein concentration and thereby decreasing interstitial colloid osmotic pressure. Albumin is normally excluded from approximately 40% of the pulmonary interstitial space by the matrix proteins collagen, hyaluronic acid, and laminin.[67] An increase in the interstitial fluid volume disrupts the structure of interstitial matrix proteins and decreases the albumin exclusion volume (Fig. 6-10A); this, in turn, increases the volume available for albumin equilibration, which allows albumin protein concentration to decrease. Therefore, the increase in the albumin distribution volume amplifies the decrease in interstitial colloid osmotic pressure, which would not drop to the same extent without the concomitant decrease in the exclusion volume. Figure 6-10B indicates the effect of albumin exclusion on the colloid

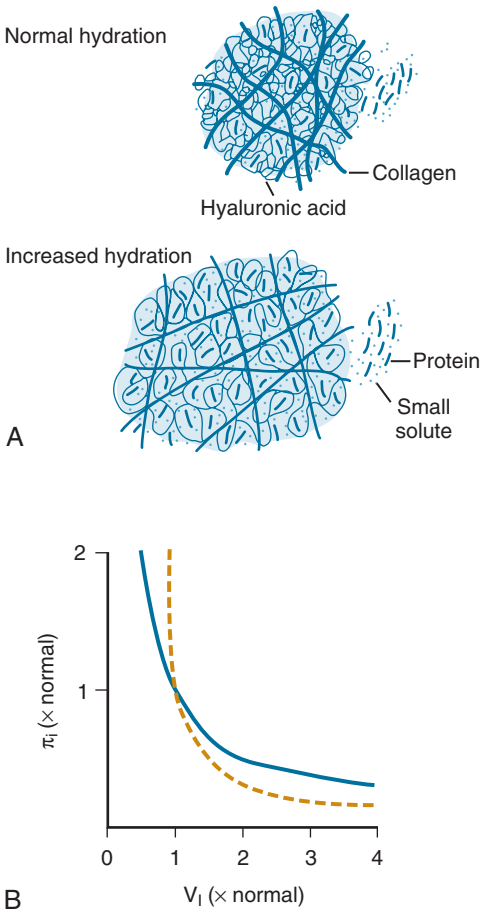

FIGURE 6-10 ■ **A,** Schematic diagram showing the pulmonary interstitial matrix. Normally, protein is excluded from 40% of the interstitial space. When interstitial water content increases, the matrix is disrupted and the exclusion volume decreases, making more of the matrix accessible to proteins. The increased distribution volume helps to maintain a lower concentration of protein and decreased colloid osmotic pressure than would otherwise occur. (Redrawn from Parker JC, Falgout HJ, Parker RE, et al: The effect of fluid volume loading on exclusion of interstitial albumin and lymph flow in the dog lung. Circ Res 45:440–450, 1979.) **B,** With an increase in interstitial volume (V_I), the colloid osmotic pressure (π_i) of extravascular proteins decreases. The *solid line* represents the decrease in π_i occurring by dilution of a fixed interstitial space when V_I increases. The *dashed line* is the decrease in π_i that occurs when exclusion volume is initially present and is decreased with increasing V_I. (Redrawn from Taylor AE, Parker JC, Kvietys PR, Perry M: Pulmonary interstitium in capillary exchange. Ann N Y Acad Sci 384:148–168, 1982.)

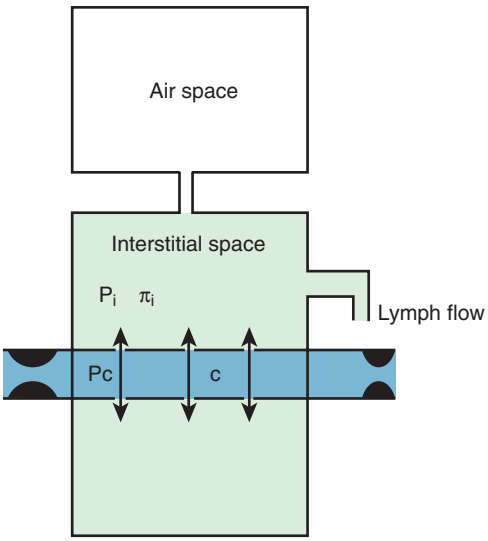

FIGURE 6-11 ■ Schematic representation of the pulmonary capillary tissue–lymphatic system. Starling's forces are capillary hydrostatic pressure (Pc), plasma colloid osmotic pressure (πc), interstitial hydrostatic pressure (P_i), and colloid osmotic pressure of tissue fluid (π_i). The alveolar epithelial junctions are tight compared with the interendothelial junctions in lung and thereby restrict solute transport into the air spaces. The *background shading* represent plasma proteins in plasma, tissue fluid, and lymph. The lymph flow represents the overflow in the system, that is, the difference between the amount of fluid filtered and the amount reabsorbed. A major determinant of Pc is the precapillary-to-postcapillary resistance ratio as regulated by the smooth muscle tone of the arteries and veins, represented by the narrowings in the precapillary and postcapillary vessels. (Redrawn from Malik AB: Mechanisms of neurogenic pulmonary edema. Circ Res 57:1–20, 1985.)

osmotic pressure when the interstitial fluid volume is increased. For the same increase in the interstitial fluid volume, the interstitial oncotic pressure is lower when albumin exclusion is decreased, indicating the critical role of this safety factor.[67] In addition, the role of the bronchial circulation in lung fluid balance edema generation and/or clearance has received attention by virtue of its ability to modulate lymph clearance under basal conditions and after lung injury.[34,80]

Transcapillary Exchange

Fluid Flux Equation

The Starling equation describes filtration of fluid across the capillary wall. The equation states:

$$Jv = LpS[(Pc - Pi) - \sigma d(\pi c - \pi i)] \quad (3)$$

where Jv is the net transcapillary filtration rate (in cm^3/sec), Lp is the hydraulic conductivity of the membrane, S is the surface area, Pc is the pulmonary capillary hydrostatic pressure, Pi is the interstitial hydrostatic pressure, πc is the capillary plasma colloid osmotic (or oncotic) pressure, and πi is the interstitial fluid colloid osmotic (oncotic) pressure. The term σd is the osmotic reflection coefficient of the vessel wall; σd = 0 if the membrane is freely permeable to the molecules crossing the membrane, and σd = 1 if the membrane "rejects" the molecule, thus being impermeable. Because albumin is the dominant plasma protein in terms of concentration, we consider here primarily the σd of albumin. LpS has been defined as the capillary filtration coefficient (Kf,c).

According to convention, Pc acts outward (i.e., from the vessel to the extravascular space) and Pi acts inward, whereas πc acts inward and πi acts outward (Fig. 6-11). The direction and magnitude of movement of water

across the vessel wall are determined by the sum of hydrostatic and colloid osmotic pressure differences across the wall. Pc + πi constitutes the driving force for filtration, and πc + Pi is the driving force for absorption. The ability of these pressures, called the *Starling forces,* to determine filtration and absorption is dependent on the semipermeable nature of the endothelial barrier—that is, the ability of the endothelial barrier to restrict the free flux of plasma proteins. Therefore, plasma and interstitial colloid osmotic pressures are a direct function of plasma and interstitial protein concentrations, respectively.

Because Pc decreases along the alveolar capillary, filtration is more likely to occur at the arterial end of the pulmonary capillary, and absorption at the venous end. However, this is an idealized situation, because some vessels only filter fluid and other vessels only absorb it. Regional pulmonary capillary pressures determine whether vessels filter or absorb fluid. Dilation of a small pulmonary artery increases Pc, and this increases net transcapillary filtration rate, whereas a constricted pulmonary artery reduces Pc, and this increases net absorption rate. Only about 2% to 5% of the plasma perfusing the pulmonary circulation is filtered, and of this, 80% to 90% is absorbed back into capillaries and venules. The residual fluid in the extravascular space ultimately enters the lymphatic circulation, through which it is returned to the circulation.[67]

In the healthy human lung, the Starling forces have defined average values. Pc at mid-lung level is 10 mm Hg, Pi is −3 mm Hg, πc is 25 mm Hg, and πi is 19 mm Hg.[67] The most accurate of these pressures is πc, which is a direct function of plasma protein concentration and thus can be easily determined by an osmometer. The other values are determined indirectly and hence represent best estimates.

The summation of Starling's forces in the lung indicates that there is a net outward filtration pressure. Assuming that σd = 1 and, according to the values just given, the net filtration pressure is 7 mm Hg. This indicates that filtration across pulmonary vessels is greater than absorption. It must be noted that Pc and Pi in the lungs vary according to the height in the lung. When upright, both pressures are greater in the dependent regions of the lung than in the lung apex.

The slightly negative Pi value within alveolar septae results from the retractile force of the layer of surfactant at the air-liquid interface; the more negative Pi values toward the hilum are generated by the elastic wall tension of vessels and radial traction exerted by the alveolar attachment sites during lung inflation.[67] Increasing lung volume decreases Pi at both sites, whereas a reduction in lung volume increases Pi.

The total osmotic pressure of plasma is approximately 6000 mm Hg, whereas the colloid osmotic (or oncotic) pressure is only 25 mm Hg. The oncotic pressure plays a critical role in fluid exchange across the vessel wall because the barrier is semipermeable to plasma proteins. In contrast, electrolytes (which are responsible for most of the osmotic pressure of 6000 mm Hg) rapidly equilibrate on both sides of the vessel wall.

The transcapillary oncotic pressure gradient (Δπ = πc − πi) is determined by the albumin concentration gradient:

$$\Delta\pi = \sigma d RT(Civ - Ci) \quad (4)$$

where R is the gas constant, T is the absolute temperature, σd is the albumin osmotic reflection coefficient, and Civ and Ci are the intravascular and interstitial albumin concentrations, respectively. The equation indicates that Δπ varies in proportion to the transcapillary albumin concentration difference (Civ − Ci), which implies that, as a result of increased permeability and the beginning of albumin leakage from the vessel, a decrease in (Civ − Ci) causes a decrease in Δπ. It is also important to note from this equation that the effective Δπ is determined by σd, which is dependent on the permeability characteristic of the vessel (see subsequent explanation).

To determine LpS or Kf,c experimentally, a known change is made in either the hydrostatic or osmotic gradient, and the change in Jv is measured.[67] Quantitative inferences regarding hydraulic conductivity can then be made. Such inferences must be made carefully, however, because changes in surface area secondary to recruitment of pulmonary capillaries will also change Kf,c.

The reflection coefficient (σd) defines the permeability of the transported molecule across the capillary. The reflection coefficient is a critical constant in determining the effective Δπ value. The reflection coefficient for albumin, which does not pass freely across the pulmonary endothelial barrier, is 0.8.[67] Albumin σd decreases when endothelial albumin permeability is increased. A decrease in σd results in a decrease in Δπ, which then becomes less of an absorptive force offsetting the hydrostatic force favoring filtration.

Solute Flux Equation

The movement of solutes across the porous endothelial barrier (Js) is often defined by the linear equation of Kedem and Katchalsky[81]:

$$Js = Jv(1 - \sigma f)Cm + PS(\Delta C) \quad (5)$$

where Cm is the mean concentration of the solute within the endothelial pores (or interendothelial junctional clefts), σf is the solvent drag reflection coefficient,[82] PS is the permeability surface area product, and ΔC is solute concentration difference across the endothelial monolayer. The first term, Jv(1 − σf)Cm, represents the convective transport of solute or ultrafiltration. The second term, PS(ΔC), represents the diffusive transport of solute. Cm is the mean concentration of solute in the membrane and is therefore between the concentration on the blood side and the lower concentration on the interstitial side. It can be taken as the average only at very low levels of Jv and approaches blood concentration at high Jv.[82] Under ideal conditions, σd = σf, but ideal conditions often do not apply. Because of this and because Cm is usually unknown, Equation 5 is useful only under relatively limited experimental conditions.[67] Specialized equations that consider multiple pores and the effects of

protein and barrier charge as well as effect of Jv and protein concentrations within the pore are beyond the scope of this text.

Diffusion

Diffusion is a key factor in the delivery of gases and solutes across vessel walls. Diffusion is described by the following equation:

$$J = DA\left(\frac{dc}{dx}\right) \quad (6)$$

where J is flux or amount of substance transferred per unit time, D is diffusibility of the membrane for a particular molecule, A is the diffusional pathway cross-sectional area, and dc/dx is the concentration gradient of the solute across the membrane. The component of solute flux that is due to diffusion can also be written as J = PS(Civ − Ci), where P is capillary permeability of the substance, S is the capillary surface area, Civ is the intravascular concentration of substance within the capillary, and Ci is concentration of substance in the interstitial liquid.

Diffusion of solutes varies according to characteristics of the solute. Diffusion of lipid-insoluble macromolecules such as proteins is restricted to pores (or interendothelial junctions). Only approximately 0.02% of the capillary surface area constitutes the so-called pores.[83] Diffusion of these molecules becomes restricted at molecular weights above 60 kD because the size of the molecule is greater than that of the junctional pores. The permeability of these molecules is also influenced by their electrostatic charge in relation to the negative charge on endothelial cell membrane as well as charge interactions between molecules.[84] In addition to paracellular transport through junctions, transport of macromolecules such as albumin also occurs by means of vesicles involving a transcytotic mechanism.[85] There is evidence that transcytosis of albumin across the endothelial barrier (which does not fit the standard model described by the solute flux equation) is governed by a 60-kD albumin "docking" molecule or receptor that activates the signaling machinery responsible for formation of vesicles and their transport to the basolateral membrane.[85]

Sites of Fluid and Solute Exchange

Capillary Endothelium

It is important to note that most of the fluid and solute exchange occurs at the level of the pulmonary microvascular endothelium, which is of the continuous nonfenestrated type, because this layer has the largest surface area available for both diffusion and filtration. Several pathways are available for transport of solutes and water: vesicles, interendothelial junctions, and transendothelial channels. Low-molecular-weight lipid-soluble substances and water can diffuse directly through endothelial cells (transcellular pathway) as well as between cells (paracellular pathway). Lipid-soluble (lipophilic) molecules such as carbon dioxide and oxygen diffuse rapidly across the entire capillary endothelial surface area. Water also freely crosses the entire surface area of the membrane by means of aquaporin water channels.[86] Macromolecules and low-molecular-weight water-soluble molecules are transported via interendothelial junctions as well as the transcellular route. The molecular basis of the endothelial transport pathways is summarized in Figure 6-12, which demonstrates the interactions at the level of the intercellular junctions, the extracellular matrix, and a specific vesicular pathway.[85,87–92]

Because lymph provides an estimate of interstitial fluid concentrations of various solutes, the lymph-to-plasma concentration ratio (CL/CP) of solutes and the radius of these solutes can be measured to provide an approximation of the sieving characteristic of pulmonary microvessel endothelial cells.[82] The plasma concentration of these solutes remains constant, but there is a decrease in the lymph concentration with an increase in the solute radius. This finding emphasizes the size-selective nature of the pulmonary microvascular endothelial barrier.[82]

Another important characteristic of the pulmonary capillary wall barrier is the extracellular matrix, which consists of a complex array of molecules: laminin, type I and type IV collagen, proteoglycans, fibronectin, and vitronectin.[67] The three-dimensional arrangement of matrix proteins provides a restrictive barrier to the transport of molecules, and the matrix can sieve molecules of different molecular weights.[93] Therefore, both endothelium and extracellular matrix are barriers to solute transport. Increases in vascular permeability may be the result of alterations in one or both of these barriers.

Alveolar Epithelium

Alveolar epithelial type I and type II cells lining the terminal alveoli serve as a barrier to movement of water and solutes into the alveolar space. The calculated interepithelial junctional radius is only approximately 2 Å, much smaller than the junctional radius of the pulmonary endothelial cells, and differs considerably from that in the pulmonary artery.[94] Most lipid-insoluble molecules do not cross the epithelial barrier. Water and ions can penetrate this barrier only to a limited degree, whereas low-molecular-weight lipid-soluble substances such as oxygen and carbon dioxide are freely permeable.

Alveolar-Capillary Septum

The alveolar-capillary barriers have both thin and thick portions, as described previously. The thick septum is defined by its greater interstitial space, which is filled with connective tissue fibers, type I and type IV collagen, laminin, fibronectin, vitronectin, and proteoglycans. Fluid and solute exchange occurs primarily in the thick septum because it is the more compliant portion of the barrier. Gas exchange occurs through the thin portion of the septum, which is a relatively noncompliant space because endothelial and epithelial cells are virtually adherent to each other.[67]

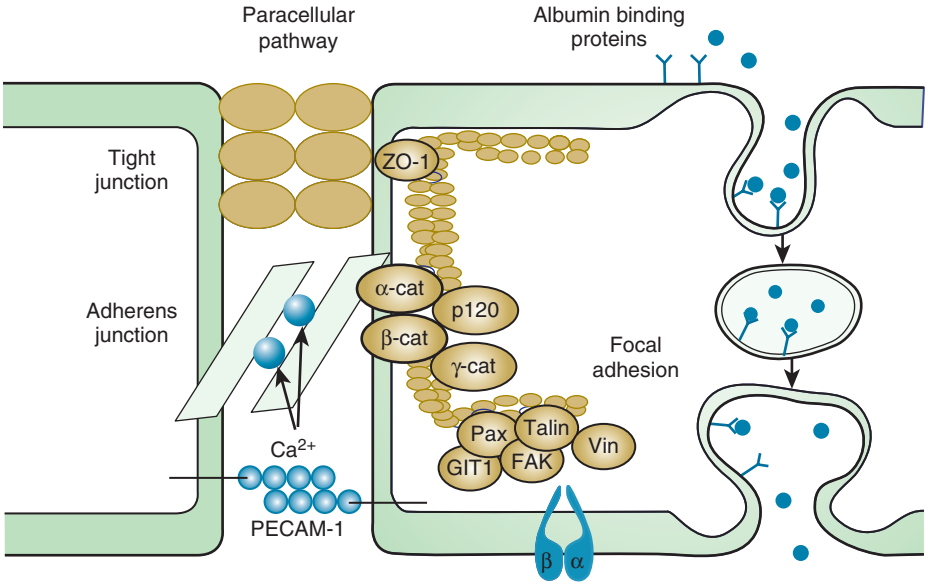

FIGURE 6-12 ■ Schematic representation of molecular pathways of transendothelial transport. In a **paracellular pathway** of diffuse transport at intercellular junctions, there is polar organization of tight and adherens junctions of endothelial cells and interactions of linking proteins that form junctions. Solutes of less than 7.5-nm radius (e.g., albumin is 3.6 nm) can diffuse through junctions. Cell-cell connections include tight junctions composed of transmembrane-occluding proteins linked to the actin cytoskeleton by the zona occludens family (ZO-1); adherens junctions mediated by Ca^{2+}-dependent association of cadherin proteins in turn linked to the α-, β-, and γ-catenin (cat) complex; and platelet-endothelial cell adhesion molecule-1 (PECAM-1)–associated junctions. Cell-matrix tethering is maintained by focal adhesion plaques composed of α- and β-integrin transmembrane proteins linked to the actin cytoskeleton by a complex of proteins, including talin, paxillin (Pax), vinculin (Vin), and focal adhesion kinase (FAK). Fibronectin and vitronectin are in the subendothelial matrix compartment and are bound by integrin receptors that span plasma membrane. Endothelial cells maintain tight connections with each other and the underlying matrix to tilt the balance toward increased barrier integrity. In a **transcellular pathway** of vesicular (nondiffusive) transport, vesicular transport of albumin occurs by either solid- or fluid-phase pathways. The endothelial cell surface expresses albumin-binding proteins (Y) that bind albumin (*solid circles*). Formation of vesicles contain albumin bound to albumin-binding proteins and those free in cytosol. The vesicle membrane fuses with the abluminal cell membrane, and albumin bound to binding protein and free albumin are extruded to the abluminal side. (For references, see text.)

Pulmonary Lymphatic Vessels

The lung has an extensive network of lymphatic channels that are involved in the drainage of fluid and solutes and trafficking of lymphocytes and other blood-formed elements. The terminal lymphatics are found in loose areolar tissue surrounding pulmonary vessels and, to some extent, in the thick interstitial septum. There are two primary interstitial compartments, the extra-alveolar and alveolar, and lymphatics are largely confined to the extra-alveolar interstitium. Fluid is believed to leak from capillaries in the alveolar walls and move toward the spaces surrounding airways, where it enters the distal ends of lymphatics.[66] The fluid in the alveolar walls is presumably propelled by the prevailing pressure gradient toward the extra-alveolar space.[8] The pulmonary lymph flow increases in response to increased interstitial fluid volume (see Fig. 6-9), reflecting the ability of pulmonary lymphatics to drain the lung interstitial compartment. However, the relationship between interstitial fluid volume and lymph flow is not linear. Beyond a critical fluid volume, pulmonary lymph flow can no longer increase in proportion to the increase in fluid volume. This "lymphatic failure" may be related to impaired pumping or propulsive force of lymphatics, constriction of terminal lymphatics by extravascular fluid compression, and compartmentalization of fluid in the alveoli in such a way that it is inaccessible to the lymphatic system. Whatever the mechanism of "lymphatic failure," the relative inability to adequately drain the interstitium is a primary cause of edema formation.[66]

Lung Interstitium

Interstitial Pressures

An interstitial liquid pressure gradient has been measured from the alveolar wall to the lung hilum.[8] As indicated in Figure 6-13, interstitial pressure decreases from the alveoli to hilar interstitial space. This decrease in pressure is the basis for interstitial drainage of the liquid filtered across the microvessels. The filtered fluid moves along the interstitial fluid pressure gradient into the connective tissue surrounding the pulmonary artery, airways, and veins.[66] The lymphatic vessels of the perivascular space then effectively drain this excess fluid. When fluid filtration exceeds the pumping capacity of the lymphatic system, fluid first accumulates in the hilar regions and in sheaths around the large pulmonary vessels, where pressure is lowest and interstitial compliance is highest. This

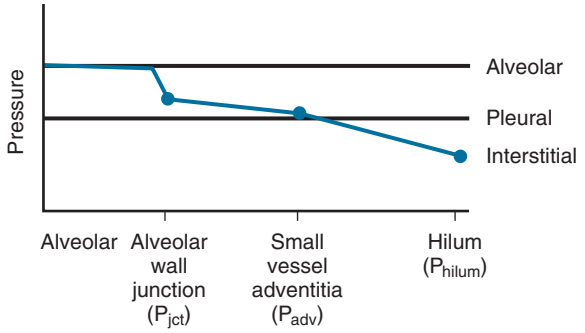

FIGURE 6-13 ■ Pressure gradient in the interstitium of the lung. Fluid from alveolar vessels in the thick septa moves down the pressure gradient to alveolar wall junctions (P_{ict}), to the adventitia surrounding small vessels (P_{adv}), and to the hilum (P_{hilum}). Experiments were done in isolated dog lung with an alveolar pressure of 5 cm H_2O and a pleural pressure of 0 cm H_2O, and pressures were measured at the hilum, in small vessel adventitia, and at the alveolar wall junction. (Redrawn from Staub NC: Pathophysiology of pulmonary edema. *In* Staub NC, Taylor AE [eds]: Edema. New York: Raven, 1984, pp 719–746.)

accounts for the "cuffs" of fluid that are typically observed around vessels in edematous lungs and that are often visible near the hila in chest radiographs.

Interstitial Compliance

The compliance of interstitial tissue is a nonlinear function and has two phases[95]: a low compliance at low interstitial fluid volumes and high compliance during the interstitial edema or alveolar flooding phase. At low levels of tissue hydration, tissue pressure changes markedly in response to a small change in tissue volume, indicative of low tissue compliance. Tissue expands with increased levels of hydration, and compliance increases dramatically. The increase in compliance occurs as the tissue fluid pressure approaches alveolar pressure. At an interstitial fluid pressure of greater than zero (i.e., values greater than the alveolar pressure), the tissue fluid accumulates with only a small change in the interstitial pressure. The high-compliance portion of the curve may represent the transition from interstitial edema to alveolar edema[67]; that is, the pressure inflection point may be the maximum interstitial volume before alveolar flooding occurs. This inflection point occurs at a lung weight gain of 35% to 50% and an interstitial pressure of 2 to 3 cm H_2O.[1] The abrupt increase in compliance attenuates further increases in interstitial hydrostatic pressure, which might forestall edema formation.

The lung is unique in that there are regional differences in compliance of the lung interstitium. The interstitial spaces surrounding large vessels or bronchi have higher compliance than interstitium in the septal region.[95] Once the perivascular spaces surrounding extra-alveolar vessels and bronchi are filled with fluid, the interstitial pressures equilibrate throughout the interstitial space. The continuing high level of fluid filtration then increases interstitial pressure to a critical level, and the epithelial barrier is breached (potentially facilitated by injury to the alveolar epithelium), resulting in rapid flooding of alveoli.[67]

Transvascular Transport of Plasma Molecules

A list of the factors governing the transport of plasma proteins across the vascular endothelial monolayer is presented in Table 6-1. As is evident from this list, these factors can be subdivided into plasma and hemodynamic forces, properties of the permeant molecules, and properties of the lung endothelium and the underlying extracellular matrix.

Capillary Endothelial Permeability

Pore Theory

The pore theory describes the transport of lipid-insoluble molecules according to their size through cylindric or long, slit-shaped water-filled channels between endothelial cells, although it does not distinguish the type of paracellular pathway by which these molecules are transported (these pathways are listed in Table 6-2). Pore theory is based on the premise that selected areas form a system of "pores" whose combined total area represents less than 0.02% of the total endothelial surface area.[83] The size selectivity of the endothelial monolayer for plasma proteins is determined by the ratio of molecular radius to pore radius.[96] In most analyses, the heterogeneous pore radii in vascular endothelial cells range from 5 to 280 Å. The ratio of small to large pores is estimated to range from 30,000 : 1 for dextran transport[97] to 438 : 1 for lymph protein fluxes.[82] Albumin

TABLE 6-2. Routes of Endothelial Transport of Lipid-Insoluble Molecules

Transcellular (Cell Membrane)

Consists of three barriers in series (plasma membrane, cytoplasm, plasma membrane).

Vesicles

Involves equilibration of luminal and abluminal fluids.

Transport may be dependent on concentration gradient and rate of vesicular turnover.

Small and Large "Pores"

Continuous route exists from the luminal to the abluminal sides.

Flux of water and solutes across these pathways can be diffusive and convective.

Diffusive and convective transport may be coupled.

Molecular sieving (i.e., restriction of solute permeation as molecular size approaches the pore dimension) is a characteristic of pore pathways.

Fused Plasmalemmal Channels

Created by transient fusion of two or more vesicles.

Exhibit the same characteristics as junctional large pores.

TABLE 6-3. Physical Characteristics of Tracer Molecules Used to Determine Selectivity of the Pulmonary Vascular Endothelial Barrier

Molecule	Molecule Weight (kD)	Stokes-Einstein Radius (Å)	D_{37}*
Mannitol	0.182	4.4	0.9
Sucrose	0.342	5.2	0.721
Inulin	5.5	11–15	0.296
Cytochrome *c*	12	16.5	0.13†

BSA, bovine serum albumin.

molecules have a Stokes-Einstein radius of 36 Å, and therefore are transported through both large and small pores.

The pathways of fluid and solute exchange across the continuous pulmonary vascular endothelial cell monolayer are shown in Figure 6-12. Lymph has long been used to make inferences about the pore sizes of the endothelial barrier in many studies involving assessment of lung vascular permeability,[66] although several caveats exist. One caveat is that that lymph solutes become concentrated during their passage through the lymphatic circulation,[82,98] indicating that lymph may not necessarily reflect the interstitial fluid or events occurring at the endothelial barrier. Despite these caveats, much valuable information has been obtained from these studies on the mechanism of increased vascular permeability in the intact pulmonary microcirculation.[82]

In an attempt to validate the pore theory, selectivity of the pulmonary vascular endothelial cell barrier (i.e., the monolayer without its constituent extracellular matrix components) for different-sized molecules (varying from 0.18 to 340 kD and listed in Table 6-3) was determined with the use of cultured endothelial monolayers.[99] Predictably, the permeability of the endothelial monolayer to tracer molecules decreased with increasing molecular weight. The transendothelial flux of protein fractions in a 20% fetal calf serum solution confirmed the selective nature of the cultured endothelium in contrast to lack of selectivity of gelatin-coated microporous filters without the endothelial monolayer. When modeled according to the pore theory, these data better represent a two-pore model; the calculated pore radii were 65 Å and 304 Å for small- and large-pore pathways, respectively, and the ratio of small pores to large pores was 160:1.[99] Neutral dextrans with molecular weights of 6 to 500 kD also diffused across the endothelium in a similar manner. Thus, the endothelial barrier discriminates between solutes according to their molecular size, and size selectivity is consistent with a diffusional pathway through pores of heterogeneous radii. Two critical shortcomings of the pore theory, however, are that it does not account for either molecule-pore interactions that result from frictional and electrostatic effects within these hypothetical pores[95] or the vesicular transport of these molecules.[92]

Mechanisms of Increased Endothelial Permeability

In the following sections, some of the important mechanisms contributing to the increase in pulmonary vascular permeability are discussed. Specific mechanisms are covered in greater detail in reviews by Dudek and Garcia[68] and by Minshall et al.[85]

Characteristics of Increased Vascular Endothelial Permeability. A variety of bioactive agonists, cytokines, growth factors, and mechanical forces alter pulmonary vascular barrier properties and serve to increase vascular permeability.[6,68,100,101] The serine protease thrombin represents an ideal model for the examination of agonist-mediated lung endothelial activation and barrier dysfunction (Fig. 6-14). Thrombin evokes numerous endothelial cell responses that regulate hemostasis, thrombosis, and vessel wall pathophysiology and is recognized as an important mediator in the pathogenesis of acute lung injury[68] (discussed in detail in Chapter 55). Thrombin increases endothelial leakiness to macromolecules by ligating its specific cell membrane receptor, resulting in cell activation.[102,103] Direct activation by thrombin is dependent upon its ability to proteolytically cleave the extracellular NH_2-terminal domain of the PAR-1 receptor, a member of the family of proteinase-activated receptors (PARs).[102,103] The cleaved NH_2-terminus, acting as a tethered ligand, is then able to

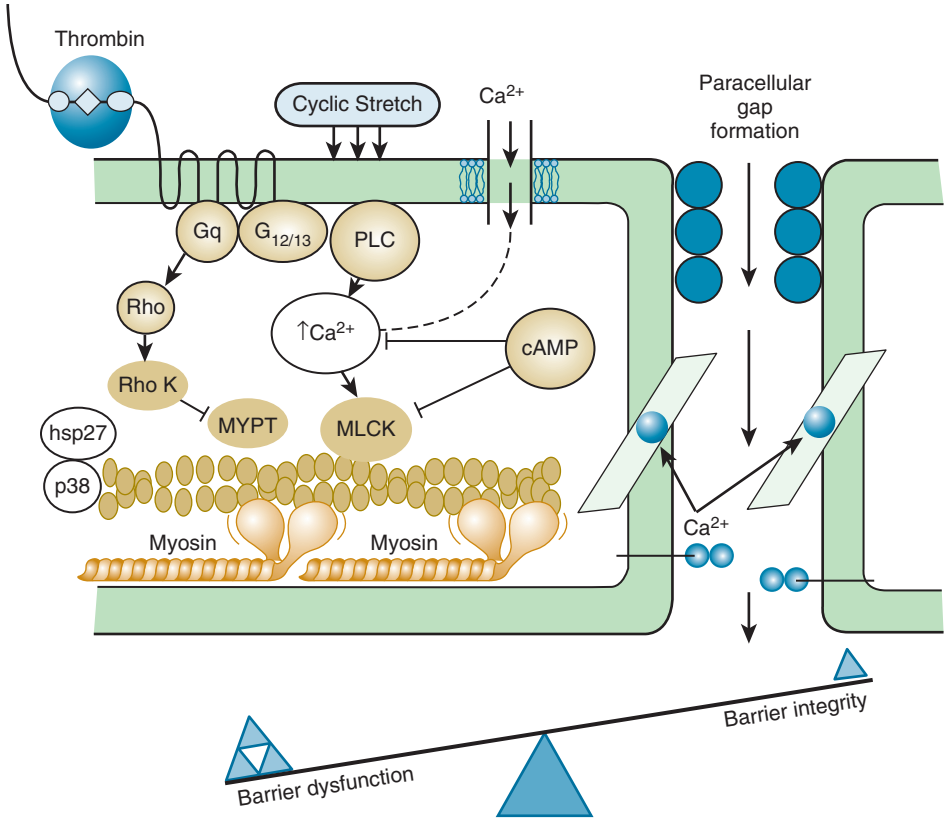

FIGURE 6-14 ■ Schematic depicting disruption in endothelial cell (EC) barrier homeostasis by thrombin. In this working model of barrier regulation, under basal conditions, a balance exists between actomyosin contractile and cellular adhesive forces. When contractile forces predominate, as depicted in the thrombin-stimulated model, ECs pull apart to form paracellular gaps, favoring barrier disruption. Thrombin cleavage of the PAR-1 receptor on the surface of EC activates both heterotrimeric G proteins (G_q, $G_{12/13}$) and small GTPases such as Rho. Activated Rho (Rho GTP) induces Rho kinase (Rho K), which via phosphorylation of the phosphatase regulatory subunit inhibits the myosin light chain phosphatase (MYPT). Rho kinase and myosin light chain kinase (MLCK) activation occurs via independent pathways. Increased cytosolic Ca^{2+} (via inositol triphosphate [IP_3] production) activates the Ca^{2+}/calmodulin-dependent MLCK, with conformational changes allowing the enzyme to access the preferred substrate (myosin light chain [MLC]). Rho kinase and MLCK activation both culminate in increased MLC phosphorylation, which in turn enables actomyosin contraction resulting in increased stress fiber formation, cellular contraction, paracellular gap formation, and ultimately barrier dysfunction. Increases in cyclic AMP (cAMP) influence both Ca^{2+} mobilization and MLCK activity. Also depicted are other representative regulatory proteins whose activity either increases or decreases EC tension. Inhibition of heat shock protein 27 (hsp27) activity, by p38 mitogen-activated protein kinase (MAPK)–catalyzed phosphorylation, also induces actin stress fiber formation, and the actin capping/severing protein gelsolin is likewise involved in stress fiber–dependent contraction.

activate the receptor and initiate a number of downstream effects, including the activation of phospholipases A_2, C, and D; increase in cytosolic Ca^{2+}; and release of von Willebrand factor, endothelin, NO, and PGI_2.[103–105] Thrombin binding alone without receptor cleavage is insufficient to elicit the complex signaling cascade that results in increased endothelial permeability.[104,106] The effect of thrombin on endothelial permeability is rapid (within 2 minutes) and reversible[101] and, like histamine, is critically dependent on G protein–transduced signals.[30,68] These intracellular signals result in increases in cytosolic calcium, activation of the contractile apparatus, and characteristic alterations in the cytoskeletal elements, a feature of other inflammatory mediators as well.[26,68,100,107]

Intracellular Ca^{2+} Shifts. The increase in vascular endothelial permeability is signaled in many edemagenic models by a rise in $[Ca^{2+}]_i$.[100,108] The thrombin-induced increase in pulmonary vascular permeability is partially inhibited by decreasing the availability of cytosolic Ca^{2+}.[103,109,110] The direct application of Ca^{2+} ionophore (to increase intracellular Ca^{2+}) also increased transendothelial albumin permeability,[110,111] decreased transendothelial electrical resistances, and increased hydraulic conductivity of intact microvessels.[111] Increased $[Ca^{2+}]_i$ may operate by signaling cytoskeletal rearrangement via actin polymerization/depolymerization that requires interactions of F-actin with actin-binding proteins.[68,112,113] This is now well appreciated to occur via activation of Ca^{2+}-dependent kinase systems (MLCK, Ca^{2+}/calmodulin-dependent kinase II, protein kinase C [PKC], etc.),[112–114] and phosphorylation of cytoskeletal proteins involved in endothelial barrier regulation, such as vimentin,[112,115] caldesmon,[115] β-catenin,[116] vinculin,[117] α-actinin,[118] myosin light chain (MLC),[109] filamin,[113] cortactin,[119] VASP,[120] and microtubule-associated proteins.[121]

Thrombin and other permeability-increasing agents such as histamine cause a rapid initial rise in cytosolic [Ca^{2+}] in pulmonary artery endothelial cells, followed by a second phase of slow decay.[103,122,123] The initial Ca^{2+} rise in endothelial cells is caused by mobilization from intracellular stores in response to increased inositol polyphosphate generation (particularly inositol 1,4,5-triphosphate) derived from phospholipase C–activated hydrolysis of phosphoinositides.[110,122] The second phase is caused by Ca^{2+} influx through store-operated channels[123] and, although not as well understood, this is the critical Ca^{2+} signal responsible for the increase in permeability.[124] Inhibition of the lipoxygenase pathway of arachidonate metabolism abolished this long-lived Ca^{2+} rise and changes in F-actin cytoskeletal reorganization,[125] which suggests that lipoxygenase products open Ca^{2+} channels and prolong the rise in $[Ca^{2+}]_i$, which in turn provides the signal for cytoskeletal reorganization. Lipoxygenase products, namely monohydroxyeicosatetraenoic acids (HETEs), directly increase lung vascular permeability by opening Ca^{2+} channels as described. HETEs thus generated may be messengers responsible for this second critical phase of the Ca^{2+} increase.[126]

Protein Kinase C Activation and Other Barrier-Regulatory Signals. Despite the clear contribution of MLCK/Rho kinase–driven increases in MLC phosphorylation to tension development and increased vascular permeability, alternate pathways that do not require an increase in MLC phosphorylation are also involved in barrier regulation. PKC is a family of serine/threonine kinases comprising at least 12 isotypes, with the conventional and novel isoforms of this kinase family requiring a rise in cytosolic Ca^{2+} for activation (see Siflinger-Birnboim and Johnson[127]). PKC-mediated pathways exert a prominent effect on barrier regulation in a time- and species-specific manner likely reflecting differences in PKC isotype-specific expression in different species[101,109,115]; PKC activation is also an important signal transduction pathway by which extracellular mediators, including thrombin, increase transendothelial albumin flux, and thus may be causally linked to phosphorylation of cytoskeletal proteins such as caldesmon, an actin-, myosin-, and calmodulin-binding protein present in actomyosin cross-bridges and stress fibers.[115] Finally, p60src kinase and p38 mitogen-activated protein (MAP) kinase activation also has been linked to endothelial stress fiber formation and contractile regulation, endothelial cell migration, and cytokine-induced permeability.[107,119,128] The mechanism through which p38 MAP kinases exert these effects is unclear but may involve the actin binding proteins caldesmon and hsp27, known p38 MAP kinase targets whose actin polymerization regulatory activity is influenced by phosphorylation.[109]

Basement Membrane and Matrix Components. Cell-matrix adhesions are essential for barrier maintenance and restoration and exist in dynamic equilibrium with endothelial contractile forces.[129] An organized basement membrane and extracellular matrix surrounding the endothelium may control transendothelial solute flux, and this may be dependent on particular extracellular matrix constituents (e.g., certain matrix proteins are known to restrict albumin transport because of the negative charge of their glycosaminoglycan constituents).[82] In vivo studies indicate that the interstitial matrix is capable of 14-fold reduction in diffusive transport of albumin.[130] Application of extracellular matrix consisting primarily of type I collagen to microporous filters produced a 10-fold reduction in the transport of albumin. Albumin restriction was not increased by coating the filters with fibronectin, which indicates that only certain matrix components impose a restrictive barrier.[131]

Endothelial focal adhesions are composed of extracellular matrix proteins (collagen, fibronectin, laminin, vitronectin, proteoglycans), transmembrane integrin receptors, and cytoplasmic focal adhesion plaques (containing α-actinin, vinculin, paxillin, and talin), which combine to provide additional adhesive forces in barrier regulation and form a critical bridge for bidirectional signal transduction between the actin cytoskeleton and the cell-matrix interface[29,132] (see Fig. 6-12). The core matrix proteins, because of their position and points of contact with endothelial cells, may determine cell-substratum adhesion and thereby determine vascular permeability in normal conditions and in response to inflammatory mediators such as tumor necrosis factor.[133] Extracellular stimuli can be transmitted to the cytoskeleton through focal adhesion rearrangement linked to integrin ligation, and antibodies to β_1-integrin alter endothelial attachment, cell spreading, and permeability.[134] Integrin binding to the extracellular matrix induces the attachment of integrins to intracellular actin fibers, a process that stimulates tyrosine phosphorylation of multiple focal adhesion proteins as well as tyrosine phosphorylation–dependent Ca^{2+} influx.[135] The extracellular matrix can also be remodeled by endothelial cell–released proteases, causing endothelial cells layered on this matrix to become more permeable.[133]

Endothelial Water Permeability and Albumin Transcytosis. The pulmonary vascular endothelium provides the primary resistance to the transvascular flow of water,[82] although the relative distribution of transcapillary water flow through the paracellular and transcellular pathways remains controversial.[77,136] Albumin is a major determinant of endothelial water permeability because albumin's interaction with the vessel wall regulates the vessel wall hydraulic conductivity.[137] This observation forms the cornerstone of the "fiber matrix" hypothesis, which specifies that interactions between albumin and the glycocalyx component of the endothelium and hyaluronic acid and sulfated proteoglycans regulate water flow across the endothelial barrier.[138]

Hydraulic conductivity has been measured in endothelial cells grown on matrix-covered porous filters.[139] Hydraulic conductivity across filters alone was 100-fold less than hydraulic conductivity across the pulmonary artery endothelial monolayer. These values are 10- to 100-fold greater than those reported for intact vessel walls,[137] which reflects the lack of a series resistance to albumin movement in the absence of basement membrane and adjacent interstitial components.[130] Exposure of monolayers to albumin (0.5 to 2.5 mg/mL) decreased the hydraulic conductivity in a concentration-dependent

manner. Physicochemical interaction of albumin with endothelial cells may be responsible for this effect because the response did not occur when albumin was replaced with a 70-kD dextran molecule.[139] From work with frog mesenteric vessels, it has been suggested that interactions of albumin with the capillary endothelium occurred by association of arginine residues on the albumin molecule with negative charge on the endothelium.[137] This interaction has been confirmed in mammalian pulmonary vascular endothelial cells in which the arginyl residues of albumin are required for the response; this raises the possibility that a charge interaction of albumin with the endothelial cell is mediated via the arginyl residues.[139]

The transport of albumin from the abluminal to the luminal side of the endothelial monolayer presents an intriguing potential for an active mechanism of albumin transport, which may regulate the plasma albumin concentration.[140] Studies indicate that transendothelial flux of proteins such as insulin, transferrin, and albumin involves recognition by receptors located on the luminal side of the endothelial cell.[92,141,142] Receptor-mediated transcytosis of solutes is an important mechanism of transport across the pulmonary microvascular endothelial barrier. Albumin binds to the endothelial cell surface protein glycoprotein 60 (gp60) or albondin on the luminal side of the endothelium.[92,141,142] Once bound, albumin activates signaling via the tyrosine kinase pathway, thereby activating the formation of vesicles,[76] and albumin crosses the endothelial cell by shuttling from the luminal to the abluminal sides of the cell.[92,141,142]

Several "albumin receptors," such as gp60[143] and the smaller 18-kD and 31-kD cell surface proteins (specific for denatured albumin),[91,144] have been described. Albumin binding to endothelial cells and its potential role in transendothelial flux of albumin was explored with bovine pulmonary artery endothelial cell monolayers.[145] In the presence of unlabeled albumin (0 to 60 mg/mL), binding of tracer ^{125}I-labeled albumin to endothelial monolayers was saturated at 5 mg/mL unlabeled albumin, which indicates that unlabeled albumin competed with labeled albumin for sites on the endothelial surface. Binding of ^{125}I-labeled albumin to endothelial monolayers was reduced at 4°C, which indicates that albumin binding was reversible. Binding of ^{125}I-labeled albumin was independent of the concentration of other unlabeled proteins. The apparent equilibrium binding affinity constant (K_d) for albumin binding is 7.2×10^{-5} mol, with a maximum number of 4.2×10^{7} binding sites per cell. Albumin binds with a higher affinity in pulmonary microvessel endothelial cells, which is consistent with a greater number of vesicles present in these cells.[92]

The lectin *Ricinus communis* agglutinin (RCA) binds to gp60 in rat epididymal fat pad endothelial cells.[143] RCA also precipitates gp60 on plasmalemmal membrane, which indicates that gp60 is present in these cells.[145] Addition of RCA to the endothelial monolayer reduced ^{125}I-labeled albumin permeability by 40%, which was similar to the decrease in albumin permeability observed with excess unlabeled albumin, although several other lectins that did not bind to gp60 had no effect. These findings demonstrate a role for albumin binding to endothelial cell membrane gp60 in the transendothelial flux of albumin. Although the proportion of albumin transport in macrovascular endothelium dependent on binding of albumin is 40%, there are relatively few vesicles in macrovascular endothelium in comparison with microvessel endothelial cells. It is conceivable that pulmonary microvessel cells have a greater proportion of albumin transport dependent on gp60 because these cells have far more vesicles. Another study has employed antibody directed against gp60 to cross-link, and thereby to activate, the receptor.[76] This was shown to increase preferentially the transcellular permeability of albumin, which indicates the importance of gp60 in regulating lung fluid balance. Whether gp60 activation plays an active role in mediating increased lung vascular permeability in disease states is unknown; however, receptor-linked transport of albumin may be important in the transport of lipids such as albumin-linked long-chain free fatty acids and hormones.[146] The up-regulation of gp60 may be a factor in inflammatory responses characterized by increased pulmonary vascular endothelial permeability to albumin.

Strategies to Reverse Permeability and Restore Barrier Integrity

Despite significant progress in understanding the molecular and cellular events regulating increased permeability, mechanisms of vascular barrier restoration are less well understood, and a wide range of potential therapeutic agents for modulating barrier function in a clinically advantageous way are under investigation. Historically, however, increasing the level of cyclic nucleotides has represented the sole strategy for retarding the edema phase observed in inflammatory lung syndromes. Increases in intracellular cyclic AMP (cAMP) concentrations decrease pulmonary vascular endothelial permeability and inhibit the permeability-increasing effects of thrombin and histamine in association with inhibition of F-actin reorganization.[147–149] The reduction in paracellular permeability involves activation of cAMP-dependent protein kinases that phosphorylate proteins such as MLCK,[114] thereby reducing its capacity to phosphorylate MLCs, as well as regulating phosphatases that dephosphorylate proteins such as MLCs (see Fig. 6-12), which serves to reduce stress fiber formation.[147,149–151] Increases in cellular cAMP also prevent the increase in $[Ca^{2+}]_i$ and isotype-specific PKC activation, downstream signals regulating permeability.[149]

Recently, additional agonists have been identified that augment lung endothelial barrier function, and either attenuate or prevent agonist-mediated barrier dysfunction.[152–156] Given that alteration in endothelial permeability is a key event in angiogenesis, it is not surprising that angiogenic growth factors such as hepatocyte growth factor,[153] angiopoietin,[154] and sphingosine 1-phosphate (S1P)[152] are now recognized to have significant barrier-enhancing properties. For example, S1P, a sphingolipid metabolite generated by numerous cell types, including

endothelium and platelets, is a potent endothelial cell chemotactic and angiogenic factor, which effects robust and sustained endothelial barrier enhancement.[152] Ligation of endothelial differentiation gene-1 (EDG1) receptor by S1P results in strong barrier enhancement in vitro[152,157] and in vivo.[158,159] S1P significantly attenuates thrombin-induced barrier disruption,[152] while rapidly restoring barrier integrity in the isolated perfused murine lung.[159] A single intravenous dose of S1P, given 1 hour after intratracheal endotoxin administration, produced highly significant reductions in multiple indices of inflammatory lung injury, including vascular leak, as demonstrated in both murine[158,159] and canine[159] models of acute lung injury (ALI). This profound barrier enhancement is mediated by G protein–dependent signaling cascades, leading to cytoskeletal rearrangement with increased peripheral actin resulting in increased endothelial junctional integrity (Fig. 6-15).[152,160]

Other barrier-promoting agonists that have been identified include the S1P analogue FTY720, statins, activated protein C, adenosine triphosphate (ATP), high-molecular-weight hyaluronan, methylnaltrexone, and oxidized phospholipids (for review, see Wolfson et al[161]). FTY720, an unphosphorylated S1P analogue, is a derivative of the natural immunosuppressant myriocin that has been recently described to cause peripheral lymphopenia by inhibiting cellular egress from lymphoid tissues.[162] FTY720 induces delayed endothelial barrier enhancement through a G_i-coupled receptor, which acts through a unknown mechanism that is EDG1 independent and distinct from the pathways described for S1P.[163] Nevertheless, intraperitoneal FTY720 protected against intratracheal lipopolysaccharide (LPS) in a murine model of ALI.[159] Simvastatin, a hydroxymethylglutaryl coenzyme A reductase inhibitor that lowers serum cholesterol levels, has been demonstrated to improve endothelial barrier function through activation of a Rac1-dependent cytoskeleton mechanism that is independent of its cholesterol-lowering effects.[164] Similarly, activated protein C, an anticoagulant, confers a barrier-protective actin configuration and enhances the vascular barrier in vitro and in vivo.[165] Through a mechanism that does not involve adenosine receptors, ATP induces barrier enhancement via phospholipase C- and Rac1-dependent cytoskeleton reorganization.[166,167] In addition, injection of nonhydrolyzable ATP in mice confers protection from endotoxin-induced lung injuries.[168] High-molecular-weight hyaluronan associates with CD44 receptors, which transactivate EDG1 to induce Akt1- and Rac1-dependent pathways.[169] Methylnaltrexone is a peripherally restricted mu opioid receptor antagonist that protects against the edemagenic morphine agonist DAMGO as well as thrombin

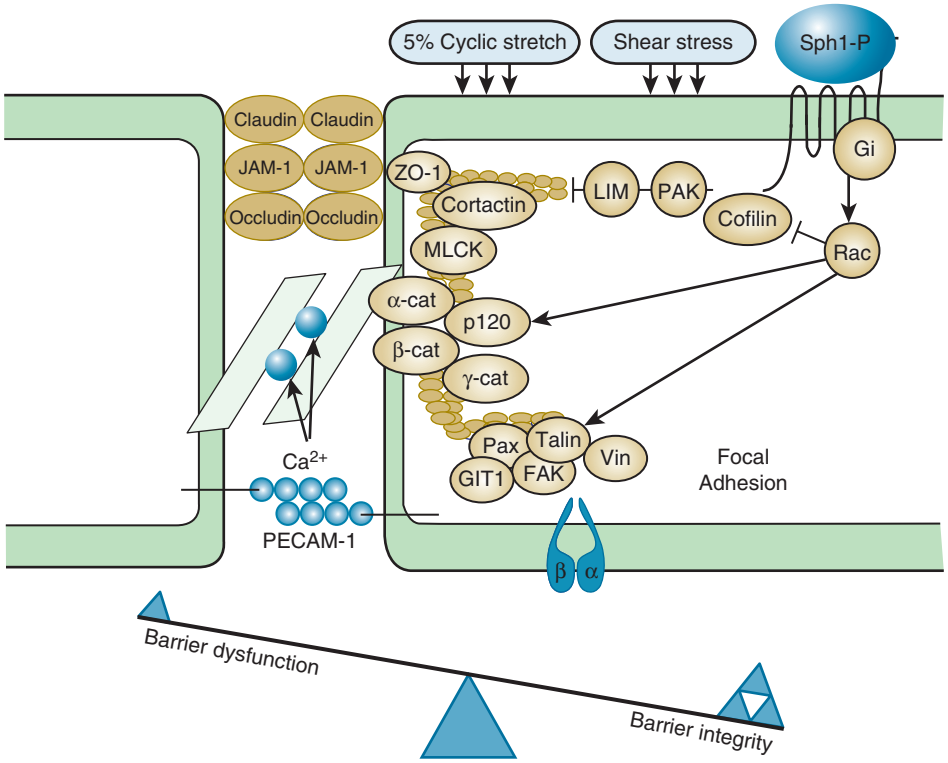

FIGURE 6-15 ■ Schematic depicting enhanced endothelial cell barrier function by sphingosine 1-phosphate (Sph1-P), a platelet-derived lipid growth factor, which activates specific G protein–coupled EDG (endothelial differentiation gene) receptors, leading to profound cytoskeletal rearrangement and increased barrier function in vitro and in vivo. Ligation of EDG results in activation of the small GTPase Rac, a signaling cascade that results in cytoskeletal rearrangement and increased cortical actin with increased linkage to the adherens junction and focal adhesions. Rac activation initiates intracellular events dependent on specific protein kinase C (PKC) isotypes, p21-associated kinase (PAK), LIM kinase, the actin-severing protein cofilin, and MLCK, which all contribute to increased cell-cell and cell-matrix tethering. Abbreviations as in Figures 6-12 and 6-14. (For references see text.)

and LPS challenge via inhibition of EDG3 activation.[170] Lastly, oxidized phospholipids confer barrier enhancement by inducing a unique zip-like configuration of peripheral actin through activation of Rac1- and Cdc42-dependent pathways.[171] Furthermore, treatment with OxPAPC at the onset of high-tidal-volume mechanical ventilation was protective in a murine model of ventilator-induced lung injury.[172]

The identification of novel biologically compatible agents that can preserve or restore vascular integrity offers promise for the future management of pulmonary edema associated with increased vascular leak in the critically ill. Notably, nearly each of these agents has been successfully evaluated in preclinical models of ALI and one agent, FTY720, is in Phase III trials, while three other agents—statins, activated protein C, and methylnaltrexone—are currently approved by the Food and Drug Administration for other medical conditions. Thus, the prospects for the rapid translation of these lung vascular barrier-protective strategies to clinical practice are high.

PULMONARY VASCULAR GENOMICS

Understanding the genetic basis of pulmonary vascular disease has the potential to offer invaluable insights into the functional significance and role of individual genes in the normal physiology as well as pathobiology of the pulmonary circulation. Several complex lung diseases are characterized by a component of vascular dysfunction, including asthma, chronic obstructive pulmonary disease, and pulmonary hypertension; however, ALI, including its most severe form ARDS, represents lung pathologies that are primarily defined by derangements in vascular function. Accordingly, a growing literature on the genetic basis for ALI is of great interest. Candidate gene-based association studies have become the preferred type of analysis, relying on the identification of common variants, usually single nucleotide polymorphisms (SNPs), between unrelated controls and cases. Since ALI is a clinical syndrome that occurs in patients with complex phenotypes, genomic studies are difficult to design and must be carefully interpreted. Nonetheless, several promising candidate genes have now emerged; for example, an intronic Alu insertion/deletion (I/D) polymorphism of ACE has been shown to correspond to variance in plasma ACE activity, with greater enzymatic activity associated with the D allele.[173] Subsequently, the homozygous ACE deletion (DD) has been implicated in the development and prognosis of ARDS in a European population.[174] Separately, pre–B-cell colony-enhancing factor (PBEF), previously a largely unknown cytokine, was identified as a novel biomarker in cell and animal models relevant to the pathobiology of ALI as well as in bronchoalveolar lavage fluid samples from patients with ALI.[175] PBEF was also found to induce increased endothelial permeability,[176] and an association study identified a specific SNP in the PBEF gene corresponding to a transcription factor binding site, the -1543C/-1001G haplotype, that conferred increased susceptibility to ALI as well as ALI mortality.[175] Several other genes, including those for MLCK,[177] interleukin-6,[178] interleukin-10,[179] macrophage migration inhibitory factor,[180,181] vascular endothelial growth factor,[182] and the growth arrest and DNA damage-inducible gene GADD45α,[183] have also demonstrated some degree of association with ALI and are plausibly related to its pathobiology, making them intriguing targets for further investigation.

Appendix can be found on Expert Consult

KEY POINTS

- The pulmonary circulation serves both respiratory and nonrespiratory functions.
- The low-pressure, low-vascular-resistance characteristics of the pulmonary circulation differ substantially from the systemic circulation, as do the responses to hypoxia.
- Hypoxic pulmonary vasoconstriction serves to improve gas exchange by redirecting perfusion away from poorly ventilated (i.e., hypoxic) regions of the lung; despite extensive study, the mechanism(s) underlying this important reponse remain unknown.
- The pulmonary microvessels serve as primary sites for fluid and solute exchange, chiefly in the thick portion of the alveolar walls, which depends on the balance of forces that govern fluid filtration. Fluid is continuously being filtered in healthy human lungs and removed through pulmonary lymphatics.
- A variety of pathophysiologic events and mediators can perturb this balance and culminate in either hydrostatic or high-permeability pulmonary edema.
- Increases in vessel wall permeability characterize acute lung injury and other inflammatory lung disorders. A variety of pathogenic mechanisms are involved in the development of leaky pulmonary vessels that are intimately linked to the endothelial cytoskeleton, through paracellular and transcytotic pathways. The end result of lung vascular injury is an accumulation of protein-rich fluid in the extravascular spaces.

CHAPTER 6
APPENDIX

ENDOTHELIAL CELL FUNCTION

The main function of the pulmonary circulation is to deliver the entire output of the right ventricle as a thin film of blood within alveolar capillaries to facilitate the uptake of oxygen and the elimination of carbon dioxide. As described in Chapter 6, the structure of blood vessels and the physiologic principles that regulate blood flow in the lungs are admirably suited to this purpose, and one of the accompaniments of this rich perfusion is the constant extravasation and subsequent removal of fluid and solutes from the lung parenchyma. These fundamental operating factors have recently been enriched by new knowledge concerning the molecular mechanisms that underlie the regulation of endothelial cell permeability and that govern the formation, maturation, and death of endothelial cells, topics that are discussed in this appendix.

EFFECTS OF CELLULAR AND MOLECULAR CHARGE

The permeability of pulmonary microvessels to fluid and solutes depends in part on the properties of the endothelium and the underlying extracellular matrix. The intact endothelial cell membrane is nonthrombogenic, due in part to the release and effect of prostacyclin (prostaglandin I_2) and to the negative cell membrane charge of circulating blood and endothelial cells.[1,2] The endothelial cell surface has a complex molecular composition consisting of sialyl residues that are responsible for its negative charge.[3] Collectively known as the glycocalyx, the glycoproteins and glycolipids in this meshwork combine to form an endothelial cell surface layer of anionic polymers that is variable across the vasculature. The plasmalemmal membrane, vesicles, and paracellular channel structures contain microdomains of anionic sites consisting of distributions of glycosaminoglycans, sialoconjugates, and monosaccharide residues.[3–5] The selective permeability of the endothelial barrier to plasma proteins such as albumin is related in part to the anionic charge of the albumin molecule as well as the surface charge on the endothelial cell. For example, flux of albumin across glomerular capillaries is critically dependent on the negative charge of the capillary endothelial cells and the extracellular matrix proteins constituting the basement membrane.[6] Disruption of cell surface negative charge sites results in "leakage" of albumin across the capillary-matrix complex.[6]

The endothelial cell membrane surface charge influences the transport of albumin, which has an isoelectric point of 4.1.[3] The distribution of charge sites provides a means of preferentially gating albumin across the endothelial monolayer. Neutralization of negative charges on pulmonary vascular endothelial cells with cationic ferritin increases the flux of ^{125}I-labeled albumin, indicating that cell surface negative charge contributed significantly to albumin transport. Another charge-related effect is the result of negative charge distribution of interstitial macromolecules (heparan sulfate, chondroitin sulfate, and other complex proteoglycans), which potentially leads to repulsion of albumin and its increased transport through specific domains of the matrix.[7–9]

Because of its intrinsic negative charge, albumin permeability is greater than would have been predicted from its molecular size. For example, dextran sulfate (negatively charged dextran, whose molecular weight of 500 kD is much greater than that of albumin) was found to be threefold more permeable than neutral dextran of the same molecular weight. Data on sheep lung lymph also indicated that plasma-to-lymph transport of negative dextrans across the pulmonary vascular endothelial barrier is greater than transport of neutral dextrans.[9] Thus, the negatively charged molecules are transported preferentially across the endothelial barrier because of charge-related gating phenomena, despite the net negative charge of endothelial cell membranes.[9]

REGIONAL DIFFERENCES IN ENDOTHELIAL PERMEABILITY

Endothelial cells from different sites in the vasculature have many common features, but specific properties of the cells distinguish large vessel endothelial cells from those of small vessels within an organ and distinguish among those from different organs (e.g., between the blood-brain barrier and pulmonary vascular endothelial cells).[4,10,11] The albumin permeability value in cultured pulmonary microvessel endothelial cells is approximately one half to one fifth of the value of similarly

cultured cells from the main-stem pulmonary artery,[12] a feature also noted in vivo.[13] Interestingly, cells from microvessels are significantly more restrictive to sucrose and inulin than cells from large vessels, which indicates that transport occurring via paracellular pathways is reduced to a greater degree. The greater restriction to sucrose and inulin in comparison with albumin indicates that other routes of albumin transport (i.e., vesicles) are involved in albumin flux across pulmonary microvessel endothelial cells. The greater complexity of the intercellular junctions could account for the significantly lower inulin and sucrose permeabilities observed in pulmonary microvessel endothelial cells. Finally, microvascular cells proliferate at a higher level than macrovascular cells and retain phenotypically distinct calcium and cyclic nucleotide signaling responses as well as oxidant-mediated signaling transduction.[11]

Studies of endothelial cells from different sites in the vasculature have identified organ-specific antigens on capillary endothelial cells that may be responsible for the different degrees of permeability of regional vascular beds.[11,13,14] There are phenotypic differences in the lectin binding domains of different pulmonary vascular endothelial cells.[12] Lectins (*Ricinus communis* agglutinin and peanut agglutinin) bind to pulmonary microvessel endothelial glycoproteins (galactose-containing glycoproteins with molecular weights of 160 to 220, 60, and 30 to 40 kD). Differences in cell surface glycoproteins of endothelial cells in vascular beds that are related to the permeability characteristics of these vascular endothelial cells in situ have also been described.[15,16]

CYTOSKELETAL ALTERATIONS

Majno and Palade[17] first observed that lung endothelial cells exhibit a rounded morphology, producing paracellular gaps during inflammatory edema. This profound conformational change in the endothelial cell architecture was similarly observed after thrombin or histamine challenge,[18–21] and disruption in the integrity of the endothelial cell monolayer is now recognized as a cardinal feature of inflammation. The dramatic cell shape change, which results in paracellular gap formation, implicates the direct involvement of endothelial structural components comprising cytoskeletal proteins: microfilaments, microtubules, and intermediate filaments.[22] A useful paradigm to understand the basis for cytoskeletal influences on barrier regulation is via their effects on the balance of competing contractile forces, which generate centripetal tension, and adhesive cell-cell and cell-matrix tethering forces, which promote monolayer integrity.[22] This equilibrium is intimately influenced by the dynamic microfilamentous actin-based endothelial cytoskeleton via a variety of actin-binding proteins (capping, nucleating, and severing proteins), which are critical participants in cytoskeletal rearrangement and tensile force generation as well as in the regulation of endothelial junctional stability.[22] G-actin is a globular monomer that assembles reversibly to form polymerized actin fibers (or F-actin), conferring strength to structural elements regulating cell shape, particularly when accompanied by phosphorylated myosin.[22] F-actin filaments within peripherally distributed cortical bands are essential for maintenance of endothelial integrity and basal barrier function. Edemagenic agents, such as thrombin, initiate cytoskeletal rearrangement characterized by the loss of peripheral actin filaments with a concomitant increase in organized F-actin cables that span the cell as "stress fibers."[18] The formation of cytoplasmic stress fibers, critical to cellular contraction and increased intracellular tension, occurs via the coordinate activation of the small GTPase Rho and Ca^{2+}/calmodulin-dependent myosin light chain linase (MLCK), which together increase the level of phosphorylated myosin light chains (MLCs) in a spatially distinct manner (Fig. 6A-1).[23–27] The resultant increases in actin stress fiber formation and actomyosin cellular contraction disrupt the barrier-regulatory balance with tethering forces and destabilize cytoskeletal-junctional linkages, culminating in increased vascular permeability (see Fig. 6A-1). Consistent with this model, thrombin-induced endothelial cell permeability and formation of intercellular gaps is associated with disruption in the integrity of paracellular adherens junctions and reorganization of focal adhesion plaques.[24,28–31] Direct inhibition of either MLCK or Rho kinase as well as Ca^{2+}/calmodulin antagonism attenuates thrombin-induced MLC phosphorylation, gap formation, and barrier dysfunction,[25–27] as well as the increased vascular permeability observed in many,[21,24,32,33] but not all,[34–36] models of lung edema. The role of these gaps in increasing paracellular permeability has also been determined by osmotically shrinking endothelial cells with addition of hypertonic solution to the cell-bathing medium.[37] This resulted in formation of intercellular gaps and increased paracellular permeability, effects that were reversed by rehydrating the cells.[37]

The role of microtubule proteins in barrier regulation is becoming increasingly appreciated,[38,39] whereas the function of intermediate filaments in endothelial cell barrier regulation is much less defined.[22] Microtubules are polymers of α- and β-tubulin that form a lattice network of rigid hollow rods spanning the cell in a polarized fashion from the nucleus to the periphery while undergoing frequent assembly and disassembly.[40,41] Microtubules and actin filaments exhibit complex but intimate functional interactions during dynamic cellular processes.[39–42] Microtubule disruption with agents such as nocodazole or vinblastine induces rapid assembly of actin filaments and focal adhesions,[39,42] isometric cellular contraction[39] that correlates with the level of MLC phosphorylation, increased permeability across endothelial cell monolayers,[39,42] and increased transendothelial leukocyte migration,[42] events that can be reversed or attenuated by microtubule stabilization with paclitaxel. The mechanisms involved in these effects are poorly understood; however, microfilament-microtubule crosstalk represents an intriguing area of endothelial cell barrier regulation.

Besides activation of the contractile apparatus by receptor-mediated pathways, mechanical signals are also transduced to the endothelial cell cytoskeleton.[43,44]

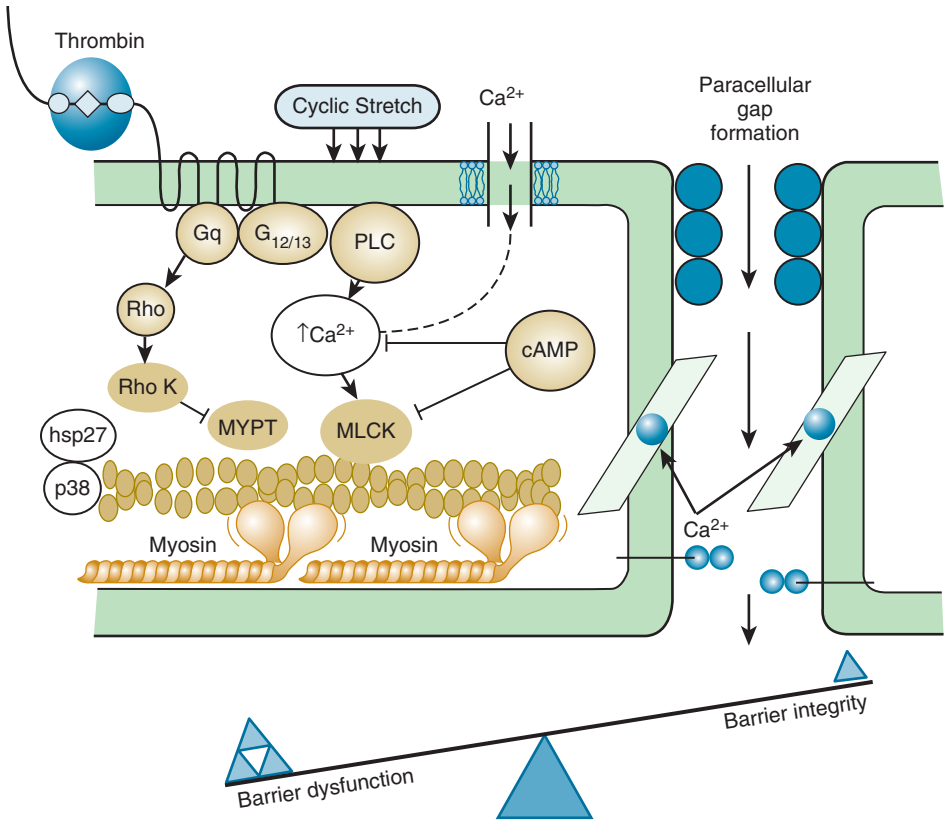

FIGURE 6A-1 ■ Schematic depicting disruption in endothelial cell (EC) barrier homeostasis by thrombin. In this working model of barrier regulation, under basal conditions, a balance exists between actomyosin contractile and cellular adhesive forces. When contractile forces predominate, as depicted in the thrombin-stimulated model, ECs pull apart to form paracellular gaps, favoring barrier disruption. Thrombin cleavage of the PAR-1 receptor on the surface of EC activates both heterotrimeric G proteins (G_q, $G_{12/13}$) and small GTPases such as Rho. Activated Rho (Rho-GTP) induces Rho kinase (Rho K), which via phosphorylation of the phosphatase regulatory subunit inhibits the myosin light chain phosphatase (MYPT). Rho kinase and myosin light chain kinase (MLCK) activation occurs via independent pathways. Increased cytosolic Ca^{2+} (via inositol triphosphate [IP_3] production) activates the Ca^{2+}/calmodulin-dependent MLCK, with conformational changes allowing the enzyme to access the preferred substrate (myosin light chain [MLC]). Rho kinase and MLCK activation both culminate in increased MLC phosphorylation, which in turn enables actomyosin contraction resulting in increased stress fiber formation, cellular contraction, paracellular gap formation, and ultimately barrier dysfunction. Increases in cyclic AMP influence both Ca^{2+} mobilization and MLCK activity. Also depicted are other representative regulatory proteins whose activity either increases or decreases EC tension. Inhibition of heat shock protein 27 (hsp27) activity, by p38 mitogen-activated protein kinase (MAPK)–catalyzed phosphorylation, also induces actin stress fiber formation, and the actin capping/severing protein gelsolin is likewise involved in stress fiber–dependent contraction.

Although the mechanism for this signal transduction is not well understood, the complex array of proteins that constitutes the lung endothelial glycocalyx may be involved. Nuclear magnetic resonance techniques have demonstrated that cell surface proteoglycans behave as viscoelastic anionic polymers, undergoing shear-dependent conformational changes that may function as blood flow sensors to transduce signals into endothelial cells.[45] Components of the glycocalyx, such as heparan sulfate proteoglycans and sialoproteins, modulate cell-cell and cell-matrix adhesions via effects on the cytoskeleton and alter endothelial barrier properties.[46–48] Syndecan is a heparan sulfate proteoglycan known to influence cytoskeletal organization, cell-cell adhesion, and motility,[47] and mediates cationic peptide–induced signaling that leads to endothelial cytoskeletal rearrangement and barrier dysfunction.[46] Cationic peptide–mediated barrier dysfunction is associated with syndecan-1 and syndecan-4 clustering and actin stress fiber formation, whereas removal of cell surface heparan sulfated proteoglycans attenuates these responses.[46] Thus, the glycocalyx in general, and heparan sulfate proteoglycans in particular, may represent not only sensors for mechanical stress and cytoskeletal rearrangement, but endothelial-surface binding domains for inflammatory cationic peptides as well. This provides potential mechanistic insight for the recent observation that neutrophil-derived cationic peptides are responsible for the increase in vascular permeability produced during endothelial cell interaction with activated neutrophils.[49,50]

ANGIOGENESIS

New blood vessel formation, or angiogenesis, is a complex process involving endothelial cell activation,

migration, maturation, and remodeling. These events may occur in a variety of contexts including during normal development and growth, in response to wound healing, or as part of the pathogenesis of a number of cancers and autoimmune diseases.[51] In the embryo, endothelial cells differentiate from angioblasts[52] and then give rise to the early vascular plexus and primitive blood vessels, a process referred to as vasculogenesis.[53] Angiogenesis is then defined by the generation of new capillaries by endothelial cells either by sprouting or by splitting from preexisting vessels. Sprouting angiogenesis involves endothelial detachment from the basement membrane, migration, and subsequent proliferation, tube formation, and, finally, functional maturation of the new vessel. Angiogenesis characterized by the splitting of existing vessels involves endothelial proliferation within the vessel of origin followed by the generation of a separate lumen and a capillary pillar that then splits from the original vessel and matures into a new vessel.[54] While the mode of angiogenesis may vary according to the organ involved or the initiating angiogenic signals, non-sprouting is the primary process in lung vascular development.[55]

A number of angiogenic factors are now recognized as capable of activating endothelial cells, including extracellular matrix proteins and their integrin receptors,[56] one of the most important of which is vascular endothelial growth factor (VEGF). This is evidenced by its key role in vasculogenesis: mice lacking the VEGF receptor, Flt-1, fail to develop fully functional blood vessels.[57] In addition, VEGF has been found to mediate angiogenesis in malignant gliomas[58] and in a number of other tumors.[59] These findings have led to the inhibition of VEGF as a promising therapeutic strategy in the management of patients with advanced malignancies.[60] In patients with lung disease, pulmonary hypertension is a devastating condition that is characterized by aberrant angiogenesis. Evidence suggests that VEGF signaling modulates disease progression,[61] and therapies that affect VEGF signaling have shown promise in a rat model of pulmonary hypertension.[62]

APOPTOSIS AND ENDOTHELIAL CELL DYSFUNCTION

Endothelial cells have relatively low turnover rates due in part to the protective effects of physiologic mechanical forces, including shear stress and cyclic stretch. However, due to the positioning of the endothelium at the surface of blood and tissue, endothelial cells are constantly exposed to multiple biochemical and biophysical stresses, such as endotoxins, tumor necrosis factor-α (TNF-α), and oxidative stress. One potential consequence of excessive stress is apoptosis, or programmed cell death. Apoptotic cells undergo a well-ordered morphologic and molecular pattern of death, including cytoskeletal rearrangement, membrane blebbing, nuclear condensation, DNA fragmentation, and cell shrinkage (see reviews by Lu et al.[63] and Pober and Min[64]). Frequently, apoptotic cells do not elicit an inflammatory response and are phagocytosed by neighboring cells.[65] In contrast, cells undergoing necrosis demonstrate cellular and nuclear swelling, often accompanied by inflammation in damaged tissues.[66] Thus, endothelial cells may undergo apoptosis or necrosis, depending on the stimulus. Upon death and detachment of cells from vessel walls, if the subendothelial basement membrane damage is limited to a small fraction of the endothelial cell lining, viable neighboring cells can spread quickly and cover the damaged space to attenuate procoagulant effects. However, more severe damage is likely to lead to extensive loss of endothelial cells, after which platelets will be exposed to the damaged basement membrane and induce thrombosis.[67]

There are two fundamental signaling pathways by which apoptosis is mediated, the extrinsic and intrinsic pathways. The extrinsic pathway is initiated by external death ligands, whereas the intrinsic pathway is triggered by internal apoptotic signals and involves mitochondria. These pathways merge and share mechanisms utilizing the aspartate-specific cysteinyl proteases (caspase) cascades.[63] The best-characterized extrinsic pathways are the binding of Fas ligand (FasL) to Fas receptors[68] and TNF-α to TNF receptor 1,[69] which trigger adapter proteins to be recruited to activate the initiator caspase of the caspase cascade. Fas/FasL-mediated lung apoptosis has been implicated in acute lung injury and acute respiratory distress syndrome (ARDS). Furthermore, Fas/FasL-mediated apoptosis induces the release of cytokines, leading to the progression from ARDS to pulmonary fibrosis, in which excess collagen deposition causes the destruction of normal lung architecture.[70] In contrast, the intrinsic pathway may be initiated upon exposure to stresses, such as cytotoxic drugs, oxidants, radiation, and growth factor deprivation, which results in mitochondrial release of several apoptogenic proteins into the cytosol, such as cytochrome *c* that readily binds to Apaf-1 to activate caspase-9. A common mediator of endothelial cell injury is neutrophil-generated reactive oxygen species (ROS), a by-product of the partial reduction of molecular oxygen. The most potent pathway for generating ROS is catalyzed by the enzyme phagocyte oxidase, which is expressed by neutrophils and macrophages, although vascular cells express the homologous nonphagocyte oxidase. ROS may react directly with cellular macromolecules or combine with nitric oxide to form even more reactive peroxynitrite. These oxidative stresses can cause barrier dysfunction and may antagonize TNF responses.[71] There are a variety of stimuli, either extrinsic or intrinsic, that may cause apoptosis in lung endothelial cells. Understanding the mechanisms by which these stimuli induce apoptosis and dysfunction may ultimately point toward novel therapeutic strategies for diseases involving the pulmonary vasculature.

INTRODUCTION AND PHYSIOLOGY

Although the mammalian respiratory system is designed primarily for gas exchange, it also contributes to acid-base regulation in combination with the kidneys. Increased metabolism results in the production of large amounts of carbon dioxide (CO_2) and fixed acids. CO_2 concentration can be adjusted rapidly and precisely by the respiratory center in defense of arterial and body pH. Conversely, alterations in the pressure of carbon dioxide (P_{CO_2}) due to changes in alveolar ventilation can be the primary cause of abnormalities in pH. The ability of the kidneys to rapidly dispose of nonvolatile acids (or bases as appropriate) is somewhat slower than the respiratory system, but nonetheless critical. Only a brief review of acid-base chemistry can be provided here; the reader is referred elsewhere for more comprehensive review.[1]

Choice of Respiratory and Metabolic Parameters

By the early 20th century, the importance of reactions of CO_2 and bicarbonate ion (HCO_3^-) with H^+ and OH^- in acid-base balance was established:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^- \quad (1)$$

$$CO_2 + OH^- \leftrightarrow HCO_3^- \quad (2)$$

Reaction 2 provides the dominant pathway to HCO_3^- from CO_2,[2] but rates of formation of either H_2CO_3 (carbonic acid) in Reaction 1, or HCO_3^- directly in Reaction 2 are relatively slow. Rates of each are normally accelerated by carbonic anhydrase, present in erythrocytes, vascular endothelium, alveolar epithelium, and in most cells, including the kidney.[2-4] Under physiologic conditions, $[H_2CO_3]$ is small compared with $[CO_2]$ and the relative amounts of HCO_3^- and CO_2 can be calculated from the Henderson-Hasselbalch equation:

$$pH = pK_a + \log\left[HCO_3^-\right]/\alpha\, P_{CO_2} \quad (3)$$

where pH indicates the negative logarithm of the H^+ concentration, and the constant pK_a (= 6.1 at 37°C) designates the negative logarithm of the apparent dissociation constant of CO_2 through the equilibria with carbonic acid and its dissociation products in Reaction 1. It is the pH at which the concentrations of HCO_3^- and dissolved CO_2 are equal. In Equation 3, dissolved CO_2 has been replaced by $\alpha\, P_{CO_2}$, where α is the solubility coefficient and is equal to 0.03 $mmol \cdot L^{-1} \cdot mm\ Hg^{-1}$ at 37°C. These values remain relatively constant with clinical

changes in pH and ionic strength,[5] however, they are significantly influenced by temperature (see later discussion on hypo- and hyperthermia). For convenience, taking the appropriate values for α and pK_a and the antilog of the expression yields

$$H^+ = 24\ P_{CO_2}/HCO_3^- \quad (4)$$

with P_{CO_2} and HCO_3^- in their usual units (mm Hg and mmol/L, respectively), H^+ concentration is obtained in nanomoles per liter, which can be readily converted to pH (pH of 7.4 corresponds to a H^+ concentration of 40 nmol/L). Better understanding of the properties of this buffer system is obtained by examining the plasma values of each component. Ordinarily, buffering in both directions is most efficient when the pK_a is close to the prevailing pH. At a normal plasma pH of 7.4, there is 20 times more HCO_3^- than dissolved CO_2. The large difference between the pK_a and normal pH values in the case of the HCO_3^-/CO_2 buffer system might seem a disadvantage; however, protection is afforded against increased nonvolatile acid generation, which represents the more frequently encountered physiologic disturbance.[6] Higher HCO_3^- concentrations permit greater buffering of significant quantities of acid, and the CO_2 produced can be rapidly eliminated by increasing ventilation.

Measurements of P_{CO_2} and pH are readily made in arterial blood, but the pH detected is that in plasma rather than that in the red blood cells; plasma pH is about 0.2 units greater than erythrocyte pH. The intracellular acid-base status of the body compartments is seldom measured, and the plasma pH is often assumed to be representative of the body as a whole and its changes reflecting qualitatively what is happening in cells. This simplification is frequently inappropriate. For example, intracellular pH may be acidotic in patients with hypokalemia, but who have an alkaline plasma. It is therefore more exact to refer to deviations of plasma pH as *acidemia* and *alkalemia* rather than as acidosis and alkalosis. The latter terms refer to processes and do not designate the actual pH or compartments.

Plasma HCO_3^- is routinely calculated from measured arterial P_{CO_2} and pH using Equation 2. Alternatively, HCO_3^- can be estimated from the total CO_2 that can be released from plasma with a strong acid (the *CO_2 content*). CO_2 content is usually measured with electrolyte concentrations in venous blood and will be about 5% higher than arterial HCO_3^- because it also includes H_2CO_3, dissolved CO_2, carbonate, and CO_2 bound to amino acids (carbamates). Venous CO_2 content is generally about 2 to 4 mEq/L higher than the arterial plasma HCO_3^-. If the difference in these values is significantly greater than 4 mEq/L, then a clerical error may have occurred, the arterial and venous samples were not taken concurrently, the cardiac output is low, or the metabolic rate is high with exertion. The pH and P_{CO_2} of blood are particularly likely to change if blood samples are exposed to air, if they are not kept cool, or if analysis is delayed. Exposure to air decreases P_{CO_2}, raises pH, and more gradually decreases CO_2 content. Nonetheless differences in CO_2 content of arterial and venous plasma are usually quite small, and venous samples can be used to provide reasonable estimates of the arterial HCO_3^- and directional changes.

The Henderson-Hasselbalch equation indicates that pH can be calculated from two variables: P_{CO_2} and HCO_3^-. P_{CO_2} can be interpreted as a "ventilatory" parameter that reflects the adequacy of ventilation relative to the rate of CO_2 production. If arterial P_{CO_2} exceeds the normal range (35–45 mm Hg), then the patient is hypoventilating, and conversely, if the P_{CO_2} is lower, the patient is hyperventilating. These terms should be distinguished from hyperpnea and hypopnea, which refer to the total ventilation, and from tachypnea and bradypnea, which indicate respiratory rate. Rather than total ventilation, the key parameter that determines P_{CO_2} at any rate of CO_2 production is alveolar ventilation, because ventilation of dead space does not lead to the loss of CO_2. The effect of changing the V_D/V_T ratio of dead space (V_D) to tidal volume (V_T) is shown in Figure 7-1, where CO_2 production is assumed to be 200 mL/min.

The utility of P_{CO_2} as a ventilatory parameter is readily illustrated by a few brief examples. A heavily exercising person who has a normal P_{CO_2} is neither hyperventilating nor hypoventilating, despite the obvious hyperpnea and tachypnea. A person may demonstrate hypoventilation (high P_{CO_2}) from either a fall in alveolar ventilation at a constant metabolic rate or a rise in the rate of CO_2 production without a proportionate increase in alveolar ventilation. Patients with severe lung disease hypoventilate despite both hyperpnea and tachypnea at rest, because they are ventilating a large dead space. An increase in CO_2 production may be caused by an increased

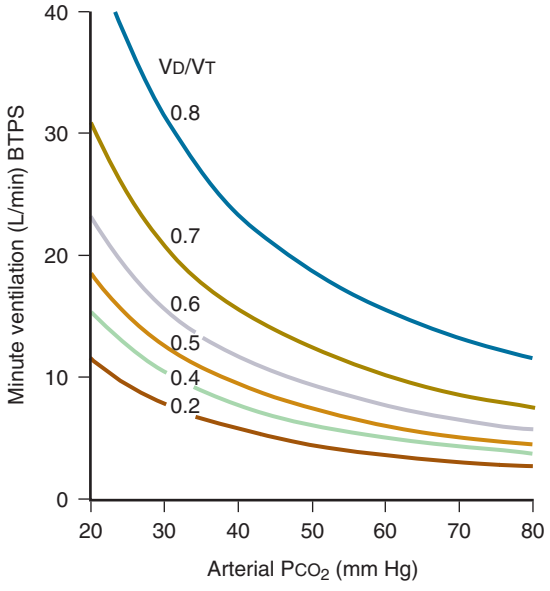

FIGURE 7-1 ■ The relationships among minute volume of ventilation (V_E), arterial P_{CO_2}, and the ratio of dead space to tidal volume (V_D/V_T) in a patient producing 200 ml of CO_2 each minute. BTPS, volume corrected for body conditions (body temperature, ambient pressure, and saturation with water vapor).

metabolic rate (e.g., exercise or fever) or, occasionally, by an acute release of CO_2 from HCO_3^- stores due to a severe, acute metabolic acidosis, such as occurs during and after cardiopulmonary arrest or a grand mal seizure, when large amounts of lactic acid are produced and HCO_3^- is converted to CO_2. Regardless of the cause of ventilation failing to keep pace with CO_2 production, the concomitant increase in arterial P_{CO_2} is classified as hypoventilation. Conversely, hyperventilation with a fall in P_{CO_2} is frequently seen as a respiratory compensation for metabolic acidosis, hypoxia, anxiety or other conditions that stimulate ventilation.

In contrast to P_{CO_2}, interpretation of changes in the HCO_3^- in Equation 3 is not as simple or straightforward and has remained more problematic. Because CO_2 is the only volatile acid in significant amounts in the blood and is directly regulated, it is accurately defined as a "ventilatory" or "respiratory" parameter. It would be ideal if HCO_3^-, as an easily measured base, could be considered a "nonrespiratory" or "metabolic" parameter in the same manner as CO_2 is considered respiratory. An ideal "metabolic" parameter should be uninfluenced by changes in P_{CO_2} and should represent the predominant base. However, as shown in Figure 7-2, HCO_3^- may vary significantly with P_{CO_2} in some solutions. If CO_2 is bubbled through a saline solution containing HCO_3^- ("unbuffered" solution), the bicarbonate remains relatively constant over a broad range of P_{CO_2}. A different circumstance is observed in isolated samples of whole blood in vitro: HCO_3^- concentrations rise appreciably as P_{CO_2} increases.

The difference in the responses of biologic fluids to CO_2 exposure is determined by differences in the buffering systems in these compartments. As indicated in Figure 7-2, the production of HCO_3^- from CO_2 in blood is increased when H^+ becomes associated with other buffer anions, which include hemoglobin, proteins, and inorganic phosphates. Red cell hemoglobin is particularly important and effective in buffering H^+ for three reasons. First, the hemoglobin concentration is extremely high within red blood cells. Second, there is an abundance of titratable imidazole groups on the hemoglobin molecule, whose pK_a is very close to the pH within the cells and thus able to titrate large amounts of H^+. Third, the buffering capacity of hemoglobin is very enhanced by its oxylabile character (the Haldane effect) so that at low PO_2 values, such as those encountered in systemic capillaries and venous blood, its affinity for H^+ is increased, allowing more CO_2 conversion to HCO_3^-. The opposite occurs in the lungs as the blood is oxygenated in the pulmonary capillaries.

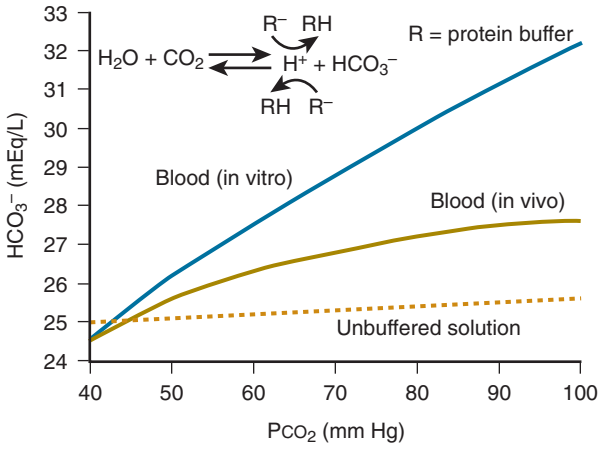

FIGURE 7-2 ■ The relation between P_{CO_2} and HCO_3^- in samples of isotonic saline with 25 mEq/L $NaHCO_3$ (unbuffered solution), in samples of whole blood (in vitro), and in samples of arterial blood drawn from patients 20 minutes after exposure to elevations of P_{CO_2} (in vivo).

Recognition that HCO_3^- concentration is not independent of P_{CO_2} in either plasma or blood (and is not strictly "nonrespiratory") and that other nonbicarbonate buffer pairs participate in H^+ buffering led to the development of alternative approaches yielding more reliable and quantitative measures to compensate for buffering related specifically to blood buffers. Among many schemes devised for this purpose, mention should be made of the HCO_3^--pH graphs of Davenport[7] and the concepts of buffer base and base excess of Sigaard-Anderson.[8] Each of these can predict accurately in vitro changes in blood after addition of acid or base or exposure to high or low P_{CO_2}, but have proved less reliable when patients are exposed to metabolic and respiratory challenges. The actual response of HCO_3^- to an acute change in P_{CO_2} was determined empirically in normal subjects and it was found that, when P_{CO_2} increased to 78 mm Hg, arterial plasma HCO_3^- increased only 3 mEq/L.[9] The range of HCO_3^- that would be expected in 95% of samples obtained in a normal population after acute increases in P_{CO_2} is indicated in Figure 7-3A. However, there is a tendency for HCO_3^- to fall somewhat more when animals are hyperventilated, as noted in Figure 7-3B,[10] due to a slight increase in lactate, which in turn may be due to an alkalosis-mediated increase the activity of the enzyme phosphofructokinase (see later discussion).[11] The relatively small changes in HCO_3^- that occur in response to acute changes in P_{CO_2}[1] are responsible for the popularity of HCO_3^- as a useful though by no means ideal "seat-of-the-pants" metabolic parameter among clinicians and the gradual decline in the use of the buffer base system for diagnostic purposes. This has been furthered by a growing appreciation that rigorous quantitation of acid-base deficits or excess with the intent of rapid chemical correction by either changes in ventilation or provision of fixed acids or bases, although appealing theoretically, have not proved useful or defensible (see discussion on treatment of metabolic acidosis). Regardless of which metabolic parameter is used, it must ultimately be validated with empirical observations made in subjects who are intentionally hyperventilated or hypoventilated (see Fig. 7-3).

The Strong Ion Approach

The traditional Henderson-Hasselbalch/van Slyke acid-base approach for analyzing acid-base problems has been challenged by an alternative paradigm, the "strong ion approach," applied to physiologic fluids.[12,13] The

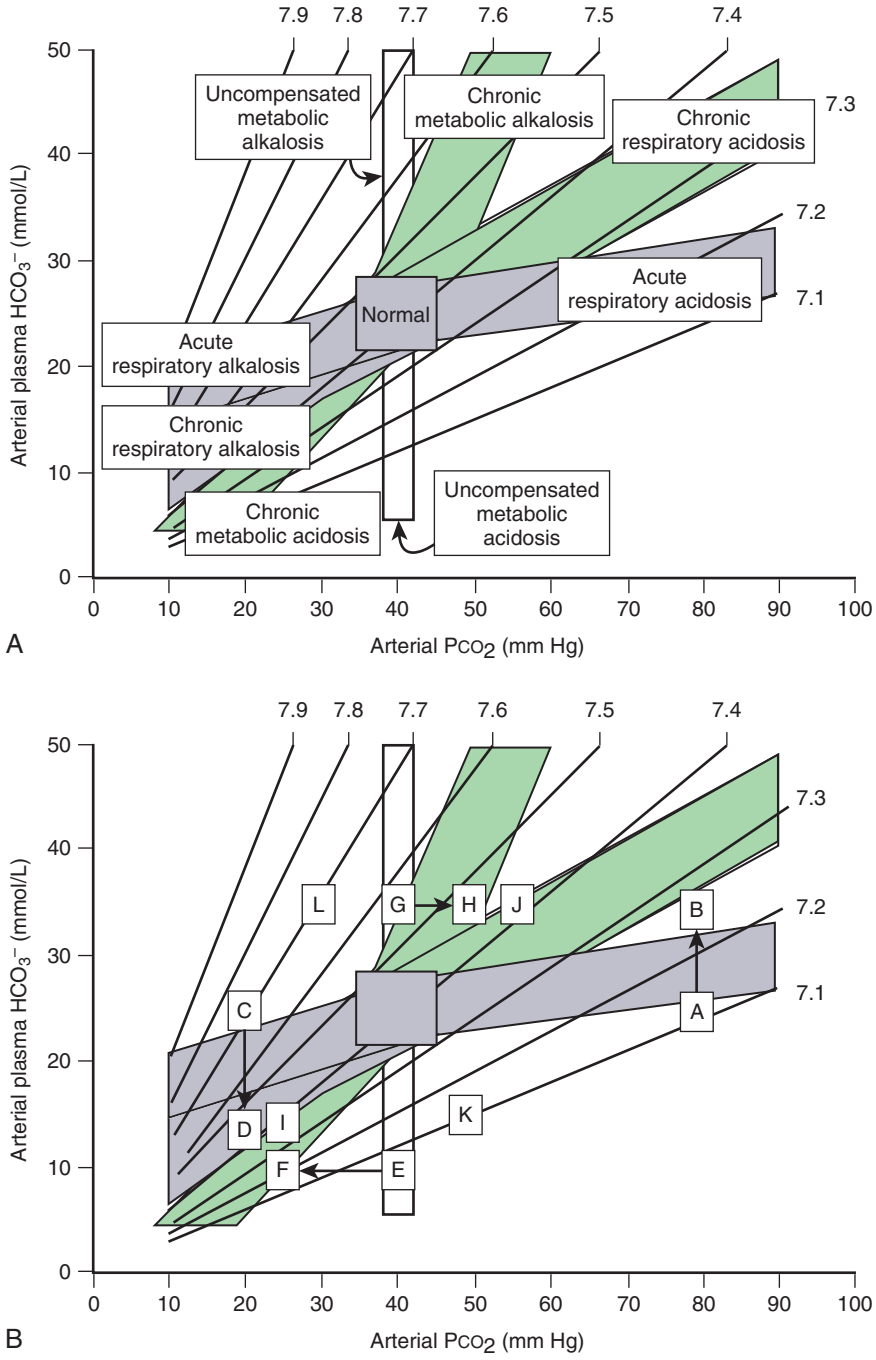

FIGURE 7-3 ■ The relation between HCO_3^- and P_{CO_2} in a variety of clinical disorders. For discussion, see text. **A,** The 95% confidence levels for acute and chronic respiratory and metabolic abnormalities.[11,85] **B,** The interpretation of examples in Table 7-1 is based on the assumption that P_{CO_2} is a purely respiratory parameter and HCO_3^- is a purely metabolic parameter.

"metabolic" parameter was divided into two components. A distinction was made between "strong" acids and bases, which are completely dissociated, and weak buffer molecules, which are partially dissociated, at physiologic pH. "Strong" ions include the electrolytes and many organic and inorganic ions such as lactate, acetoacetate, and sulfate, with pK_a values such that within clinically relevant pH ranges, they are fully dissociated. The weak buffers consist primarily of serum proteins and phosphate, with pK_a values less than one unit from physiologic pH. There are several advantages to this conceptual approach. The value of pH is calculated on the basis of three simple assumptions: (1) the total concentrations of each of the ions and acid-base pairs is known and remains unchanged, (2) the solution remains electroneutral, and (3) the dissociation constants of each of the buffers are known. Both the pH and the bicarbonate are dependent variables, which can be calculated from the concentrations of the strong and weak electrolytes and the P_{CO_2}. The strong ion differ-

ence (SID) is calculated by subtracting the strong anions from the strong cations. An increase in chloride relative to sodium results in a decrease in SID and acidification of the plasma. This explains why saline infusion results in acidosis. The strong ion approach also provides a more exact estimate of H^+ concentrations than the Henderson-Hasselbalch equation because the dissociation constant of water is also considered, but this is a relatively small correction.[14]

The relatively complex nature of the equations and increased parameters incorporated in the strong ion approach limit its clinical application and adoption. Solution of these equations requires knowledge of numerous electrolytes and protein and phosphate concentrations, which may not always be available simultaneously with arterial blood gases. In clinical circumstances, whatever extra precision the strong ion approach may theoretically provide over more conventional analyses, measurement errors of all the input parameters and the need to assume a single effective pK_a value for the many proteins in blood and tissue will reduce any putative superiority of this approach. P_{CO_2} and pH are directly measured and the bicarbonate either calculated from these parameters or estimated from the total CO_2 content, and they need not be calculated from the balance of electrolytes and weak buffers, many of which are unknown. Although the distinction between strong and weak acids and bases is readily made in plasma, it is less precise in other biologic fluids such as urine and gastrointestinal secretions. For these reasons, we have therefore chosen to retain the older approach.

Nomenclature of Acid-Base Disorders

In using CO_2 and HCO_3^- to estimate the respiratory and metabolic factors determining pH, the nomenclature of the acid-base disorders becomes quite simple with an additional assumption that compensation for a primary deviation is never complete. If arterial pH is low, the primary disorder must be an acidosis, and if high, a primary alkalosis is present. A secondary or compensatory change in either the respiratory or the metabolic parameter restores pH toward normal, but this effect should remain incomplete. On the basis of this approach, abnormal combinations of pH, P_{CO_2}, and HCO_3^- can be designated in terms of a primary disorder and any compensation that might be present.

Examples of virtually every combination of such changes are provided in Table 7-1 and illustrated in Figure 7-3. Figure 7-3A indicates the ranges in which HCO_3^- and P_{CO_2} changes have been observed in normal persons subjected to acute or chronic respiratory or metabolic changes. Figures 7-3A and B are based on the simple assumption that HCO_3^- changes reflect metabolic events, whereas changes in P_{CO_2} reflect respiratory events (as indicated in Table 7-1). Some comments concerning the reliability of this preliminary analysis are provided in Table 7-1 and are discussed later in the chapter. Horizontal deviations on these coordinates indicate respiratory changes, whereas vertical deviations designate metabolic changes. Four primary disorders (A, C, E, and G) and four compensatory responses (B, D, F, and H) are shown in Figure 7-3. Each of the latter responses returns the pH toward 7.4, but never fully, and the pH remains abnormal in the same direction as the primary change. Note that if respiratory and metabolic parameters change proportionately, pH remains unchanged (I and J). In this circumstance, the disorder is considered a "mixed" combination of primary disorders. Another "mixed" disorder arises when both parameters are altered in a fashion that changes the pH in the same direction (K and L) and neither change can be considered as compensatory. A third type of "mixed" disorder must be entertained if a patient simply fails to "compensate" in the expected manner for a primary disorder after sufficient time has elapsed.

Because the three variables must be related by Equation 2, not all combinations of pH, P_{CO_2}, and HCO_3^- are possible. One combination (M), which is chemically impossible and cannot be plotted, must represent a laboratory error or timing differences at which various parameters were obtained, is indicated in Table 7-1. "Triple disorders" may also be encountered involving a mixture of two independent processes that induce a metabolic alkalosis and a metabolic acidosis (detected by an increase in the anion gap), plus either a respiratory alkalosis or a respiratory acidosis. Measurement of specific organic acids in plasma may permit identification of even more complex disorders.

Several caveats should be heeded regarding both this and other systems that classify acid-base disorders strictly on the basis of pH, P_{CO_2}, and a metabolic parameter. Distinction between primary and compensatory disorders is based simply on which alteration was proportionately greater at the time the blood was drawn rather than on the sequence of events involved. For example, it is common for patients with chronic obstructive pulmonary disease (COPD) to be admitted to the hospital with compensated respiratory acidosis. With therapy, the P_{CO_2} may decrease, leaving what might otherwise in the absence of the clinical history be taken as "a primary metabolic alkalosis with secondary respiratory compensation." Winters[15] suggested that a distinction be made between the "physiologic" language commonly used by the physician and the "laboratory" terminology that is strictly based on blood parameters.

Laboratory definitions of primary and secondary or compensatory alterations of acid-base disorders assume that one is greater than the other and that there has been sufficient time for compensatory processes to reach their full quantitative expression. As discussed later, complete respiratory compensations occur within hours, but full renal compensation takes several days. Thus, in any rapidly evolving and changing disease scenarios, clinicians should not always assume that lack of an expected compensations dictates consideration of a second or third primary disorder. Under some circumstances, however, compensation (correction to normal pH) may be complete in the apparent absence of what could be identified as a second primary disorder. For example, full compensation is observed among COPD patients who are chronically hypercapnic, whose lung function can

TABLE 7-1. Laboratory Classification of Acid-Base Disorders

Location in Figure 7-3	Metabolic Parameter HCO_3^- (mEq/L)	pH	Respiratory Parameter P_{CO_2} (mm Hg)	Preliminary Interpretation	Comments Based on Bands (Fig. 7-3)
Normal range	23–27	7.38–7.42	38–42		
A	25	7.12	80	Respiratory acidosis	A small increase in (uncompensated) HCO_3^- usually occurs with acute respiratory acidosis
B	35	7.25	80	Respiratory acidosis (compensated)	Compensation has not reached expected confidence levels
C	25	7.71	20	Respiratory alkalosis (uncompensated)	A decrease in HCO_3^- would be expected; acute respiratory alkalosis

Interpretation based on assumption that P_{CO_2} and HCO_3^- are respiratory and metabolic parameters.

improve over the course of the day with clearance of secretions. With better ventilation and $\dot{V}_A/\dot{Q}$ matching, arterial P_{CO_2} falls and pH increases to normal or even higher than normal levels before the kidneys can quantitatively respond (see discussion on compensations later). Full compensation is also characteristic of the chronic hyperventilation observed at high altitude.

If HCO_3^- were a strictly metabolic ("nonrespiratory") variable, then changes in P_{CO_2} would result in movement along a line perpendicular to the HCO_3^- axis (e.g., A and C in Fig. 7-3B). The actual response of HCO_3^- to acute and chronic changes can be indicated by the 95% confidence bands shown in Figure 7-3. Note that both A and C deviate from the expected responses to acute changes in P_{CO_2} (see comments in Table 7-1). Because P_{CO_2} is assumed to be a reliable index variable of ventilation, E and G represent metabolic changes without respiratory compensation.

Compensations

Respiratory Acidosis

Although the acute increase in HCO_3^- is relatively modest after onset of hypercapnia, HCO_3^- continues to rise if hypercapnia persists and reaches a peak value after about 5 days. This is related primarily to an increase in the exchange of H^+ for Na^+ in the proximal tubule and increased HCO_3^- reabsorption (see later discussion). Increases in plasma HCO_3^- require an initial net loss of H^+, which is made possible by the loss of increased quantities of NH_4^+ in the urine. Once plasma HCO_3^- has reached a new steady state, H^+ secretion need only be sufficient to reabsorb HCO_3^- from the tubular fluid, and NH_4^+ and H^+ excretion usually return to normal. In contrast, excretion of both net NH_4^+ and net H^+ remains elevated in chronic metabolic acidosis, because the daily load of nonvolatile acids must be excreted, over and above the acid excretion needed for reabsorption of HCO_3^-. Differences in NH_4^+ and net H^+ excretion in chronic respiratory and metabolic acidosis may be related to the fact that proximal tubular fluid contains high concentrations of HCO_3^- in chronic respiratory acidosis but low concentrations in chronic metabolic acidosis. Increased HCO_3^- flux into the proximal tubular cells in chronic respiratory acidosis keeps intracellular pH relatively alkaline compared with the situation observed in chronic metabolic acidosis. Intracellular acidosis stimulates secretion of NH_4^+ in chronic metabolic acidosis.[16]

TABLE 7-2. Rules of Chronic Compensation

Primary Disorder	Secondary Compensation	EXAMPLES	
		Primary Change	Compensation
↑ P_{CO_2}	↑ HCO_3^-: 4 mEq/L for each 10-mm Hg increase in P_{CO_2} (±3 mEq/L)	P_{CO_2}: 40 → 80	HCO_3^-: 24 → 40 pH: 7.1 → 7.32
↓ P_{CO_2}	↓ HCO_3^-: 2.5 mEq/L for each 10-mm Hg decrease in P_{CO_2} (±3 mEq/L)*	P_{CO_2}: 40 → 20	HCO_3^-: 24 → 19 pH: 7.70 → 7.60
↓ HCO_3^-	↓ P_{CO_2}: 1–1.5 mm Hg for each mEq/L decrease in HCO_3^-	HCO_3^-: 24 → 9	P_{CO_2}: 40 → 25 pH: 7.00 → 7.20
↑ HCO_3^-	↑ P_{CO_2}: 0.5–1.0 mm Hg for each mEq/L increase in HCO_3^-	HCO_3^-: 24 → 4	P_{CO_2}: 40 → 50 pH: 7.56 → 7.46

*HCO_3^- seldom falls below 18 mEq/L in acute and 16 mEq/L in chronic respiratory alkalosis.

Respiratory Alkalosis

Hypocapnia results in a decrease in renal acid excretion and a fall in HCO_3^- that becomes fully evident within 2 to 3 days. As indicated in Table 7-2, HCO_3^- decreases by 2.5 mEq/L for each decrease of 10 mm Hg in P_{CO_2}[17] and does not generally fall much below 16 mEq/L in respiratory alkalosis unless there is an independent metabolic acidosis present. In contrast, an increase of about 4 mmol of HCO_3^- may be expected when P_{CO_2} is increased in steps of 10 mm Hg. Confidence bands for chronic compensation are indicated in Figure 7-3A.

Metabolic Acidosis

Respiratory compensation for metabolic disorders is quite fast (within minutes) and reaches maximal values within 24 hours. A decrease in P_{CO_2} of 1 to 1.5 mm Hg should be observed for each milliequivalent decrease of HCO_3^- in metabolic acidosis.[18] A simple rule for deciding whether the fall in P_{CO_2} is appropriate for the degree of metabolic acidosis is that the P_{CO_2} should be equal to the last two digits of the pH. For example, compensation is adequate if the P_{CO_2} decreases to 28 when the pH is 7.28. Alternatively, the P_{CO_2} can be predicted by adding 15 to the observed HCO_3^- (down to a value of 12). Although reduction in P_{CO_2} plays an important role in correcting any metabolic acidosis, evidence suggests that it may in some respects be counterproductive because it inhibits renal acid excretion.

Metabolic Alkalosis

Compensation for metabolic alkalosis results in a decrease of ventilation and a rise of P_{CO_2} by about 0.6 to 0.7 mm Hg for each milliequivalent increase in HCO_3^-, but it seldom results in a P_{CO_2} much greater than 55 mm Hg[19] because the accompanying hypoxemia from hypoventilation generates an opposing ventilatory stimulus. Furthermore, compensatory increases in P_{CO_2} may be more pronounced in patients with metabolic alkalosis who have not lost K^+. Losses of K^+ are associated with an intracellular rise in H^+, including the neurons of the respiratory center.[20] A variety of other factors have been reported that can increase P_{CO_2} values in patients with metabolic alkalosis.[21] Respiratory compensation for metabolic alkalosis, like that for metabolic acidosis, can have a counterproductive effect on renal H^+ transport: increases in P_{CO_2} associated with metabolic alkalosis decrease intracellular pH in the kidney, thereby promoting acid secretion and further increasing serum HCO_3^- levels.[22]

Role of the Kidney in Acid-Base Balance

Response to Acidosis and Excretion of Acid

Daily about 1 mEq/kg of "fixed" acids (i.e., acids other than H_2CO_3) are produced in metabolism with a typical protein diet. These nonvolatile acids cannot be excreted by the lungs and must be lost by other routes, or buffered, to avoid progressive retention. Both sulfate and phosphate are produced, and these may be accompanied by a variety of organic acids, some of which escape metabolism and contribute to the daily acid load. Successful elimination by the kidneys depends on both tubular H^+ transport and the presence of urinary buffers. In absence of buffers, less than 0.1 mEq of acid/L would be excreted even at the lowest urinary pH (4.5) generated by the kidneys.

Three kinds of buffers are found in urine: bicarbonate, ammonium, and titratable acids. Daily there is filtration of 3600 mEq of HCO_3^- with trivial losses in the urine. Most of the filtered HCO_3^- is reclaimed by an exchange of intracellular H^+ for Na^+ (through a Na^+-H^+ antiporter, "NHE_3") rather than direct HCO_3^- reabsorption, although the latter process may be stimulated in acidotic states. Intracellular H^+ is derived from carbonic anhydrase–mediated hydration of CO_2 to H_2CO_3 and the dissociation of H_2CO_3 to H^+ and HCO_3^-. H^+ entering the proximal tubule combines with HCO_3^- and rapidly regenerates CO_2 and H_2O, accelerated by the presence of carbonic anhydrase (type IV) on the luminal surface of the proximal tubule cells. The HCO_3^- formed within proximal tubule cells moves across the basolateral membranes in exchange for Cl^- ($Na^+/HCO_3^-/CO_3^{2-}$ symporter).

Removal of HCO_3^- from proximal tubular fluid is essential, and failure to do so inevitably leads to hyperchloremic acidosis. However, HCO_3^- reabsorption does not result in acid excretion in the urine and therefore cannot contribute to fixed acid excretion. Unlike HCO_3^-, titratable acids and ammonium do reach the urine, and H^+ is carried into the urine by these buffers. The principal titratable anion is $H_2PO_4^-$, but during ketoacidosis, β-hydroxybutyric acetate also can act as an effective buffer. NH_4^+ is produced from glutamine by the proximal tubular cells and can be stimulated by chronic acidosis. NH_4^+ is secreted into the proximal tubule; some of this ion is reabsorbed in the thick ascending limb of the tubule, and a fraction is converted into NH_3. This increases medullary concentration of NH_3, which diffuses into the collecting ducts. Because the collecting duct fluid tends to be very acid, NH_3 becomes "trapped" as NH_4^+. Details regarding renal metabolism and excretion of NH_3 and NH_4^+ can be found elsewhere.[23]

Movement of H^+ into the proximal nephron differs in a number of important respects from transport in the distal nephron. Because the proximal tubule is responsible for absorbing most of the filtered HCO_3^-, considerably more H^+ transport occurs at this location than distally (~3600 mEq, as described earlier, vs. 50–100 mEq of fixed acids). However, the ability of the proximal tubule to concentrate H^+ is limited, and the fluid leaving the proximal tubule has a pH of about 6.8. Although the more distal portions of the tubule secrete less total H^+ than the proximal tubules, they increase H^+ concentration by almost 1000-fold compared with plasma, producing a urinary pH as low as 4.5. This permits net renal excretion of the acids normally generated by metabolism. Distal tubular acid secretion is mediated by H^+-ATPase and K^+/H^+-ATPase on the luminal surface of the intercalated cells of the collecting tubules and by transporters on inner medullary cells. This process is accelerated by electrogenic Na^+ reabsorption by adjacent principal cells, a process that makes the electrical potential of the tubular lumen more negative and thereby enhances secretion of H^+.

Because CO_2 readily diffuses across cell membranes, the P_{CO_2} and pH of the renal tubular cells are affected promptly by changes in arterial P_{CO_2}. These changes initiate changes in renal H^+ excretion, with an increase during hypercapnia and decrease by hypocapnia.

Response to Alkalosis

Alkalosis can be initiated by losses of acid in the gastric fluid or urine, a shift of hydrogen ions into the cells (frequently associated with hypokalemia), excessive alkali administration, or decreases in the extracellular volume (e.g., following diuretics). Under normal circumstances, an abrupt increase in plasma HCO_3^- above the normal threshold of 25 mEq/L initiates a prompt compensating renal loss of HCO_3^-, by both decreased proximal reabsorption and increased distal secretion.[24,25] Understanding the pathogenesis of metabolic alkalosis must explain not only how it is initially generated but also the manner in which it is maintained.

The second or "maintenance" phase of metabolic alkalosis can be attributed to several mechanisms that reduce HCO_3^- losses by the kidneys: (1) Decreases in renal perfusion due to extracellular contraction result in increases in the renin-angiotensin-aldosterone system, which increases reabsorption of Na^+ especially by the principal cells of the collecting duct. This is associated with increased hydrogen ion secretion via the apical proton pump H^+-ATPase in the adjacent A-type intercalated cells. (2) Reduced concentrations of Cl^- reaching the macula densa in the late thick ascending limb and early distal tubule also stimulate the renin-angiotensin-aldosterone system. Furthermore, reductions in Cl^- reaching the collecting duct reduce exchange of HCO_3^- for Cl^- through the apical chloride/bicarbonate exchanger in the B-type intercalated cells. (3) Hypokalemia stimulates secretion of H^+ ion by H^+/K^+-ATPase in the collecting duct. It also increases NH_4^+ secretion with generation of alpha ketoglutamine, which is metabolized to HCO_3^-. Hypokalemia causes an intracellular acidosis and a reduction in glomerular filtration rates which also reduce HCO_3^- losses in the urine.[26] During the maintenance phase, the urine becomes relatively acidotic, a phenomenon that actually worsens or at least maintains the alkalosis that was originally generated by vomiting. This is sometimes referred to as *paradoxical aciduria* or *alkalosis of contraction*. In effect, acid-base balance is sacrificed to conserve Na^+ and defend extracellular fluid (ECF) volume. Increased distal nephron Na^+ delivery and increased Na^+ reabsorption drives K^+ secretion. More K^+ is lost from the kidneys than the gastric losses with vomiting. In effect, even the intracellular electrolyte status is imperiled to maintain ECF volume. Cl^- in the glomerular filtrate is largely reabsorbed during the maintenance stage, and little appears in the urine.[27]

Intracellular Acid-Base Physiology

Intracellular buffers are an important early defense against acid-base perturbations. Metabolic acidosis induced by HCl infusions is rapidly buffered by plasma HCO_3^- and other buffers, but acid diffuses into the interstitial space over a period of 15 minutes and into cells over 2 to 4 hours to be buffered. Ultimately, approximately 40% of the infused acid is buffered extracellularly, primarily by HCO_3^-, and the remainder cellularly and by bone buffers. In contrast, almost all respiratory acidosis buffering is intracellular or with bone, because HCO_3^- cannot directly neutralize carbonic acid. However, the fall in pH that is associated with a rise in P_{CO_2} can be moderated by electroneutral exchange of red cell HCO_3^- for Cl^- and by increases in plasma HCO_3^- mediated by the movement of H^+ from the ECF into cells in exchange for Na^+ and K^+. Buffering of respiratory acidosis by these means is relatively modest (~1 mmol/L for each 10 mm Hg in P_{CO_2}). More substantial buffering requires renal secretion of H^+, which increases plasma HCO_3^- concentrations by 4 mmol/L for each 10-mm Hg increase in P_{CO_2}.

Temperature is an important physiologic variable, and its effects on acid-base status are relevant to intracellular

as well as extracellular buffers. Reeves and Rahn[28] proposed that metabolic and respiratory mechanisms function to preserve the ionic charge on proteins, including enzymes and chemoreceptors involved in pH regulation, rather than maintain a constant intracellular and extracellular pH. Because enzyme function is influenced by ionic charge, maintenance of a constant charge is presumably homeostatically advantageous. Only imidazole groups of histidine and, to a lesser extent, the α-NH_3^+–terminal amino groups of peptides are present in significant concentrations and change their extent of dissociation appreciably in physiologic pH ranges. The pH of the intact organism is then regulated in a manner that keeps the dissociation of the imidazole groups constant at various temperatures. When sealed samples of blood are cooled to 15°C, the CO_2 content of the blood must remain constant, but the pH increases to 8.0 and the P_{CO_2} falls to 12 mm Hg. Despite these dramatic changes in pH and P_{CO_2}, the fraction of the imidazole groups that are dissociated remains virtually unchanged. This phenomenon can be attributed to the fact that changes in temperature have a similar effect on the dissociation constants of water and imidazole. Independence of protein charge from temperature changes was presumably important in our poikilothermic ancestors. It also facilitates clinical interpretation of acid-base balance in hypothermia and hyperthermia, because acid-base parameters measured at 37°C can provide a reasonable index of the acid-base status of the patient, regardless of whether the patient's temperature is normal, elevated, or depressed. Temperature corrections, however, are needed for P_{CO_2} and P_{O_2} in order to accurately assess lung gas exchange efficiency by the alveolar gas equation.

The relatively hidden environment of the intracellular fluid has begun to be probed since the late 1980s by a combination of microelectrodes and imaging methods utilizing fluorescent dyes and magnetic resonance spectroscopy. What has emerged is a process of transmembrane acid-base exchanges with the ECF that, combined with chemical buffering, accomplish very impressive intracellular pH regulation in the face of acidotic and alkalotic challenges, particularly in critical organs such as the heart and brain.[29] To defend against intracellular acidosis, cells activate both membrane H^+ translocating ATPases and Na^+/H^+ antiporters to export H^+. Both processes are energy-requiring; the first uses adenosine triphosphate (ATP) directly and the second utilizes the inward electrochemical gradient for sodium flux established by continued Na^+K^+-ATPase pumping that maintains a lower intracellular Na^+ concentration. Less has been studied on the mechanisms of defense against intracellular alkalosis, but evidence points to the activation of both neutral and electrogenic transporters that export HCO_3^- in exchange for chloride (anion exchangers similar to AE-1 in red cells responsible for Cl^-/HCO_3^- exchange) or couple HCO_3^- export to other cations like sodium ($Na^+/HCO_3^-/CO_3^{2-}$ symporter).

METABOLIC ACIDOSIS

Anion Gap Concept

The most useful classification of metabolic acidosis is based on the concept of the anion gap, whose calculation is made by subtracting the sum of plasma concentrations of Cl^- and HCO_3^- from that of Na^+ (Fig. 7-4). This difference provides an index of the relative concentrations of plasma anions other than Cl^- and HCO_3^-. Normally, the anion gap is between 8 and 16 mEq/L, although somewhat lower values (5–11 mEq/L) have been observed when newer techniques for measuring ion activities rather than total concentrations are used.[30,31] Among other anions present in plasma are albumin (with multiple anionic groups at physiologic pH that normally constitute about half of the gap), lactate, pyruvate,

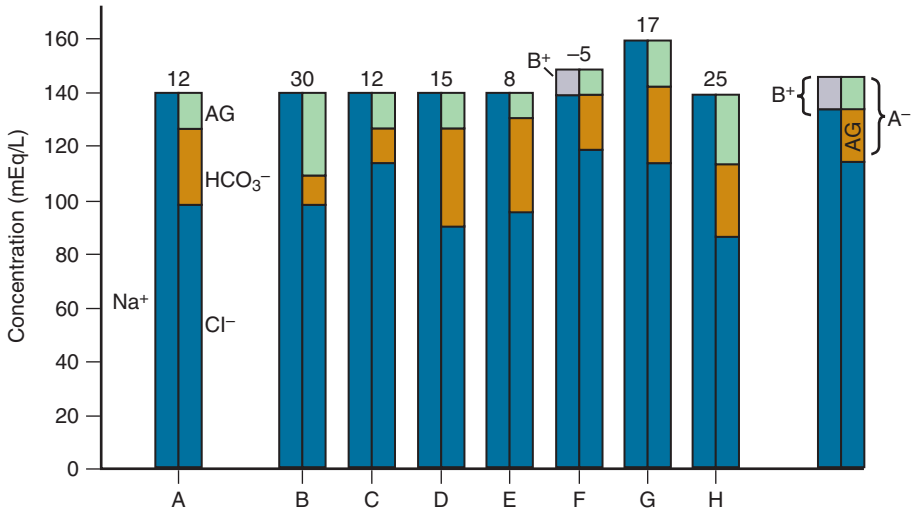

FIGURE 7-4 ■ Anion gap (AG) profiles are shown for eight different conditions (see text). The value of the AG is shown above each bar. **A,** normal; **B,** anion gap acidosis; **C,** hyperchloremic acidosis; **D,** primary metabolic alkalosis; **E,** secondary metabolic alkalosis; **F,** excess cations (B^+) other than Na^+; **G,** hypernatremia; **H,** excess anion gap in absence of acidosis. The bar outside the graph demonstrates the relation between excess cations (B^+), excess anions (A^-), and the anion gap (AG).

sulfate, and phosphate. Elevations of the anion gap usually indicate accumulation of some acid other than HCl in the plasma and are generally accompanied by a similar decrease in HCO_3^- ("anion gap acidosis") (B in Fig. 7-4). Alternatively, reduction in [HCO_3^-] may be caused by an increase in [Cl^-] without an increase in the anion gap ("hyperchloremic acidosis") (C in Fig. 7-4).

Examples of both anion gap and hyperchloremic metabolic acidosis are discussed later, along with a third and less common form, "dilutional acidosis." However, some general comments concerning the anion gap concept are warranted. First, although addition of acids other than H_2CO_3 and HCl to plasma tends to increase the anion gap, this effect is somewhat less than might be expected, because H^+ tends to combine with negative groups on the albumin molecules, thereby reducing the contribution of this protein to the anion gap. Alkalosis tends to increase the number of anionic groups on albumin, thereby increasing the anion gap. Recognition of this phenomenon may be helpful when the CO_2 content of the blood is available but the arterial pH and P_{CO_2} are not. For example, if an elevated HCO_3^- is related to a primary metabolic alkalosis, then the anion gap tends to be greater than when it is secondary to a compensatory respiratory acidosis (compare D and E in Fig. 7-4). Second, because approximately half of the anion gap is normally related to negative charges on albumin, hypoalbuminemia decreases the anion gap by about 2.5 mEq/L for each decrease in albumin concentration of 1 g/dL.[32] Third, electroneutrality requires that the sum of known cations (Na^+) and unknown cations (B^+) must equal the sum of known anions ($Cl^- + HCO_3^-$) and unknown anions (A^-)[1]:

$$Na^+ + B^+ = (Cl^- + HCO_3^-) + A^- \quad (5)$$

Consequently, the anion gap must equal the difference between the unknown anions and cations (see Fig. 7-4):

$$\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-) = A^- - B^+ \quad (6)$$

A low anion gap may therefore reflect an increase in cations other than Na^+ (e.g., calcium [Ca^{2+}], magnesium [Mg^{2+}], lithium [Li^+], and abnormal cationic proteins in multiple myeloma) (see F in Fig. 7-4). As illustrated in Figure 7-4, the "anion gap" is actually less than the concentration of unknown anions, by a value equal to the concentration of unknown cations. Fourth, losses of water during dehydration increase the levels of all solute concentrations, including those that compose the anion gap (see G in Fig. 7-4). Retention of water has the opposite effect. Fifth, administration of large quantities of sodium salts of anionic antibiotics (e.g., penicillin and related drugs) or other anions (e.g., lactate, citrate, acetate) can also increase the anionic gap without acidosis (see H in Fig. 7-4). If anions of this type have not been administered and the patient is not dehydrated, then an increased anion gap suggests an underlying metabolic acidosis, even if the pH is normal or high (H in Fig. 7-4).

Finally, because much of the H^+ produced in the body is buffered by non-HCO_3^- buffers within cells, the decrease in HCO_3^- tends to be less than the increase in the anion gap when metabolic acidosis is present. For example, the increase in the anion gap averages about 60% more than the decrease of HCO_3^- in lactic acidosis. Because ketones are more readily lost in the urine than lactate, the increase in the anion gap is generally similar to the decrease in HCO_3^- in conditions that result in ketoacidosis[33] (see later discussion). Conversely, if the decrease in HCO_3^- exceeds the increase in the anion gap, it is likely that at least part of the acidosis is caused by a non–anion gap acidosis.

Causes

Lactic Acidosis

Approximately 1400 mEq of lactate are normally produced each day,[34] but production can increase by an order of magnitude in heavy exercise. At rest, production is balanced by consumption and precisely regulated so that serum levels are kept at about 1 mEq/L. Most lactate is produced by the skeletal muscles, but with various stresses such as ischemia, profound hypoxemia, sepsis, and high sympathetic tone, other tissues may also generate lactate. In resting healthy individuals, the liver and, to a lesser extent, the kidneys are responsible for most of its consumption,[34] with oxidation in red skeletal muscle accounting for the remainder. During physical exertion, although lactate is the main gluconeogenic precursor in liver and kidneys, oxidation in working muscle accounts for 70% to 80% of lactate disposal. Newer work and analysis of glycolytic intermediary metabolism suggest we may have to reconsider our classic thinking about what we have long termed "lactic acidosis." From a strict biochemical standpoint, it is lactate and not lactic acid that is generated at the terminal point in glycolysis when pyruvate is reduced to lactate by lactate dehydrogenase (LDH), a step that consumes rather than produces a proton (Fig. 7-5).

$$\text{Pyruvate} + \text{NADH} + H^+ \leftrightarrow \text{Lactate} + NAD^+$$

In terms of proton production, stiochiometric analysis of the glycolytic pathway shows the pathway to be proton neutral. Thus, the acidosis that develops when lactate rises with exercise and possibly with other conditions associated with lactate accumulation and acidosis may be misleading.[35] It has been suggested, in fact, that if there were no lactate formation, the degree of acidosis arising in these circumstances would even be greater. The hydrogen ion that is formed in states of "lactic acidosis" arises from ATP whose hydrolysis generates a hydrogen ion.

$$ATP + H_2O \leftrightarrow ADP + PO_4^- + H^+$$

Under conditions where adenosine diphosphate (ADP) is not rephosphorylated, H^+ will accumulate. This occurs with true O_2 deficiency in ischemic (severe hypoperfusion) or very hypoxemic states when O_2 delivery cannot be maintained to support aerobic metabolism. Although the production of excessive quantities of lactate is thought to be linked in some way to tissue hypoxia in many clinical conditions associated with lactic

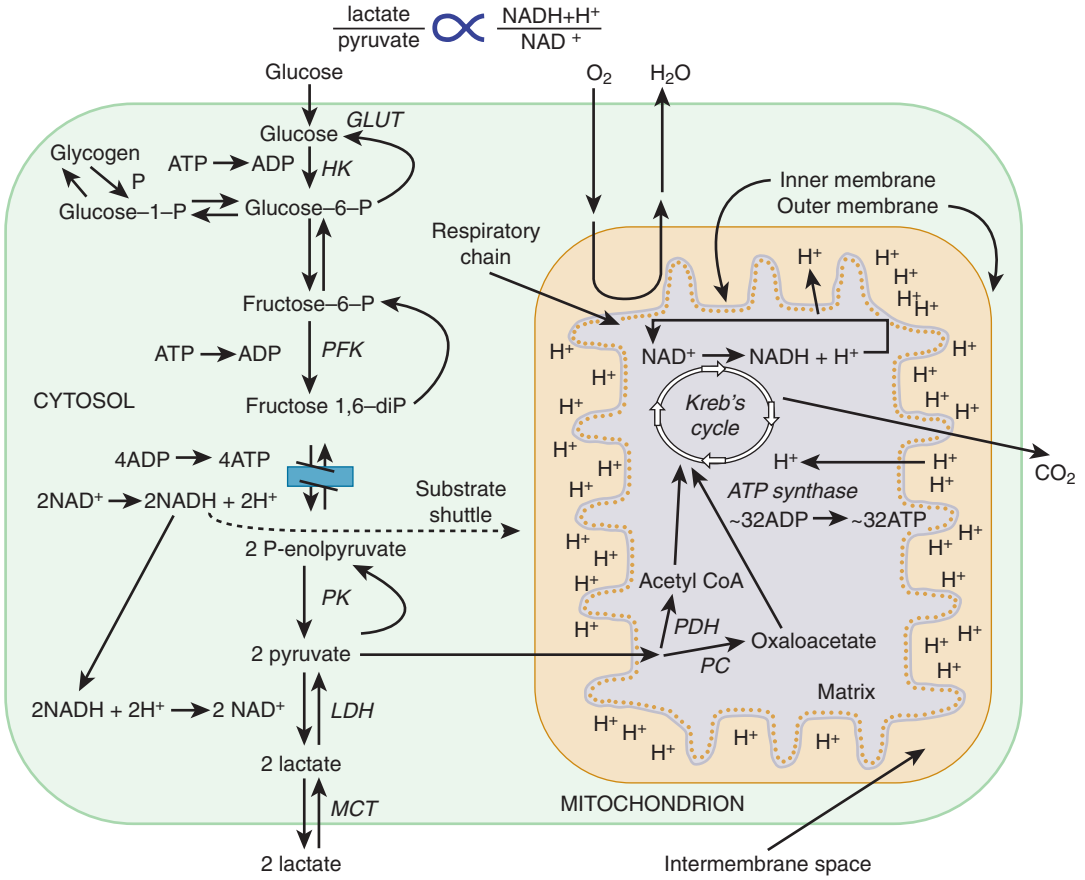

FIGURE 7-5 ■ The metabolic events responsible for the development of lactic acidosis during hypoxia are indicated schematically. Both enhancements and reduction of metabolic reactions that produce lactic acid are shown (see text). Factors affecting the balance between lactate and pyruvate are indicated in the equation at the top of the figure. ADP, adenosine diphosphate; ATP, adenosine triphosphate; CoA, coenzyme; k, constant; LDH, lactate dehydrogenase; NAD^+, nicotinamide adenine dinucleotide (oxidized); NADH, nicotinamide adenine dinucleotide (reduced); P, phosphate; PC, pyruvate carboxylase; PDH, pyruvate dehydrogenase; PFK, phosphofructokinase; PK, pyruvate kinase. Stoichiometry is not shown for most of the reactions within the mitochondrion (other than ADP and ATP).

acidosis, the evidence of tissue hypoxia is largely negative when sought for in maximally exercising muscle[36] or in sepsis,[37] though it would be difficult to detect small local regions of tissue hypoxia. The benign, or rather efficacious, nature of lactate has been demonstrated in "lactate clamp" studies,[38] in which lactate concentration is raised to 4 mM by infusion of a sodium lactate/lactic acid mixture along with glucose and lactate tracers. Under these conditions, lactate is the preferred fuel and because its disposal via gluconeogenesis or oxidation involves proton removal, lactate infusions have a mild alkalinizing effect. Nevertheless, the increase in lactate and production of acid during heavy exercise is presumably attributable to an increase in the fraction of glucose diverted to glycolytic rather than mitochondrial metabolism.

As indicated in Figure 7-5, glucose is normally metabolized to pyruvate, which is in equilibrium with lactate, at a ratio of 1:10 at rest and rising to 1:100 with exercise. Metabolism of lactate can occur only if it is converted back to pyruvate either in the cytosol or in the mitochondria (see discussion later). Pyruvate can be transported into the mitochondria in either of two ways. In gluconeogenic organs, CO_2 can be added to pyruvate by the enzyme pyruvate carboxylase to form oxaloacetate, which can then be converted to phosphoenol pyruvate and converted to glucose-6-phosphate (G-6-P) and glucose. Alternatively, pyruvate can be oxidized to acetyl coenzyme A (CoA) by pyruvate dehydrogenase (PDH). Acetyl CoA then combines with oxaloacetate and is metabolized to form both ATP and nicotinamide adenine dinucleotide (NAD^+). In absence of oxygen, reduced NADH cannot be oxidized to NAD^+, and ATP production by the cytochrome system is blocked. Because the carboxylase reaction requires ATP and the dehydrogenase reaction requires NAD^+, pyruvate can no longer enter the mitochondria, and concentrations of both cytosolic pyruvate and lactate increase. Increased cytosolic NADH results in a disproportionate lactate increase. In addition, accumulation of cytosolic ADP, adenosine monophosphate (AMP), and phosphates activates phosphofructokinase and pyruvate kinase. This in turn increases metabolism of glycogen and glucose, which are effectively converted to lactate, a sequence of events referred to as the *Pasteur effect*. In effect, hypoxia promotes lactic acidosis both by increasing lactate production and by reducing its metabolism (see Fig. 7-5).

Anaerobic production of ATP is much less efficient than aerobic production. For each millimole of glucose

converted to 2 mmol of pyruvate, a net of 2 mmol of ATP is produced. In the absence of oxidative metabolism, NADH and H^+ accumulate, encouraging lactate formation. If, in contrast, pyruvate is metabolized aerobically, an additional 36 mmol of ATP is produced by way of the Krebs cycle. Note that the protons and electrons can be "shuttled" across the mitochondrial membranes in a manner that tends to equalize the redox potentials of the mitochondria and cytoplasm.

As mentioned previously, in many supposedly hypoxic tissue states, such as heavy exercise, seizures, and sepsis, O_2 delivery is not always insufficient and other causes for increased lactate formation and acidosis must be considered. One important cause is heightened sympathetic activation and catecholamine stimulation of glycolysis in excess of mitochondrial capacity for pyruvate uptake and metabolism arising from stimulated membrane ATP utilization by Na^+/K^+-ATPase and accumulation of ADP, H^+, and phosphate.[37] It has been suggested that lactate itself can enter the mitochondria in what has been termed the *intracellular lactate shuttle* under conditions in which pyruvate entry for reasons not entirely known may be insufficient by the classic entry pathways.[38,39] Mitochondrial lactate entry is facilitated by a monocarboxylic transporter-LDH complex localized on the inner mitochondrial membrane where pyruvate can be regenerated for utilization in the Krebs cycle. Other reasons given for increased cytosolic lactate production include regeneration of NAD^+ to maintain high rates of glycolysis and to provide necessary redox equivalents to support high glycolytic and electron transport chain function.[40]

The diagnosis of lactic acidosis is based on the presence of an acidosis and a lactate concentration significantly greater than the normal concentration of 1 mEq/L (usually >5 mEq/L). Regardless of the actual role of lactate generation in acidification, use of the term "lactic acidosis" is justified by the presence of both acidosis and increased lactate contractions in this condition. Arterial lactate samples are usually collected because unless a mixed venous sample is obtained, peripheral venous samples reflect blood lactate concentrations leaving only a portion of the body and may therefore be unrepresentative of the whole body. Under normal circumstances, lactate concentrations exceed those of pyruvate by a factor of 10. Significant increases in this ratio suggest true tissue hypoxia, states of high adrenergic tone, or nonhypoxic abnormalities in intermediary metabolism.

Considering the marked arterial hypoxemia in some patients with severe respiratory insufficiency or cyanotic heart diseases, it may seem paradoxical that lactic acidemia is not observed more frequently. Lactic acidosis is much more likely to appear when tissue perfusion is impaired than when arterial P_{O_2} is moderately reduced. Several compensations for chronic arterial hypoxemia help minimize tissue hypoxia: cardiac output and hematocrit rise, and hemoglobin O_2 affinity falls if pH declines in those with CO_2 retention, because of increased 2,3-diphosphoglycerate concentrations.

Skeletal muscle represents the principal site of lactate turnover. During moderate exercise, blood lactate levels normally remain unchanged despite elevated production. In a progressive (ramp) test, when work rates increase above what is referred to as the *anaerobic threshold*, lactate concentrations increase because the rate of rise in lactate production exceeds its rate of disposal. Although it was formerly thought at this level of exercise O_2 consumption exceeds O_2 delivery to the muscle cell mitochondria, this now seems somewhat less likely and it may be linked to rising catecholamine-stimulated nonhypoxic glycolysis.[40] During vigorous exercise, lactate levels may transiently increase to 20 mEq/L or greater. Excessive production of lactate by skeletal muscles can also be observed during grand mal seizures and may accompany severe shivering in the hypothermic patient (Table 7-3).

Cohen and Woods[41] divided the causes of lactic acidosis into two types: type A, in which tissue hypoxia is evident, and type B, in which the tissue P_{O_2} appears to be normal. Type A disorders include all forms of shock, adult respiratory distress syndrome, acute hypoxemia, and a variety of conditions that impair oxygen delivery, such as carbon monoxide poisoning and severe anemia. As explained above, the actual role of tissue hypoxia in Type A disorders remains controversial. Type B disorders, which are not usually associated with tissue hypoxia, include common illnesses that may be associated with lactic acid accumulation; a variety of drugs and poisons that can induce lactic acidosis (associated with

TABLE 7-3. Causes of Anion Gap Acidosis

KETOACIDOSIS
Diabetes mellitus
Starvation
Ethanol
Inheritable errors of metabolism
LACTIC ACIDOSIS
Type A: Tissue Hypoxia
Poor tissue perfusion: shock due to hypovolemia, sepsis, cardiogenic, idiopathic
Severe hypoxemia: pulmonary disorders (e.g., asthma, excessive inhaled β_2-adrenergic agents), acute respiratory distress syndrome, carbon monoxide poisoning
Exercise above anaerobic threshold, seizures, shivering
Rhabdomyolysis
Severe anemia, carbon monoxide
Type B: Altered Lactate Metabolism without Hypoxia
Liver disease, renal failure, diabetes mellitus, malignancies (especially hematopoietic)
Drugs: biguanides, ethanol, methanol, salicylates, ethylene glycol, isoniazid toxicity, zidovudine (AZT), metformin, chemotherapy, nitroprusside, propofol
Rhabdomyolysis
Hereditary: glucose-6-phosphatase deficiency, fructose-1,6-phosphatase deficiency
D-Lactic acidosis
UREMIA
MISCELLANEOUS TOXIC ANIONS
Ethylene glycol (glyceraldehyde, oxalate, hippurate)
Methanol (formaldehyde, formate)
Paraldehyde (acetoacetate)
Salicylates
Aminocaproic acid

myoglobinemia recently following propofol administration[42]), and congenital metabolic enzyme deficiencies. In diabetic patients, low insulin levels reduce the metabolism of pyruvate by PDH, resulting in an increased lactate concentration. Evidence has also been reported that accumulation of ketones in the plasma may inhibit the monocarboxylic acid pump that is responsible for hepatic uptake of lactate.[43] In some patients with diabetic ketoacidosis (DKA), elevated lactate may be caused by ECF volume depletion due to osmotic diuresis induced by hyperglycemia. Malignancies, particularly lymphoproliferative and myeloproliferative disorders, may result in overproduction of lactic acid. Renal or hepatic failure may also lead to lactic acidosis.

Although L-lactate is usually the cause of lactic acidosis, D-lactate accumulation due to intestinal bacterial metabolism has been documented in patients with short bowel syndrome, bowel ischemia, or obstruction; it can be detected only if an appropriate bacterial enzyme is used in the lactic acid assay.[44] D-Lactic acidosis can also be expected with use of Ringer's lactate solution, which contains a racemic mixture of lactic acid stereoisomers. However, much of the D-lactate is lost in the urine because, unlike L-lactate, it is not reabsorbed by the renal tubules, and some of the D-lactate is metabolized in mammals.[45] The anion gap therefore may be relatively normal. Furthermore, although neurologic changes have been described in patients with D-lactic acidosis, there is reason to believe that these may be caused by other metabolites absorbed from the gastrointestinal tract rather than by the D-lactate itself.[45] D-Lactic acidosis may be treated by avoiding foods that contain lactobacillus (e.g., yogurt and sauerkraut), by decreasing dietary carbohydrates, and by administration of oral antibiotics.

Diabetic Ketoacidosis

Accumulation of acetoacetate, β-hydroxybutyrate, and acetone ("ketone bodies") is referred to as *ketoacidosis*. This disorder appears to require both increased mobilization of free fatty acids from lipid stores and their excessive conversion within hepatocytes to ketone bodies (Fig. 7-6). Triglycerides within fat are normally broken down by lipase into free fatty acids and glycerol. The activity of lipase is enhanced by low concentrations of insulin and increased concentrations of glucagon, catecholamines, and growth hormone. Free fatty acids released from adipocytes are taken up by the liver and linked to CoA to form acyl CoA. Acyl CoA is either transformed by esterification to triglycerides and lipoproteins or transferred into the mitochondria as a complex with carnitine and then metabolized to CO_2 and water in the Krebs cycle or converted to ketone bodies. The fraction of acyl CoA that is transferred into the mitochondrial matrix is increased by raised glucagon concentrations. This transport is mediated by the enzyme acylcarnitine transferase I (ACT I), which in turn is inhibited by the amount of malonyl CoA present. Normal inhibition of ACT I by malonyl CoA is indicated by the *curved arrow* in Figure 7-6. The concentration of malonyl CoA falls when glucagon is increased or insulin deficiency is present, and transport of the acyl fragment into the mitochondrial matrix is consequently increased. Increased

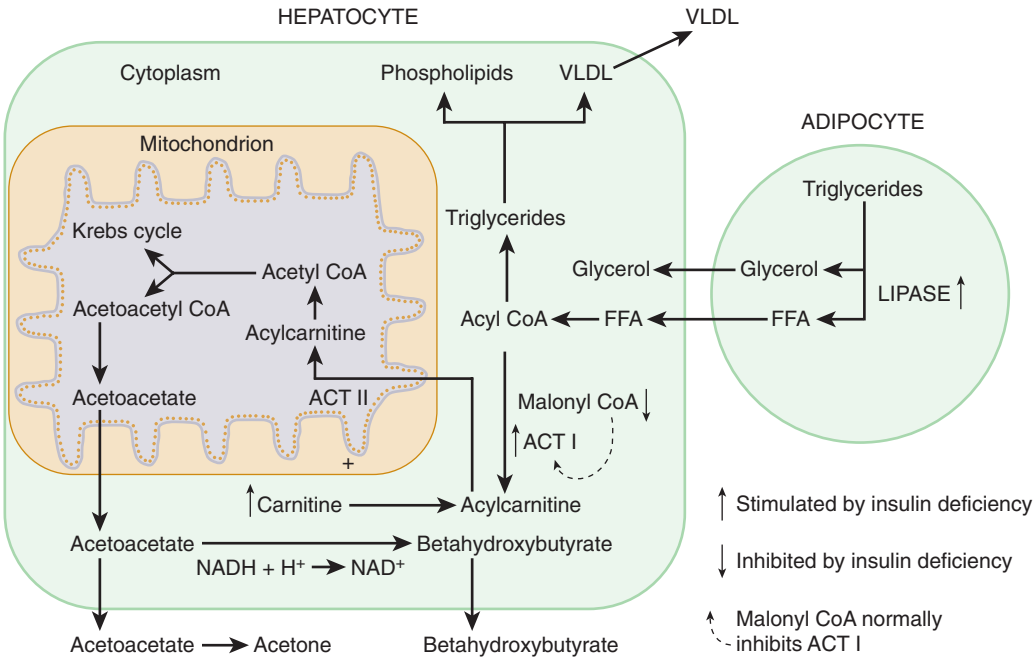

FIGURE 7-6 ■ Factors encouraging ketoacidosis. Some reactions are stimulated by insulin deficiency (*broad arrow up*), whereas others (*broad arrow down*) are inhibited by insulin deficiency and increased glucagon. The *open curved arrow* indicates that acylcarnitine transferase (ACT) I is normally inhibited by malonyl coenzyme A (CoA). FFA, free fatty acid; NAD^+, nicotinamide adenine dinucleotide (oxidized); NADH, nicotinamide adenine dinucleotide (reduced); VLDL, very-low-density lipoprotein.

glucagon also increases the amount of carnitine present, further accelerating movement of acyl CoA into the mitochondria. The acyl CoA complex entering the mitochondria is degraded successively to form acetyl CoA, which under normal circumstances is incorporated into the Krebs cycle and oxidatively metabolized to CO_2. In DKA, the quantities of acetyl CoA produced exceed the capacity of handling by the Krebs cycle and are converted to ketone bodies. Ketoacids are normally taken up and metabolized to CO_2 and water by muscle and kidney rather than by the liver, but this process may be reduced in DKA.[45]

An equilibrium normally exists between β-hydroxybutyrate, acetoacetate, and acetone. There is usually two to three times as much β-hydroxybutyrate as acetoacetate, but this ratio may be significantly increased if tissue P_{O_2} is reduced. Because standard tests for ketones measure acetone (which is not an acid) and acetoacetate but do not detect β-hydroxybutyrate (which is not a ketone), hypoxia may lead to an underestimate of the severity of "ketoacidosis." In normal subjects, the ratio of β-hydroxybutyrate to acetoacetate is 2 : 1. With DKA, this ratio increases to 2.5 : 1 to 3 : 1, and with poor tissue perfusion and associated lactic acidosis, it can exceed 8 : 1.[46] As insulin sensitivity and volume status improve with therapy, conversion of β-hydroxybutyrate to acetoacetate may increase the amount of ketone bodies detected, which may be misinterpreted as worsening of the ketoacidosis.[47]

Starvation often leads to ketoacidosis within 1 or 2 days, particularly after exercise,[48] but HCO_3^- levels seldom decline below 18 mEq/L. Starvation ketoacidosis is also attributed to decreased insulin concentrations, but these do not fall to levels as low as those encountered in DKA, and there is evidence that ketosis stimulates insulin secretion with normal pancreatic function. Alcoholics who binge and then abruptly stop drinking and eating may develop severe ketoacidosis,[49] which may be underestimated because of a disproportionate rise in β-hydroxybutyrate. They usually become dehydrated from vomiting prior to hospital admission and they may develop severe acidosis, frequently with concomitant lactic acidosis. Glucose concentrations are frequently low, and glucose (given with thiamine to avoid acute beriberi) stimulates insulin secretion and corrects the ketoacidosis. Insulin must generally be avoided in these patients. Supplementation with K^+, PO_4^{3-}, and Mg^{2+} is frequently required. Several congenital errors of metabolism that result in ketoacidosis have also been described. Ingestion of a high-fat diet, paraldehyde, or isopropyl alcohol may also result in a positive test for ketones.

Uremic Acidosis

Renal insufficiency does not usually produce an anion gap acidosis until the glomerular filtration rate falls below 20 mL/min and blood urea nitrogen and creatinine increase to more than 40 mg/dL (14.3 mmol/L) and 4 mg/dL (354 μmol/L), respectively. However, there is some variation in the filtration threshold at which anion gap acidosis occurs because of differences in diet and sites of renal damage.[46] The loss of nephrons is accompanied by a decrease in the ability to excrete both NH_4^+ and anions. Numerous anions normally kept low by normal renal clearance contribute to the anion gap, including sulfate, phosphate, and lactate. With acute renal failure, HCO_3^- concentrations characteristically decline by 1 to 2 mEq/day, but more rapid decreases occur in the presence of hypercatabolism. Hemodialysis becomes necessary when HCO_3^- level falls to less than 10 mEq/L. Milder forms of renal insufficiency may be accompanied by hyperchloremic acidosis (see later discussion).

Toxic Forms of Anion Gap Acidosis

As noted in Table 7-3, numerous substances can be converted to hydrogen ions and anions by metabolism, resulting in an anion gap acidosis. Central nervous system (CNS) stimulation by large ingestions of aspirin initially can cause hyperventilation in adults, but is soon followed by an anion gap metabolic acidosis. Salicylates are themselves anions, but most of the acidosis observed after an overdose is related to formation of organic acids, particularly lactic acid and ketones.[50] With very high aspirin concentrations, red cell HCO_3^-/Cl^- exchange is impaired and this may lead to tissue CO_2 retention, which may not be apparent in arterial blood owing to the previously mentioned ventilatory stimulation. The initial respiratory alkalosis contributes to lactate production. $NaHCO_3$ administration promotes both redistribution of salicylates from tissues to blood and urinary excretion by ionic trapping, but severe alkalosis and K^+ losses must be avoided; hemodialysis may be helpful. Glucose infusions are used to increase the cerebrospinal fluid (CSF) concentration of glucose, which is frequently decreased.[51]

Volatile alcohol ingestions are frequent causes of metabolic acidosis, most commonly methanol, isopropanol, or ethylene glycol. Methanol, which is converted to formic acid, and ethylene glycol, which is converted to oxalic acid and other toxic anions, are both metabolized by alcohol dehydrogenase and cause acidosis directly through their metabolites. Although isopropyl alcohol ingestion leads to CNS depression and urinary ketones (acetone), it is not metabolized to an organic acid, and acidosis is seen only if vascular collapse and lactic academia occur. Ethanol (to a serum concentration of 100–150 mg/L), or preferably fomepizole, should be used to inhibit the formation of toxic metabolites from methanol and ethylene glycol, and hemodialysis may be used to clear these metabolites.

Alcohols and ethylene glycol should be suspected if serum osmolality by freezing point depression exceeds by more than 20 mmol/L that calculated from laboratory values of Na^+, glucose, and urea by the following equation:

$$\text{Serum osmolality} = 2 \times [Na^+] + \text{BUN}/2.8 + \text{glucose}/18 \quad (7)$$

where sodium is in mEq/L and blood urea nitrogen (BUN) and glucose are in milligrams per deciliter. Vapor pressure measurements of osmolality do not detect the presence of volatile alcohols. The "osmolar gap" may

also be increased in "pseudohyponatremia" (due to the presence of excess lipid or protein in the plasma) and after administration of mannitol or radiopaque dyes, and these factors also need to be assessed.

Hyperchloremic Acidosis

Metabolic acidosis in the absence of an elevated anion gap is usually associated with hyperchloremia. Hyperchloremic acidosis may be observed in a variety of renal and gastrointestinal disorders, the latter being more common.

Renal Tubular Acidosis

Metabolic acidosis arises from a variety of renal tubular disorders. Disorders of renal tubular function that result in hyperchloremic acidosis can be divided into four categories that can be differentiated by their clinical and laboratory characteristics.[52] Particular defects in various membrane transport proteins that account precisely for certain inherited forms of renal tubular acidosis (RTA) have been identified,[53–56] but the classic definitions still remain the most useful clinically, and these are outlined here.

Type 1 Renal Tubular Acidosis. Type 1, or "classic," RTA involves defects in distal tubular acid secretion. Only distal nephrons can produce an acidic urine, so that with injury or dysfunction, it is impossible for urine pH to be lowered below 5.3, regardless of how acidotic the patient. Serum HCO_3^- can be below 10 mEq/L. Urinary HCO_3^- excretion is usually low, because most HCO_3^- reabsorption occurs proximally. HCO_3^- infusion therefore can be used to prove that the defect is distal (type 1 RTA) rather than proximal (type 2 RTA): the fraction of filtered HCO_3^- lost in urine remains low in type 1 but is high in type 2 RTA. Another defect observed with type 1 RTA is an inability to generate high P_{CO_2} in the urine after infusion of HCO_3^-. Normal subjects produce urine with P_{CO_2} values that exceed those in the plasma by more than 30 to 100 mm Hg. This phenomenon is related to distal tubular H^+ transport to form H_2CO_3. The subsequent generation CO_2 from HCO_3^- in the distal nephron is relatively slow because there is little carbonic anhydrase on the luminal surface. Dissipation of the CO_2 from urine beyond the collecting ducts is inefficient because of the small surface-to-volume ratio of the lower urinary tract. Because patients are unable to secrete H^+ ions in the distal tubules, their urinary P_{CO_2} remains less than 40 mm Hg.

As indicated in Table 7-4, many disorders are associated with distal RTA. It can be caused by a wide variety of mutations, most of which affect carbonic anhydrase II, anion exchanger, or the proton pump (H^+-ATPase) in intercalated cells of the renal cortical collecting duct.[57] Chronic acidosis leads to osteopenia with Ca^{2+}, Mg^{2+}, and PO_4^{2-} loss in the urine. Precipitation of Ca^{2+} and PO_4^{2-} is normally inhibited by tubular secretion of citrate. As citrate secretion tends to be reduced, this and an alkaline urine with calciuria and hypocitraturia appears to be responsible for nephrolithiasis and nephrocalcinosis that characterize distal RTA.[58] K^+ losses tend to be increased because of increased exchange of K^+ for Na^+ in the distal tubule. Concentration defects are common.

In absence of therapy, acidosis progresses relentlessly in distal RTA because fixed acids cannot be excreted

TABLE 7-4. Causes of Hyperchloremic Acidosis

RENAL TUBULAR ACIDOSIS

Type 1 (Distal, Classic), Hypokalemic

- Congenital defects without systemic disease (anion exchanger, AE1 deficient) or with systemic disease (e.g., Ehlers-Danlos, sickle cell anemia)
- Hyperglobulinemia (e.g., systemic lupus erythematosus, idiopathic pulmonary fibrosis, Sjögren's syndrome, thyroiditis, chronic active hepatitis, biliary cirrhosis, vasculitis)
- Drug toxicity (e.g., amphotericin B, toluene, analgesics, lithium)
- Nephrocalcinosis (e.g., primary hyperparathyroidism, vitamin D intoxication, hyperoxaluria, Fabry's disease, Wilson's disease)
- Tubular and interstitial renal disease (e.g., pyelonephritis and obstructive renal disease, renal transplant rejection)

Type 2 (Proximal), Hypokalemic

- Congenital disorders: isolated or associated with mental retardation, ocular abnormalities
- Selective (acetazolamide, sulfonamides) or associated with loss of glucose, phosphate, amino acids, low-molecular-weight proteins, lysozyme, light chains, uric acid
- Genetic (e.g., cystinosis, Wilson's disease)
- Dysproteinemias (e.g., multiple myeloma, monoclonal gammopathy)
- Drug or chemical toxicity (e.g., outdated tetracycline, heavy metals, ifosfamide)
- Secondary hyperparathyroidism with hypocalcemia (e.g., vitamin D deficiency or resistance)
- Renal interstitial disease (e.g., medullary cystic disease, Sjögren's syndrome, renal transplant)

Type 3

- Type I and II, carbonic anhydrase II deficiency

Type 4, Hyperkalemic

- Mineralocorticoid deficiency: Addison's disease, tuberculosis, metastatic carcinoma, autoimmune, adrenal hemorrhage, acquired immunodeficiency syndrome (AIDS), critically ill patients, drugs (ketoconazole, phenytoin, rifampin)
- Hyporeninemic states: diabetes mellitus, nephritis, lupus, AIDS
- Mineralocorticoid resistance: pseudohypoaldosteronism (congenital, spironolactone)
- Medications: potassium-sparing diuretics (amiloride, triamterene), angiotensin-converting enzyme inhibitors, trimethoprim, pentamidine, nonsteroidal anti-inflammatory drugs, cyclosporine A, β-adrenergic inhibitors, α-adrenergic agonists, heparin, digitalis overdose, lithium, insulin antagonists (diazoxide, somatostatin), succinylcholine

NONRENAL HYPERCHLOREMIC ACIDOSIS

- Diarrhea
- Pancreatic drainage
- Ureterosigmoidostomy
- Cholestyramine (diarrhea), NH_4Cl and hyperalimentation with amino acid infusions, $CaCl_2$
- Toluene exposure (hippurate production)
- Loss of ketones that could have been converted to bicarbonate

at their rate of production. Hypokalemia may be particularly severe with consequent muscle weakness or even paralysis. Treatment with 1 mEq/kg $NaHCO_3$ daily (roughly the rate of bodily fixed acid generation) is usually sufficient in adults; more is required in children. Bone demineralization is reduced by this therapy, and K^+ losses are minimized.

Type 2 Renal Tubular Acidosis. In type 2 or proximal RTA, HCO_3^- reabsorption is impaired because of a defect in the proximal ion exchange of H^+ for Na^+, which is mediated by an apical membrane Na^+/H^+ antiporter. Normally, HCO_3^- is completely removed from glomerular filtrate until serum HCO_3^- concentrations exceed 22 to 24 mEq/L, and maximal reabsorption rates are not observed until concentrations are about 28 mEq/L. In proximal RTA, maximal reabsorption values may top out at a serum concentration of about 18 mEq/L. The distal tubules cannot absorb more than 15% to 20% of the filtered load of HCO_3^-, so HCO_3^- is lost in the urine, causing the urine pH to rise even when the patient is acidotic. When serum HCO_3^- is normalized to 25 mmol/L by HCO_3^- infusion, more than 10% of the filtered HCO_3^- is lost in the urine in type 2 RTA, compared with less than 5% in normal subjects and those with type 1 RTA. If serum HCO_3^- level falls below the HCO_3^- recovery threshold, then urinary HCO_3^- loss ceases, urine pH falls, and the acidosis does not progress. A typical patient will have a stable serum HCO_3^- value in the range of 12 to 20 mEq/L. It is common to find that patients with proximal RTA do maximally acidify their urine, but only in the presence of a significant metabolic acidosis. In some patients, it may be necessary to decrease serum HCO_3^- to less than their usual level with NH_4Cl administration before maximal urine acidification is observed.

Proximal RTA may be an isolated tubular lesion, but it is more frequently associated with other proximal tubular defects that lead to loss of glucose, phosphate, amino acids, and low-molecular-weight proteins (Fanconi's syndrome). Nephrolithiasis and nephrocalcinosis are not characteristic, but patients are susceptible to osteomalacia and rickets if the acidification defect is associated with calcium and phosphate loss. They require much more $NaHCO_3$ (10–15 mEq/kg/day) to correct their acidosis than do patients with distal RTA. Sodium citrate is better tolerated than $NaHCO_3$, and thiazides can decrease administered alkali needs. Large amounts of $NaHCO_3$ exacerbates losses of K^+, and supplements and/or potassium-sparing diuretics are commonly required. Serum phosphate may be reduced if there is a defect in is reabsorption, and alkaline phosphatase may be increased. Some illnesses associated with proximal RTA are indicated in Table 7-4.

Type 3 Renal Tubular Acidosis. A true type 3 RTA includes features of both proximal and distal forms, but it does not have great clinical significance. The largest patient group in this category, rarely seen nowadays, was infants or young children with hereditary distal RTA that manifested some proximal bicarbonate loss transiently. A similar combination of defects is also observed in a small number of patients with an inherited form of carbonic anhydrase II deficiency.[59]

Type 4 Renal Tubular Acidosis. Type 4 RTA is caused by either decreased aldosterone production or tubular hyporesponsiveness to the hormone. Because aldosterone stimulates distal secretion of H^+ and K^+, deficiency results in hyperchloremic hyperkalemic acidosis, whereas other forms of RTA are usually associated with hypokalemia. Hyperkalemia suppresses proximal NH_3 production. Consequently, even though urine pH may be low, the amount of acid lost may be insufficient to avoid acidosis. A wide variety of disorders lead to low aldosterone production (see Table 7-4), but decreased renin secretion in older patients with diabetic renal disease is common. Decreased aldosterone production occurs in critically ill patients with sepsis and cardiogenic shock. Potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, intravenous solutions, and heparin (which can inhibit aldosterone secretion) may also cause hyperkalemia and type 4 RTA. Hyperkalemia is associated with a high incidence of arrhythmias (25%), hypertension, and weakness.

Most K^+ found in the urine is secreted into the cortical collecting duct, and detection of decreased secretion is facilitated by calculating the transtubular potassium gradient (TTKG):

$$\text{TTKG} = \left\{[K^+]_{\text{urine}} / [K^+]_{\text{plasma}}\right\} \Big/ \left\{[\text{Osm}]_{\text{urine}} / [\text{Osm}]_{\text{plasma}}\right\} \qquad (8)$$

where [Osm] designates osmolality. This ratio corrects the urine–to–plasma potassium ratio for urine concentration, which occurs more distally in the nephron. The TTKG should be greater than 8 in patients with hyperkalemia and should increase after administration of mineralocorticoids in patients with aldosterone deficiency. Failure of TTKG to increase after mineralocorticoids suggests loss of tubular sensitivity.

Acidosis of Progressive Renal Failure

Hyperchoremic RTA without hyerkalemia is characteristic of many renal diseases associated with loss of renal tissue and a decrease in the glomerular filtration rate. Retention of acid in these patients is attributable to a decrease in the ability of the kidneys to excrete NH_4^+. Although the decline in serum bicarbonate is relatively modest, it is generally recommended that serum HCO_3^- concentrations should be maintained above 22 mEq/L with modest $NaHCO_3$ supplementation to minimize bone reabsorption, insulin resistance, and protein catabolism.[60]

Gastrointestinal Causes of Hyperchloremic Acidosis

Diarrhea is a more common cause of hyperchloremic acidosis than are renal tubular disorders. Cl^- is selectively absorbed by the bowel in exchange for HCO_3^-, more so in the colon than proximally. Normally, stool fluid volume and Cl^- losses are modest, but significant HCO_3^- loss can occur in diarrhea. Lactic acid and other organic acids are produced by bowel microorganisms, and these reduce the actual HCO_3^- stool concentrations.[61] However, these organic anions are not readily absorbed from the

colon with fast transit, and the net result is that HCO_3^- is lost from the body, whereas serum Cl^- is increased without a rise in the anion gap. Absorption of NH_4^+ generated by gut bacteria contributes to the acidosis. Passage of urine into the bowel after ureterosigmoidostomy or ureteroileostomy can produce hyperchloremic acidosis.

Each liter of diarrheal fluid can result in the loss of 200 mEq of HCO_3^-. Pancreatic and biliary fluid contain 50 to 100 mEq of HCO_3^-/L, and severe hyperchloremic acidosis occurs after losses of these fluids. Cholestyramine contains an anion-exchange resin that can generate hyperchloremic acidosis by releasing Cl^- in exchange for HCO_3^-. K^+ losses in diarrheal stool (30–60 mEq K^+/L) in exchange for Na^+ can be severe. Furthermore, extracellular volume depletion promotes aldosterone secretion, which in turn enhances urinary K^+ loss. Chronic acidosis increases renal NH_4^+ secretion, distinguishing it from RTA, which can be detected by measuring the urine net charge (see later).

Miscellaneous Causes of Hyperchloremic Acidosis

Respiratory alkalosis is normally compensated by a decrease in proximal HCO_3^- reabsorption. Correction of respiratory alkalosis may transiently produce a hyperchloremic acidosis, as can some hyperalimentation fluids, NH_4Cl, or $CaCl_2$. Toluene, inhaled by glue sniffers, is converted to benzoic acid and hippurate, which are rapidly renally excreted with cations, resulting in hyperchloremic acidosis. Some intravenous solutions of synthetic amino acids that may be titrated with excess HCl (hydrochloric acid) and saline infusions lower HCO_3^- and increase Cl^- concentrations (see later discussion).

Urine Net Charge and Osmolar Gap

Measurement of the urine net charge (UNC), or urine anion gap, can be used to help distinguish between hyperchloremic acidosis due to diarrhea or to RTA. Unlike serum, the urine seldom contains significant HCO_3^- in acidotic patients, but K^+ and NH_4^+ concentrations can be considerable. The UNC is calculated from the following equation:

$$UNC = Na^+ + K^+ - Cl^- \quad (9)$$

If urinary NH_4^+ is high, then urinary Cl^- concentration will exceed that of Na^+ plus K^+, and the UNC will be negative by 20 to 50 mEq/L. UNC provides an estimate of urine NH_4^+ and is negative with hyperchloremic acidosis caused by diarrhea because renal NH_4^+ production is increased in response to the metabolic acidosis. In contrast, UNC is more positive in patients with RTA, with impaired production and/or excretion of NH_4^+. The presence of ketones and other anions can also cause UNC to be negative, and direct NH_4^+ measurements provide a more reliable index of renal tubular acid metabolism.[62] NH_4^+ concentrations have also been estimated by calculating the urine osmolar gap, which represents the difference between observed and calculated urine osmolarity.

Dilutional Acidosis

A modest acidemia is observed when water dilutes blood after being pulled from cells by increased extracellular solute concentrations such as glucose.[63] It is generally attributed to the fact that plasma HCO_3^- falls to a greater degree than does P_{CO_2}, which is regulated by the brain.[64] Saline infusions may have a similar effect; however, the dilution that occurs with inappropriate antidiuretic hormone secretion is not usually accompanied by acidosis.[65]

Clinical Manifestations

Perhaps the most obvious sign of metabolic acidosis is the respiratory response, which consists of slow but deep breathing known as Kussmaul's respiration. It is particularly effective because the dead-space contribution to ventilation is minimized. Patients with metabolic acidosis are often asymptomatic and their hyperventilation may not be clinically obvious. With more severe acidosis, dyspnea may be troubling and patients complain of headache, nausea, and vomiting. This may be followed by confusion, stupor, and even coma, which are particularly likely to be present in respiratory acidosis. Acidosis may reduce the myocardial catecholamine responsiveness and induce arteriolar vasodilation, but these effects are largely blunted by increased catecholamine and cortisol secretion.[66] Venoconstriction is characteristic of acidosis[67] and may shift blood into the central volume and trigger pulmonary edema.[68] Arrhythmias, including ventricular fibrillation, can be fatal.

Hyperkalemia (despite total body K^+ depletion) is sometimes observed with metabolic acidosis. It is often associated with DKA, but this is related in large part to the plasma hyperosmolarity that causes water and K^+, the main intracellular cation, to exit cells. Infusions of organic acids are much less likely to cause hyperkalemia than are infusions of inorganic acids,[69] and the conventional wisdom that serum K^+ increases in a predictable fashion with metabolic acidosis[70] has not proved to be very useful. Nor is hyperkalemia found in most patients with types 1, 2, or 3 RTA or with diarrhea because of the simultaneous losses of both HCO_3^- and K^+ that occur with these disorders.

Chronic retention of more than 10 mEq H^+/day may be tolerated over a period of years in patients with chronic renal disease because of buffering by bone alkaline constituents (calcium, phosphate, and carbonate).[71] When acid production exceeds the release of bone buffers, a fall in HCO_3^- is inevitable. Recent evidence suggests that the acid load of the typical protein-rich Western diet may not be fully excreted by the kidneys and the very slight failure to eliminate the entirety must be handled by bone buffering. Over many decades of life, this cumulative bone buffering may help to explain the high incidence of osteopenia and osteoporosis in the elderly.

Therapy

Treatment of metabolic acidosis should focus primarily on correcting the metabolic disorder responsible for its emergence and the hemodynamic, oxygenation, and electrolyte derangements that ensue, rather than the academia itself. For example, insulin and volume replacement are the mainstays of diabetic therapy, dialysis for uremic acidosis, and reversal of shock, local ischemia, and hypoxemia for lactic acidosis. If another illness is responsible for lactic acidosis (see Table 7-3), then appropriate therapy must be selected.[1]

$NaHCO_3$ administration or other alkaline agents for metabolic acidosis is clearly indicated in patients with chronic metabolic acidosis, such as those with significant hyperchloremic acidosis (e.g., RTA) to prevent bone and muscle catabolism, relieve exertional dyspnea, and promote growth in children. In acute severe metabolic acidosis (especially the endogenous anion gap acidoses), it is becoming clear that HCO_3^- administration is not always helpful or effective. However, alkalinizing agents are still indicated for associated severe hyperkalemia or to enhance excretion of acid metabolites of certain toxins.[72] In severe DKA despite arterial pHs as low as 6.8, bicarbonate administration does not alter rates of glucose correction or ketoacid clearance when compared with equivalent sodium administration given as NaCl. Equivalent evidence in sespis, severe hypoxemia, and cardiogenic shock (again in randomized saline-controlled studies described previously for DKA) found no obvious benefits and often slightly worse parameters in the bicarbonate-treated patients (for review of these studies, see reference 72). A number of possible negative consequences of attempted alkalinization in these conditions have been articulated. These include a shift of the oxygen-hemoglobin dissociation curve to the left that may impair O_2 delivery in already hypoxic tissues, greater lactic acid production[73] or suppression of hepatic lactate clearance with an increase in pH, and nonmetabolic generation of CO_2 from HCO_3^- with paradoxical intracellular acidosis.[74] Increases in P_{CO_2} associated with $NaHCO_3$ may not be observed in the arterial blood even though mixed venous P_{CO_2} is significantly increased.[75] Excessively rapid infusions of $NaHCO_3$ may result in a paradoxical diminution of CSF and brain interstial pH if they reduce the drive to breathe.[76] Equilibration of HCO_3^- with the CSF is much slower than the corresponding equilibration of CO_2, and the rise in P_{CO_2} caused by hypoventilation tends to make the CSF more acid before the HCO_3^- can diffuse into this compartment. Because the usual alkaline solutions administered are extremely hypertonic, there may be an abrupt fall in serum K^+ as potassium is returned to the cellular compartment. $NaHCO_3$ infusions should be kept as low as possible (usually < 200 mmol) to avoid volume overload, which may alternatively be minimized by hemodialysis against a $NaHCO_3$ solution. As the underlying disorders improve, both ketone bodies and lactate may be metabolized to HCO_3^-, resulting in the development of post-therapeutic alkalosis. Although it is often claimed that when the pH is much lower than 7.2, $NaHCO_3$ infusions may prove to be lifesaving by enhancing cardiac contractility and response to pressors, the supporting data are rather unconvincing. As mentioned previously in studies comparing equivalent NaCl and $NaHCO_3^-$, any brief benefits noted with bicarbonate in blood pressure may simply be the result of volume expansion by any sodium-containing fluid. Regardless of the cause of acidemia, if base administration is considered necessary, $NaHCO_3$ is preferable to lactate solutions, because lactate is completely ionized at any pH still compatible with life and it does not provide buffering until it is converted to HCO_3^- by normal hepatic function.

As a first estimate of the amount required to raise serum HCO_3^- by a given number of milliequivalents per liter, it is common practice to assume that HCO_3^- enters a space 40% or 50% of the total body weight. Not infrequently, much more is required to repair the deficit. However, no attempt should be made to increase the pH to more than 7.2 with such infusions, and it is prudent to raise the HCO_3^- concentration no more than halfway toward normal during the first day. Determinations of arterial blood P_{O_2}, P_{CO_2}, HCO_3^-, and pH must be repeated at frequent intervals to monitor the response to therapy.

However, given the failure of controlled trials to show any benefit with bicarbonate administration in the most severe endogenous anion gap metabolic acidoses and the negative observations alluded to earlier, it may be better, although difficult, to refrain from using alkalinizing fluids at all in these circumstances. In fact, animal organ and cellular studies reveal the surprising and counterintuitive findings that recovery from ischemia or O_2 deprivation is clearly enhanced when the perfusing media is acidic and recovery is worse under alkalotic conditions, a phenomenon termed *the pH paradox*.[72] Many explanations have been offered, the most intriguing being that acidosis may blunt the activity of many enzymes and proteins responsible for much of the associated excessively activated oxidative and proinflammatory pathways in hypoxic and septic injuries that may perpetuate ongoing injury. Another potential argument against aggressive attempts to reduce lactic acidosis, independent of treating the initial cause(s) is the failure of dichloroacetate, a compound that stimulates PDH activity and pyruvate entry into the mitochondria, to alter outcomes in patients with severe lactic acidosis.[77] By limiting lactate formation, the drug may deny cells a preferred fuel under stress as proposed by Brooks and colleagues.[39]

METABOLIC ALKALOSIS

For both diagnostic and therapeutic reasons, it is helpful to divide the causes of metabolic alkalosis into those associated with a decrease in the extracellular volume (chloride responsive) and those associated with a normal or increased extracellular volume (chloride resistant) (Table 7-5).

TABLE 7-5. Causes of Metabolic Alkalosis

Loss of H^+ from the body

CHLORIDE-RESPONSIVE WITH URINE Cl^- < 20 mEq/L

Gastrointestinal losses of chloride: stomach (vomiting, aspiration, villous adenomas, congenital chloride-wasting diarrhea)

Renal losses of chloride: loop and thiazide diuretics, posthypercapnic

Sweat losses of chloride: cystic fibrosis

Hyperventilation in chronic respiratory acidosis

CHLORIDE-RESISTANT WITH URINE Cl^- > 20 mEq/L AND HYPERTENSION

Hyperaldosteronism (primary or secondary), Cushing syndrome, cortisol 11-beta-ketoreductase deficiency, licorice, etc.

Liddle's syndrome: increased epithelial sodium channel (ENaC) in collecting duct.

CHLORIDE-RESISTANT WITH URINE Cl^- > 20 mEq/L, HYPOTENSION OR NORMOTENSION

Bartter's syndrome: impaired reabsorption of sodium ions and chloride ions in the thick ascending loop of Henle (variants)

Gitelman's syndrome: impaired thiazide-sensitive sodium/chloride transporter (NCCT) in the distal convoluted tubule occurs

EXCESSIVE INTAKE OF HCO_3^-

Milk-alkali syndrome

Administration of poorly absorbed anions (e.g., penicillin)

Bicarbonate dialysis in end-stage renal disease

Recovery from ketoacidosis or lactic acidosis after bicarbonate administration

Massive blood transfusions (citrate)

EXTRACELLULAR FLUID VOLUME CONTRACTION

Causes

Chloride Responsive Alkalosis

Gastrointestinal Losses. As indicated previously, gastrointestinal tract acid losses generate an alkalosis that is initially associated with increased renal Na^+ excretion. ECF volume depletion causes the glomerular filtration rate to fall and is associated with increased aldosterone secretion. Each of these effects enhances HCO_3^- reabsorption, and alkalosis persists even after all initiating factors (e.g., protracted vomiting and continuous nasogastric suction) have abated. In these patients, Cl^- is avidly reabsorbed from the tubules and urine concentrations remain lower than 10 mEq/L. Correction of the metabolic alkalosis depends on replacement of Cl^- losses, principally given as saline. Although diarrhea usually generates a hyperchloremic acidosis (see earlier discussion), alkalosis may rarely be seen with Cl^--HCO_3^- exchange across the ileal mucosa[78] due to villous adenomas of the colon.

Renal Losses. Diuretics are the most common cause for excessive renal losses of ECF. When Na^+ delivery of to the distal nephron persists despite extracellular volume depletion (e.g., after diuretic therapy), H^+ secretion by this segment is enhanced. In these conditions, Cl^- concentrations in the urine may be appreciable. Both loop diuretics (furosemide, bumetanide, ethacrynic acid) and thiazides can promote H^+ and K^+ secretion from the more distal segments of the nephron. This frequently results in severe hypokalemic alkalosis.

Losses in Sweat. Metabolic alkalosis has also been reported in patients with cystic fibrosis, who tend to lose proportionately more Cl^- than HCO_3^- in their sweat.

Alkalosis is not infrequently observed in mechanically ventilated patients treated for chronic hypercapnia. Care must be taken to avoid abrupt increases in ventilation, which may result in life-threatening metabolic alkalosis. The arterial pH and plasma levels of HCO_3^- of these persons may remain high and inhibit spontaneous ventilation unless Cl^- losses are restored, generally in the form of KCl. Acetazolamide may also be helpful because it inhibits renal tubular HCO_3^- reabsorption, but its use requires careful monitoring in those not mechanically ventilated with limited lung function (forced expiratory volume in 1 second [FEV_1] < 1 L) and avoided in those with renal or hepatic insufficiency.

Administration of sodium salts of penicillin or other anions that cannot be reabsorbed by the renal tubules may stimulate acid and K^+ losses in patients who are volume depleted.

Chloride-Resistant Alkalosis

Metabolic alkalosis may also be associated with either normal or increased ECF volume, particularly in the presence of excessive aldosterone secretion. Mineralocorticoids act to increase both H^+ and K^+ secretion and Na^+ retention by the distal nephron. This results in a hypokalemic alkalosis that is associated with a modest ECF volume expansion. Na^+ and Cl^- retention appears to be limited by ECF expansion, and output and intake of Na^+ become equal. Unlike situations in which the ECF is decreased, Cl^- is lost in the urine with metabolic alkalosis that is caused by excessive mineralocorticoid secretion (urine Cl^- > 20 mEq/L). Maintenance of the metabolic alkalosis is a result of persistent excess mineralocorticoid secretion as well as hypokalemia.

Any alteration in the renin-angiotensin-aldosterone axis that promotes aldosterone secretion also causes this form of metabolic alkalosis (see Table 7-5) by its stimulatory effects on two different populations of cells in the distal nephron.[79] Distal tubular exchange of K^+ for Na^+ appears to be confined to principal cells, located in the cortical collecting duct. Because more Cl^- ions than cations are left behind, a negative lumen potential is established that facilitates H^+ secretion by the more distally positioned alpha intercalated cells. Patients with edema due to liver disease, nephrotic syndrome, or congestive heart failure may secrete excessive aldosterone because their effective arterial blood volume is reduced, even though their total ECF volume is increased. The development of hypokalemic alkalosis is particularly likely to occur when they receive diuretics.

The pathogenesis of several forms of congenital hypokalemic, hypochloremic metabolic alkalosis with hyperaldosteronism (Bartter's syndrome and Gitelman's syndrome) has been traced to a variety of abnormalities in renal tubular transporters.[80]

Excessive Intake of HCO_3^-

Although the kidneys normally can excrete large quantities of HCO_3^-, metabolic alkalosis may occasionally be generated by excessive intake of HCO_3^- or other anions that are metabolized to HCO_3^-, especially in patients with renal insufficiency. For example, metabolic alkalosis may be observed in patients who ingest extremely large amounts of HCO_3^- and milk (milk-alkali syndrome), after fasting (due to conversion of ketones to HCO_3^-),[81] and after transfusions of large amounts of blood (conversion of citrate to HCO_3^-).[82] In the absence of volume depletion or renal disease, alkalosis due to increased HCO_3^- intake rapidly resolves once intake is restricted.

Extracellular Fluid Contraction

Water loss from plasma may induce a modest alkalemia that is sometimes referred to as a "contraction" alkalosis and is related to the relatively greater increase of HCO_3^-, compared with P_{CO_2}. It would probably be more appropriate to designate this as a *concentration alkalosis* to distinguish it from the alkalosis of contraction that is caused by ECF fluid depletion, which promotes renal acid excretion and alkalemia (see earlier discussion).[65,83]

Clinical Manifestations

Metabolic alkalosis is frequently overlooked and often remains untreated even after discovery. Nevertheless, it may be associated with significant mortality.[84,85] Alkalosis tends to increase the affinity of hemoglobin for oxygen, thereby reducing oxygen delivery to the tissues. It also decreases ventilation by suppressing the carotid body and may constrict the peripheral vasculature, further limiting oxygen supply to tissues.

Neuromuscular hyperirritability may be observed in alkalosis and has been attributed in part to increased calcium binding to albumin. Twitching and tetany may be preceded by Chvostek's and Trousseau's signs, and seizures can ensue. Metabolic alkalosis is usually associated with hypokalemia, which may be responsible for both supraventricular and ventricular arrhythmias.[85] Alkalosis promotes intracellular movement of K^+ and may also cause an increase in the anion gap because of removal of H^+ from albumin and increased generation of lactate.

Therapy

Treatment of metabolic alkalosis depends on the status of the ECF volume. Patients with ECF volume loss can be distinguished from those with excess volume on the basis of urine Cl^-, which is usually lower than 10 mEq/L in the former and higher than 20 mEq/L in the latter setting. For patients who have sustained severe volume losses, fluids that contain Na^+, Cl^-, K^+, and Mg^{2+} are frequently indicated.

Fluid administration to edematous patients with alkalosis is usually inappropriate. Spironolactone is useful in the presence of excessive mineralocorticoid secretion. The carbonic anhydrase inhibitor acetazolamide may be helpful and in patients with posthypercapnic alkalosis, although it may increase loss of K^+. Although NH_4Cl and arginine hydrochloride may be used to treat alkalosis, their use must be avoided in patients with severe liver disease (as for acetazolamide) because they may precipitate hepatic coma by decreasing urea synthesis and/or elevating NH_3 concentrations. These agents may also induce hyperkalemia and increase urea levels in patients with azotemia. Infusions of HCl (at a concentration of 100–200 mEq/L) may be safer in patients with liver and kidney disease, but these infusions require central access confirmed radiologically by location of the catheter tip in the superior vena cava to minimize the likelihood of tissue necrosis and hemolysis caused by the acid infusion. Alternatively, intubation and intentional hypoventilation to increase the P_{CO_2}, thereby reducing arterial pH, may be employed. Severe metabolic alkalosis can also be treated by hemodialysis. Histamine H_2 receptor antagonists or gastric proton pump (H^+/K^+-ATPase) inhibitors are useful in patients receiving nasogastric suction.

RESPIRATORY ACIDOSIS

General Considerations

Respiratory acidosis is a frequently frustrating problem for patients with respiratory insufficiency. P_{CO_2} is normally kept within narrow limits by the respiratory center within the CNS. Chemoreceptors that respond to changes in P_{CO_2} are present in the medulla, close to the floor of the fourth ventricle, and in the carotid bodies. Both sites are stimulated by pH changes associated with alterations in P_{CO_2}. Normally, arterial P_{CO_2} is controlled primarily by the central chemoreceptors. However, they may be suppressed by chronic hypoxia and hypercapnia; mostly in patients with severe COPD. When this occurs, ventilation is maintained by the carotid bodies responding to alterations in P_{O_2} and pH. If P_{O_2} is raised excessively, carotid body output may be suppressed, leading to progressive hypercapnia and narcosis. Acute increases in P_{CO_2} are buffered by non-HCO_3^- buffers to form HCO_3^-, but HCO_3^- concentrations seldom exceed 30 mEq/L during the first 24 hours of hypercapnia. Increases in P_{CO_2} result in an intracellular acidosis within the renal tubular cells that favors acid excretion, and over the next few days, acid excretion is accelerated by a rise in NH_4^+ formation.

Causes

Any process interfering with ventilation can lead to respiratory acidosis (Table 7-6; see also Chapter 73). COPD is the most frequent cause of this problem, related primarily to mechanical conditions that decrease alveolar ventilation. Interstitial lung disease is less likely to increase P_{CO_2} values unless it is severe. Extensive infiltrative processes (including pneumonias and all forms of pulmonary edema) and large pleural effusions can

TABLE 7-6. Causes of Respiratory Acidosis

CENTRAL NERVOUS SYSTEM DEPRESSION
Drugs: opiates, sedatives, anesthetics
Oxygen therapy in chronic obstructive pulmonary disease
Obesity-hypoventilation syndrome
Central nervous system disorders
NEUROMUSCULAR DISORDERS
Neurologic: multiple sclerosis, poliomyelitis, phrenic nerve injuries, high cord lesions, Guillain-Barré syndrome, botulism, tetanus
End plate: myasthenia gravis, succinylcholine chloride, curare, aminoglycosides, organophosphorus
Muscle: hypokalemia, hypophosphatemia, muscular dystrophy
AIRWAY OBSTRUCTION
Chronic obstructive pulmonary disease
Acute aspiration, laryngospasm
CHEST WALL RESTRICTION
Pleural: effusions, empyema, pneumothorax, fibrothorax
Chest wall: kyphoscoliosis, scleroderma, ankylosing spondylitis, extreme obesity
SEVERE PULMONARY RESTRICTIVE DISORDERS
Pulmonary fibrosis
Parenchymal infiltration: pneumonia, edema
ABNORMALITIES IN BLOOD CO_2 TRANSPORT
Decreased perfusion: heart failure, cardiac arrest with cardiopulmonary resuscitation, extensive pulmonary embolism
Severe anemia
Carbonic anhydrase inhibition—high-dose acetazolamide
Red cell anion exchange: high-dose loop diuretics, salicylates, nonsteroidal anti-inflammatory drugs

decrease alveolar ventilation. With significant acute pulmonary artery embolic obstruction, wasted ventilation may increase suddenly and explain sudden increases in ventilation or hypercapnia if ventilation cannot be increased. In such situations, dead-space ventilation may be measured directly by sampling both arterial blood and mixed expired gases. A paralyzed diaphragm or extensive rib fractures that lead to a unilateral flail chest can produce a paradoxical mode of ventilation. When inhalation occurs in the unaffected lung, air is forced out of the contralateral lung and some of this exhaled air is inhaled by the normal lung; the opposite sequence of events occurs when the unaffected lung exhales. This pattern of ventilation is referred to as "pendelluft" or "pendulum breathing"; it can result in rebreathing with respiratory acidosis.

Hypoventilation is the most serious complication of a wide variety of neuromuscular disorders (see Table 7-6). The central respiratory centers may be depressed acutely or chronically by narcotics or by any process that injures the brain stem, including chronic hypoxemia and hypercapnia. A complex disturbance of the respiratory center may be encountered in patients with the obesity-hypoventilation syndrome. Apneic episodes during sleep are common in these persons and are related to airway obstruction or to a central failure to initiate ventilation, or both.

Rarely, if cardiac output is low, if anemia is severe, and/or if certain drugs that interfere with the normal high efficiency of red cell CO_2 transport and exchange are used (see Table 7-6), CO_2 retention in the tissues may develop and yet not be reflected in the arterial P_{CO_2}.[86] In fact, as CO_2 rises in the vicinity of the central chemoreceptors, ventilation may be stimulated sufficiently to cause a paradoxical arterial hypocapnia that can be mistakenly taken as evidence of a primary respiratory alkalosis. If some measure of P_{CO_2} is taken in the venous circulation (mixed venous P_{CO_2}), one will find an elevated P_{CO_2} and lower pH, revealing the true state of CO_2 homeostasis.[87]

Clinical Manifestations

If hypoventilation is caused by neuromuscular or mechanical problems, the patient will be dyspneic and tachypneic. In contrast, if the respiratory center is impaired, ventilation may be reduced without any sense of dyspnea.

The physiologic and clinical consequences of respiratory acidosis tend to be more serious in acute than in chronic states. Elevations in P_{CO_2} cause systemic vasodilation that is particularly evident in the cerebral circulation. Cerebral blood flow and intracerebral pressures increase and may lead to a picture of pseudotumor cerebri with papilledema, retinal venous distention, and retinal hemorrhages. The patient may complain of dyspnea and manifest myoclonic jerks, asterixis, tremor, restlessness, and confusion. Coma may be observed at P_{CO_2} values of 70 to 100 mm Hg when hypercapnia onset is abrupt. Significantly higher levels may be well tolerated in patients with chronic respiratory acidosis, who have much higher HCO_3^- concentrations from renal compensation. Peripheral vasodilation and increased cardiac output promote warm, flushed skin and a bounding pulse. Arrhythmias are observed occasionally. Mild increases in serum phosphate and K^+ and decreases in lactate and pyruvate have been described in acute respiratory acidosis, and a modest increase in serum Na^+ may occur in both acute and chronic hypercapnia.[88]

Therapy

Treatment of respiratory acidosis depends on the restoration of adequate ventilation. In COPD, attention must be focused on bronchodilation, adequate oxygen supplementation, and relief of anxiety and other reasons for increased metabolic rate. Indiscriminate and uncontrolled administration of high concentrations of oxygen should be avoided. The phenomenon of oxygen-induced hypercapnia in these patients is usually observed in the emergency room and intensive care unit when they present severely hypoxemic, already hypercapnic, and tired. Sudden correction of arterial hypoxemia causes further hypercapnia by a combination of three mechanisms: (1) by depression of formerly high hypoxia-driven peripheral chemoreceptor drive causing more

hypoventilation, (2) relief of hypoxic pulmonary vasoconstriction in poorly ventilated lung regions that further reduce the ability of these units to eliminate CO_2 as local perfusion increases without concomitant increase in local ventilation, and (3) significant correction of hypoxemia causes hemoglobin to be better saturated so that previously buffered protons on deoxyhemoglobin are released with subsequent generation of new CO_2 from HCO_3^- stores (Haldane effect). Low-flow oxygen generally suffices to increase P_{O_2} to satisfactory levels (~60 mm Hg and arterial oxygen saturation [Sa_{O_2}] ~ 90%); greater elevations are neither needed nor advisable. If the use of a ventilator becomes necessary, care must be taken that P_{CO_2} is not decreased by more than 10 mm Hg each hour to avoid life-threatening metabolic alkalosis.

Central respiratory depression may be relieved by naloxone if opiates are responsible. Aminophylline acts as a respiratory center stimulant, but blood levels must be monitored carefully. Correction of pH with HCO_3^- is generally contraindicated in patients with respiratory acidosis, because it decreases the respiratory chemoreceptor drive.[89] However, infusions of $NaHCO_3$ are used to moderate acidosis in patients being mechanically ventilated who are intentionally hypoventilated to minimize lung injury ("permissive hypercapnia"), although this remains controversial[90] because of the possible moderating influences of acidosis on inflammatory and oxidative injuries described above with reference to metabolic acidosis.

RESPIRATORY ALKALOSIS

Although respiratory alkalosis is a common disorder and, at times, is a serious prognostic sign, it seldom has a significant impact on the clinical status of patients and generally requires little in the way of specific therapy to reverse hyperventilation directly. In view of the rapidity with which CO_2 equilibrates between extracellular and cellular compartments, this observation is somewhat puzzling. Changes in pH related to hyperventilation are quickly moderated by tissue buffering and, to a lesser extent, by release of lactic acid, as described earlier. However, HCO_3^- concentrations do not usually fall below 18 mEq/L acutely, and even with renal compensation, a HCO_3^- concentration below 16 mEq/L should raise the possibility of an independent metabolic acidosis.

General Considerations

Many manifestations of respiratory alkalosis may be related in part to a fall in free serum Ca^{2+} due to increased binding to serum proteins. Phosphate may also decline slightly and sometimes fall to rather low concentrations in patients who have prolonged severe respiratory alkalosis.[86] It has been suggested that this decline in phosphate is related to activation of glycolysis and phosphorylation of the glucose metabolites thereby produced. Mild hyponatremia and hyperchloremia, as well as hypokalemia,[69] have also been reported in patients with acute respiratory alkalosis. Some of the CNS changes of acute respiratory alkalosis may be caused by hypocapnic cerebral vasoconstriction leading to reduced blood flow and tissue hypoxia. Often, deliberate hyperventilation is used to reduce cerebral blood flow in states of impending brain herniation from high intracranial pressure, but evidence is mounting that it is useful only for a few hours as a temporizing measure to allow more definitive pressure relief by other means.

Causes

It is convenient to divide the causes of respiratory alkalosis into three major categories: hypoxia, pulmonary diseases, and CNS disorders (Table 7-7). Both central (arterial) and peripheral (capillary) hypoxia are causes of hyperventilation. Decreases in arterial P_{O_2} stimulate the carotid bodies directly. In contrast, tissue hypoxia caused by decreased cardiac output, shock, severe anemia, or excessive hemoglobin oxygen affinity results in the production of lactic acid and other stimuli, which are sensed in blood by the carotid chemoreceptors and by other less well defined chemoreception in the affected tissues themselves. Acute ascent to altitudes greater than 8000 feet may lead to acute mountain sickness. Symptoms generally include dyspnea, malaise, headache, insomnia, anorexia, nausea, vomiting, periodic respiration, and tachycardia. These hypoxic manifestations diminish gradually over a few days as acclimatization occurs.

Many pulmonary disorders are associated with hyperventilation. Hypoxia certainly plays a role, but in addition, receptors have been described in lung tissue that are activated by local irritant stimuli and fluid

TABLE 7-7. Causes of Respiratory Alkalosis

CENTRAL NERVOUS SYSTEM DISORDERS

accumulation[91] and remain so even after hypoxemia has been corrected.

CNS disorders are among the most common causes of respiratory alkalosis. Anxiety can provoke hyperventilation ("hyperventilation syndrome"). Central stimulation of respiration is also common in a wide variety of intracerebral injuries. Many drugs and hormones (notably salicylates, theophylline, and progesterone) stimulate ventilation (see Table 7-7), and hyperventilation may be an early sign of both sepsis due to gram-negative bacteria and hepatic insufficiency due to the accumulation of ammonia and amines that are known to be responsible for respiratory center stimulation.

Clinical Manifestations

Panic, weakness, and a sense of impending doom are common, as are paresthesias and muscle weakness or cramping. As in metabolic alkalosis, Trousseau's and Chvostek's signs can often be elicited and overt tetany or seizures may follow, particularly in patients with previous seizure diatheses. Vision and speech may become impaired and syncope can follow. Transient electrocardiographic changes can resemble those of myocardial ischemia; this finding can be particularly misleading because it is not uncommon for hyperventilating patients to complain of chest discomfort.

Therapy

Reassurance and rebreathing in a small paper bag are frequently all that is needed to control hyperventilation attacks associated with anxiety. In more severe cases, β-adrenergic inhibitors have proved useful, and specific therapy for anxiety may be indicated. Administration of acetazolamide or corticosteroids before ascent to high altitudes may prevent acute mountain sickness in susceptible persons. Ventilation is stimulated by acetazolamide, but the mechanism by which corticosteroids work remains unknown. Correction of respiratory alkalosis in other conditions, such as hepatic coma and pulmonary disorders, depends on treatment of the primary disorder. CO_2 inhalation by patients with hepatic coma has not been helpful.[92]

KEY POINTS

- Current theory and practice justify the use of P_{CO_2} and HCO_3^- as useful "respiratory" and "metabolic" parameters for analyzing changes in acid-base balance when they are critically judged in the context of each patient's history, physical examination, and other imaging and laboratory information.
- The relative magnitude and the direction in which each parameter changes make it possible to classify primary, compensatory, and mixed disorders.
- Alterations in the blood gas values can be misleading, because changes in laboratory variables may be consistent with but cannot prove a specific sequence of clinical events, particularly if the temporal progression of the disease is not well appreciated.
- The "anion gap" approach to analysis of acid-base problems continues to be a useful tool for detecting a variety of problems; both increases and decreases in this parameter can yield important clinical information.
- In terms of therapy, the most effective measures are those that treat the underlying cause, and if one must attempt chemical remediation, it should be done judiciously and be closely monitored.

INTRODUCTION

Pulmonary pharmacology is concerned with the action of drugs on target cells of the lung. Learning the mechanisms and action of drugs will improve our understanding of their use in therapy. This should lead to advances in drug development, making treatment more specific and maximizing the beneficial effects of therapy. Drugs may also be used as specific probes to analyze pathophysiologic processes in lung disease. This chapter concerns the general pharmacologic principles of drug action in the lung, with particular emphasis on the application of pharmacology to understanding lung diseases and their therapy.

CELL INTERACTIONS IN THE LUNG

The structure of human lungs is complex, with over 40 different cell types. Each cell type may be subject to different control mechanisms and may be influenced in a variety of ways. Whereas some cells, such as airway smooth muscle, have been extensively investigated, other cells have been less well characterized.

There may be complex interactions between different cells in the lung, and damage to one cell type may lead to abnormal function in a different cell type. These interactions are now beginning to be investigated using systems biology approaches that analyze complex interactive networks using newly developed mathematical modeling approaches.[1] Analysis of cell-to-cell communication may be important in understanding the mode of action of various pharmacologic agents, because drugs usually act on many cell types both directly and indirectly through cell-cell interactions.

Vascular Endothelium

Vascular endothelial cells are activated by many different agonists to release vasodilators, including nitric oxide (NO) and prostacyclin.[2] Thus, acetylcholine (ACh), which relaxes vessels in vitro through the release of NO, induces a constrictor response if endothelial cells are removed mechanically. Endothelial cells play a critical role in regulating both the bronchial and the pulmonary circulations, and NO is the predominant vasodilator in these vessels.[3]

Airway Epithelium

Airway epithelium releases many mediators that may affect airway and vascular smooth muscle in the airway wall and thereby play a critical role in the regulation of airway caliber. Airway epithelial cells release relaxant factors, including NO and prostaglandins, and mechanical removal of airway epithelium causes enhanced contractile and reduced relaxant responses of airway smooth muscle in vitro.[4] The existence of an epithelium-derived relaxant factor (EpDRF) different from NO and prostaglandins has been demonstrated in superfusion experiments, but its identity has never been determined. The effect of epithelial removal is most striking for the effects of peptides, such as tachykinins and bradykinin. This is explained by the release of prostaglandin (PG) E_2 from epithelial cells and by degradation by the enzyme neutral endopeptidase (NEP), which is expressed in high concentration by airway epithelial cells. Epithelial cells also synthesize several other mediators, including peptides such as endothelin-1 (a potent constrictor peptide, chemokines that attract inflammatory cells such as neutrophils and eosinophils), and growth factors that result in structural changes in the airways (e.g., fibrosis, airway smooth muscle hyperplasia). Epithelial cells synthesize several key cytokines, such as thymic stromal lymphopoietin (TSLP), which plays a key role in regulating dendritic cells to orchestrate airway inflammation, interleukin (IL) -33, which orchestrates T lymphocytes and B-cell–activating factor (BAFF), which regulates B lymphocytes, thus playing a critical role in linking innate and acquired (Fig. 8-1) immunity.[5]

Inflammatory Cells

Many stimuli produce effects on airway function by releasing mediators from inflammatory cells in the airways. A good example is allergen, which does not directly constrict airway smooth muscle, but activates airway mast cells to release bronchoconstrictor mediators, such as leukotriene (LT) D_4 and histamine, which then contract airway smooth muscle cells. Another example is adenosine, which releases histamine from mast cells in asthmatic airways. These are examples of *indirect* bronchoconstrictors, in contrast to *direct*

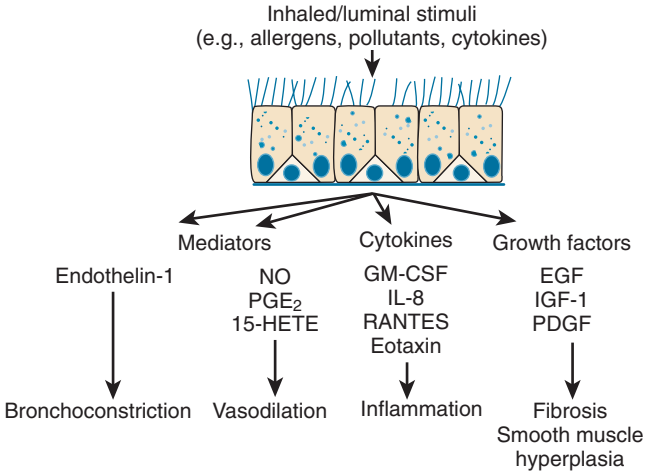

FIGURE 8-1 ■ Epithelial cells as a source of inflammatory mediators. Airway epithelial cells may be activated by stimuli in the airway lumen to produce a wide variety of inflammatory mediators that have effects on airway function. EGF, epidermal growth factor; GM-CSF, granulocyte-macrophage colony stimulating factor; 15-HETE, 15 hydroxyeicosatetraenoic acid; IGF-1, insulin-like growth factor-1; IL-8, interleukin-8; NO, nitric oxide; PDGF, platelet-derived growth factor; PGE_2, prostaglandin E_2; RANTES, release by activated normal T cells expressed and secreted.

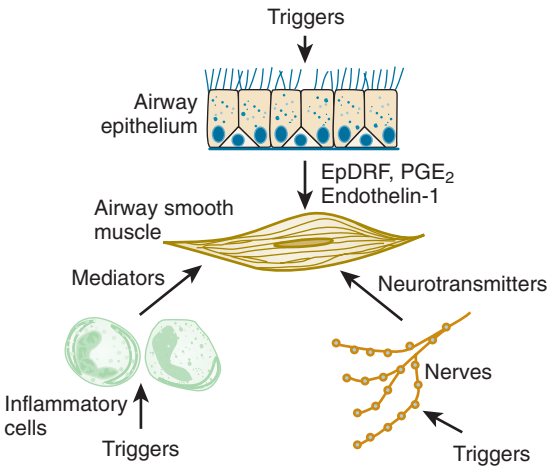

FIGURE 8-2 ■ Cell interaction in the airways. Airway smooth muscle tone may be determined by the direct effect of agonists acting on receptors on airway smooth muscle cells or indirectly via the release of mediators from epithelial cells, inflammatory cells or nerves, which may be triggered by various factors. EpDRF, epithelium-derived relaxing factor; PGE_2, prostaglandin E_2.

bronchoconstrictors, such as histamine, methacholine, and LTD_4, which act directly on airway smooth muscle cells (Fig. 8-2). Other inflammatory cells (e.g., macrophages and eosinophils) may also be involved in indirect bronchial challenges and may be activated by allergens through low affinity immunoglobulin (Ig) E receptors (FcεRII, CD23).

Nerves

Several stimuli may also activate nerves to release bronchoconstrictor neurotransmitters. Thus, irritant gases (e.g., sulfur dioxide) may activate sensory nerves to cause reflex cholinergic bronchoconstriction. Other stimuli (e.g., bradykinin) may activate sensory nerves to release tachykinins.[6] Other mediators may release neurotransmitters from motor nerves via activation of prejunctional receptors. These stimuli that evoke bronchoconstriction via neural mechanisms are also examples of indirect bronchoconstrictors.

RECEPTORS

Nearly all hormones, neurotransmitters, mediators, cytokines, and growth factors produce their effects by interacting with specific protein recognition sites, or receptors, on target cells. Because receptors are specific, they allow a cell to recognize only selected signals from the myriad of molecules that come into contact with the cell. Receptors play an important role in disease, because their function may be altered, resulting in abnormal cellular responsiveness. Many drugs used in the treatment of pulmonary diseases stimulate (agonists) or block (antagonists) specific receptors.

There have been major advances in elucidating the function, regulation, and structure of receptors. This has been made possible by the development of radioligand binding, in which highly potent radiolabeled agonists or antagonists are used to characterize and directly quantify and map receptors. Many different receptors have been cloned, making it possible to deduce their amino acid structure and to determine the critical parts of the receptor protein that are involved in ligand binding and interaction with second messenger systems. Receptor cloning and production of pure receptor proteins has also made it possible to produce specific antibodies for use in immunocytochemical studies. Furthermore, advances in molecular biology have made it possible to study the regulation of receptor genes. Some receptors termed "orphan receptors" have also been cloned, but their endogenous ligands have not yet been identified. This has led to the discovery of new endogenous ligands and identification of novel drug targets. The cloning of the human genome has revealed many orphan receptors. Understanding their functions could lead to novel therapies.

Receptor Classification

Most receptors are proteins located within the cell membrane. They interact with specific ligands outside the cell, leading to a conformational change that results in activation of a second messenger system within the cell and subsequently to a cellular response. Cell surface receptors include (Fig. 8-3):

- Guanine-nucleotide binding protein (G protein)–coupled receptors (GPCRs; e.g., β-adrenergic receptors, chemokine receptors).
- Ion-channel–linked receptors (e.g., nicotinic receptors).
- Enzyme-linked receptors (e.g., platelet-derived growth factor receptors).
- Cytokine and growth factor receptors, which usually have at least two subunits (e.g., IL-5 receptors).
- Intracellular receptors, such as steroid and thyroid receptors, are intracellular and the ligand diffuses into the cell and usually binds to cytosolic receptors, which translocate to the nucleus and interact with recognition binding sites on DNA to regulate the transcription of target genes.

Molecular cloning techniques have made it possible to recognize several receptor families that share a common structure and to trace the evolutionary lineage of receptors within receptor families.

G Protein–Coupled Receptors

Many different receptors interact with G proteins, which act as a coupling mechanism linking receptor activation to second messenger systems. All of these receptors appear to have structural similarities and are members of a large supergene family. More than 1000 GPCRs, making up greater than 1% of the human genome have now been cloned and sequenced.[7,8] Each receptor is a single polypeptide chain, ranging in size from approximately 400 to more than 1000 amino acids with seven hydrophobic sequences that cross the cell membrane.

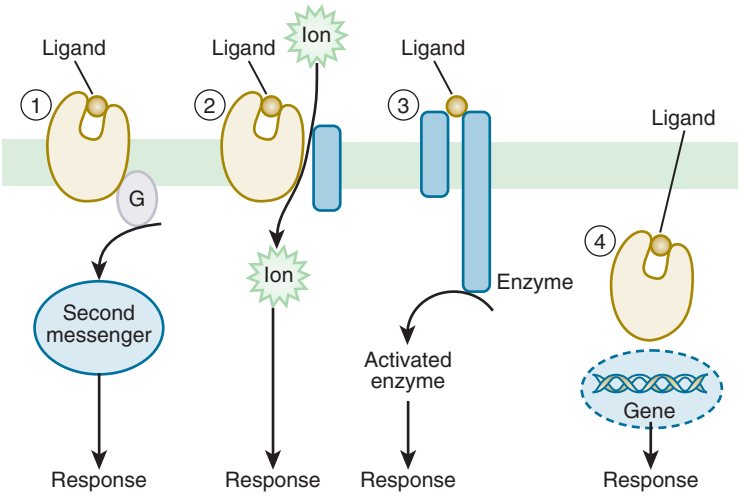

FIGURE 8-3 ■ Several classes of receptor are recognized. (1) G protein–coupled receptors, which activate second messengers to induce a response; (2) receptor-operated ion channels; (3) enzyme-linked receptors; (4) intracellular receptors, which translocate to the nucleus to regulate gene expression.

Many drugs used in the treatment of respiratory diseases work through interaction with GPCRs. In addition, many unknown (orphan) GPCRs have been discovered and are now targets for the development of novel drugs.[9] For example, polymorphisms of the orphan receptor G protein for asthma susceptibility (GPRA) was discovered when polymorphisms of its gene were linked to increased asthma susceptibility and airway hyperresponsiveness.[10] The endogenous agonist of this receptor has now been identified as neuropeptide S, which has been linked to anxiety and arousal, but the function of neuropeptide S in asthma has not yet been defined.[11]

Rhodopsin as a Model Receptor

The first and most carefully characterized GPCR was rhodopsin in light-sensitive rods of the retina, which is coupled to a unique G protein called transducin, and this has served as a useful structural model for other receptors in this group. Analysis of the amino acid sequence of rhodopsin revealed seven hydrophobic (lipophilic) stretches of 20 to 25 amino acids that are linked to hydrophilic regions of variable length. The most likely spatial arrangement of the receptor in the cell surface membrane is for the seven hydrophobic sections (each of which is in the form of an α-helix) to spanning the cell membrane. The intervening hydrophilic sections are exposed alternately intracellularly and extracellularly with the amino (N)-terminal exposed to the outside and the carboxy (C)-terminal within the cytoplasm. The extracellular regions of rhodopsin recognize the specific ligand (retinal) and the intracellular regions interact with transducin. All other GPCRs share this serpentine motif. More recently, the three-dimensional structure of other GPCRs, including the β_2-adrenergic receptor, have been characterized, and these generally conform with the rhodopsin model.[12]

Structure

All GPCRs share the common feature of seven similar hydrophobic transmembrane segments (7TM). There is

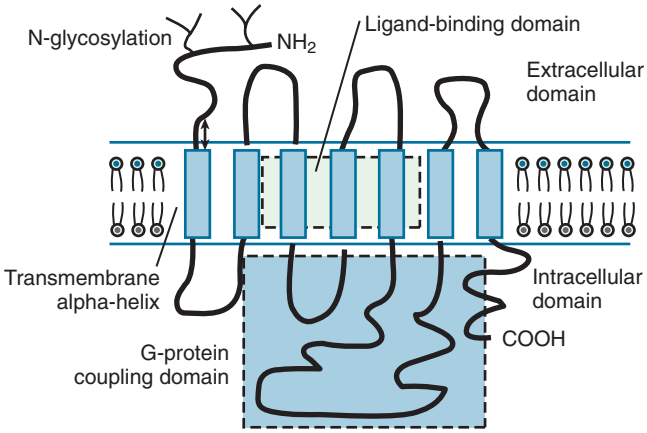

FIGURE 8-4 ■ Structure of a G protein–coupled receptor. The peptide chain is folded seven times across the cell membrane. The hydrophobic segments that cross the cell membrane are in the form of an α-helix. Small ligands interact deep within the cell membrane between the α-helices, whereas peptide ligands interact with the extracellular parts of the receptor. Intracellular loops (especially the third intracellular loop) are important in interaction with the G protein. Most of these receptors are glycosylated at extracellular loops.

also some sequence homology of the intracellular loops (which interact with various species of G proteins) but less similarity in the extracellular domains. For example, there is a 50% homology between rat β_2-adrenergic and muscarinic M_2-receptors. There is also close homology between the same receptor in different species. Thus, there is 95% homology between rat and pig heart M_2-receptors. These similarities demonstrate that G receptor–linked receptors form part of a supergene family that may have a common evolutionary origin.

Members of the G protein receptor supergene family are generally 400 to 500 amino acids in length and the receptor cDNA sequence consists of 2000 to 4000 nucleotide bases (2–4 kb) (Fig. 8-4).[8] The molecular weight of the cloned receptors predicted from the cDNA sequence is 40 to 60 kDa, which is usually less than the molecular mass of the native receptor, when assessed by SDS

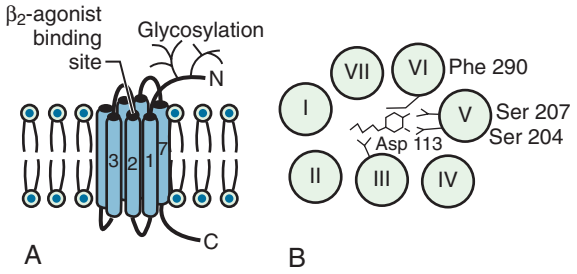

FIGURE 8-5 ■ Ligand-binding domain of the β_2-adrenergic receptor, showing the clustering of the 7 transmembrane domains to form a binding cleft (**A**) and the interaction between the catecholamine and the critical amino acids in the transmembrane domains (**B**). Asp, aspartate; Phe, phenylalanine; Ser, serine.

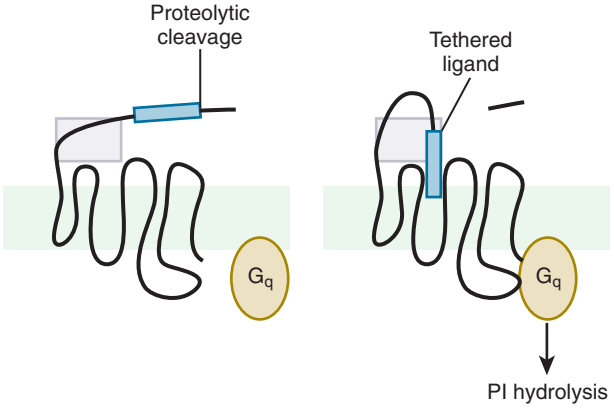

FIGURE 8-6 ■ Proteinase-activated receptors (PARs) are G protein–coupled receptors that are activated by proteinases, such as thrombin (PAR1, 2, 4) and tryptase (PAR2). Cleavage occurs at the N-terminal end of the receptor to reveal a tethered ligand sequence that then inserts into the binding cleft of the receptor, resulting in coupling of a G protein (usually G_q) to effector mechanisms such as phosphoinositide (PI) hydrolysis.

polyacrylamide gel electrophoresis. This discrepancy is explained by *glycosylation* of the native receptor. For example, β_2-receptors contain two sites for glycosylation on asparagine (Asn/N) residues near the N-terminus, and it is estimated that N-glycosylation accounts for 25% to 30% of the molecular mass of the native receptor. Receptor glycosylation does not affect receptor affinity for ligand or coupling to G proteins, but may be important for the trafficking of the receptor through the cell during down-regulation or for keeping the receptor correctly orientated in the lipid bilayer.

Another feature of these receptors is palmitoylation, when cysteine residues covalently bind palmitic acid via a thioester bond, thus anchoring the receptor chain to the cell membrane. This confers three-dimensional stability on the receptor. Disruption of this bond in β-receptors (by mutation of Cys341) alters both binding characteristics and coupling to G proteins and may affect desensitization of the receptor.[13]

Deletion mutagenesis (deleting sections of the peptide sequence) and site-directed mutagenesis (substitution of single amino acids in the polypeptide chain) have established that the ligand-binding domain is well conserved between members of the same family. In the case of β-adrenoceptors, there is good evidence for a ligand-binding cleft between the transmembrane spanning domains within the cell membrane.[14] Critical amino acids for the interaction of endogenous adrenergic agonists (norepinephrine and epinephrine) are asparagine (Asp) in the third transmembrane loop (TM3, Asp113) and serines in TM5 (Ser204, Ser207), which interact with the hydroxy groups on the catechol ring (Fig. 8-5).

The binding site for antagonists differs from those of naturally occurring ligands and for antagonist binding to β-receptors TM7 appears to be critical. Binding of substance P to the NK_1-receptor occurs to extracellular domains of the receptor, whereas antagonist binding of the nonpeptide NK_1-antagonist CP96,345 binds to a transmembrane domain (His197).[15]

One special type of GPCR is the proteinase-activated receptor (PAR), exemplified by receptors for thrombin and tryptase.[16] There are currently four PARs recognized; thrombin activates PAR1, 3, and 4, whereas trypsin, mast cell tryptase, and other serine proteases activate PAR2. Ligands for these receptors are enzymes that cleave a site on the extracellular domain of the receptor, thus revealing an active site that then binds to and activates the remaining receptor protein (Fig. 8-6). PAR may play an important role in lung diseases, leading to a search for specific antagonists.[16]

Receptor Dimerization

It is now recognized that most GPCRs undergo physical association with themselves (homodimerization) but also with other GPCRs (heterodimerization) and that this may profoundly influence receptor function and interaction with signaling pathways, providing a novel mechanism of receptor interactions that may be relevant to pulmonary disease.[17-19] Recognition of GPCR heterodimers might also lead to the development of new drugs that recognize only the heterodimers and therefore have a greater selectivity. For example, heterodimerization between prostaglandin E (PGE_1) receptors and β_2-receptors in airway smooth muscle cells results in uncoupling of β_2-receptors and a diminished bronchodilator response to β_2-agonists (Fig. 8-7).[20] β_2-Receptors are also known to dimerize with β_1-, β_3-, opioid-, and angiotensin (AT_1)-receptors. Heterodimerization of chemokine receptors may be important in determining cell recruitment and may account for why selective antagonist of one receptor may inhibit responses to other chemokines that signal through different receptors.[21] For example, CXCR1/CXCR2 and CCR2/CCR4 heterodimers have been identified and appear to be induced when the chemokine ligands for both receptors are present together.

G Proteins

G proteins link activation of 7TM receptors to enzymes or ion channels that then mediate the characteristic response.[22] All G proteins have GTPase activity and

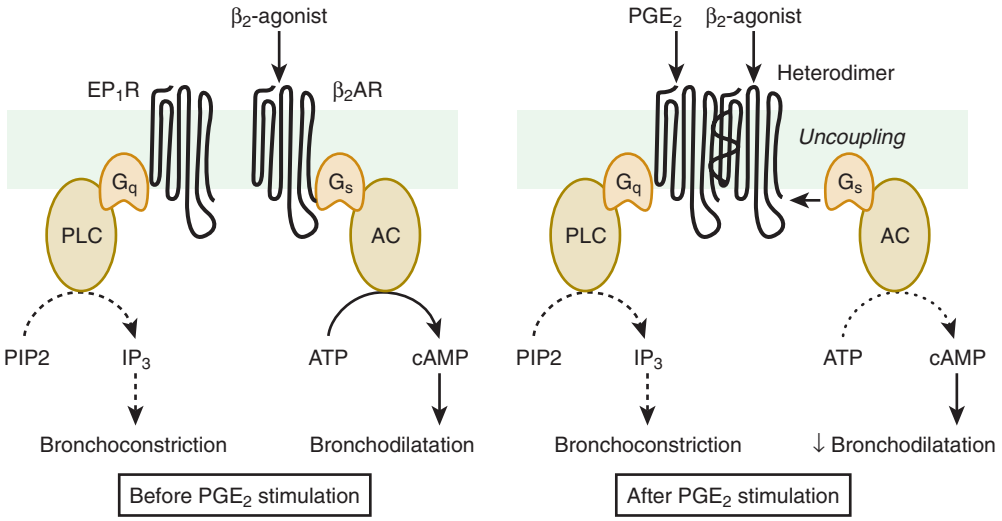

FIGURE 8-7 ■ Heterodimerization of prostaglandin E_1-receptors (EP_1R) and β_2-adrenergic receptors (β_2AR) in airway smooth muscle cells. Under basal conditions (*left panel*), a β_2-agonist activates a stimulatory G protein (G_s) thus stimulating adenylyl cyclase (AC) to increase cyclic 3′,5′-adenosine monophosphate (cAMP) and produce bronchodilatation. Prostaglandin $(PG)E_2$ (*right panel*) promotes the dimerization of EP_1R with β_2AR, uncoupling it from Gs, thus reducing the bronchodilator response to a β_2-agonist. EP_1R signals through a different G protein (Gq)–coupled to phospholipase C (PLC) and the formation of inositol-1,4,5-trisphosphate (IP_3), which releases calcium ions to cause bronchoconstriction, but PGE_2 alone does not activate this pathway sufficiently to induce bronchoconstriction.

catalyze the conversion of guanosine triphosphate (GTP) to guanosine diphosphate (GDP). Several distinct G proteins have now been characterized and cloned. They are made up of three separate units and are termed "heterotrimeric G proteins"; the α-subunit interacts with the receptor, binds GTP, and interacts with the effector enzyme, such as adenylyl cyclase and phospholipase C. The β- and γ-subunits are hydrophobic and are associated as a βγ complex within the cytoplasmic surface of the cell membrane. G proteins are freely diffusible within the cell membrane and the pool of G proteins may interact with several receptors. In the resting state, the G protein exists as a αβγ heterotrimer with GDP occupying the binding site on the α-subunit. When a receptor is occupied by an agonist, a conformational change occurs and the intracellular loops of the receptor protein acquire a high affinity for αβγ, resulting in the dissociation of GDP and its replacement with GTP, which in turn causes α-GTP to dissociate from the βγ-subunits (Fig. 8-8). α-GTP is the active form of the G protein and diffuses to associate with effector molecules, such as enzymes and ion channels. This process is terminated by hydrolysis of GTP to GDP via the GTPase activity of the α-subunit. The resulting α-GDP dissociates from the effector molecule and reassociates with βγ, in readiness for activation again.[23]

In addition to the classical heterotrimeric G proteins with αβγ-subunits, there are several other small G proteins with GTPase activity, such as the Rho, Rab, and Rac subfamilies, that are not activated directly by GPCRs, but play a key role in regulating actin and cytoskeletal organization.[24] Rho activates specific Rho kinases leading to a cascade of interacting signals with in the cell. For example, Rho GTPases are involved in contractile responses in airway smooth muscle and in fibrosis so that

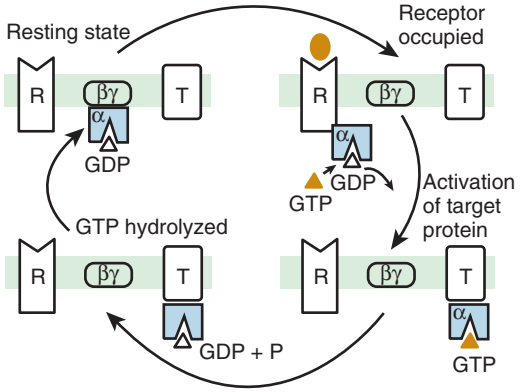

FIGURE 8-8 ■ Transducing function of G proteins is shown. G proteins couple receptor activation to a target membrane protein, such as an enzyme (e.g., adenylyl cyclase) or an ion channel (T). Each G protein is made up of three subunits (α, β, and γ) (not shown). In the inactive state, guanine diphosphate (GDP) binds to the α-subunit, but when a receptor (R) is activated, it interacts with the α-subunit, displacing GDP for guanine triphosphate (GTP), and resulting in the association of the α-subunit with the effector system. GTP is then hydrolyzed by the intrinsic GTPase activity of the α-subunit, resulting in activation of T. This then allows the α-subunit to associate with the βγ-subunits, which remain fixed in the hydrophobic cell membrane. The α-subunit is therefore believed to act as a "shuttle," coupling receptor activation to stimulation of the target protein.

Rho kinase inhibitors might have therapeutic potential in asthma.[25] Rab GTPases are involved in secretion and may therefore play a role in mucus secretion and in mast cell degranulation.[26]

Several receptors, such as β-receptors and vasoactive intestinal polypeptide (VIP)-receptors, stimulate

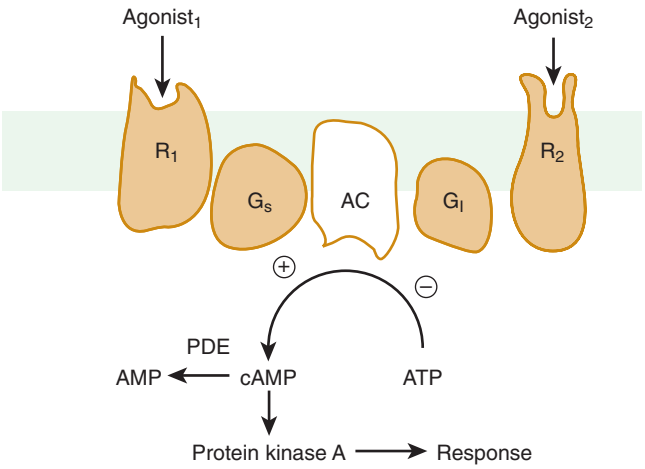

FIGURE 8-9 ■ G proteins and adenylyl cyclase are depicted. Receptors (R_1, R_2) are coupled to G proteins that stimulate (G_s) or inhibit (G_i) adenylyl cyclase (AC), resulting in increased or decreased formation of the second messenger, cyclic adenosine 3′,5′-monophosphate (cAMP) from adenosine triphosphate (ATP). cAMP is degraded to adenosine monophosphate (AMP) via phosphodiesterases (PDE). cAMP activates protein kinase A, which phosphorylates target proteins, leading to a response.

adenylyl cyclase via the stimulatory G protein G_s, whereas activation of other receptors, such as muscarinic M_2-receptors inhibit adenylyl cyclase via G_i (Fig. 8-9).[22] G_s may be stimulated directly by cholera toxin, whereas G_i is inhibited by *Pertussis* toxin, so that these toxins have proved to be useful in elucidating the involvement of a particular G protein in a particular receptor-mediated response. Other G proteins are now recognized. They couple receptors, which activate phosphoinositide hydrolysis (G_0, G_q) and activate particular ion channels in the cell membrane (e.g., G_k, which is coupled to potassium channels). G proteins may play a very important role in the regulation of cell responsiveness, and there is evidence that receptors may become uncoupled from G proteins under certain conditions. For example, in fatal asthma, there is evidence for a reduced responsiveness of airway smooth muscle to β-agonists, yet the number and affinity of β-receptors on airway smooth muscle is not reduced and the response to other smooth muscle relaxants is not impaired, suggesting that the receptors have become *uncoupled* in severe asthma.[27]

Whereas receptors affect the function of G proteins, G proteins also influence the interaction of ligands with their receptors. Thus, when coupled to an inactive G protein, the receptor exists in a state of high affinity for the agonist. Agonist binding releases G_α from contact with the receptor, resulting in a reduction in agonist affinity, referred to as the "guanine-nucleotide shift."

Second Messengers

The ligand that activates a receptor is described as the first messenger and leads, via activation of a G protein, to the typical cellular response via a second messenger, such as a change in intracellular calcium ion (Ca^{2+}) concentration or cyclic 3′,5′-adenosine monophosphate (cAMP) concentration. Whereas the number of surface receptors that may respond on any particular cell is very large, only a very limited number of signal transduction and second messenger systems have been described. Thus, the surface receptors determine cellular responsiveness and sensitivity, rather than the intracellular mechanisms that are activated by the receptor-ligand interaction. Considerable progress has been made in understanding the intracellular mechanisms involved in receptor-mediated effects, through the development of techniques such as intracellular dye indicators that reflect intracellular concentrations of ions (e.g., fura-2, which detects intracellular Ca^{2+} concentrations), via more sensitive biochemical assays and via the development of patch clamping techniques.

Adenylyl Cyclase

Many receptors produce their effects by interaction with the membrane-bound enzyme adenylyl cyclase (AC) to either increase or decrease production of cyclic 3′,5′ adenosine monophosphate (cAMP) (see Fig. 8-9). At least nine closely related forms of AC have now been differentiated, and there is increasing evidence that these isoforms may be differentially regulated.[28] Thus, protein kinase C (PKC) phosphorylates and activates certain isoforms (types 1,2,3), which may be a mechanism for receptor interactions whereas PKC has no effect on other isoforms (4,5,6). The formation of cAMP leads to the characteristic cellular response via the activation of a specific protein kinase, protein kinase A (PKA), by dissociating a regulatory (inhibitory) subunit. PKA then phosphorylates serine and threonine residues on specific proteins, such as regulatory proteins, ion channels, and enzymes within the cell, which lead to the characteristic response. For example, in airway smooth muscle cells, PKA phosphorylates large conductance calcium-activated potassium (K^+) channels, which open, leading to K^+ efflux from the cell, hyperpolarization and relaxation.[29] PKA also phosphorylates and therefore inactivates myosin light chain kinase, resulting in a direct relaxant effect on the contractile machinery.

It is now increasingly recognized that cAMP also activates signaling mechanisms other than PKA, such as ion channels and the ubiquitous guanine nucleotide exchange factors Epac 1 and 2.[30] For example, cAMP-induced inhibition of IL-5 in human T lymphocytes is independent of PKA.[31] Conversely, β_2-agonists inhibit the release of certain cytokines from airway smooth muscle cells via an effect on PKA, because these responses are completely inhibited by transfection with the selective endogenous PKA inhibitor called "PKA inhibitor-α."[32]

Phosphodiesterases

cAMP is hydrolyzed within cells by a family of enzymes termed "phosphodiesterases" (PDEs). At least 12 PDE families have now been distinguished on the basis of substrate specificity, inhibition by selective inhibitors, and by molecular cloning.[33] In airway smooth muscle, PDE3 and PDE4 isoenzymes are involved in

cAMP-mediated relaxation, whereas in inflammatory cells (mast cells, eosinophils, neutrophils, macrophages, T-lymphocytes) and airway epithelium, PDE4 predominates. This has led to the development of several selective PDE4 inhibitors for the treatment of asthma and chronic obstructive pulmonary disease (COPD), although side effects after oral administration are a major problem that has limited development.[34] Each PDE has several isogenes and each subtype of PDE has several splice variants, so multiple forms of PDE exist in the cell. This may allow precise control of intracellular cyclic nucleotide concentrations. For example, there are four distinct PDE4s (PDE4A, PDE4B, PDE4C, and PDE4D), each of which has several splice variants that are differentially expressed and regulated.[35] This may be relevant in drug design. Thus, inhibition of one subtype may mediate the desired effect and another may be responsible for side effects. For example, PDE4B appears to mediate the anti-inflammatory effect of PDE4 inhibitors, whereas PDE4D mediates the nausea and vomiting that are often dose-limiting.[36,37]

Phosphatidylinositol Hydrolysis

Another signaling system involves breakdown of a membrane phospholipid, phosphatidylinositol (PI), which results in increased intracellular Ca^{2+} concentration. Over 100 receptors are coupled via G_q or G_i to the membrane-associated enzyme phosphoinositidase or phospholipase C (PLC), which converts phosphoinositide(4,5)bisphosphate (PIP2) to inositol (1,4,5)trisphosphate (IP_3) and *1,2 sn*-diacylglycerol (DAG) (Fig. 8-10). Four main groups of PLC have now been identified (PLC-β, PLC-γ, PLC-δ, PLC-ε), each of which has subclasses (e.g., PLC-β1, PLC-β2, PLC-β3) based on amino acid structure of different cloned genes.[38] These isoenzymes are differentially coupled to different receptors and are subject to differential regulation.

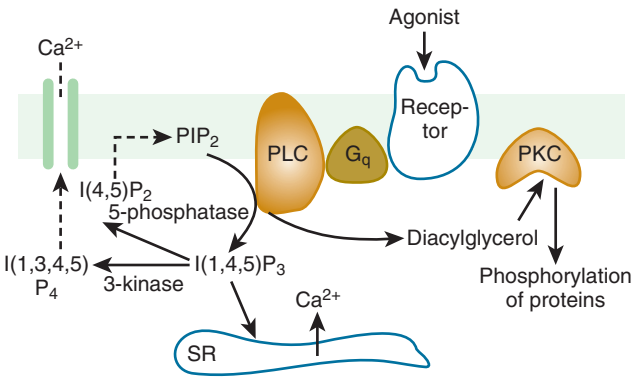

FIGURE 8-10 ■ Phosphoinositide hydrolysis is shown. Occupation of a surface receptor leads to activation of the enzyme phospholipase C (PLC) via a G protein (G_q). PLC converts phosphoinositide 4,5,-bisphosphate (PIP_2) to inositol (1,4,5) trisphosphate and diacylglycerol. $I(1,4,5)P_3$ binds to receptors on sarcoplasmic/endoplasmic reticulum (SR) to release calcium ions (Ca^{2+}), resulting in a rise in intracellular Ca^{2+} concentration and cell activation. $I(1,4,5)P_3$ is dephophorylated to $I(4,5)P_2$, inositol phosphate and inositol, which is then re-incorporated into membrane phophoinositides. In some cells, it is further phosphorylated to $I(1,3,4,5)P_4$, which may be involved with calcium entry and refilling of intracellular stores. Diacylglycerol activates protein kinase C (PKC), which phosphorylates various regulatory proteins in the cell.

IP_3 binds to a specific receptor on endoplasmic/sarcoplasmic reticulum, leading to the release of Ca^{2+} from intracellular stores. Thus, PI hydrolysis links occupation of a surface receptor to intracellular Ca^{2+} release. Most of the mediators that contract airway smooth muscle act on receptors activating PI hydrolysis in airway smooth muscle.[39] IP_3 is broken down into the inactive IP_2 by IP_3 kinase and subsequently to inositol, which is reincorporated into phophoinositides in the cell membrane. IP_3 may also be phosphorylated by IP_3 kinase to IP_4, which may be involved in opening receptor-operated calcium channels and the refilling of intracellular stores. Using the fluorescence indicator dye fura-2, it has been possible to monitor changes in intracellular [Ca^{2+}] in response to receptor-mediated activation. In addition, IP_3 has been introduced into cells in a "caged" inactive form that may then be activated by a flash of light, to allow the kinetics of activation to be investigated. The use of these techniques in single cells has demonstrated that calcium release in response to agonists or IP_3 occurs in a series of oscillations, which is probably mediated via calcium-induced calcium release and the opening of calcium channels on the cell membrane.[40] The frequency of oscillation may be important in the type of cell activation that ensues.

The formation of DAG activates PKC by causing it to translocate to the cell membrane and by dramatically increasing its sensitivity to Ca^{2+}. Activated PKC is then capable of phosphorylating various cell membrane-associated proteins, including some receptors, G proteins, and regulatory proteins. Many isoenzymes of PKC are now recognized, and they play a critical role in the regulation of inflammatory and structural cells of the airways, although the role of individual isoenzymes in regulating cell function is not yet clear, because selective inhibitors have been difficult to find.[41] One isoenzyme may be activated by arachidonic acid, a product of phospholipase A_2 hydrolysis. DAG is also formed by the activation of phospholipase D on phosphatidic acid, representing yet another level of complexity.[42] PKC may be activated directly by tumor-promoting phorbol esters, such as phorbol 12-myristate 13-acetate (PMA), which have therefore been useful in examining the role of PKC. In some species, PMA and other phorbol esters cause prolonged contractile responses in airway smooth muscle, but in other species, bronchodilation is observed. It has been suggested that PKC may be important for the prolonged contractile responses seen in asthmatic airways. Several PKC isoenzymes have been identified in human airway smooth muscle.[43] PKC inhibitors, such as staurosporine (which is not very selective) and Ro 31-8220, have been developed and may be useful in elucidating the role of PKC, but they are nonselective for different isoforms. PKC is involved in activation of inflammatory cells and in particular the release of oxygen-derived free radicals from these cells.[44]

Guanylyl Cyclase

It was previously believed that, while relaxation of smooth muscle is brought about by receptors that activate cAMP, contraction is due to the production of another cyclic nucleotide, cyclic 3′,5′-guanosine monophosphate (cGMP), formed by the activation of guanylyl cyclase.[45] This is now known to be incorrect and the increase in cGMP is secondary to a rise in intracellular Ca^{2+} concentration. Indeed, cGMP causes relaxation of smooth muscle and is the major mechanism of vasodilation after nitrovasodilators (such as sodium nitroprusside) and dilators (such as ACh), which release NO from endothelial cells. cGMP is also involved in the relaxant response of airway smooth muscle to nitrovasodilators and to atrial natriuretic peptide (ANP), which is a potent bronchodilator in vitro.[46] Guanylyl cyclase existing in particulate form binds natriuretic peptides, but also acts in a soluble form that binds NO.[47] cGMP is broken down by PDEs, and in particular the PDE5 isoenzyme.[48] PDE5 inhibitors have potent vasodilator effects on pulmonary vessels and weak bronchodilator effects.

Ion Channel–Coupled Signaling

G proteins may also couple receptors to ion channels, including K^+, Na^+, and Ca^{2+} channels. Thus, certain muscarinic receptors are coupled via G proteins (G_0) to K^+ channels and to Ca^{2+} channels. In airway smooth muscle, β_2-receptors are directly coupled via G_s to the opening of large conductance K^+ (maxi-K) channels, and the same channels are inhibited by M_2-receptors via G_i.[29] These G proteins allow rapid cell activation by GPCR, in contrast to the slower responses mediated by changes in cyclic nucleotides.

Cytokine Receptors

The effects of cytokines are mediated via specific surface receptors, many of which have now been cloned. There is a very complex network of cytokines and chemokines (small chemotactic cytokines) that orchestrate the inflammation in asthma, COPD, and interstitial lung disease. All of their complex effects are mediated by surface receptors.[49]

Chemokine Receptors

Chemokines, such as CXCL8 (IL-8), CCL5 (regulated on activation, normal T cell expressed and secreted [RANTES]), and CCL11 (eotaxin), bind to receptors that are coupled to G proteins. Their receptors have the typical 7TM GPCR structure.[50,51] Many chemokines have overlapping activities and interact with common receptors on target leukocytes. Over 20 chemokine receptors have now been characterized. They appear to be differentially expressed on different inflammatory cells, thus explaining the differential chemotactic effects of these cytokines. For example, eosinophils express CCR3 that is activated by CCL5, CCL13 (MCP-4), CCL11, CCL24 (eotaxin-2), and CCL26 (eotaxin-3), thus accounting for the selective chemotactic effects of these chemokines on eosinophil migration. Because of the 7TM structure of chemokine receptor, small molecule inhibitors are feasible. This has led to the development of several chemokine antagonists for the treatment of asthma and COPD.[52,53]

Most cytokine receptors have a primary structure that is quite different from the 7TM-spanning segments associated with G protein–linked receptors. Many cytokine receptors have at least two subunits that interact to activate signal transduction pathways within the cell.[54] Thus, the receptor for tumor necrosis factor-α (TNF-α) is a 55-kD peptide that has a single transmembrane-spanning helical segment, an extracellular domain that binds TNF-α, and an intracellular domain.[55] The intracellular domain leads to activation of several kinases and ceramide, which subsequently lead to the activation of transcription factors, such as nuclear factor-κB (NF-κB) and activator protein-1 (AP-1). The structure of the receptor is analogous to the nerve growth factor receptor. A second receptor for TNF p75 has also been cloned, but differs markedly in sequence, and may be linked to different intracellular pathways.[55] There are now almost 30 receptors and 20 cytokines in the TNF superfamily, which have complex and interacting signal transduction pathways.[56]

Molecular cloning has now revealed that, although cytokines may be structurally diverse, their receptors may be grouped into various families that share structural homology.[57] One family of receptors includes the receptors for IL-1 and platelet-derived growth factor (PDGF); these receptors belong to the immunoglobulin superfamily, which includes T-cell antigen receptors and certain cell-surface adhesion molecules. Another cytokine receptor superfamily, the hematopoietin receptor superfamily includes receptors for IL-2, IL-3, IL-4, IL-5, IL-6, IL-7, interferons, and granulocyte-macrophage colony stimulating factor (GM-CSF). Prolactin, growth factor, and erythropoietin receptors are also included in this family. The receptor proteins are oriented with an extracellular N-terminal domain and a single hydrophobic transmembrane-spanning segment. There is striking homology in the extracellular ligand-binding domain with four conserved cysteine residues. There is very close homology between the receptors for IL-3, IL-5, and GM-CSF, all of which stimulate growth of eosinophils. Molecular cloning has demonstrated that each of these receptors consists of α and β chains and share a common β chain, which may explain why they have overlapping biologic activities.

The second messenger system used by cytokines is highly complex, involving many interacting pathways that allow for the possibility of signal splitting, so the same activating signal may result in the activation of several parallel pathways. Which signal pathway predominates is determined by other signals impinging on the cell. Most cytokines activate a group of transcription factors and result in prolonged cellular activation and gene transcription, in contrast to the relatively rapid and transient signaling of most GPCRs.

Enzyme-Linked Receptors

Some receptors contain an enzyme domain within their structure, so that when the enzyme is activated by a ligand, the enzyme becomes activated, leading to signal transduction through the formation of a specific substrate within the cell. The best characterized of these enzyme-linked receptors are receptor tyrosine kinases (RTKs), which have intrinsic protein tyrosine kinase activity.

Receptor Tyrosine Kinases

Activation of RTKs results in phosphorylation of tyrosine residues on certain target proteins that are usually associated with cell growth and chronic activation of cells. More than 50 different RTKs belonging to at least 14 distinct families have now been identified.[58] These receptors include the growth factor receptors epithelial growth factor (EGF) receptor, PDGF receptor, vascular-endothelial growth factor (VEGF) receptors, and insulin (Fig. 8-11). Small molecule inhibitors, such as gefitinib and erlotinib, which block EGF receptors, have been developed for treating lung cancer.[59]

All RTKs share a similar general structure, consisting of a large extracellular N-terminal portion, which contains the ligand recognition domain, a single short membrane-spanning region (α-helix), and a cytoplasmic C-terminal portion (~250 amino acids) that contains the tyrosine kinase activity and autophosphorylation sites. The extracellular domain usually contains cysteine-rich regions and/or immunoglobulin-like motifs, with a large number of disulfide bonds forming a highly specific tertiary structure that is needed to establish ligand-binding specificity. All RTKs (with the exception of the insulin receptor family) undergo a transition from a monomeric to a dimeric state (either homodimers or heterodimers) following binding of their specific ligands. Another characteristic of RTKs is that they undergo internalization into two types of intracellular vesicles: pitted vesicles coated with the protein clathrin and smooth vesicles lacking clathrin. There is a spontaneous internalization, but this is rapidly accelerated when the receptor is occupied by a ligand. A proportion of the receptors are degraded, whereas a proportion is recycled to the cell surface.

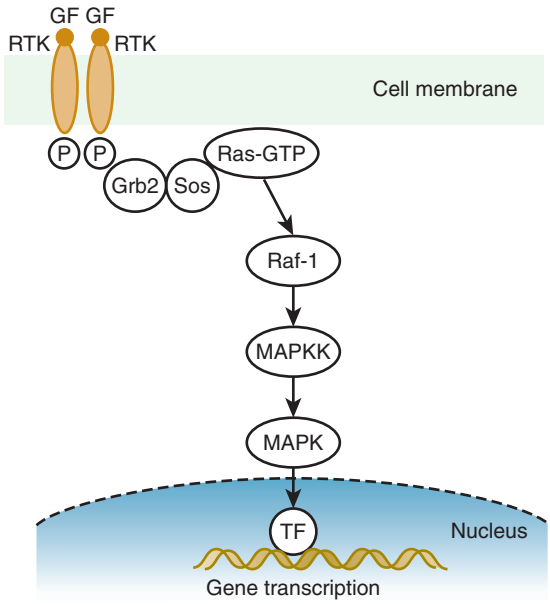

FIGURE 8-11 ■ Activation of receptor tyrosine kinase receptors (RTK) by growth factors (GF) results in a cascade of enzyme activation, involving the adaptor proteins Grb2, Sos, and Ras-GTP, leading to the activation of Raf-1 and mitogen-activated protein kinases (MAPK), which then activate transcription factors (TF) to regulate expression of genes involved in cell proliferation. MAPKK, MAPK kinase.

Signal Transduction

RTKs phosphorylate intracellular molecules containing Src homology 2 and 3 (SH2 and SH3) domains. These SH2 and SH3 domains are short sequences of about 100 and 50 to 60 amino acids, respectively, that function to specify the interaction with a target protein.[60] The SH2 motifs recognize phosphotyrosine residues and are responsible for interactions with autophosphorylated RTKs, whose specificity depends on the amino acid sequences surrounding both the tyrosine autophosphorylation site on the RTK and the substrate's SH2 domain. RTK substrate proteins containing SH2 and SH3 motifs may contain enzymatic activity. The best-characterized RTK enzyme substrates are cytoplasmic protein tyrosine kinases, such as Src, Syk, the $p21^{ras}$-GTPase-activating protein (GAP) and PLC-γ1. Alternatively, the substrate may function as adaptor proteins, composed almost entirely of SH2 and SH3 domains. Examples include Grb2 and the p85 subunit of PI3K.

Most RTKs stimulate the mitogen-activated protein kinase (MAPK) pathways through a complex multistep signaling cascade initiated by translocation of the adaptor protein Grb2 to the cytoplasmic membrane. This results in the activation of Ras proteins, small-molecular-weight GTPases, which in turn activate Raf (a serine/threonine kinase that activates the MAPK pathway[61]). There is increasing evidence that RTKs may interact with several cell-signaling pathways to elicit their effects, and it now seems likely that specific pathways are selected under certain conditions. For example, PDGF, which may exist in the dimeric forms AA, BB or AB, may interact with different receptor dimers (αα, αβ, ββ), resulting in activation of different signal transduction pathways.

MAPK Pathways

RTKs and other extracellular signals activate several MAPK cascades, resulting in a cascade of kinase activation that results in activation of transcription through the transcription factors Jun, Elk-1, and ATF2.[62,63]

Receptor Serine/Threonine Kinases

Similar to RTKs, there are some receptors that are linked to serine/threonine kinase activity. The best known

example is transforming growth factor-β (TGF-β), which exists in three mammalian isoforms encoded by separate genes, all of which may have complex and divergent effects on cell activity.[64] TGF-β receptors signal through regulatory Smad pathways within the cell, including Smad2 and Smad3, together with coactivator Smads, whereas inhibitory Smads, such as Smad6 and Smad7 act as a feedback inhibitory mechanism. Some of the effects of TGF-β are mediated via inhibition of cyclins that regulate the cell cycle, and this may account for the diverse effects of TGF-β depending on the stage of the cycle.[65]

Receptor Protein Tyrosine Phosphatases

Little is known about the third type of enzyme-linked receptors, which have a high level of intrinsic enzyme activity.[66] Occupation by a ligand may turn this enzyme activity off, thus resulting in cell activation. These receptors appear to be important in cell differentiation and include CD45 (also known as "leukocyte common antigen") that is involved in T-lymphocyte signaling.[67]

Ion Channel Receptors

Although several receptors are linked via G proteins to ion channels, such as Ca^{2+} and K^+ channels as discussed previously, other receptors are ion channels themselves. The best-characterized example is the nicotinic acetylcholine receptor (nAChR), which is made up of four subunits that form a cation channel. When activated by Ach, the channel opens to allow the passage of Na^+ ions.[68] This type of receptor, which can respond rapidly because no intracellular mechanisms are involved, is known as a fast receptor and is usually involved in synaptic transmission (Fig. 8-12). nAChRs are involved in ganglionic transmission in parasympathetic ganglia within the airways and are blocked by hexamethonium, which therefore blocks ganglionic transmission and cholinergic reflex bronchoconstriction. nAChRs are widely distributed and α4β2 nAChRs in the brain are responsible for nicotine addiction. Varenicline is a partial antagonist of α4β2 nAChRs acting to block the addictive effects of nicotine and its withdrawal symptoms.[69] Ion channel receptors are oligomeric proteins containing approximately 20 transmembrane segments arranged around a central aqueous channel. Binding of the ligand and channel opening occur very rapidly (within milliseconds). Other examples include glutamate and gamma-aminobutyric acid ($GABA_A$) receptors. This is in contrast to the *slow* receptors, such as GPCRs, which involve a series of catalytic steps.

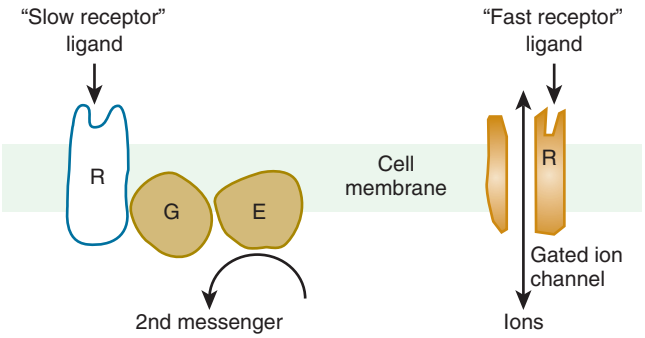

FIGURE 8-12 ■ Fast and slow receptors are depicted. Some receptors are ion channels and consist of several subunits grouped around an aqueous channel through which ions (e.g., Na^+, K^+, Ca^{2+}, Cl^-) enter or leave the cell when agonists bind to one or more of the subunits. Such receptors function very rapidly (in milliseconds) and are involved in neurotransmission (e.g., nicotinic receptors in airway ganglia). Other receptors, which are coupled via G proteins (G), produce their effects more slowly, because a sequence of enzymatic events is necessary before a response occurs. E, enzyme; R, receptor.

Intracellular Receptors

Several ligands cross the cell membrane to interact with intracellular (cytosolic) receptors rather than surface receptors. There is a family of steroid receptors that recognize different endogenous steroids such as glucocorticoids, mineralocorticoids, androgens, and estrogens. Indeed, steroid receptors belong to a supergene family, which also includes thyroid hormone, retinoic acid (vitamin A), and vitamin D receptors.[70] The exploration of cDNA libraries for related sequences has led to the discovery of over 40 "orphan" nuclear receptors, whose ligands are now being identified.[71] One new class of nuclear receptors so identified are the peroxisome proliferator–activated receptors (PPARs), α, γ, and β/δ subtypes have been characterized and selective ligands have now been identified. PPAR may be involved in metabolism and inflammation and may be endogenously activated by lipid mediators.[72] For example, PPAR-γ agonists, such as rosiglitazone, appear to have anti-inflammatory effects on lung inflammation and are also potentially antifibrotic. Thus, they have the potential for treating small airway fibrosis in COPD as well as interstitial lung diseases. Several other orphan receptors, including liver X receptors (LXR), farnesoid X receptors (FXR), pregnane X receptors (PXR), and retinoic acid X receptors (RXR), appear to play roles in the inflammatory processes and may lead to the discovery of novel anti-inflammatory treatments.[73]

Intracellular receptors share a common general structure. There is a central DNA-binding domain, characterized by the presence of 2 "zinc fingers," which are loops stabilized by four cysteine/histidine residues around a zinc ion. These zinc fingers anchor the receptor to the double helix at specific hormone response elements (HREs) in the promoter region of target genes. Ligands bind in the C-terminal domain, which also contains sequences important for binding of associated chaperone proteins (e.g., heat shock proteins) and a nuclear localization signal, involved in transporting the receptor from the cytoplasm into the nucleus. The N-terminal domain is involved in transcriptional regulation and in the interaction with other transcription factors.

Steroid Receptors

Several steroid receptors have now been cloned and their structures have been shown to differ. However,

there is some homology between these receptors: they interact with nuclear DNA, where they act as modulators of the transcription of specific genes. Only a limited number of genes appear to respond directly to steroids. Glucocorticoid receptors (GRs) are normally present in the cytosol in an inactive form bound to two molecules of a 90-kDa heat shock protein (hsp90), which cover the DNA-binding domain. Binding of a steroid to its receptor results in the dissociation of hsp90. The occupied receptor then undergoes a conformational change that allows it to bind to DNA.[74,75]

The DNA-binding domain of steroid receptors is rich in Cys residues. Formation of a complex with zinc is able to fold the peptide chain into a finger-shaped conformation, and the zinc is coordinated by four Cys residues. GRs have two "zinc fingers" which are loops of approximately 15 residues, each of which is held in shape by four cysteine residues surrounding an atom of zinc. Zinc fingers are essential for the interaction with the DNA double helix. Steroid receptors recognize specific DNA sequences—the so-called glucocorticoid response elements (GREs) which have the consensus sequence GGTAnnnTGTTCT. Dimers of GR occupied by steroid bind to the GRE on the DNA double helix and either *increase* (+GRE) or much less commonly *decrease* (–GRE) the rate of transcription by influencing the promoter sequence in the target gene. Indeed, repression of target genes may be the most important aspect of corticosteroid action in inflammatory diseases such as asthma, because corticosteroids may inhibit the transcription of many cytokines that are involved in chronic inflammation. The major mechanism of gene repression is mediated via an interaction between the activated glucocorticoid receptor and transcription factors, such as NF-κB and AP-1 that are activated via inflammatory signals such as cytokines. NF-κB activates inflammatory genes by recruiting coactivator molecules that have histone acetyltransferase activity, leading to acetylation of core histones associated with inflammatory genes, which results in increased gene transcription. Activated GRs inhibit coactivator molecules and also recruit histone deacetylase-2 (HDAC2) which deacetylates the hyperacetylated histones, resulting in switching off of the activated inflammatory genes (Fig. 8-13).[75]

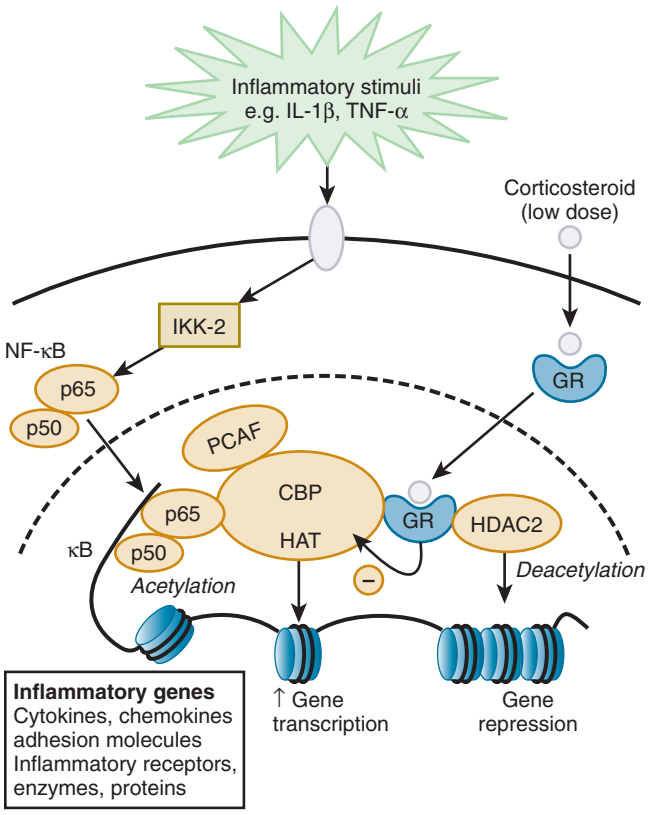

FIGURE 8-13 ■ Corticosteroid suppression of activated inflammatory genes. Inflammatory genes are activated by inflammatory stimuli, such as interleukin-1β (IL-1β) or tumor necrosis factor-α (TNF-α), resulting in activation of IKK2 (inhibitor of I-κB kinase-2), which activates the transcription factor nuclear factor κB (NF-κB). A dimer of p50 and p65 NF-κB proteins translocates to the nucleus and binds to specific κB recognition sites and also to coactivators, such as CREB-binding protein (CBP), which have intrinsic histone acetyltransferase (HAT) activity. This results in acetylation of core histone H4, resulting in increased expression of genes encoding multiple inflammatory proteins. Glucocorticoid receptors (GR), after activation by glucocorticoids, translocate to the nucleus and bind to coactivators to inhibit HAT activity directly and recruit histone deacetylase-2 (HDAC2), which reverses histone acetylation, leading in suppression of these activated inflammatory genes.

Receptor Subtypes

The existence of receptor subtypes is often first indicated by differences in the potency of a series of agonists in different tissues. This could be due to differing proportions of coexistent receptor subtypes, or may indicate the existence of a novel receptor subtype. Molecular biology can resolve these possibilities, because molecular techniques can discriminate between different subtypes of receptor and show that they are encoded by different genes. Thus, the human β_1-receptor is clearly different from the β_2-receptor in its amino acid sequence, with a 54% homology, and the NK_1-receptor, which is selectively activated by substance P, has a 48% homology with the NK_2-receptor, which is activated by the related tachykinin neurokinin A. A third tachykinin receptor, NK_3-receptor, which is selectively activated by neurokinin B has also been cloned. Molecular biology techniques have thus confirmed the evidence for the existence of receptor subtypes obtained by classical pharmacologic techniques, using the rank order of potency of different agonists and antagonists.

Using cross-hybridization in which a known receptor cDNA sequence is hybridized with a genomic library, it has also been possible to detect previously unknown subtypes of a receptor. For example, an atypical β-receptor, which does not clearly fit into the β_1- or β_2-receptor subtypes, has been suspected in adipose tissue and in some smooth muscle preparations. A distinct β_3-receptor has been identified, cloned, sequenced, and expressed.[76] The β_3-receptor is clearly different from either β_1- or β_2- receptors (~50% amino acid sequence homology). β_3-Receptors appear to be important in

regulation of metabolic rate, but they have not been detected in lung homogenates.[77] Without the techniques of molecular biology, this receptor would probably still remain undiscovered. A putative β_4-receptor in cardiac tissue has also been proposed, based on atypical β_1-receptor–mediated responses in cardiac tissue, but this has not been confirmed by cloning.[78]

Molecular biology has been particularly useful in advancing our understanding of muscarinic receptors. Five distinct muscarinic receptors have been cloned from rat and human tissues.[79] The m1-, m2- and m3-receptors correspond to the M_1-, M_2-, and M_3-receptors identified pharmacologically, whereas m4- and m5-receptors are previously unrecognized pharmacologic subtypes that occur predominantly in the brain, and for which no selective drugs have yet been developed. Interestingly, m4-receptors have been demonstrated in rabbit lung using antibodies against the cloned m4-receptor, and their presence has been confirmed by cDNA probes for the m4-receptor. These m4-receptors are localized to vascular smooth muscle and to alveolar walls, but they have not been observed in lungs of other species, including humans.[80] The reason for so many different subtypes of a receptor that recognize a single agonist is still not certain, but it seems likely that they are linked to different intracellular pathways and that the regulation of the intracellular portion of the amino acid sequence may be unique to each receptor subtype. The m1-, m2-, and m5-receptors stimulate PI hydrolysis through a *Pertussis*-insensitive G protein, whereas m2- and m4-receptors inhibit AC via G_i. It is possible that the difference in protein structure may reflect regulation at a transcriptional level from DNA through different promoters, leading to variations in tissue or developmental expression, or to differences at a posttranslational level, allowing regulation by intracellular mechanisms such as phosphorylation at critical sites on intracellular loops.

Receptor Interactions

Activation of one receptor may influence the function of a separate receptor via a number of interacting mechanisms. The opposing effects of receptors that increase and decrease ACe activity via G_s and G_i, respectively, is well described. In airway smooth muscle, M_2-receptors inhibit AC, whereas β_2-receptors stimulate this enzyme. Thus, there are opposing effects. This may explain why it is more difficult for β-agonists to reverse contraction of airway smooth muscle induced by cholinergic agonists compared to histamine. Conversely, β-agonists may also influence the expression of M_2-receptors.[81] Several other interactions between receptors are recognized. Receptors that increase cAMP oppose the effects of receptors that elevate intracellular Ca^{2+} via several mechanisms, including stimulation of Ca^{2+} sequestration and exchange.[82]

PI hydrolysis leads to activation of PKC, which then phosphorylates receptors and G proteins, resulting in uncoupling and impaired receptor function (Fig. 8-14).[83] In airway smooth muscle, this may be an important interaction in inflammation, because inflammatory mediators

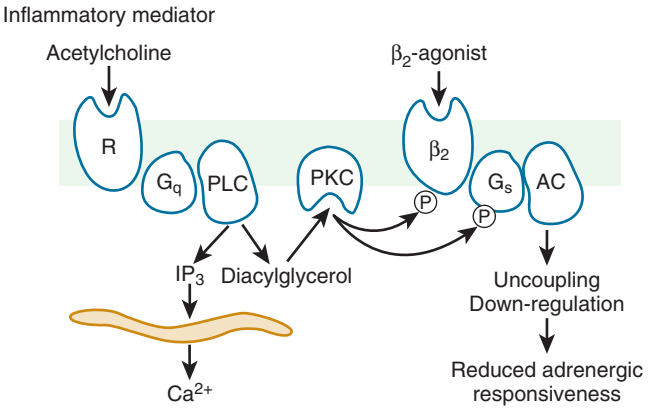

FIGURE 8-14 ■ Receptor interactions. The activation of one surface receptor may affect the function of a different receptor type via interaction of intracellular mechanisms. For example, activation of an inflammatory mediator or muscarinic receptor (R) on airway smooth muscle cells may stimulate phosphoinositide hydrolysis, with activation of protein kinase C (PKC) via diacylglycerol formation. This may result in phosphorylation (P) of other receptors, such as β_2-receptors (β) or a stimulatory G protein (G_s), resulting in down-regulation and uncoupling of β-receptors, with reduced responsiveness to β-agonists. AC, adenylyl cyclase; G_q, receptor-coupled G protein that activates phosphoinositide hydrolysis; IP_3, inositol (1,4,5) trisphosphate; PLC, phospholipase C.

will stimulate PI hydrolysis in airway smooth muscle cells, and will phosphorylate G proteins via activation of PKC, leading to uncoupling of β_2-receptors. This may explain the reduced bronchodilator response to β-agonists in vitro observed in airways taken from patients with fatal asthma attacks. G protein–receptor kinases (GRKs) may be activated by GPCR occupation and then phosphorylate other receptors, leading to altered signaling in heterologous GPCRs.[84] Receptor interactions may also occur through receptor heterodimerization as discussed previously.

An additional type of interaction may operate at the level of gene transcription: Cytokines may activate transcription factors that have an effect on a target gene. Furthermore, steroid receptors may interact with the same gene with an opposing effect. There may also be a direct interaction between transcription factors within the cytoplasm. For example, activated glucocorticoid receptors bind directly to the AP-1 complex and thereby prevent its interaction with the target gene. In human lung, for example, cytokines such as TNF-α and phorbol esters that activate PKC lead to activation of AP-1 and NF-κB binding to DNA; this effect may be blocked by glucocorticoids. cAMP may exert a profound modulatory effect on MAPK signaling pathways and may activate the transcription factor cAMP response element–binding protein (CREB), which itself interacts with GRs and with AP-1.[85]

A good example of receptor interaction is provided by the interaction of β_2-receptors and GR, an effect that is relevant to the treatment of asthma and COPD. Thus, for example, combination inhalers containing a long-acting β_2-agonist and a corticosteroid are now commonly

used as first-line therapy. Corticosteroids increase the expression of β_2-receptors in lungs and thus enhance the effects of β_2-agonists and prevent receptor down-regulation.[86,87] In turn, β_2-agonists increase the action of GR by facilitating nuclear translocation to the cytoplasm and increasing the binding of GR to GRE, thus increasing the effects of corticosteroids.

DRUG-RECEPTOR INTERACTIONS

The binding of a drug to its receptor is a dynamic process and follows the laws of mass action. At equilibrium, there is a balance between the rate of association and the rate of dissociation of a drug. The concentration of drug giving half maximal activation is the EC_{50}, which describes the potency of the drug. The *affinity* of the drug describes the balance between association and dissociation and can be quantified as the dissociation constant K_d, which is the logarithm of the concentration of drug needed to occupy 50% of the receptors. Drugs with a low K_d therefore have a high affinity for their receptor.

Radioligand Binding

Binding between a hormone or drug and its receptor may be studied directly by radioligand binding. A radiolabeled ligand (usually a high-affinity antagonist, such as [^{125}I]iodocyanopindolol for β-receptors) is incubated with a receptor preparation (either a membrane preparation from the tissue of interest or, in the case of some ligands, with intact cells). The binding interaction between ligand and receptor obeys the law of mass action. As the concentration of ligand is increased, the proportion of ligand binding to receptors increases until saturation occurs when all the receptors are occupied. Nonspecific binding to nonreceptor sites is determined by parallel incubations with radioligand in the presence of an excess of unlabeled agonist or antagonist (e.g., 200 μM isoproterenol or 1 μM propranolol for β-receptors). Specific binding (i.e., total nonspecific binding) may be analyzed by a Scatchard plot, which will give a straight line if a single class of binding site is involved, the slope of which is related to binding affinity ($1/K_d$) and the intercept on the x-axis gives the maximum number of binding sites (Bmax)—a measure of receptor density (Fig. 8-15). Radioligand-binding studies can also be used to investigate selectivity of drugs for the receptor using competition between the competitor drug and a fixed concentration of radioligand. Receptors may be characterized in this way, using the rank order of potency of agonists or antagonists.

Binding studies can also be used to determine the distribution of receptors in tissues, using autoradiography. The radioligand is incubated with frozen sections of the tissue of interest using optimal conditions and using an excess of nonradiolabeled competitor to define nonspecific binding, as in membrane-binding studies. The distribution of specific binding is then used to **indicate and map** tissue localization of receptors.

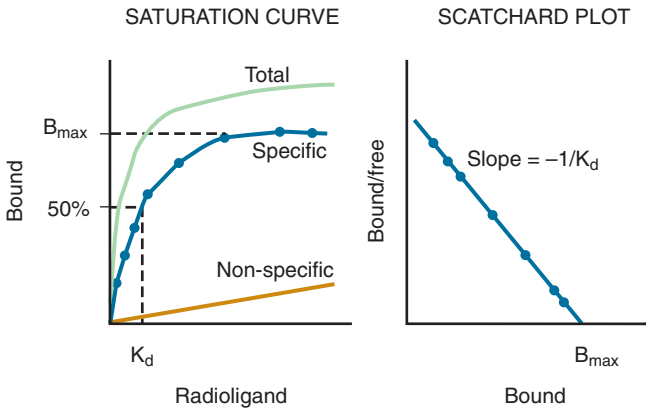

FIGURE 8-15 ■ A Scatchard plot of receptor binding (bound) is shown. With a single receptor population, a plot of bound/free against bound ligand gives a straight line with a slope inversely related to the dissociation constant (K_d) and an intercept equal to the maximal number of binding sites (Bmax).

Agonists and Antagonists

After binding to the receptor, the response is activated via second messenger systems described previously. Different agonists may elicit variable degrees of response, which is described as *efficacy*. A drug that produces less than a maximal response (Emax) is known as a *partial agonist*. In airway smooth muscle, isoproterenol is a full agonist and produces a maximal response, whereas albuterol and salmeterol act as partial agonists, giving less than 50% of the maximal relaxation seen with isoproterenol.

Antagonists have zero efficacy. They block the effects of an agonist by interfering with its binding to the receptor. When antagonists interact with agonists at a common receptor, the antagonism is competitive. This can be demonstrated by a rightward shift in the log concentration-response curve (Fig. 8-16). For true competitive antagonism (e.g., between a β_2-antagonist and a β-agonist in airway smooth muscle), the shift is parallel. The amount of shift observed with each concentration of agonist can be used to calculate the affinity of the antagonist for the particular receptor.

Sometimes, a drug interferes with an agonist effect in a noncompetitive manner by inhibiting any of the steps that lead to the typical agonist effect. This results in a nonparallel shift in the agonist dose-response curve and a reduced maximal response (see Fig. 8-16). Studies with overexpressed GPCRs or mutated receptors have demonstrated that there may be constitutive activation of the receptor in the absence of agonists. Drugs that reduce this constitutive activation by binding to the receptor are known as *inverse agonists*.[88] It is now clear that many drugs that were assumed to be antagonists at GPCRs act as inverse agonists, and this may be explained by stabilization of the inactive state of the receptor.[89] There may be constitutive overactivity of GPCRs in disease, and this could account for phenomena such as bronchoconstriction after β-adrenergic blockers in asthmatics but not in

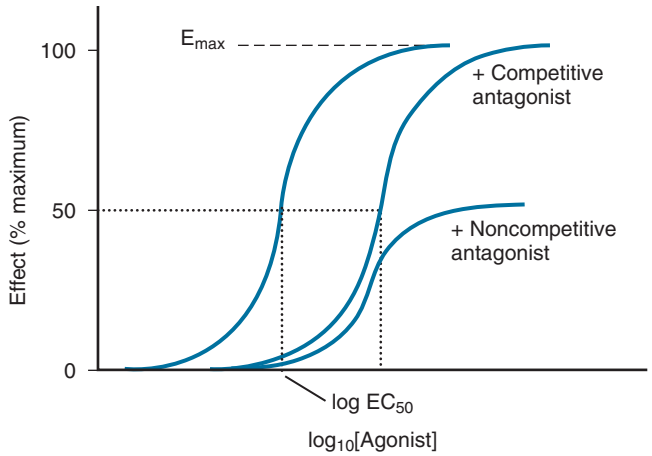

FIGURE 8-16 ■ Dose-response curve to an agonist is affected by the presence of antagonists. A competitive antagonist causes a parallel rightward shift in the dose-response curve, with an increase in the concentration of drug that yields half-maximal activation (EC_{50}) but no change in the maximal response (Emax), whereas a noncompetitive antagonist shifts the dose-response to the right in a nonparallel fashion and also decreases Emax.

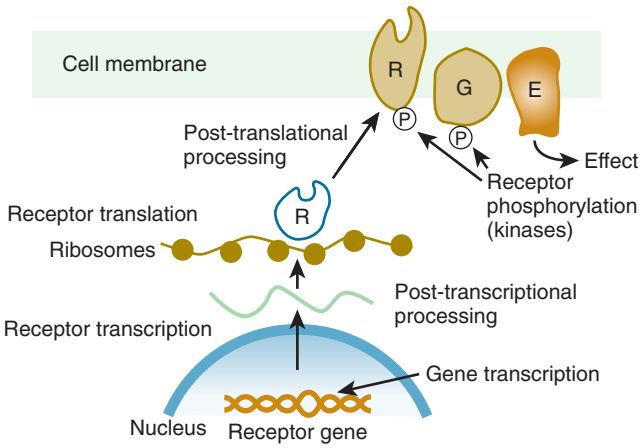

FIGURE 8-17 ■ Regulation of receptor expression. The expression and function of surface receptors can be regulated in several ways, including effects on receptor synthesis (gene transcription, posttranscriptional processing/mRNA stability, protein translation and posttranslational processing). Once the receptor is inserted in the membrane, it can be inactivated and uncoupled by phosphorylation via various kinases. E, effect; G, G protein; P, phosphorylation; R, receptor.

normal individuals, for example, as a result of the inverse agonism of certain β-blockers.[88]

Another type of antagonism relevant to lung diseases is *functional antagonism*, which describes an interaction between two agents that have opposite functional effects on the same cellular response. Thus, β-agonists act as functional antagonists in airway smooth muscle because they counteract the contractile effects of any spasmogen, including histamine, LTD_4, thromboxane, bradykinin, and ACh.

Two drugs may interact to produce effects that are more than additive. When two drugs given together produce a greater effect than the additive effect of the drugs given separately the result is known as *synergy*. *Potentiation* occurs when one drug given alone has no effect, but increases the response to a second drug. *Tolerance* refers to a diminishing response to a drug that is administered repeatedly, whereas *tachyphylaxis* usually describes tolerance of rapid onset. Tolerance may be seen after only one administration of a drug. *Desensitization* is a term that includes rapid and long-term loss of response.

The interaction between a ligand and its receptor has several characteristics. Binding is rapid reversible, and temperature-dependent. There is stereoselectivity with the *levo*-isomer (*R*-isomer) usually binding more effectively than the *dextro*-isomer (*S*-isomer). Many ligands are a mixture of the active *R*-isomer with the inactive *S*-isomer. Thus, the racemic mixture has half of the activity. It is claimed that for some racemates the inactive isomer is actually detrimental. For example, *S*-albuterol (levalbuterol) has been reported to increase airway hyperactivity in animal models, observing that the *R*-albuterol is more effective than *RS*-albuterol.[90] However, no clear advantage of *R*-albuterol over *RS*-albuterol has been demonstrated in clinical studies.[91]

RECEPTOR REGULATION

Receptors are subject to many regulatory factors operating at several sites (Fig. 8-17). Some factors influence the gene transcription of receptors, either increasing or decreasing transcription. Other factors influence the stability of mRNA and thus the amount of receptor protein that is formed. Translation of receptor protein may also be regulated. Once the receptor protein is inserted into the membrane, the receptor may be regulated by phosphorylation as a result of various receptor kinases. Receptor phosphorylation is one of the major means or receptor regulation.[92] Some receptors are also tyrosine-nitrated or ubiquitinated, resulting in abnormal function and increased degradation.

Desensitization

Tachyphylaxis or desensitization occurs with most receptors when exposed to an agonist. This phenomenon has been studied in some detail with β_2-receptors and involves several distinct processes that may operate simultaneously or sequentially.[93]

G Protein–Receptor Kinases

In the short term, desensitization involves *phosphorylation* that uncouples the GPCR from G_s, via the action of enzymes called *G protein receptor kinases*, of which seven are now identified.[94] This has been studied in most detail for β-receptors, which are phosphorylated by GRK2, also known as β-adrenergic receptor kinase (βARK). The site of this phosphorylation appears to be on the Ser/Thr-rich region of the third intracellular loop and the C-terminal tail, because their replacement reduces the rate of desensitization. GRK2 is also involved

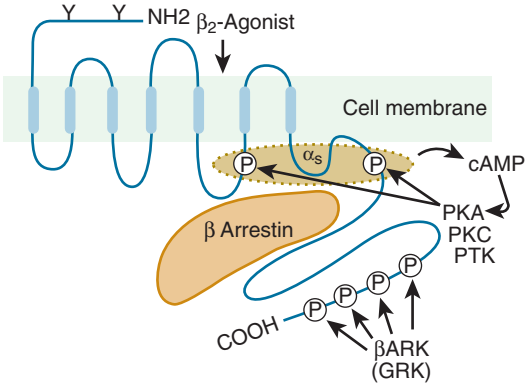

FIGURE 8-18 ■ Mechanisms of short-term desensitization of β_2-adrenergic receptors. The β-receptor is phosphorylated by β-adrenergic receptor kinase (βARK) and other G protein receptor kinases (GRK) on its carboxyl tail (COOH), resulting in increased binding of β-arrestin, which leads to uncoupling of the receptor from the α-subunit of the stimulatory G protein (α_s) and internalization of the receptor. Protein kinase A (PKA), activated by an increase in cyclic 3′,5′ adenosine monophosphate (cAMP), phosphorylates the receptor at other sites on the third intracellular loop or may phosphorylate GRK. Protein kinase C (PKC) and protein tyrosine kinases (PTK) may also phosphorylate the receptor, resulting in uncoupling.

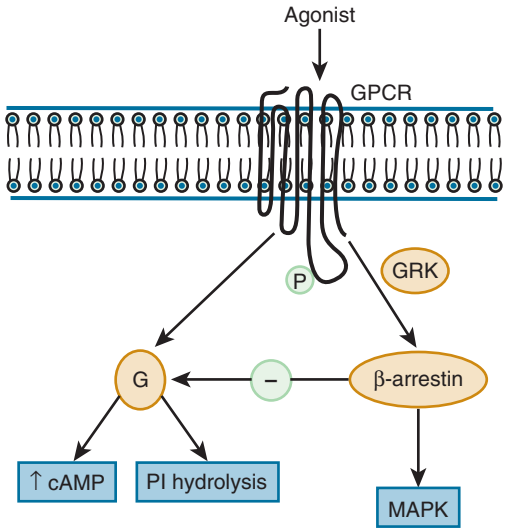

FIGURE 8-19 ■ G protein–coupled receptors signal through G proteins and also via β-arrestins. When the receptor is occupied by its agonist, signal transduction pathways are activated, such as changes in cyclic AMP (cAMP) or increased phosphoinositide (PI) hydrolysis. Agonists also phosphorylate the receptor via G protein receptor kinases (GRK), which recruit β-arrestin that then stimulates other signaling pathways, such as mitogen-activated protein kinases (MAPK) and also inhibits G protein–mediated signal transduction.

in the phosphorylation of several other receptors, including muscarinic and tachykinin receptors. The expression of GRK2 varies among cells. There is low expression of GRK2 in airway smooth muscle cells that show resistance to desensitization, whereas expression of this enzyme is high in mast cells, which are much more easily desensitized.[95] GRK2 expression is increased in lungs after exposure to β_2-agonists, thus contributing to uncoupling of β_2-receptors.[96] Expression is increased by corticosteroids, which reverse uncoupling and restore responsiveness to β_2-agonists.[97] GPCRs are also regulated by other kinases, including PKA and PKC.[92] For β_2-receptors, this appears to be via phosphorylation of GRK2, enhancing its ability to uncouple receptors, rather than direct phosphorylation of β_2-receptors.

Arrestins

Another protein, β-arrestin, is also involved in uncoupling the phosphorylated β-receptor from the G protein and in resensitization of receptors (Fig. 8-18). There are two β-arrestins, and they appear to be universally expressed and involved in the coupling of many GPCRs. β-Arrestins determine whether β_2-receptors are degraded within the cell by endocytosis or are recycled to the cell membrane (Fig. 8-19).[98] In addition to terminating receptor function, β-arrestins also allow receptors to interact with signal transduction pathways (such as MAPK and PI3K) independently and therefore allow the receptor to regulate different responses in the cell. Ligands that preferentially stimulate the interaction between receptor and β-arrestins have now been identified, and these drugs may have a different spectrum of activity from the classical drugs that activate receptor–G protein coupling. Ligands that are biased toward receptor–G protein interaction with less effect on β-arrestins do not desensitize the receptor and thus have greater and more prolonged effects.

Down-Regulation

Longer-term mechanisms of desensitization include down-regulation of surface receptor number, a process that involves internalization (*sequestration*) of the receptor and its subsequent degradation. Down-regulation of β_2-receptors results in a rapid decline in the steady-state level of β_2-receptor mRNA. This suggests that down-regulation is achieved in part either by inhibiting the gene transcription of receptors or by increased posttranscriptional processing of the mRNA in the cell. Using actinomycin D to inhibit transcription, it has been found that β_2-receptor mRNA stability is markedly reduced in these cells after exposure to β-agonists.[99] Furthermore, by isolating nuclei and performing a nuclear run-on transcription assay, it is apparent that β-agonist exposure does not directly alter receptor gene transcription. Longer-term exposure to β-agonists may also result in inhibition of β-receptor gene transcription, mediated via the effects of a CREB. Long-term exposure to β-agonists results in reduced transcription of β_2-receptors in the airways.[100,101]

Steroid Modulation

Certain G protein–linked receptors are also influenced by glucocorticoids. Thus, pulmonary β-receptors are increased in density by pretreatment with glucocorticoids.[102] Corticosteroids increase the steady-state level of

β_2-receptor mRNA in cultured smooth muscle cells, indicating that steroids may increase β-receptor density by increasing the rate of gene transcription. The increase in mRNA occurs rapidly (within 1 hour), preceding the increase in β-receptors, and then declines to a steady-state level about twice normal. The cloned β-receptor gene contains three potential glucocorticoid responsive elements, and incubation of human lung with glucocorticoids results in a doubling of the rate of transcription.[102] By contrast, corticosteroids decrease transcription of tachykinin NK_2 receptors.[103]

Receptor Ontogeny

Another area in which molecular biology of receptors may be relevant is in studying the development of receptors and the factors that determine expression of particular receptor genes during development. In fetal lung, there is a marked increase in the expression of β_2-receptors in the perinatal period, an effect that is critically dependent on glucocorticoids.[104] There may be differential expression of receptor subtypes during development. For example, muscarinic receptor subtypes in the lung show differential changes during the perinatal period.[105] Receptors also play an important role in lung development. For example, receptors for hepatocyte growth factor are expressed in airway epithelium during lung development and appear to be involved in the branching of airways.[106]

Pulmonary Diseases

There are several pulmonary diseases in which altered expression of receptors may be relevant to understanding their pathophysiology. Molecular biology offers a new perspective in investigating these abnormalities of receptor expression by providing insights into whether the abnormality arises through altered transcription of the receptor gene or abnormalities in posttranscriptional or posttranslational processing. There is some evidence that β-adrenoceptor function may be impaired in airway smooth muscle of patients with fatal asthma.[107] However, binding and autoradiographic studies have not demonstrated any reduction in β-receptors in airway smooth muscle, suggesting that the reduced bronchodilator responses to β-agonists may be due to uncoupling of the receptor.[108] Similarly, no differences in muscarinic receptors have been detected in asthmatic lungs using binding approaches.[108]

Relatively few studies have explored whether there are any differences in the expression of mediator receptors in asthmatic airways. There is some evidence for increased expression of platelet-activating factor (PAF)-receptor mRNA in lungs of asthmatic patients, although whether this has functional significance is not known.[109] Bradykinin B_1- and B_2-receptors are up-regulated by inflammatory stimuli such as TNF-α, and this effect appears to be due to prolongation of mRNA half-life.[110] There is also evidence for increased NK_1-receptor expression in the lungs of patients with asthma and COPD.[111,112]

Transcriptional Control

Receptor genes, like other genes, may be regulated by transcription factors, which may be activated within the cell under certain conditions, leading to increased or decreased receptor gene transcription, which may in turn alter the expression of receptors at the cell surface. Little is known about the transcription factors that regulate receptors, but these factors may be relevant to diseases, such as chronic inflammation. The transcription factor AP-1, a Fos-Jun heterodimer, may be activated via PKC. AP-1 has been shown to increase transcription of several genes, including some receptor genes. For example, the gene coding for the NK_1-receptor has an AP-1 site, which leads to increased gene transcription and a GRE site, which conversely results in decreased transcription.[113] Chronic cell stimulation, via activation of PKC, may therefore lead to an increase in NK_1-receptor gene expression, which could lead to increased neurogenic inflammation. An increased NK_1-receptor gene expression is present in asthmatic airways.[111] By contrast, glucocorticoids reduce NK_1-specific mRNA in human lungs, probably via an inhibitory effect of glucocorticoid receptors on AP-1.

ION CHANNELS

Movement of ions across the cell membrane is important in determining the state of cell activation. Ions cross the cell membrane through protein-lined pores called "channels," several of which have now been cloned and characterized electrophysiologically. Most channels are made up of distinct subunits that are grouped together in the cell membrane (e.g., nAChRs as discussed previously). Whether the channel is open or closed depends on different factors for each channel, but may be determined by receptor activation, the polarization of the cell membrane, or the presence of particular ligands that interact directly with the channel.

Calcium Channels

Voltage-Gated Channels

Several types of calcium ion (Ca^{2+}) channels have now been identified and characterized electrophysiologically by molecular cloning and with the use of antagonists and toxins. Voltage-gated channels mediate Ca^{2+} entry into cells in response to membrane depolarization. Electrophysiologic studies reveal different Ca^{2+} currents designated L-, N-, P-, Q-, R-, and T-type. High-voltage-activated Ca^{2+} channels that have been characterized biochemically are complexes of a pore-forming α1-subunit of approximately 190 to 250 kDa, a transmembrane, disulfide-linked complex of α2- and δ-subunits, an intracellular β-subunit, and in some cases, a transmembrane γ-subunit. Ten α1-subunits, four α2δ complexes, four β-subunits, and two γ-subunits are now identified.[114] The Cav1 family of α1-subunits conduct L-type Ca^{2+} currents, which initiate muscle contraction, endocrine secretion,

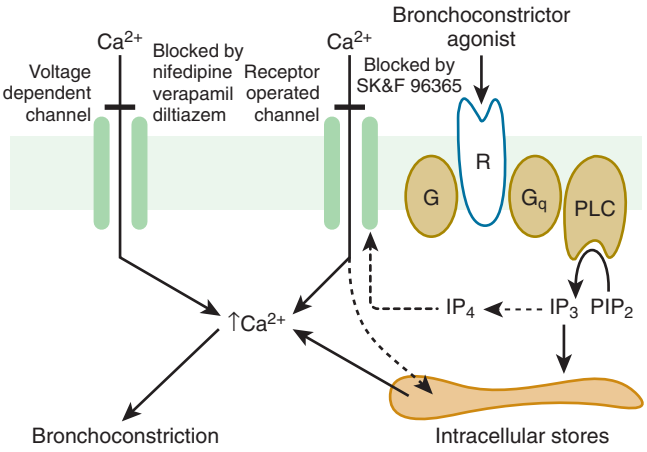

FIGURE 8-20 ■ Calcium ion (Ca^{2+}) channels. There are at least two classes of calcium channels in the cell membrane. One is activated by depolarization (voltage-dependent channels) and the other via receptors (R). Calcium ions (Ca^{2+}) are also released from intracellular stores via phosphoinositide hydrolysis and the action of inositol (1,4,5) trisphosphate (IP_3). G, G protein; IP_4, inositol (1,3,4,5) tetrakis phosphate; PIP_2, phosphoinositide 4,5,-bisphosphate; PLC, phospholipase C.

and gene transcription and are regulated by protein phosphorylation. The Cav2 family of α1-subunits conduct N-type, P/Q-type, and R-type Ca^{2+} currents, which initiate rapid synaptic transmission and are regulated primarily by direct interaction with G proteins and SNARE proteins and secondarily by protein phosphorylation. The Cav3 family of α1-subunits conduct T-type Ca^{2+} currents, which are activated and inactivated more rapidly and at more negative membrane potentials than other Ca^{2+} current types.

L-Type channels (for long-lasting) open in response to depolarization of the cell, resulting in influx of Ca^{2+} to increase intracellular Ca^{2+} concentration (Fig. 8-20); these channels are blocked by dihydropyridines, such as nifedipine, and by verapamil. Voltage-sensitive calcium channels are important in contractile responses of pulmonary vascular smooth muscle, but are less important in the contractile response of airway smooth muscle or in the activation of inflammatory cells. T-Type calcium channels are also opened by depolarization but are insensitive to dihydropyridines. Electrophysiologic studies have revealed the presence of both L- and T-channels in airway smooth muscle, although the L-channels are less sensitive to dihydropyridines than the L-channels in the myocardium.[115] N-Type channels, which are largely restricted to neurons, are also sensitive to depolarization and insensitive to dihydropyridines, but are blocked by ω-conotoxin.

Receptor-Operated Channels

Receptor-operated channels (ROCs) are channels that open in response to activation of certain receptors; these receptors are not well defined but, recently, blockers have been developed. Contraction of airway smooth muscle in response to agonists such as acetylcholine and histamine is independent of external Ca^{2+} and is not associated with ^{45}Ca uptake, suggesting that calcium entry is not important for initiation of contractile responses. Entry of Ca^{2+} via ROCs may be important in refilling intracellular stores. ROCs are members of an increasing group of calcium channels called transient receptor potential (TRP) cation channels, which is a superfamily of at least over 30 channel proteins divided into 6 main groups. TRP channels are involved in regulation of inflammatory cells, structural cells, and sensory nerves and may be important novel targets for drug discovery.[116] For example, TRPV channels on sensory nerves mediate the response to capsaicin and acids. TRPC3 and TRPC6 are expressed in human airway smooth muscle and may correspond to ROCs involved in Ca^{2+} entry.[117]

A rise in intracellular Ca^{2+} concentration is associated with cell activation, but recovery depends on removal of Ca^{2+} by sequestration or by pumping Ca^{2+} out of the cell in exchange for Na^+. In airway smooth muscle, there is a pump that exchanges $3Na^+$ for each Ca^{2+}. It is linked to the activity of Na^+-K^+-ATPase, which maintains the inwardly directed Na^+ gradient by exchanging intracellular Na^+ for extracellular K^+. In airway smooth muscle, there is also an active uptake of Ca^{2+} into intracellular stores that may be stimulated by cAMP.[39]

I_{CRAC}

When Ca^{2+} is released from intracellular stores via the action of IP_3, these stores are refilled by calcium entry via specific channels called CRAC, measured as a current called I_{CRAC} (Ca^{2+} release-activated Ca^{2+} current) that is activated by depletion of intercellular stores (store-operated calcium entry).[118] This is an important mechanism in inflammatory cells, such as mast cells and T lymphocytes. Inhibitors of I_{CRAC} are therefore potential immunomodulators or antiallergy drugs. TRPC1 is thought to function as a component of store-operated calcium channels.[119]

In airway smooth muscle, several types of calcium channels have been identified. These may lead to contraction via different spasmogens. L-Channels respond to depolarization, and ROCs are activated by various spasmogens, but contraction initially is independent of Ca^{2+} entry and due to release of Ca^{2+} from internal stores in response to IP_3. These internal stores are then refilled via store-operated calcium channels. In addition, cyclic adenosine diphosphate (cADP)-ribose also mobilizes calcium from the sarcoplasmic reticulum by acting on ryanodine receptors.[39]

Potassium Channels

Recovery of cells after depolarization depends on the movement of potassium ions (K^+) out of the cell via K^+ channels in the cell membrane. This results in hyperpolarization of the cell with relaxation of smooth muscle and inhibition of cell activity. Conversely, blockade of K^+ channels with drugs such as tetraethylammonium and 4-aminopyridine results in increased excitability or

hyperresponsiveness of cells. More than 50 different K^+ channel genes have been identified in humans, using selective toxins, patch-clamping techniques, and cloning.[120] K^+ channels may be subdivided into four main classes:

1. *Voltage-gated channels*, which open on depolarization of the membrane, which are rectifying channels that return the cell membrane to its previous polarized state. This is a diverse group of channels, some of which are blocked by α-dendrotoxin.
2. *Ca^{2+}-activated channels* open in response to elevation of intracellular Ca^{2+} concentration. Large conductance (maxi-K and big) K^+ channels are found in smooth muscle and neurons and are blocked by the scorpion venoms charybdotoxin and iberiotoxin as well as several small molecules.[121] Small conductance channels, some of which are blocked by apamin are found in neurons.
3. *Receptor-coupled channels* are opened by certain receptors via a G protein, but no specific blockers have been found.
4. *ATP-sensitive channels* are opened by a fall in intracellular ATP concentration. These channels are found in smooth muscle and in the islet cells of the pancreas. They are blocked by sulfonylureas, such as glibenclamide, and are opened by drugs such as cromakalim (BRL 34915), its active enantiomer lemakalim (BRL 38227), RP 53891, and by HOE 245.

K^+ channels play an important role in relaxation of airway smooth muscle.[122,123] β-Agonist-induced bronchodilation is markedly inhibited by charybdotoxin,[124] indicating that opening a maxi-K channel is involved in the relaxant response. K^+ channel openers, such as cromakalim and levcromakalim act on ATP-sensitive K^+ channels and are dilators of animal and human airways.[125] K^+ channel openers therefore have potential as bronchodilators and vasodilators, although when given orally, they may cause cardiovascular side effects due to systemic vasodilation which limit their usefulness in asthma therapy.[122] K^+ channels are also involved in neurotransmitter release. Cromakalim inhibits cholinergic neurotransmission and the release of neuropeptides from sensory nerves in airways.[126] Modulation of neurotransmission is also mediated by opening of maxi-K channels, because charybdotoxin reverses the modulatory effect of many agonists on sensory and cholinergic nerves.[127] K^+ channels are also involved in mucus secretion.[128] K^+ channel openers therefore have several potential applications in the therapy of airway disease.[129]

Sodium Channels

Na^+ channels are involved in depolarization and release of neurotransmitters. Drugs that block Na^+ channels, such as tetrodotoxin and local anesthetics, act as nerve blockers. However, tetrodotoxin has no direct effect on smooth muscle, however. Na^+ channels in airway epithelium (ENaC) play an important role in regulating mucus hydration and mucociliary clearance and play a key role in alveolar fluid absorption. ENaC dysfunction is important in acute respiratory disease syndrome and in cystic fibrosis.[130,131] Each channel is comprised of three subunits designated α, β, and γ, and several new drugs that target these channels are in development for the treatment of lung disease.

Chloride Channels

Although less well characterized than other ion channels, it is increasingly recognized that chloride (Cl^-) channels play an important role in pulmonary physiology and pathology. The cystic fibrosis transmembrane regular (CFTR) that is functionally abnormal in cystic fibrosis plays a critical role in airway hydration and has been extensive investigated. Calcium-activated Cl^- channels (CLCA) play an important role in mucus secretion and are now targeted to treat mucus hypersecretion.[132] Volume- and voltage-dependent Cl^- channels appear to play a role in airway responses to indirect bronchoconstrictors and are blocked by furosemide and cromolyn sodium.[133]

ENZYMES

Many drugs produce their therapeutic effect by inhibition of particular enzymes. Most commonly the drug molecule is a substrate analogue that acts as a *competitive inhibitor*. The interaction between drug and enzyme obeys the law of mass action and may be analyzed in the same way as drug-receptor interactions. An example is L-N^G-nitro arginine, which acts as a competitive inhibitor of NO synthase by substituting for the natural substrate L-arginine. The enzyme blockade may be overcome by increasing the concentration of L-arginine, whereas D-arginine, which is not a substrate for this enzyme has no effect. Many drugs act noncompetitively. An example is aspirin, which noncompetitively blocks cyclooxygenase by acetylating the active (catalytic site) of the enzyme. Another type of interaction involves a false substrate, where the drug undergoes chemical transformation by the enzyme to form a product that subverts the normal metabolic pathway. The best example of this is α-methyldopa which mimics DOPA, causing norepinephrine to be replaced by methylnorepinephrine, which is inactive.

Enzymes are increasingly recognized as playing an important part in the pathophysiology of various diseases and are increasingly a target for drug therapy. Drugs that inhibit 5-lipoxygenase, which generates leukotrienes, such as zileuton, are now used in the treatment of asthma. Drugs that inhibit neutrophil elastase may be useful in the future management of cystic fibrosis and COPD, whereas drugs that inhibit tryptase and chymase from mast cells may be potential treatments in asthma.

Protein Kinases

Signal transduction within cells is regulated by *kinases*, which phosphorylate substrate molecules that are often

themselves kinases, resulting in a cascade of phosphorylation. Over 700 kinases are now recognized in the human genome. Kinase cascades link the activation of surface receptors to functional responses, including secretion, differentiation, and gene expression. For example, multiple kinases are activated when cells are exposed to the proinflammatory cytokines IL-1β and TNF-α.[134,135] MAPK and PI3K cascades are of particular important in inflammatory responses, as well as cell proliferation and survival, as discussed previously. Many novel kinase inhibitors are now in development and are predicted to be the major development in drug therapy in the future.[136]

MAP Kinases

Over 10 MAPK have been identified, and these kinase cascades include a MAPK kinase (MAPKK or MEK) and a MAPKK/MEK kinase (MAPKKK/MEKK) (Fig. 8-21). These signaling pathways serve as a means of connecting cell-surface receptors to specific transcription factors and other regulatory proteins, thus allowing extracellular signals to regulate the expression of specific genes. There is now increasing recognition that there are interactions between the MAPK pathways, resulting in different cellular responses to the same activating stimuli. MAPK may be activated by several types of stress and other extracellular stimuli. Selective inhibitors, such as SB203580, which blocks the p38α pathway, and PD098059, which blocks the extracellular signal-regulated kinase (ERK) pathway have now been developed and this has resulted in a better understanding of these complex signaling pathways. p38α/β MAPK inhibitors are now in clinical development for the treatment of inflammatory diseases, such as COPD and asthma, but they may have to be delivered by inhalation because there is a high risk of systemic side effects.[62,135]

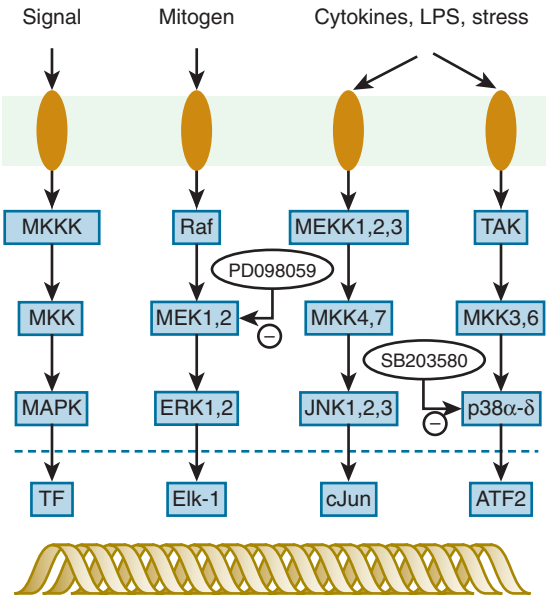

FIGURE 8-21 ■ Mitogen-activated protein kinase pathways. Extracellular signals activate mitogen-activated protein (MAP) kinase kinase kinase (MAPKKK), MAP kinase kinase (MAPKK), MAP kinase (MAPK), and then transcription factors (TF). Three major cascades are now recognized. ATF, activating transcription factor; ERK, extracellular signal-regulated kinase; JNK, Jun N-terminal kinase; LPS, lipopolysaccharide; MEK, MAP/ERK kinase; TAK, transforming growth factor-β-activating kinase.

Phosphoinositide 3-Kinases

PIP2 is converted to PI(1,4,5)trisphosphate (PIP3) by the enzyme phosphoinositide-3-kinase (PI3K), which results in phosphorylation of the downstream kinases Akt (protein kinase B) and mammalian target of rapamycin (mTOR) (Fig. 8-22). This signal transduction pathway is of critical importance in regulation of cell proliferation and inhibition of apoptosis, as well as many other cellular functions such as metabolism, chemotaxis, and cytokine secretion. Several isoforms of PI3 kinase are now recognized, which are differentially regulated and expressed. For example, PI3K-γ is expressed in monocytes and granulocytes and plays a key role in chemotactic responses and inflammatory cytokine release, whereas PI3K-δ is involved in mediating corticosteroid resistance

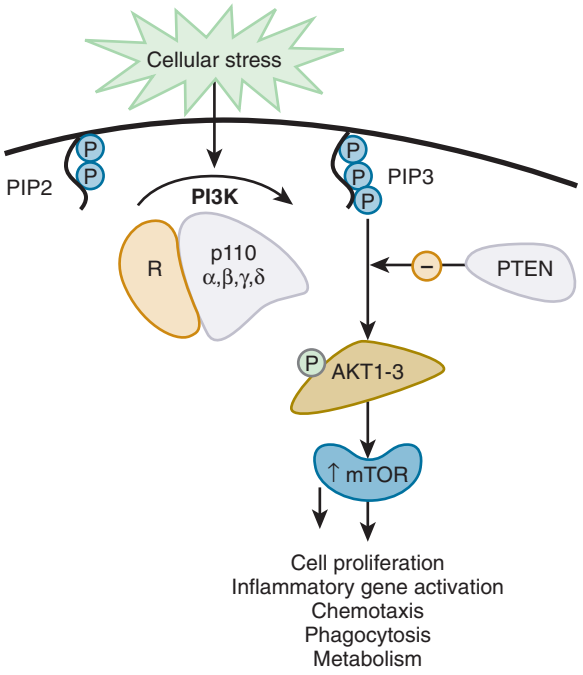

FIGURE 8-22 ■ Phosphoinositide-3-kinase (PI3K) converts phosphoinositide (4,5) diphosphate (PIP2) to phosphoinositide (3,4,5) trisphosphate (PIP3) in response to various cellular stresses, including oxidative stress and inflammatory mediators, acting on receptor tyrosine kinases or G protein–coupled receptors. PI3K consists of a regulatory subunit (R, p85, or p101) and a catalytic domain (p110) of the α-, β-, γ-, or δ-subtype. Activated PI3K then phosphorylates Akt1-3 (protein kinase B), which then phosphorylates mammalian target of rapamycin (mTOR). Further kinase cascades lead to a variety of cellular responses, including proliferation, activation of inflammatory genes, chemotaxis, phagocytosis. and metabolic functions. The activation of PI3K is inhibited by PTEN (phosphatase and tensin homologue deleted on chromosome 10).

induced by oxidative stress.[137] An endogenous inhibitor of the PI3K pathway PTEN (phosphatase and tensin homologue deleted on chromosome 10) is an important feedback mechanism, and this enzyme is often defective and mutated in cancers, including lung cancer.[138] PI3 kinase inhibitors, such as wortmannin and LY294002, have proved to be useful in elucidating the role of PI-3K-Akt signaling pathways, but isoenzyme-selective inhibitors are now in development for the treatment of inflammatory diseases, such as asthma and COPD.

Protein Phosphatases

The effects of kinases are counteracted by phosphatases that dephosphorylate the protein targets of kinase activity. While there are approximately 700 protein kinases, only approximately 200 protein phosphatases have been identified, and these tend to have a broader specificity than kinases. Their regulation is less well understood than that of kinase pathways, and there are few useful inhibitors. Approximately 100 protein tyrosine phosphatases have been identified, and several of these inhibit inositol phosphates. Several MAPK phosphatases have now been identified; the best characterized is MAPK phosphate-1 (MKP-1), which is also known as dual-specificity kinase-1 (it dephosphorylates both threonine and tyrosine residues[63]). MKP-1 inhibits p38, JNK, and ERK MAPK pathways, and its gene is rapidly induced by corticosteroids, contributing to their anti-inflammatory effects.[139] As discussed previously, PTEN appears to be the major phosphatase regulating the PI3K pathways, whereas *Src* homology 2 domain-containing tyrosine phosphatases-1 and -2 (SHP-1, SHP-2) regulate multiple inflammatory, growth factor, and metabolic pathways, including PI3K signaling.

PHARMACOKINETICS

To achieve the intended pharmacologic response, it is necessary to achieve an effective concentration of a drug at its site of action in the lungs. Several steps are involved in determining the concentration of a drug at its site of action. These include *absorption*, *distribution* to various tissues, *metabolism*, and finally *excretion*.

Absorption

Absorption of drugs involves their passage across a cell membrane. For some drugs, this may involve specially mediated transport systems or movement through specific channels, but for most drugs, this involves simple diffusion down a concentration gradient. The rate of transport depends on the lipid solubility of the drug. Most drugs exist in solution as weak acids or weak bases, and there is therefore an equilibrium between the ionized form, which does not readily penetrate lipid membranes, and the nonionized fraction, which is lipophilic and may cross the cell membrane. The equilibrium between ionized and nonionized forms is determined by the *pKa* of the drug, which is defined as the pH at which 50% of the drug is in the ionized state. As an example, cromolyn sodium is a weak acid with a pKa of 2. At physiologic pH, it exists almost entirely in an ionized state and is therefore not absorbed from the gastrointestinal tract, which is why it must be delivered directly to the lungs by inhalation.

Lipid solubility is also important in determining whether absorbed drugs may cross the blood-brain barrier and exert central effects. Highly lipophilic compounds such as ethanol and nicotine readily cross the blood-brain barrier. Atropine also crosses the blood-brain barrier, which results in central nervous system side effects such as hallucinations, but its quaternary derivatives ipratropium bromide and tiotropium bromide are ionized and have low lipid solubility, so they are not able to cross the blood-brain barrier. Therefore, central side effects, such as hallucinations (which limit the use of atropine) are not seen. Similarly, the nonsedative antihistamine cetirizine differs from its parent drug hydroxazine by the presence of a carboxyl group, which makes the drug less lipophilic so central side effects such as sedation are avoided.

Distribution

The concentration of a drug obtained at the site of action is determined by the volume of distribution of the drug, its clearance and the half-life of the drug. The volume of distribution (Vd) describes the body space available to contain the drug. Thus, for parenteral drugs that are extensively bound to plasma proteins the volume of distribution will be largely confined to the vascular space, whereas for drugs that are lipid soluble the volume of distribution (Vd) will be much greater because the drug is taken up into adipose tissues throughout the body. The concentration of a drug in the blood (C) is determined by the equation:

$$C = \text{Drug Dose}/Vd$$

For example, the Vd for theophylline is approximately 35 L in a 70-kg person. An approximate loading dose required to give a plasma concentration of 15 mg/L would therefore be $C \times Vd$ or $15\ \text{mg/L} \times 35\ \text{L} = 525\ \text{mg}$. If Vd is reduced by diseases such as cardiac or renal failure, then a correspondingly lower dose is necessary to give the same plasma concentration and to avoid toxic doses.

Clearance

The clearance of a drug describes its elimination from biologic fluids; the half-life ($t_{1/2}$) is the time required to eliminate 50% of a drug from the body, after absorption and distribution are complete. Although clearance and half-life may readily be established for systemically administered drugs, little is known about the clearance of inhaled drugs because the local concentrations in the lungs are not known.

Systemically administered drugs are biotransformed to an inactive state, which usually involves oxidation, reduction, or hydrolysis, converting the drug to more

polar forms that may be more readily excreted by the kidney. Biotransformation usually takes place in the liver, but for inhaled drugs, biotransformation may also take place in the lungs. Hepatic metabolism of drugs may be increased if metabolizing enzymes are induced by drugs such as phenobarbitone and rifampicin, which increase the activity of cytochrome P-450 (CYP)-related oxidative enzymes. This results in more rapid elimination of theophylline and will require an increased dose of theophylline to maintain therapeutic levels. Decreased clearance is seen with certain drugs, including erythromycin, certain quinolone antibiotics (ciprofloxacin but not ofloxacin), allopurinol, cimetidine (but not ranitidine), serotonin uptake inhibitors (fluvoxamine), and the 5-lipoxygenase inhibitor zileuton, which interfere with CYP-450 (especially CYP 1A2) function.[140]

ROUTES OF DRUG DELIVERY

Drugs may be delivered to the lungs by oral or parenteral routes, but also by inhalation. The choice depends on the drug and on the respiratory disease.

Inhaled Route

Inhalation is the preferred mode of delivery of many drugs with a direct effect on airways, particularly for asthma and for COPD.[141] It is the only route for delivery of some drugs such as cromolyn sodium and anticholinergics and is the preferred route of delivery for β_2-agonists and corticosteroids. Antibiotics may also be delivered by inhalation in patients with chronic respiratory sepsis (e.g., in cystic fibrosis). The major advantage of delivery by inhalation of drugs is the ability to deliver doses that are effective with a much lower risk of side effects. This is particularly important with the use of inhaled corticosteroids, which largely avoids systemic side effects. In addition, drugs such as bronchodilators have a more rapid onset of action than when taken orally, so more rapid control of symptoms is possible.

Particle Size

The size of particles for inhalation is of critical importance in determining the site of deposition in the respiratory tract. The optimum size for particles to settle in the airways is 2 to 5 μm mass median aerodynamic diameter (MMAD). Larger particles settle out in the upper airways and smaller particles may remain suspended and are therefore exhaled. There is increasing interest in delivering drugs to small airways, particularly in COPD and severe asthma.[142] This involves delivering drug particles of approximately 1 μm MMAD, which is now possible using drugs formulated in hydroxyfluoralkane (HFA) propellant.[143]

Pharmacokinetics

Of the total aerosolized drug delivered, only 5% to 10% enters the lower airways with a pressurized metered-dose inhaler (pMDI). The fate of the inhaled drug is poorly understood. Drugs are absorbed from the airway lumen and have direct effects on target cells in the airway. Drugs may also be absorbed into the bronchial circulation and may then be delivered to more peripheral airways via the circulation. Whether drugs are metabolized in the airways is often uncertain, and there is little understanding of the factors that influence local absorption and metabolism of inhaled drugs. Drugs with higher molecular weights tend to be better retained in the airways. Nevertheless, it is known that several drugs have great therapeutic efficacy when given by the inhaled route. The novel inhaled corticosteroid ciclesonide is an inactive prodrug that is activated by esterases in the respiratory tract to the active principle des-ciclesonide.[144] More peripheral distribution of a drug delivered in smaller particles also increases alveolar deposition and thus is likely to increase absorption from the lungs into the general circulation, resulting in more systemic side effects. Thus, although HFA pMDIs deliver more inhaled corticosteroid to smaller airways, there is also increased systemic absorption.

Delivery Devices

Several ways of delivering inhaled drugs are possible[145]:

Metered-Dose Inhalers. Drugs were previously propelled from a canister with a chlorofluorocarbon (freon) propellant, but the propellant has been replaced by HFA, which is "ozone friendly."[146] These devices are convenient, portable, and deliver 100 to 400 doses of drug. They are usually easy to use, although it is necessary to coordinate inhalation with action of the device, so it is important that patients are taught to use these devices correctly.[147]

Spacer Chambers. Large-volume spacer devices between the metered-dose inhaler (MDI) and the patient reduce the velocity of particles entering the upper airways and the size of the particles by allowing evaporation of liquid propellant. This reduces the amount of drug that impinges on the oropharynx and increases the proportion of drug entering the lower airways. The need for careful coordination between activation and inhalation is also avoided, because the pMDI can be activated into the chamber and the aerosol subsequently inhaled from the one-way valve. Perhaps the most useful application of spacer chambers is in the reduction of the oropharyngeal deposition of inhaled corticosteroids and thus the local side effects of these drugs. Large-volume spacers also reduce the systemic side effects of drugs, because less drug is deposited in the oropharynx and therefore swallowed; it is the swallowed fraction of the drug that is absorbed from the gastrointestinal tract that makes the greatest contribution to the systemic fraction. This is of particular importance in the use of certain inhaled steroids, such as beclomethasone dipropionate, which can be absorbed from the gastrointestinal tract. Spacer devices are also useful in delivering inhaled drugs to small children who are not able to use a pMDI. Children as young as 3 years are able to use a spacer device fitted with a face mask.

Dry Powder Inhalers. Drugs may also be delivered as a dry powder using devices that scatter a fine powder dispersed by air turbulence during inhalation. These devices may be preferred by some patients, because careful coordination is not as necessary as with the MDI, but some patients find the dry powder irritating. Several multiple-dose dry powder inhalers (DPIs) are now available, which are more convenient.[148] Some devices deliver doses of pure drug and therefore avoid the problems of additives such as surfactants, which are necessary in pMDIs and which may provoke throat irritation, coughing, and even a fall in lung function–sensitive asthmatic patients. DPIs are also easier to use in children. DPIs have been developed to deliver peptides and proteins such as insulin systemically.

Nebulizers. Two types of nebulizer are available. Jet nebulizers are driven by a stream of gas (air or oxygen), whereas ultrasonic nebulizers utilize a rapidly vibrating piezoelectric crystal and thus do not require a source of compressed gas. The nebulized drug can be inspired during tidal breathing, and it is possible to deliver much higher doses of drug. Nebulizers are therefore useful in treating acute exacerbations of asthma and COPD, for delivering drugs when airway obstruction is extreme (e.g., in severe COPD), for delivering inhaled drugs to infants and small children who cannot use the other inhalation devices, and for delivering drugs such as antibiotics when relatively high doses must be delivered. Small handheld nebulizers are now in development.

Oral Route

Drugs for treatment of pulmonary diseases may also be given orally. The oral dose is much higher than the inhaled dose required to achieve the same effect (by a ratio of more than 20 : 1), so systemic side effects of oral delivery are far more common. When there is a choice of inhaled versus oral route for a drug (e.g., β-agonist or corticosteroid), the inhaled route is always preferable; the oral route should be reserved for the few patients unable to use inhalers (e.g., small children, patients with physical problems such as severe arthritis of the hand). Theophylline is ineffective by the inhaled route and therefore must be given orally. Corticosteroids may have to be given orally for parenchymal lung diseases (e.g., in interstitial lung diseases and emphysema), although it may be possible in the future to deliver such drugs into alveoli using specially designed inhalation devices and aerosols with a small particle size.

Parenteral Route

The intravenous route should be reserved for delivery of drugs in the severely ill patient who is unable to absorb drugs from the gastrointestinal tract. Side effects are generally frequent due to the high plasma concentrations.

AUTONOMIC PHARMACOLOGY

Airway nerves regulate the caliber of the airways and control airway smooth muscle tone, airway blood flow, and mucus secretion.[149] They may also influence the inflammatory process and play an integral role in host defense. Autonomic innervation is relevant to respiratory pharmacology in that many of the drugs used to treat airway diseases have effects on neural control or on autonomic receptors in the respiratory tract.

Overview of Airway Innervation

Neural control of airway function is more complex than previously recognized. Many neurotransmitters are now identified, and these act on a multitude of autonomic receptors. Three types of airway nerve are recognized (Fig. 8-23):

- Parasympathetic nerves that release Ach.
- Sympathetic nerves that release norepinephrine.
- Afferent (sensory nerves) whose primary transmitter may be glutamate.

In addition to these classical transmitters, multiple neuropeptides have now been localized to airway nerves and may have potent effects on airway function.[150] All of these neurotransmitters act on receptors that are expressed on the surface of target cells in the airway. It is increasingly recognized that a single transmitter may act on several subtypes of receptor and may lead to different cellular effects mediated via different second messenger systems.

Several neural mechanisms are involved in the regulation of airway caliber, and abnormalities in neural control may contribute to airway narrowing in disease (Fig. 8-24). Neural mechanisms may be involved in the pathophysiology of airway diseases, such as asthma and COPD, contributing to the symptoms and possibly to the inflammatory response.[6] There is a close interrelationship between inflammation and neural responses in the airways; inflammatory mediators may influence the release of neurotransmitters via activation of sensory

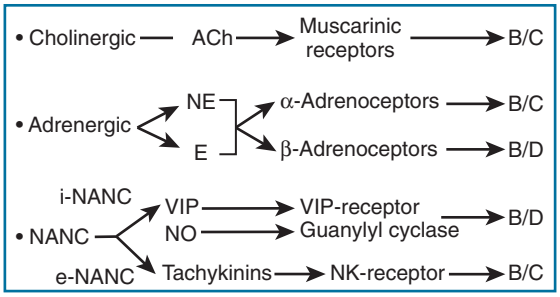

FIGURE 8-23 ■ Mechanisms of autonomic innervation of lungs. Three types of efferent neural mechanism regulate airway smooth muscle tone. Cholinergic nerves cause constriction via release of acetylcholine (ACh), which acts on muscarinic receptors. Adrenergic mechanisms include sympathetic nerves, which release norepinephrine (NE) and circulating epinephrine (E), which act on α- and β-adrenoceptors, resulting in bronchoconstriction (B/C) or bronchodilatation (B/D). Nonadrenergic noncholinergic (NANC) mechanisms include inhibitory NANC (i-NANC) B/D via release of vasoactive intestinal polypeptide (VIP) in some species, and nitric oxide (NO) and excitatory NANC (e-NANC) mechanisms, which lead to bronchoconstriction via release of tachykinins from sensory nerves.

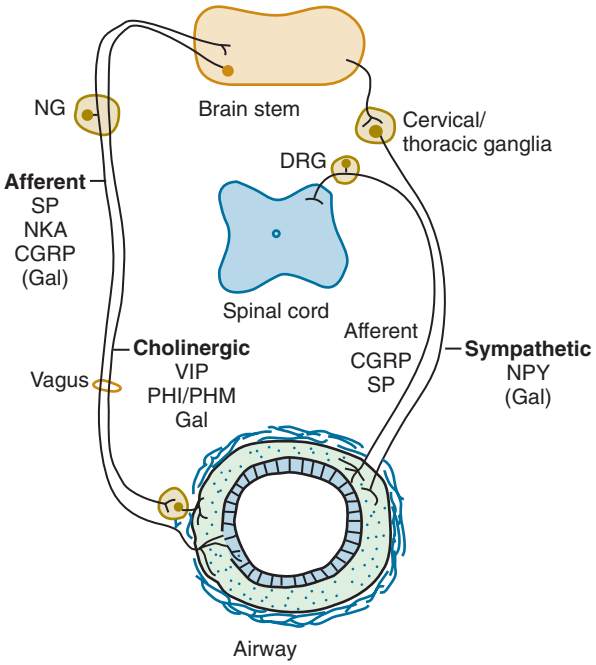

FIGURE 8-24 ■ Neural control of airways. Efferent cholinergic fibers travel in the vagus nerves and synapse in parasympathetic ganglia within the airways. The vagus nerves also transmit sensory information to the central nervous system, the nerve cell bodies of which are localized to the nodose ganglion (NG). Sympathetic nerves to the lungs arise in dorsal root ganglia (T1-7). Various neuropeptides coexist in these classical autonomic nerves. In parasympathetic nerves, vasoactive intestinal polypeptide (VIP), peptide histidine isoleucine/methionine (PHI/PHM), and galanin (Gal) are present. In sympathetic nerves, neuropeptide Y (NPY) and sometimes Gal are present. In afferent nerves (containing C fibers), substance P (SP), neurokinin A (NKA), calcitonin gene-related peptide (CGRP), and sometimes Gal exist. Some afferent fibers whose nerve cell bodies are situated in the upper thoracic dorsal root ganglia (DRG) enter the spinal cord.

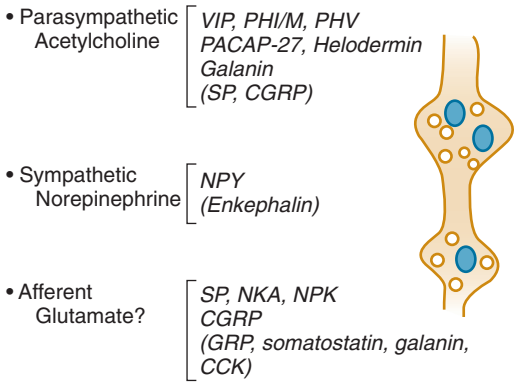

FIGURE 8-25 ■ Cotransmission in airways. Multiple neuropeptides and other transmitters coexist with classical transmitters in airway nerves. Thus, parasympathetic nerves, which contain acetylcholine (ACh), also contain vasoactive intestinal polypeptide (VIP), peptide histidine isoleucine/methionine (PHI/M), histidine isoleucine valine (PHV), helodermin, pituitary adenylate cyclase-activating peptide (PACAP-27), and galanin. Sympathetic nerves, which contain norepinephrine, also contain neuropeptide Y (NPY) and enkephalins. Afferent nerves, in which glutamate may be the primary transmitter, contain substance P (SP), neurokinin A (NKA), neuropeptide K (NPK) and calcitonin gene-related peptide (CGRP).

nerves leading to reflex effects and via stimulation of prejunctional receptors that influence the release of neurotransmitters.[151] In turn, neural mechanisms may influence the nature of the inflammatory response, either reducing inflammation or exaggerating the inflammatory response.

Neural Interactions

Complex interactions between various components of the autonomic nervous system are now recognized. Adrenergic nerves may modulate cholinergic neurotransmission in the airways, and sensory nerves may influence neurotransmission in parasympathetic ganglia and at postganglionic nerves. This means that changes in the function of one neural pathway may have effects on other pathways.

Cotransmission

Although it was once the dogma that each nerve has its own unique transmitter, it is now apparent that almost every nerve contains multiple transmitters. Thus, airway parasympathetic nerves, in which the primary transmitter is ACh, also contain the neuropeptides VIP, peptide histidine isoleucine/methionine (PHI/M), pituitary adenylate cyclase activating peptide (PACAP), helodermin, galanin, and NO (Fig. 8-25). These cotransmitters may have either facilitatory or antagonistic effects on target cells or may influence the release of the primary transmitter via prejunctional receptors. Thus, VIP modulates the release of ACh from airway cholinergic nerves. Sympathetic nerves, which release norepinephrine, may also release neuropeptide Y (NPY) and enkephalins, whereas afferent nerves may contain a variety of peptides including substance P (SP), neurokinin A (NKA), CGRP, galanin, VIP, secretoneurin, and cholecystokinin.

The physiologic role of neurotransmission may be in "fine-tuning" of neural control. Neuropeptides may be preferentially released by high-frequency firing of nerves, and their effects may therefore become manifest only under conditions of excessive nerve stimulation. Neuropeptide neurotransmitters may also act on target cells different from the primary transmitter, resulting in different physiologic effects. Thus, in airways, ACh causes bronchoconstriction, but VIP, which is co-released, may have its major effect on bronchial vessels, thus increasing blood flow to the airways. In chronic inflammation, the role of cotransmitters may be increased by alterations in the expression of their receptors or by increased synthesis of transmitters via increased gene transcription.

Afferent Nerves

The sensory innervation of the respiratory tract is mainly carried in the vagus nerves.[6] The neuronal cell bodies are localized to the nodose and jugular ganglia and input

to the solitary tract nucleus in the brain stem. A few sensory fibers supplying the lower airways enter the spinal cord in the upper thoracic sympathetic trunks, but their contribution to respiratory reflexes is minor and it is uncertain whether they are represented in humans. There is a tonic discharge of sensory nerves that has a regulatory effect on respiratory function and also triggers powerful protective reflex mechanisms in response to inhaled noxious agents, physical stimuli, or certain inflammatory mediators.

The larynx is richly supplied with sensory nerves that are derived from the superior laryngeal nerve. There are numerous sensory arborizations with the appearance of mechanoreceptors. Electrophysiologic studies indicate that many afferents function like rapidly adapting (irritant) receptors in the lower respiratory tract. It is this rich sensory innervation that allows the larynx to function as the first-line defense of the lower airways.

At least three types of afferent fibers have been identified in the lower airways.[152] Most of the information on their function has been obtained from studies in anesthetized animals. It has been difficult to apply electrophysiologic techniques to humans, so it is difficult to know how much of the information obtained in anesthetized animals can be extrapolated to human airways.

Slowly Adapting Receptors

Myelinated fibers associated with smooth muscle of proximal airways are probably slowly adapting (pulmonary stretch) receptors (SAR) that are involved in reflex control of breathing. Activation of SARs reduces efferent vagal discharge and mediates bronchodilation. During tracheal constriction, the activity of SARs may serve to limit the bronchoconstrictor response. SARs may play a role in the cough reflex because when these receptors are destroyed by a high concentration of SO_2, the cough response to mechanical stimulation is lost.

Rapidly Adapting Receptors

Myelinated fibers in the epithelium, particularly at the branching points of proximal airways, show rapid adaptation. Rapidly adapting receptors (RARs) account for 10% to 30% of the myelinated nerve endings in the airways. These endings are sensitive to mechanical stimulation and to mediators such as histamine. The response of RARs to histamine is partly due to mechanical distortion consequent on bronchoconstriction, although if this is prevented by pretreatment with isoproterenol, the RAR response is not abolished, indicating a direct stimulatory effect of histamine. It is likely that mechanical distortion of the airway may amplify irritant receptor discharge.

RARs with widespread arborizations are very numerous in the area of the carina, where they have been termed "cough receptors"; cough can be evoked by even the slightest touch in this region. RARs respond to inhaled cigarette smoke, ozone, serotonin and $PGF_{2\alpha}$, although it is possible that these responses are secondary to the mechanical distortion produced by the bronchoconstrictor response to these irritants. Neurophysiologic studies using an in vitro preparation in guinea pig trachea and bronchi show that a majority of afferent fibers are myelinated and belong to the Aδ-fiber group. Although these fibers are activated by mechanical stimulation and low pH, they are not sensitive to capsaicin, histamine, or bradykinin.

C Fibers

There is a high density of unmyelinated (C) fibers in the airways and they greatly outnumber myelinated fibers. In the bronchi, C fibers account for 80% to 90% of all afferent fibers in cats. C fibers play an important role in the defense of the lower respiratory tract. C fibers contain neuropeptides, including SP, NKA, and CGRP, which confer a motor function on these nerves. Although capsaicin has often been used to classify C fibers, it now appears that some of the C fibers are capsaicin-insensitive.[153] Bronchial C fibers are insensitive to lung inflation and deflation, but they typically respond to chemical stimulation. In vivo studies suggest that bronchial C fibers in dogs respond to the inflammatory mediators histamine, bradykinin, serotonin, and prostaglandins. They are selectively stimulated by capsaicin given either intravenously or by inhalation, which acts via TRPV1 (or vanilloid) receptors[154] and are also stimulated by SO_2 and by cigarette smoke. Because these fibers are relatively unaffected by lung mechanics, it is likely that these agents act directly on the unmyelinated endings in the airway epithelium.

Both RARs and C fibers are sensitive to water and hyperosmotic solutions, with RARs showing a greater sensitivity to hypotonic and C fibers to hypertonic saline. In the in vitro guinea pig trachea preparation, Aδ fibers and C fibers are stimulated by water and by hyperosmolar solutions; a small proportion of Aδ fibers are also stimulated by low chloride solutions, whereas the majority of C fibers are activated. Pulmonary C fibers that are activated via the pulmonary circulation appear to have different properties from bronchial C fibers. Lobeline, which stimulates pulmonary but not bronchial C fibers, causes cough when perfused through the pulmonary circulation, suggesting that pulmonary C fibers may be involved in the cough reflex.

Defense Reflexes

Afferent nerves play a critical role in defense of the airways. There are powerful protective reflexes evoked by stimulation of afferent nerve endings on the surface of the larynx that serve to limit access of noxious agents to the gas-exchanging surface. If this line of defense is breached, there are additional defensive reflexes activated within the lower respiratory tract. These reflexes include changes in the pattern of breathing (rapid shallow breathing or in infants, apnea), constriction of the airways, increased airway secretions, and increased blood flow in the tracheal and bronchial circulations. These responses comprise a coordinated response that limits the access of the noxious agent to the delicate

gas-exchanging surface of the lungs in order to preserve oxygenation.

Cough

Cough is an important defense reflex, which may be triggered from either laryngeal or lower airway afferents.[155] It is characterized by violent expiration, which provides the high shear rate needed to expel foreign particles and mucus from the lower respiratory tract. There is debate about which are the most important afferents for initiation of cough, and this may be dependent on the stimulus. Thus, RARs are activated by mechanical stimuli (e.g., particulate matter), bronchoconstrictors, and hypotonic saline and water, whereas C fibers are more sensitive to hypertonic solutions, bradykinin, and capsaicin. In normal humans, inhaled capsaicin is a potent tussive stimulus, and this is associated with a transient bronchoconstrictor reflex that is abolished by an anticholinergic drug. It is not certain whether this is due to stimulation of C fibers in the larynx, but as these are very sparse, it is likely that bronchial C fibers are also involved. Citric acid is commonly used to stimulate coughing in experimental challenges in human subjects; it is likely that it produces cough by a combination of low pH (which stimulates C fibers) and low chloride (which may stimulate laryngeal and lower airway afferents). Inhaled bradykinin causes coughing and a raw sensation retrosternally, which may be due to stimulation of C fibers in the lower airways. Bradykinin appears to be a relatively pure stimulant of C fibers.[156] PGE_2 and $PGF_{2\alpha}$ are potent tussive agents in humans and also sensitize the cough reflex. This may be relevant to airway defenses. Noxious agents may stimulate the release of prostaglandins (particularly PGE_2) from airway sensory nerves, and this may lead to enhanced sensitivity of the cough reflex and thus a greater likelihood of expelling the noxious agent if it persists. Bronchoconstriction and increased mucus secretion are often caused by the same stimuli that provoke cough, thereby increasing the efficiency of the cough reflex.

Cholinergic Nerves

Cholinergic nerves are the major neural bronchoconstrictor mechanism in human airways, and they are the major determinants of airway caliber.

Cholinergic Control of Airways

Cholinergic nerve fibers arise in the nucleus ambiguous in the brain stem and travel down the vagus nerve and synapse in parasympathetic ganglia, which are located within the airway wall. From these ganglia, short postganglionic fibers travel to airway smooth muscle and to submucosal glands.[157] In animals, electrical stimulation of the vagus nerve causes release of ACh from cholinergic nerve terminals, with activation of muscarinic cholinergic receptors on smooth muscle and gland cells, which results in bronchoconstriction and mucus secretion. Prior administration of a muscarinic receptor antagonist, such as atropine, prevents vagally induced bronchoconstriction. Cholinergic innervation is greatest in large airways and diminishes peripherally, although in humans, muscarinic receptors are localized to airway smooth muscle in all airways. In humans, studies that have tried to distinguish large and small airway effects have shown that cholinergic bronchoconstriction predominantly involves larger airways, whereas β-agonists are equally effective in large and small airways. This relative diminution of cholinergic control in small airways may have important clinical implications; anticholinergic drugs are likely to be less useful than β-agonists when bronchoconstriction involves small airways. In animals, there is a certain degree of resting bronchomotor tone caused by tonic parasympathetic activity. This tone can be reversed by atropine, and enhanced by administration of an inhibitor of acetylcholinesterase (which normally rapidly inactivates ACh released from nerve terminals). Normal human subjects also have resting cholinergic bronchomotor tone; atropine causes bronchodilation.

Extraneuronal ACh

ACh may be synthesized by several types of cells other than neurones, such as airway epithelial cells, and this may contribute to cholinergic tone in the airways, especially in small airways where cholinergic innervation is sparse.[158]

Muscarinic Receptors

Four subtypes of muscarinic receptor have now been identified by binding studies and pharmacologically in lungs.[159] The muscarinic receptors, which mediate bronchoconstriction in human and animal airways, belong to the M_3-receptor subtype, whereas mucus secretion appears to be mediated by M_1- and M_3-receptors. Muscarinic receptor stimulation results in vasodilation via activation of M_3-receptors on endothelial cells, which release NO. M_1-Receptors are also localized to parasympathetic ganglia, where they facilitate the neurotransmission mediated via nicotinic receptors (Fig. 8-26).

Inhibitory muscarinic receptors (autoreceptors) have been demonstrated on cholinergic nerves of airways in animals in vivo and in human bronchi in vitro.[159] These prejunctional receptors inhibit ACh release and may serve to limit vagal bronchoconstriction. Autoreceptors in human airways belong to the M_2-receptor subtype, whereas those on airway smooth muscle and glands belong to the M_3-receptor subtype. Drugs such as atropine and ipratropium bromide, which block both prejunctional M_2-receptors and postjunctional M_3-receptors on smooth muscle with equal efficacy therefore increase ACh release, which may then overcome the postjunctional blockade. This means that such drugs will not be as effective against vagal bronchoconstriction as against cholinergic agonists, and it may be necessary to reevaluate the contribution of cholinergic nerves when drugs that are selective for the M_3-receptors are in clinical use. The presence of muscarinic autoreceptors has been demonstrated in human subjects in vivo. A cholinergic

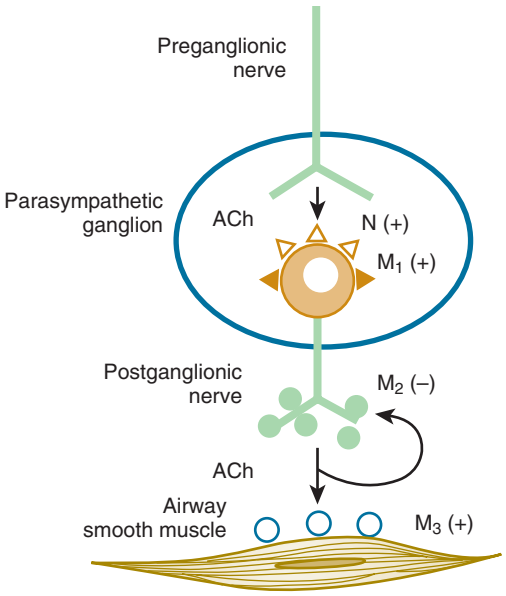

FIGURE 8-26 ■ Cholinergic neural pathways and muscarinic receptor subtypes. Preganglionic cholinergic fibers travel down the vagus nerve to relay in parasympathetic ganglia localized within the airways. Neurotransmission through ganglia is mediated via release of acetylcholine (ACh) from preganglionic terminals acting on nicotinic receptors (N) on ganglionic neurones. M_1-receptors on the same cells appear to facilitate ganglionic transmission. The postganglionic nerve terminal also releases ACh, which acts on M_3-receptors on target cells to cause contraction of airway smooth muscle and mucus secretion. M_2-receptors on preganglionic nerves act as feedback inhibitory receptors to inhibit ACh release from the nerve terminal. *Arrow,* neurotransmission.

agonist, pilocarpine, which selectively activates M_2-receptors, inhibits cholinergic reflex bronchoconstriction induced by sulfur dioxide in normal subjects, but such an inhibitory mechanism does not appear to operate in asthmatic subjects, suggesting that there may be dysfunction of these autoreceptors. Such a defect in muscarinic autoreceptors may then result in exaggerated cholinergic reflexes in asthma, because the normal feedback inhibition of ACh release may be lost. This might also explain the sometimes catastrophic bronchoconstriction that occurs with β-blockers in asthma that, at least in mild asthmatics, appears to be mediated by cholinergic pathways. Antagonism of inhibitory β-receptors on cholinergic nerves would result in increased release of ACh, which could not be switched off in the asthmatic patient. This explains why anticholinergics block β-blocker–induced asthma. The mechanisms that lead to dysfunction of prejunctional M_2-receptors in asthmatic airways are not certain, but it is possible that M_2-receptors may be more susceptible to damage by oxidants or other products of the inflammatory response in the airways. Experimental studies have demonstrated that influenza virus infection and eosinophils in guinea pigs may result in a selective loss of M_2-receptors compared with M_3-receptors, resulting in a loss of autoreceptor function and enhanced cholinergic bronchoconstriction.[160] Muscarinic receptors are also expressed on inflammatory cells. Thus, neuronal and extraneuronal ACh may have proinflammatory effects.[158]

Cholinergic Reflexes

A wide variety of stimuli are able to elicit reflex cholinergic bronchoconstriction through activation of sensory receptors in the larynx or lower airways. Activation of cholinergic reflexes may result in bronchoconstriction and an increase in airway mucus secretion through the activation of muscarinic receptors on airway smooth muscle cells and submucosal glands. Cholinergic reflexes may also increase airway blood flow, particularly in proximal airways. Stimulation of the vagus nerves in animals results in vasodilation in proximal airways that is partially reduced by atropine, suggesting a cholinergic component. The residual component is likely to be due to release of neuropeptides (such as VIP and CGRP) and NO. Cigarette smoke inhalation results in an increase in airway blood flow in pigs, through effects of exogenous NO contained in cigarette smoke, but also via release of endogenous NO from airway nerves. Cholinergic reflexes may also increase mucociliary clearance, presumably via an effect of ACh on ciliated epithelial cells.

Several inhaled irritants have been found to activate cholinergic reflexes in human airways, resulting in bronchoconstriction. These include SO_2, metabisulfite, and bradykinin. Both water (fog) and hypertonic saline also produce cough and bronchoconstriction in asthmatic patients, although the role of cholinergic reflexes in the bronchoconstrictor responses has not been fully evaluated. The activation of cholinergic reflexes by airway irritants is clearly part of a defensive reflex; the bronchoconstriction serves to reduce the penetration of the noxious substance and increases the efficiency of the cough mechanism, the increase in mucus secretion and increased mucociliary clearance result in more efficient removal of the irritant, and the increase in airway blood flow may serve to bring in inflammatory cells.

Cholinergic reflexes may also be activated from extrapulmonary afferents, and these reflexes may also contribute to airway defenses. Esophageal reflux may be associated with bronchoconstriction in asthmatic patients. In some patients, this may be due to aspiration of acid into the airways; in other cases, acid reflux into the esophagus activates a reflex cholinergic bronchoconstriction (the "reflux reflex"). Presumably, this reflex evolved to prevent aspiration of stomach contents. There are also reflexes that may be activated by stimulation of sensory receptors in the nose, resulting in bronchoconstriction and laryngeal narrowing. This may serve as an early warning system so noxious agents inhaled through the nose are prevented from being inhaled into the lungs.

Neurogenic Inflammation

Pain, heat, redness, and swelling are the cardinal signs of inflammation. Sensory nerves may be involved in the generation of each of these signs. There is now considerable evidence that sensory nerves participate in

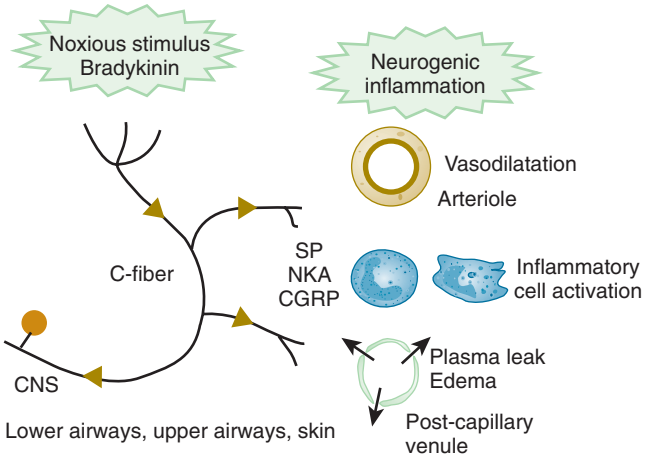

FIGURE 8-27 ■ Neurogenic inflammation in the airways. Activation of sensory nerves by noxious stimuli release neuropeptides such as substance P (SP), neurokinin A (NKA), and calcitonin gene-related peptide (CGRP), which together cause plasma exudation, vasodilatation, and inflammatory cell recruitment and activation. CNS, central nervous system.

inflammatory responses. This "neurogenic inflammation" is due to the antidromic release of neuropeptides from C fibers, via an axon reflex. The phenomenon is well documented in several organs, including skin, eye, gastrointestinal tract, and bladder.[161] There is also increasing evidence that neurogenic inflammation occurs in the respiratory tract.[162] It may contribute to the inflammatory response in asthma and COPD and may have evolved as an airway defense mechanism.

Activation of airway C fibers may release several neuropeptides, including tachykinins (SP, NKA) and CGRP. In some population of C fibers, other neuropeptides such as galanin, VIP, and NPY, are also present.[163] These peptides have potent effects on airway function and may lead to a chronic inflammatory state with narrowing of the airways (Fig. 8-27). This presumably evolved as a mechanism of defense against invading organisms and as a mechanism to repair the airway damaged by noxious agents in the respiratory tract.

Tachykinins

SP and NKA, but not NKB, are localized to sensory nerves in the airways of several species.[164] SP-immunoreactive nerves are abundant in rodent airways, but are sparse in human airways. SP-immunoreactive nerves in the airways are found beneath and within the airway epithelium, around blood vessels, and to a lesser extent, within airway smooth muscle. SP-immunoreactive nerve fibers also innervate parasympathetic ganglia, suggesting a sensory input that may modulate ganglionic transmission and so result in ganglionic reflexes. SP in the airways is localized predominantly to capsaicin-sensitive unmyelinated nerves in the airways, but chronic administration of capsaicin only partially depletes the lungs of tachykinins, indicating the presence of a population of capsaicin-resistant SP-immunoreactive nerves, as in the gastrointestinal tract. Similar capsaicin denervation studies are not possible in human airways, but after extrinsic denervation by heart-lung transplantation, there appears to be a loss of SP-immunoreactive nerves in the submucosa.

Tachykinins have many different effects on the airways, which are mediated via NK_1-receptors (preferentially activated by SP) and via NK_2-receptors (activated by NKA). Tachykinins constrict smooth muscle of human airways in vitro via NK_2-receptors. The contractile response to NKA is significantly greater in smaller human bronchi than in more proximal airways, indicating that tachykinins may have a more important constrictor effect on more peripheral airways, whereas cholinergic constriction tends to be more pronounced in proximal airways. In vivo, SP does not cause bronchoconstriction or cough, whereas NKA causes bronchoconstriction in asthmatic subjects. Mechanical removal of airway epithelium potentiates the bronchoconstrictor response to tachykinins, largely because the ectoenzyme NEP (E.C. 3.4.24.11), which is a key enzyme in the degradation of tachykinins in airways. SP also stimulates mucus secretion from submucosal glands and goblet cells, stimulates plasma extravasation, and increases airway blood flow, effects that are mediated via NK_1-receptors. Tachykinins are metabolized by NEP, and inhibition of NEP by phosphoramidon or thiorphan markedly potentiates bronchoconstriction and mucus secretion in animal and human airways. The activity of NEP in the airways appears to be an important factor in determining the effects of tachykinins; any factors that inhibit the enzyme or its expression may be associated with increased effects of exogenous or endogenously released tachykinins. Several of the stimuli known to induce bronchoconstrictor responses in asthmatic patients have been found to reduce the activity of airway NEP.[165]

Calcitonin Gene–Related Peptide

CGRP is co-stored and colocalized with SP in afferent nerves. CGRP is a potent vasodilator with long-lasting effects.[166] CGRP is an effective dilator of bronchial vessels in vitro and produces a marked, long-lasting increase in airway blood flow in anesthetized animals. Receptor mapping studies have demonstrated that CGRP receptors are localized predominantly to bronchial vessels rather than to smooth muscle or epithelium in human airways. It is likely that CGRP is the predominant mediator of arterial vasodilation and increased blood flow in response to sensory nerve stimulation in the bronchi. CGRP is a bronchoconstrictor, largely due to the release of spasmogens, such as endothelin-1. It also has eosinophil chemotactic activity.

Neurogenic Inflammation in Human Airways

Although there is clear evidence for neurogenic inflammation in rodent airways, it has been difficult to study in human airways.[162] There are few SP-immunoreactive airways in humans, as discussed previously, but there is

an apparent increase in patients with asthma, although this has not been confirmed in other studies. The role of neurogenic inflammation in response to inhaled irritants in normal individuals is likely to be minimal or absent. While capsaicin induces bronchoconstriction and plasma exudation in rodents, inhaled capsaicin causes cough and only a *transient* bronchoconstriction in humans, suggesting that neuropeptide release is unimportant in human airways. Bradykinin is a potent bronchoconstrictor and tussive agent in asthmatic patients, an effect that is reduced by a tachykinin antagonist. Because normal airways fail to constrict in response to bradykinin, although it induces cough, this provides some evidence that neurogenic inflammation may be enhanced in asthma but is not present normally. NEP inhibitors potentiate the bronchoconstrictor response to inhaled NKA in normal and asthmatic subjects, but there is no effect on baseline lung function in asthmatic patients, indicating that there is unlikely to be basal release of tachykinins. It is possible that NEP may become dysfunctional after viral infections or exposure to oxidants and airway irritants such as cigarette smoke, but this has not yet been investigated in humans. Tachykinin antagonists are effective in a variety of animal models of asthma, but there is presently little evidence that they are efficacious in human airway disease.

Neurotrophins

Neurotrophins, such as nerve growth factor (NGF), may be released from inflammatory and structural cells in airways and stimulate the increased synthesis of neuropeptides, such as SP, in airway sensory nerves, as well as sensitizing nerve endings in the airways.[167] NGF is released from human airway epithelial cells after exposure to inflammatory stimuli. Neurotrophins may play an important role in mediating bronchial hyperresponsiveness in asthma and may account for the plasticity of sensory nerves in inflammation, when increased expression of neuropeptides is found in airway sensory nerves.[168]

Bronchodilator Nerves

Neural bronchodilator mechanisms exist in airways, and there are considerable species differences.

Sympathetic Nerves

Sympathetic innervation of human airways is sparse, and there is no functional evidence for innervation of airway smooth muscle, in contrast to the sympathetic neural bronchodilator mechanisms that exist in other species.[169] Sympathetic nerves may regulate bronchial blood flow and to a lesser extent mucus secretion. Sympathetic nerves may also influence airway tone indirectly through a modulatory effect on parasympathetic ganglia; sympathetic nerve profiles have been observed in close proximity to parasympathetic ganglia and to postganglionic cholinergic nerve terminals in human airways.

Circulating Catecholamines

In the absence of sympathetic nerves, circulating epinephrine may play a role in regulating airway tone. β-Adrenergic blockade causes bronchoconstriction in asthmatic patients, but not in normal subjects, suggesting an increased adrenergic drive in asthma. This might be provided by circulating epinephrine in asthma. However, circulating concentrations of epinephrine are normal, even in acute exacerbations of asthma. The mechanism whereby β-blockers cause bronchoconstriction in asthma is still not completely understood, but may be due to blockade of prejunctional β_2-receptors on cholinergic nerves in the airways, resulting in increased ACh release in asthma, in which the normal autoreceptor feedback via prejunctional M_2-receptors may be defective (as discussed previously).

Adrenergic Receptors

β-Adrenoceptors are present in high concentration in lung tissue, and autoradiographic mapping studies show that they are localized to several cell types.[170] Binding studies show that approximately two thirds of pulmonary β-receptors are of the β_2-receptor subtype. These receptors are localized to airway smooth muscle, epithelium, vascular smooth muscle, and submucosal glands, whereas β_1-receptors are localized to submucosal glands. There is a uniform distribution of β-receptors on the alveolar wall, and the ratio of $\beta_1 : \beta_2$ receptors is 2 : 1. The possibility that β-receptors are abnormal in asthma has been investigated extensively. The original suggestion that there is a primary defect in β-receptor function in asthma has not been substantiated, and any defect in β-receptors is likely to be secondary to the disease, perhaps as a result of inflammation or as a consequence of adrenergic therapy.

α-Adrenergic receptors that mediate bronchoconstriction have been demonstrated in airways of several species, and may be demonstrated only under certain experimental conditions. However, there is now considerable doubt about the role of α-receptors in the regulation of tone in human airways, because it has proven difficult to demonstrate their presence functionally or by autoradiography. α-Receptors may play an important role in regulating airway and pulmonary blood flow.

Inhibitory Nonadrenergic Noncholinergic Nerves

There are bronchodilator nerves in human airways that are not blocked by adrenergic blockers and are therefore described as inhibitory nonadrenergic noncholinergic (i-NANC).[171] The neurotransmitter for these nerves in some species, including guinea pigs and cats, is VIP and related peptides. The i-NANC bronchodilator response is blocked by α-chymotrypsin, an enzyme that very efficiently degrades VIP, and by antibodies to VIP. However, although VIP is present in human airways and VIP is a potent bronchodilator of human airways in vitro, there is no evidence that VIP is involved in neurotransmission

of i-NANC responses in human airways. Furthermore, α-chymotrypsin, which completely blocks the response to exogenous VIP, has no effect on neural bronchodilator responses. It is likely that VIP and related peptides may be more important in neural vasodilation responses and may result in increased blood flow to bronchoconstricted airways.

The predominant bronchodilator neurotransmitter of human airways is NO. NO synthase inhibitors, such as N^G-L-arginine methyl ester, virtually abolish the i-NANC response.[172] This effect is more marked in proximal airways, consistent with the demonstration that nitrergic innervation is greatest in proximal airways. NO appears to be a cotransmitter with ACh, and NO acts as a "braking" mechanism for the cholinergic system by acting as a functional antagonist to ACh in airway smooth muscle.[173]

Neural Control in Disease

Autonomic control of airways may be abnormal and contribute to the pathophysiology in several airway diseases.

Asthma

There is compelling evidence that neural mechanisms contribute to the pathophysiology of asthma.[174] It has long been proposed that there is an imbalance in autonomic control in asthma, with a preponderance of bronchoconstrictor mechanisms (muscarinic, α-adrenergic) or a deficit in bronchodilator mechanisms (β-adrenergic). While there is no convincing evidence for a primary defect in autonomic control in asthma, there are several abnormalities that arise as a consequence of the disease. Activation and sensitization of airway sensory nerves may result in the symptoms of cough and chest tightness that are so unpleasant in asthmatic patients. Cholinergic reflex bronchoconstriction may be important, particularly during exacerbations of asthma, when anticholinergic drugs are relatively effective. The defective function of prejunctional M_2-receptors may contribute to exaggerated reflex bronchoconstriction. Furthermore, loss of neuronally produced NO by the action of superoxide anions, generated from inflammatory cells, may leave the cholinergic neural bronchoconstriction unopposed. Whether neurogenic inflammation is present in asthmatic airways is uncertain, but is favored by the possible loss of NEP in asthma, by increased synthesis of SP, and by increased expression of NK_1-receptors. On the other hand, the clinical response to tachykinin antagonists, which are very effective in animal models of asthma, has been disappointing.

COPD

The airways are structurally narrowed in COPD, so even with vagal cholinergic tone, there is a relatively greater effect on caliber than in normal airways, purely for geometric reasons. This may explain why anticholinergics are as or more effective than inhaled β_2-agonists as bronchodilators in these patients. Neural mechanisms may explain the mucus hypersecretion seen in cigarette smokers, and irritants in cigarette smoke may stimulate reflex secretion.

INFLAMMATORY MEDIATORS

Many different mediators have been implicated in pulmonary diseases, and they may have a variety of effects that could account for some of the pathologic features of inflammatory lung diseases.[175,176] Mediators such as histamine, prostaglandins, and leukotrienes contract airway smooth muscle, increase microvascular leakage, increase airway mucus secretion, and attract other inflammatory cells (Fig. 8-28). Each mediator has many effects and many mediators have similar effects, so it is theoretically unlikely that antagonizing a single mediator will have a major impact in complex diseases such as asthma. However, some mediators may play a more prominent role—for example, LTD_4 appears to be dominant bronchoconstrictor mediator in asthma, whereas LTB_4 may play a key role in the neutrophilic inflammation of COPD. Mediator antagonists and synthesis inhibitors have been very useful in elucidating the role of specific mediators in the pathophysiology of asthma and COPD. Inflammation in asthma may be acute and chronic. The chronic inflammation is likely to be mediated by cytokines released within the airway wall, and there is increasing recognition that cytokines play a critical role in orchestrating and perpetuating the chronic inflammation of asthma and COPD.

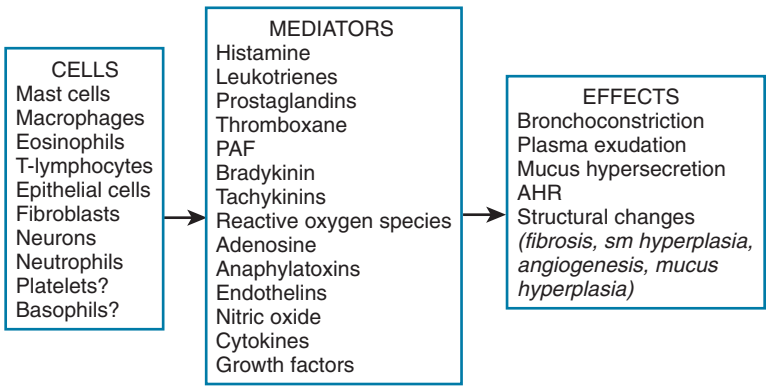

FIGURE 8-28 ■ Inflammatory mediators in asthma. Multiple inflammatory cells release a whole range of inflammatory mediators, which then act on inflammatory receptors on target cells of the airway to produce the typical inflammatory effects. AHR, airway hyperresponsiveness; PAF, platelet-activating factor; sm, smooth muscle.

Histamine

Histamine was the first mediator implicated in the pathophysiology of asthma. It has multiple effects on the airways, which are mediated by four types of histamine receptor. H_1-Receptors mediate bronchoconstriction, activation of sensory reflexes, vasoconstriction, and vasodilation of bronchial vessels and airway microvascular leakage; H_2-receptors mediate mucus secretion and vasodilation (some species); H_3-receptors mediate modulation of cholinergic and sensory nerves, but they may also act as feedback inhibitory receptors to histamine secretion in mast cells; and H_4-receptors are involved in chemotaxis of inflammatory cells.[177] Despite all of these effects, antihistamines have been disappointing in the treatment of asthma.

Leukotrienes

The cysteinyl-leukotrienes LTC_4, LTD_4, and LTE_4 are potent constrictors of human airways and appear to play an important role in the acute inflammatory response in asthma. The development of potent specific leukotriene antagonists has demonstrated that these mediators contribute approximately half of the bronchoconstrictor responses to triggers, such as allergens and exercise. Furthermore, chronic treatment shows a beneficial effect on asthma symptoms and on lung function. There is increasing evidence that LTD_4 may increase eosinophilic inflammation in the airways. LTB_4 is a potent chemotactic agent for neutrophils and is likely to play an important role in neutrophilic inflammatory diseases of the airways, such as COPD and cystic fibrosis.

Prostaglandins

Prostanoids (prostaglandins and thromboxane) are formed from arachidonic acid by the enzyme cyclooxygenase that is widely expressed in the lungs. A constitutive form of the enzyme (COX-1) releases low basal levels of prostaglandins, whereas another form of COX is inducible by endotoxin and by cytokines (COX-2). A new class of prostanoids, the isoprostanes, have been described, which are formed nonenzymatically via oxidation of arachidonic acid, and these mediators are useful markers of oxidative stress in lung diseases.[178] The most prevalent of these, 8-isoprostane (8 epi-$PGF_{2\alpha}$), is a potent constrictor of human airways.

Platelet-Activating Factor

PAF attracted considerable attention because it mimics many of the features of asthma, including smooth muscle hyperresponsiveness. Although PAF appears to be produced by the inflammatory cells involved in asthmatic inflammation and mimics many of the pathophysiologic features of asthma, potent PAF antagonists such as apafant (WEB 2086) and modipafant in chronic asthma have been clinically disappointing.[179] PAF may play a role in acute respiratory distress syndrome (ARDS).

Endothelins

Endothelins are potent peptide mediators that are potent vasoconstrictors and bronchoconstrictors.[180] They also induce airway smooth muscle cell proliferation and fibrosis and may therefore play a role in the chronic inflammation of asthma. There is evidence for increased expression of endothelins in asthma, particularly in airway epithelial cells.

Nitric Oxide

NO is produced in several cells in the airways by NO synthases.[181] An inducible form of the enzyme (iNOS) is expressed in epithelial cells and in inflammatory cells of asthmatic patients and can be induced by cytokines in airway epithelial cells in vitro. This may account for the increased concentration of NO in the exhaled air of asthmatic patients.[182] NO itself is a potent vasodilator and may increase plasma exudation in the airways; it may also amplify the Th2-lymphocyte–mediated response. When NO is produced from iNOS in the presence of oxidative stress, the potent radical peroxynitrite, a molecule that may have several detrimental effects, is produced.

Oxygen-Derived Free Radicals

Many inflammatory cells produce oxygen-derived free radicals such as superoxide anions. Oxidative stress may play an important role in asthma and in COPD.[183] Hydrogen peroxide causes contraction of airway smooth muscle and has been implicated in hyperactive airway smooth muscle in animal models. Oxygen radicals may lead to changes in receptor function, which could influence airway reactivity and may activate NF-κB to increase the expression of multiple inflammatory genes. Oxidative stress may also impair the action of corticosteroids.

Adenosine

Adenosine is released from various cell types under conditions of stress, such as hypoxia. Adenosine has a potent bronchoconstrictor effect in asthmatic patients and releases histamine from "primed" mast cells via an α_{2b}-receptor.[184] Theophylline is an antagonist of adenosine receptors, but it is unlikely that this action accounts for its antiasthma effect, although it may underlie serious side effects such as cardiac arrhythmias and seizures.

Bradykinin

Bradykinin is a potent bronchoconstrictor in asthma and causes contraction of airways largely via indirect means, particularly via activation of sensory nerves.[185] It may be an important mediator of cough in asthma, because it has the capacity to sensitize afferent nerves to various activating stimuli.[156]

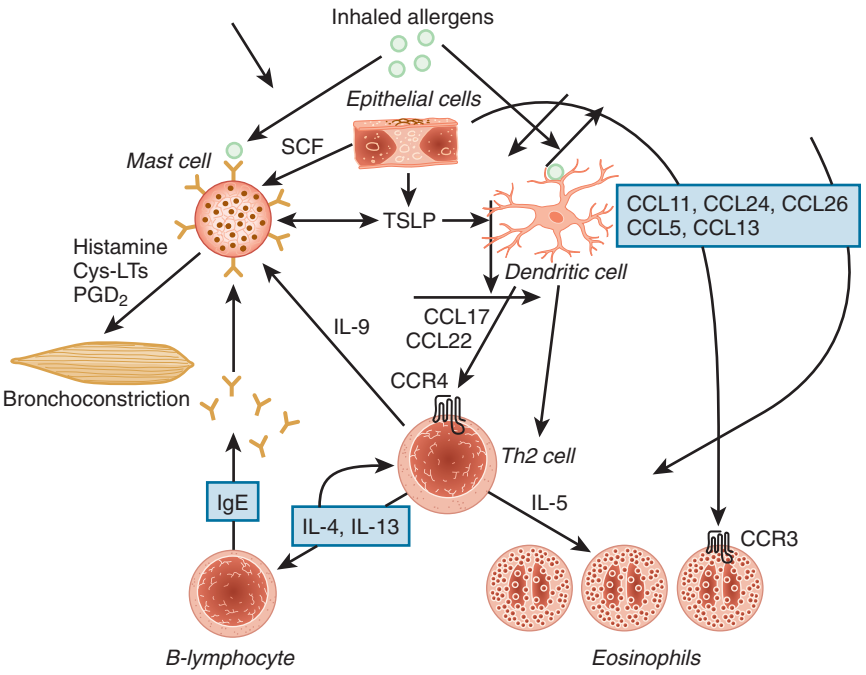

FIGURE 8-29 ■ Cytokines involved in asthma. Epithelial cells play an important role in orchestrating the inflammation of asthma through the release of multiple cytokines, including SCF (stem cell factor, which maintains mast cells in the airways), TSLP (thymus stromal lymphopoietic, which acts on dendritic cells to release the Th2 chemoattractants CCL17 and CCL22 that act on CCR4), and several chemokines that attract eosinophils by activating CCR3. T helper 2 (Th2) cells orchestrate the inflammatory response in asthma through the release of interleukin (IL)-4 and IL-13 (which stimulate B cells to synthesize IgE), IL-5 (which is necessary for eosinophilic inflammation), and IL-9 (which stimulates mast cell proliferation). Mast cells are thus orchestrated by several interacting cytokines and play an important role in asthma through the release of the bronchoconstrictor mediators histamine, cysteinyl-leukotrienes and PGD2.

Cytokines

Cytokines are increasingly recognized to be important in chronic inflammation and play a critical role in orchestrating the type of inflammatory response (Fig. 8-29). Many inflammatory cells (macrophages, mast cells, neutrophils, eosinophils, and lymphocytes) are capable of synthesizing and releasing these proteins, and structural cells such as epithelial cells, endothelial cells, and smooth muscle cells may also release a variety of cytokines and may therefore participate in the chronic inflammatory responses in asthma and COPD.[49] While inflammatory mediators such as histamine and leukotrienes may be important in the acute and subacute inflammatory responses and in exacerbations of asthma, it is likely that cytokines play a dominant role in chronic inflammation. Almost every cell is capable of producing cytokines under certain conditions. Research in this area is hampered by a lack of specific antagonists, although important observations have been made using specific neutralizing antibodies. The cytokines that appear to be of particular importance in asthma include the lymphokines secreted by T-lymphocytes: IL-4 and IL-13 are critical in switching B lymphocytes to produce IgE and for expression of vascular cell adhesion molecule-1 (VCAM-1) in endothelial cells, and IL-5, which is critical in the differentiation, survival, and priming of eosinophils. **TSLP** is produced by epithelial cells in asthma and acts on dendritic cells leading to the recruitment of Th2 cells into the airways. Other cytokines, such as IL-1, IL-6, TNF-α, and GM-CSF, are released from a variety of cells, including macrophages and epithelial cells; they may be important in amplifying inflammatory responses. TNF-α may be an important amplifying mediator in asthma and is produced in increased amounts in airways of patients with severe asthma.

By contrast, other cytokines are inhibitory to the inflammatory process: IL-10 is a potent anti-inflammatory cytokine that appears to be underexpressed in asthma and may be linked to asthma severity. Interferon-γ and IL-12 are inhibitory to Th2 cell expression and have potential as anti-inflammatory therapies.

Chemokines

Chemokines are chemotactic cytokines that orchestrate the trafficking of inflammatory cells to sites of inflammation. They activate GPCRs with the typical 7TM structure, so small molecule inhibitors are feasible candidates for therapies.[50] Most chemokines have four characteristic cysteines, and depending on the motif displayed by the first two cysteines, they have been classified into CXC, CC, C, and CX3C chemokine classes. Key chemokines in asthma include CCL11, which activates CCR3 on eosinophils and mast cells, and in COPD, CXCL1 and CXCL8, which activate CXCR2 on neutrophils and monocytes.

Multiple Mediators

It is clear that no single mediator can be responsible for all the features of asthma, and it is likely that multiple mediators constitute an "inflammatory soup," which may vary from patient to patient, depending on the relative state of activation of the different inflammatory cells and signals. There may be important interactions between the different mediators, and the concept of "priming" may be very important because a combination of mediators may have a much greater effect than each mediator alone. This may be particularly important in the actions of cytokines, which may have no effect in isolation, but may have a very pronounced effect after a cell has been exposed to another cytokine.

Anti-inflammatory Mediators

Although most attention has focused on the proinflammatory effects of mediators, other mediators appear to down-regulate the inflammatory response. IL-10 has potent anti-inflammatory effects and may show reduced secretion in asthma and COPD.[186] Several lipid mediators have anti-inflammatory effects, including lipoxins, protectins, and resolvins.[187]

TRANSCRIPTION FACTORS

In inflammatory lung diseases, there is an increased expression of several proteins involved in the inflammatory cascade. These proteins include cytokines, inflammatory enzymes, receptors for inflammatory mediators, and adhesion molecules. The increased expression of these proinflammatory proteins is usually the result of increased gene transcription. Changes in gene transcription are regulated by transcription factors, which are proteins that bind to DNA. This suggests that transcription factors may play a key role in the pathophysiology of inflammatory lung diseases, because they regulate the increased gene expression that may underlie the chronic inflammatory processes in diseases such as asthma and COPD.[188] Corticosteroids are the most effective therapy in asthma and may reduce inflammation in asthmatic airways largely by inhibiting the transcription factors that regulate abnormal gene expression.[75] Transcription factors bind to regulatory sequences, usually in the 5′ upstream promoter region of target genes, to increase or decrease the rate of gene transcription. This results in increased or decreased protein synthesis and altered cellular function. Transcription factors may be activated via surface receptors through phosphorylation by several kinases, or may be activated by ligands acting on nuclear receptors (such as corticosteroids or vitamin D_3). Transcription factors may therefore convert transient signals at the cell surface into long-term changes in gene transcription, thus acting as "nuclear messengers" (Fig. 8-30).

Several families of transcription factors exist and members of each family may share structural characteristics. These families include helix-turn-helix (e.g., POU), zinc finger (e.g., glucocorticoid receptors), basic protein-leucine zipper (CREB, NF-κB, AP-1), and β-sheet motifs (e.g., HU). Many transcription factors are common to several cell types, whereas others are cell specific and determine the phenotypic characteristics of a cell.

Transcription factors play an important role in the long-term regulation of cell function, growth, and differentiation. Transcription factors may play an important role in chronic diseases such as asthma and COPD. Thus, there is increasing evidence that transcription factors are critical in the expression of cytokine genes and may therefore be involved in inflammatory and immune diseases. Indeed, it is increasingly recognized that some therapies used in the treatment of these diseases, such as corticosteroids and cyclosporin A, may function through interaction with transcription factors. It remains a possibility that abnormal functioning of transcription factors may determine disease severity and responsiveness to treatment. Transcription factors may also interact with each other, resulting in inhibition, or sometimes enhancement, of transcriptional activity.

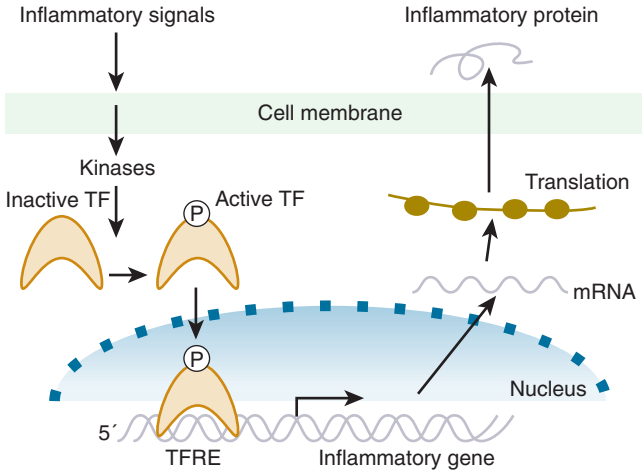

FIGURE 8-30 ■ Transcription factors and inflammation. Extracellular inflammatory stimuli activate transcription factors (TF) via kinases, which then translocate to the nucleus where they bind to transcription factor recognition elements (TFRE) in the promoter region of inflammatory genes, resulting in increased transcription and synthesis of inflammatory proteins. P, phosphorylation.

There is still little information about the regulation of transcription factors in the lungs, particularly in disease. However, molecular methods have been developed for investigation of transcription factor expression and activity. These methods include immunoblotting and immunocytochemistry to detect the transcription factor protein, electrophoretic mobility shift assays to measure transcription factor activation, and DNA footprinting to determine binding to recognition sequences in particular genes. Many transcription factors have now been identified and many are implicated in asthma and COPD. In the future, the genetic control of transcription factor expression may be an increasingly important aspect of research. This may be one of the critical mechanisms regulating expression of disease phenotypes and their responsiveness to therapy.

Activator Protein-1

AP-1 is a heterodimer of Fos and Jun oncoproteins, which is a member of the bZIP transcription family. It was originally described by binding to the TPA (tetradecanoylphorbol-13-acetate) response element (TRE) and responsible for the transcriptional activation of various genes that were activated by phorbol esters (such as tetradecanoyl acetate [TPA], also known as PMA) via activation of PKC.[189] AP-1 is a collection of related transcription factors belonging to the Fos (c-Fos, FosB, Fra1, Fra2) and Jun (c-Jun, JunB, JunD) families, which dimerize in various combinations through a region known as a "leucine zipper." AP-1 may be activated via PKC and by various cytokines, including TNF-α and IL-1β, via

several types of protein tyrosine kinase and mitogen-activated MAPKs. Jun N-terminal kinases (JNK) play a critical role in the regulation of cellular responsiveness to cytokine signals. There is increased expression of c-Fos in asthmatic airways. Certain signals rapidly increase the transcription of the *fos* gene, resulting in increased synthesis of Fos protein. Other signals lead to activation of kinases that phosphorylate c-Jun, resulting in increased activation.

Nuclear Factor-κB

NF-κB also plays an important role in the regulation several inducible inflammatory and immune genes, including iNOS, COX-2, TNF-α, IL-1β, GM-CSF, several chemokines, and adhesion molecules (Fig. 8-31).[190] NF-κB is present in the cytoplasm in an inactive form complexed to an inhibitory protein IκB. Specific kinases phosphorylate IκBe, resulting in its rapid degradation by a protease (proteasome), which reveals nuclear localization signals on NF-κB. NF-κB itself is made up of two subunits, usually a protein of 65 kDa (p65, Rel A), and a protein of 50 kDa (p50), which are members of the Rel family. Free NF-κB localizes to the nucleus, where it binds to a specific κB recognition elements on the promoter region of target genes. NF-κB may be activated by cytokines, such as TNF-α, phorbol esters, certain viruses (including rhinovirus), and oxidants. NF-κB is activated via a specific kinase IκB kinase-2 (IKK2), for which there are now small molecule inhibitors.[191] There is evidence for NF-κB activation in asthma and COPD[192,193] and many of the inflammatory genes activated in these diseases are regulated by NF-κB. Corticosteroids potently inhibit NF-κB–mediated gene transcription.

JAK-STAT

Several cytokines, including interferons and IL-6, activate specific cytosolic tyrosine kinases known as Janus kinases (JAK), of which several types have been recognized (Fig. 8-32).[194] Members of the JAK family include JAK1, JAK2, JAK3, TyK1, and TyK2 and may be differentially activated by different cytokines. Thus, IL-2 activates JAK1 and JAK3; IL-6 activates JAK1, JAK2, and JAK3; whereas IL-5 activates JAK2 only. JAKs then tyrosine phosphorylate a family of transcription factors known as signal transducers and activators of transcription (STATs).

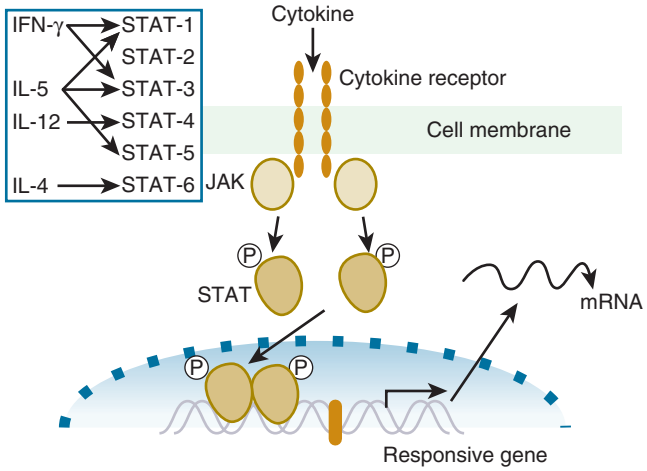

FIGURE 8-32 ■ JAK-STAT pathways. Cytokine binding to its receptor results in activation of Janus kinases (JAK), which phosphorylate (P) intracellular domains of the receptor, resulting in phosphorylation of signal transduction-activated transcription factors (STATs). Activated STATs dimerize and translocate to the nucleus where they bind to recognition elements on certain genes. IFNγ, interferon-γ; IL, interleukin.

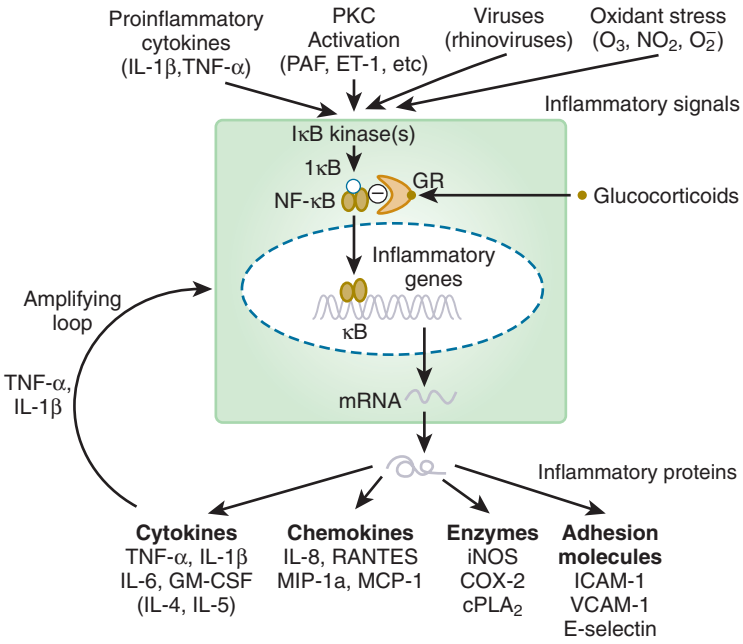

FIGURE 8-31 ■ Nuclear factor-κB (NF-κB) is activated by a variety of inflammatory signals, resulting in the coordinated expression of multiple inflammatory genes, including cytokines, chemokines, enzymes, and adhesion molecules. Activation of NF-κB by inhibitor if NF-κB (IκB) kinases leads to degradation of IκB and translocation of NF-κB to the nucleus where it binds to recognition sites (κB) in the promoter region of many inflammatory genes. The cytokines interleukin-1β (IL-1β) and tumor necrosis factor-α (TNF-α) both activate and are regulated by NF-κB and may act as an amplifying "feed-forward" loop. The actions of NF-κB are inhibited by glucocorticoids via activation of glucocorticoid receptors (GR). COX2, inducible cyclooxygenase; $cPLA_2$, inducible phospholipase A_2; ET-1, endothelin-1; GM-CSF, granulocyte-macrophage colony-stimulating factor; ICAM, intercellular adhesion molecule; IL, interleukin; iNOS, inducible nitric oxide synthase; MCP, macrophage chemotactic peptide; MIP, macrophage inflammatory protein; NO_2, nitrogen dioxide; O_2^-, superoxide anions; O_3, ozone; PAF, platelet-activating factor; PKC, protein kinase C; VCAM, vascular cell adhesion molecule.

STATs dimerize and then bind to response elements on promoter sequences to regulate the transcription of specific genes. Some STATs appear to be highly specific. Thus, STAT6 is activated only by IL-4 and IL-13, whereas STAT4 is activated only by IL-12.

GATA-3

GATA-3 plays a pivotal role in the differentiation of Th2 cells and the expression of the Th2 cytokine genes IL-4, IL-5, and IL-13.[195] It is mainly expressed in Th2 cells, and inhibition of GATA-3 using antisense oligonucleotides or dominant-negative mutants inhibits Th2 gene expression and eosinophilia in mice after allergen exposure. GATA-3 activation involves phosphorylation by p38 MAPK and its subsequent translocation to the nucleus.[196]

T-Bet

T-Bet plays a critical role in the differentiation of Th1 cells and in the secretion of IFN-γ, which suppresses Th2 cells.[197] There is a reduction in T-bet expression in asthma, which may predispose to increased Th2 cells.[198]

CREB

Increased concentrations of cAMP also result in the activation or inhibition of gene transcription. cAMP activates PKA, which phosphorylates a transcription factor (CREB), which binds to a CRE in the promoter region of certain genes.[199] CREB is a member of large family of CRE-binding proteins, including members of the adenosine triphosphate (ATF) family. CREB itself binds to another protein, CREB-binding protein (CBP), which binds several other transcription factors and acts as a coactivator molecule, which then leads to changes in chromatin structure and increased transcription. CREB appears to be important in the regulation of β_2-adrenoceptor expression; down-regulation of CREB activity may account for the reduced gene expression of β_2-adrenoceptors during chronic desensitization.

Glucocorticoid Receptors

GRs themselves are transcription factors that regulate the transcription of several steroid-responsive target genes. Glucocorticoids bind to GR in the cytoplasm, resulting in rapid nuclear localization of GR. GR binds to positive GREs, resulting in increased gene transcription (as in the case of β_2-receptors) or occasionally to negative GREs (as in the case of osteocalcin and IL-6).[74] As discussed previously, many of the anti-inflammatory effects of steroids may be due to interactions between GR and transcription factors, such as AP-1 and NF-κB, that have been activated by cytokines and that regulate the expression of several inducible genes. Although it was once believed that this was explained by a direct protein-protein interaction between GR and activated transcription factors, it is more likely that this is due to reversing the effects of these transcription factors on chromatic remodeling.[75] A small proportion of asthmatic patients are steroid-resistant and fail to respond to even high doses of oral steroids. This may be due to reduced nuclear localization of GR, to competition from activated transcription factors such as AP-1, or to abnormalities in histone acetylation patterns.[200,201]

Nuclear Factor of Activated T Cells

Nuclear factor of activated T cells (NFAT) is an example of a cell-specific transcription factor; it is largely confined to T lymphocytes. NFAT is of key importance in the regulation of the expression of IL-2 and other T-cell–derived cytokines, such as IL-4 and IL-5. Activation of T cells results in activation of calcineurin, which activates a preformed cytoplasmic NF-AT (NF-ATp). AP-1 forms a transcriptional complex with NF-AT to increase IL-2 gene expression.[202] This may be inhibited by cyclosporin A and tacrolimus (FK 506), which inhibit calcineurin, or by corticosteroids, which inhibit AP-1 directly.

Coactivators

Many transcription factors interact with large coactivator molecules, such as CBP and p300, which bind near the start site of transcription and regulate the activation of RNA polymerase II, which results in transcription of mRNA.[203] These coactivator molecules may therefore integrate the activity of several transcription factors and these may compete for binding on this molecule, resulting in negative interactions (termed "squelching"). CBP and other coactivators have intrinsic histone acetyltransferase (HAT) activity that results in the acetylation of core histones that is essential for opening up the chromatin structure and gene activation (Fig. 8-33).

Histone Modification

DNA is tightly wound around core histones in resting cells, and this configuration of the chromatin structure (DNA and associated proteins in the chromosome) is associated with gene repression or inactivation. Gene activation follows acetylation of these core histones by the HAT activity of coactivators. The consequent change in the charge on histone unwinds DNA, making it available to RNA polymerase and transcription factors, resulting in increased gene expression.[203] Increased expression of inflammatory genes that are activated by NF-κB is associated with acetylation of specific lysine residues of histone-4 (Fig. 8-34).[204] Histone acetylation is reversed by histone deacetylases (HDACs), which act as corepressors.[205] Corticosteroids switch off inflammatory genes activated by NF-κB and AP-1 by recruiting HDAC2 to the actively transcribing gene complex.[75] In asthma, there is an increase in HAT activity and a decrease in HDAC activity in bronchial biopsies.[206] In COPD, there is a marked reduction in HDAC2 activity, which may account for the corticosteroid resistance in this disease.[207] This may be secondary to oxidative stress and the formation of peroxynitrite, which result in activation of PI3K-δ and nitration of tyrosine residues on HDAC2 (Fig. 8-35).[200,208]

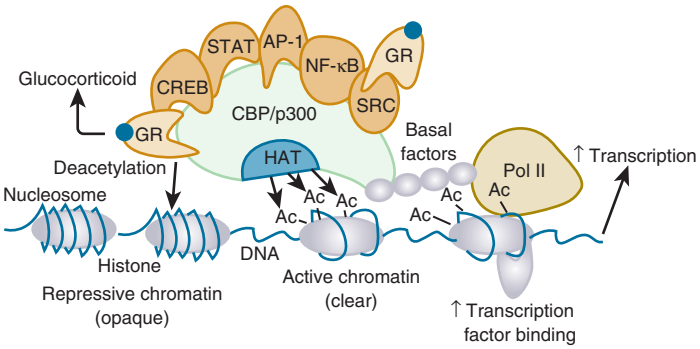

FIGURE 8-33 ■ Coactivator molecules. Multiple transcription factors bind to coactivator molecules, such as CREB-binding protein (CBP) or p300, which have intrinsic histone acetyltransferase (HAT) activity, resulting in acetylation (Ac) of histone proteins around which DNA is wound in the chromosome. This leads to unwinding of DNA, which allows increased access of transcription factors, thus resulting in increased gene transcription. Glucocorticoid receptors (GR), after activation by corticosteroids, bind to a steroid receptor coactivator that is bound to CBP. This results in deacetylation of histone, with increased coiling of DNA around histone, thus preventing transcription factor binding, leading to gene repression. AP-1, activator protein-1; CREB, cyclic adenosine monophosphate response element–binding protein; DNA, deoxyribonucleic acid; NF-κB, nuclear factor κB; Pol II, RNA polymerase II; SRC, steroid receptor coactivator molecule; STAT, signal transduction activated transcription factor.

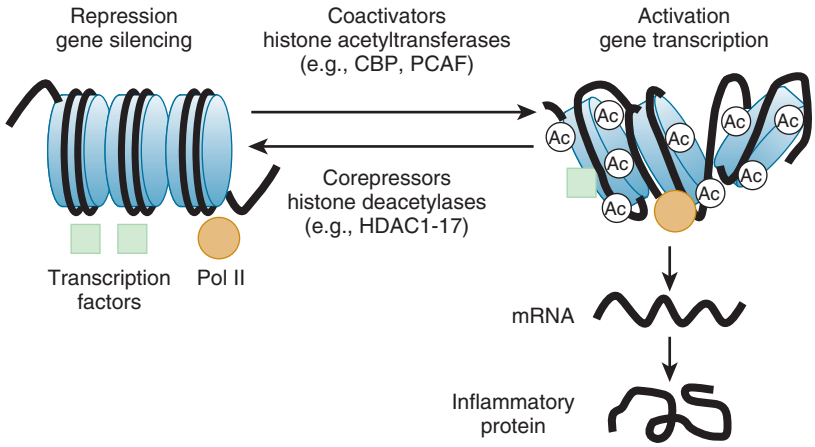

FIGURE 8-34 ■ Gene activation and repression are regulated by acetylation (Ac) of core histones. Histone acetylation is mediated by coactivators, which have intrinsic histone acetyltransferase activity, whereas repression is induced by histone deacetylases (HDACs), which reverse this acetylation. CBP, CREB-binding protein; PCAF, p300/CBP activating factor; Pol II, RNA polymerase II.

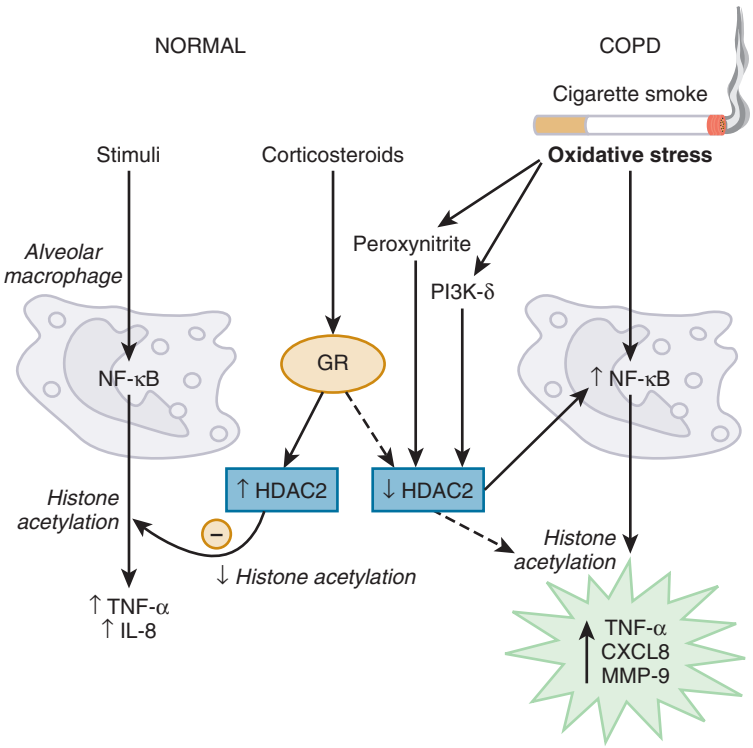

FIGURE 8-35 ■ Proposed mechanism of corticosteroid resistance in chronic obstructive pulmonary disease (COPD) patients. Stimulation of normal alveolar macrophages activates nuclear factor-κB (NF-κB) and other transcription factors to turn on histone acetyltransferase, leading to histone acetylation and subsequently to transcription of genes encoding inflammatory proteins, such as tumor necrosis factor-α (TNF-α) and CXCL8 (IL-8). Corticosteroids reverse this by binding to glucocorticoid receptors (GR) and recruiting histone deacetylase-2 (HDAC2). This reverses the histone acetylation induced by NF-κB and switches off the activated inflammatory genes. In COPD patients, cigarette smoke activates macrophages, as in normal subjects, but oxidative stress, acting through the formation of peroxynitrite and the activation of phosphoinositide-3-kinase-δ (PI3K-δ), impairs the activity of HDAC2. This amplifies the inflammatory response to NF-κB activation, but also reduces the anti-inflammatory effect of corticosteroids because HDAC2 is now unable to reverse histone acetylation.

Histones may also be modified by methylation, phosphorylation, and ubiquitination, resulting in short-term and long-term modification of chromatin structure that has a profound effect on gene expression. These epigenetic changes are increasingly recognized to be important in driving the chronicity of inflammatory diseases, such as asthma and COPD.[209] Methylation of DNA plays an important role in long-term gene suppression and is thought to be of critical importance in lung cancer where tumor suppressor genes are commonly inactivated.[210]

KEY POINTS

- Respiratory pharmacology is concerned with understanding the mechanism of action and use of drugs used to treat respiratory diseases and with the use of pharmacologic methods to elucidate pathophysiologic mechanisms of these diseases.
- Multiple receptors on or inside pulmonary cells respond to multiple external stimuli to mediate their functional effects, and these receptors are important current and future targets for drug therapy.
- The structure, coupling, signaling pathways, and interactions of these receptors provide important insights into the mechanism of action of respiratory drugs and disease mechanisms.
- Multiple interacting signal transduction pathways, including kinases and phosphatases, have now been identified in pulmonary cells.
- Transcription factors play a key role in the regulation of gene expression in pulmonary cells and have provided novel targets for the development of new drugs.
- Pulmonary pharmacology deals with the absorption, metabolism, distribution, and excretion of drugs, and there is particular emphasis in understanding the inhaled route of delivery.

Proposed Surfactant Treatment Strategies

INTRODUCTION

Pulmonary surface-active material (surfactant) allows one to breathe effortlessly. Without surfactant, the work of breathing increases markedly and respiratory distress develops rapidly. In the absence of surfactant, the work of breathing may increase from less than 2% to more than 10% of total oxygen consumption. Surfactant provides the low surface tension at the air-liquid interface that is necessary to prevent atelectasis, alveolar flooding, and severe hypoxia. A complex but highly regulated process has evolved for the synthesis, secretion, and reutilization of surface-active material. Metabolism of surfactant includes synthesis, intracellular transport, packaging of phospholipids and proteins into lamellar bodies, exocytosis, absorption to the air-liquid interface, physical separation of the surfactant components during compression at the air-liquid interface, clearance or uptake of extracellular surfactant by type II cells, intracellular processing of recycled surfactant components from alveolar fluid, and finally, secretion of recycled material. Theoretically, any of these steps could be altered in disease and lead to gas-exchange abnormalities.

The most important step in this dynamic process is the rapid adsorption of phospholipids into the air-liquid interface, and this adsorption requires the surfactant-associated proteins, especially B (SP-B). Surfactant proteins are critical for the intracellular and extracellular macromolecular organization of the phospholipids. With each breath and respiratory cycle, there is a significant swing in surface tension that squeezes some constituents from the monolayer at low lung volumes (i.e., high surface pressure) and allows others to adsorb to the air-liquid interface at high lung volumes (i.e., low surface pressure). Humans breathe about 12 times a minute, which allows a few seconds for adsorption. However, smaller species such as mice breathe about 350 times a minute and require extremely rapid rates of adsorption. Because of the duration of the respiratory cycle, it is possible that the regulation of adsorption and the role of specific surfactant components could be different in large and small animals. In addition to its well-recognized property of providing alveolar stability, surfactant is also important for maintaining the patency of small airways and preventing alveolar flooding. The critical component of surfactant that provides the low surface tension

is dipalmitoylphosphatidylcholine (DPPC). This is an unusual species of phosphatidylcholine in that both of the fatty acids at the sn-1 and sn-2 positions are saturated. DPPC molecules can pack closely together and allow the surface monolayer to withstand the high film pressures required to produce a low surface tension at low lung volumes. This chapter reviews the physiologic function of surfactant, its important components, its metabolism, its alterations in disease, and its use in replacement therapy in the treatment of hypoxic respiratory failure (newborn respiratory distress syndrome [NRDS] and acute respiratory distress syndrome [ARDS]). Additional discussion of ARDS can be found in Chapters 90 and 91. Finally, we also discuss SP-A and SP-D as important components of innate immunity and host defense.[1]

PHYSIOLOGIC FUNCTIONS OF PULMONARY SURFACTANT

The discovery of pulmonary surfactant came from direct physiologic observation and an understanding of the Laplace relationship for calculating surface tension. In 1929, von Neergaard[2] discovered that there was a marked difference in the elastic recoil properties of the lung depending on whether the lung was filled with air or saline. It takes more pressure to inflate the lungs with air than with saline (Fig. 9-1). From these observations, von Neergaard[2] deduced that the surface tension in the lung was extremely low. Clements[3] and Pattle[4] independently demonstrated that extracts of lung-lowered surface tension and the phospholipids of surfactant were responsible for lowering surface tension. Soon after this discovery, Avery and Mead[5] demonstrated that a deficiency in surface-active material caused NRDS. During a cycle of inflation and deflation with air, there is hysteresis such that as the lungs are inflated, a greater pressure is required at any given lung volume than during deflation. During inflation, surfactant must be absorbed into the surface. During deflation, as the surface area decreases, the film pressure rises and the surface tension falls, and the phospholipid molecules already present in the air-liquid interface get packed closely together. High film pressures are generated on exhaling to low lung volumes, and some components of the film such as unsaturated phospholipids and the surfactant proteins are squeezed out of the monolayer. The surface film generated at low lung volumes is thought to be composed of nearly pure (95%) DPPC. Epifluorescence studies with hydrophilic markers have shown that as the film is compressed, there are areas from which aqueous markers are excluded. Fixation of the lung with osmium vapors has shown that some of the alveolar surface is covered with multilayers of phospholipids, which serve as a reservoir of surfactant to enter the film at high lung volumes (low surface pressures). These multilayers are thought to be a ready source of surfactant when the lung expands during inspiration.[5a]

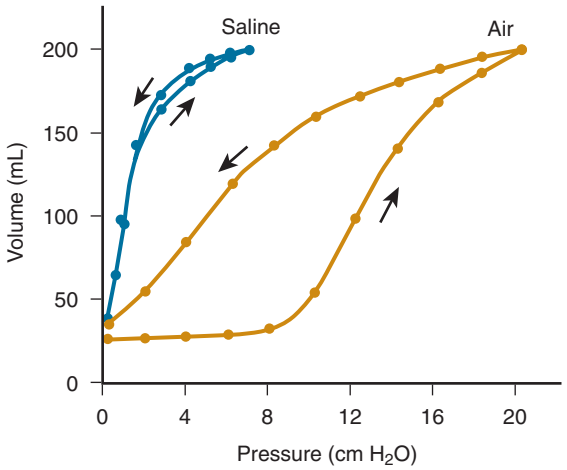

FIGURE 9-1 ■ Air and saline volume-pressure curves. This figure depicts the classic physiologic observation that led to the discovery of surfactant. It takes more pressure to inflate the lung with air than with saline. However, the pressure difference is much less than would be expected if the alveolar lining had the same surface tension as other biologic fluids. The surface tension in the alveoli that is calculated on the basis of the Laplace relationship and known alveolar dimensions is extremely low. The descending limb of the air volume-pressure curve is very reproducible and is used to estimate the surface tension of the lung and static compliance. (Adapted from Radford EP Jr: Recent studies of mechanical properties of mammalian lungs. In Remington JW [ed]: Tissue Elasticity. Washington, DC: American Physiological Society, 1957, pp 177–190.)

There are four surfactant-associated proteins, each of which has different functions. SP-A, SP-B, and SP-C were isolated from preparations of surface-active material obtained by lavage, whereas SP-D was identified in the search for extracellular matrix proteins secreted by type II cells. From in vitro studies on film formation, it became clear that SP-A, SP-B, and SP-C could increase the rate of delivery of phospholipids to the air-liquid interface. DPPC by itself has an extremely low rate of adsorption. SP-A and SP-B were found to be necessary for the formation of tubular myelin (Fig. 9-2).[6] Tubular myelin is a unique extracellular form of surfactant in which an organized lattice of surfactant bilayers is formed; these bilayers appear to have right angles in both transmission electron micrographs and freeze fracture images. Tubular myelin is the physical form of surfactant intermediate between the lamellar body that is secreted and the surface monolayer. Tubular myelin is a major component of large-aggregate surfactant, the form that sediments rapidly on centrifugation and is very surface-active. However, because SP-A–deficient mice lack tubular myelin and have normal respiratory mechanics, the formation of tubular myelin is not absolutely necessary for surfactant function.[7]

The major physiologic functions of surfactant are to lower surface tension and provide alveolar stability, but surfactant has other functions as well. Surfactant prevents alveolar flooding. A high surface tension would tend to draw fluid from the interstitium into the alveolar space. Surfactant is also important for maintaining the patency and stabilization of small airways.[8] Studies in narrow fluid-filled tubes have demonstrated the critical importance of low surface tension and the need for added surfactant to reduce opening pressures. For this reason, surfactant is important in asthma, constrictive

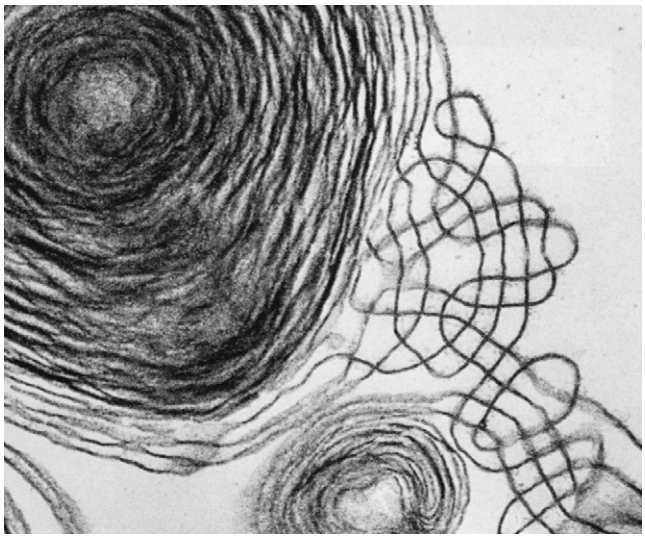

FIGURE 9-2 ■ Tubular myelin. Pulmonary surfactant forms a unique three-dimensional structure composed of phospholipids and the surfactant proteins SP-A, SP-B, and presumably SP-C. Tubular myelin is found only extracellularly and is thought to represent a reservoir of surfactant that can rapidly adsorb to the air-liquid interface. Tubular myelin is isolated as a component of large aggregate surfactant, which is the fraction that sediments readily and is most surface active. (Electron micrograph courtesy of Mary Williams, Boston University.)

bronchiolitis, and other diseases of small airways. Finally, there is also compelling evidence that SP-A and SP-D play important roles in host defense.[9,10]

TABLE 9-1. Composition of Pulmonary Surfactant

Phospholipids: 85%*	**% of Phospholipids**
Phosphatidylcholine	76.3
Dipalmitoylphosphatidylcholine	47.0
Unsaturated phosphatidylcholine	29.3
Phosphatidylglycerol	11.6

Phosphatidylethanolamine	3.3
Sphingomyelin	1.5
Other	3.4
Neutral Lipids: 5%†	
Cholesterol, free fatty acids	
Proteins: 10%‡	
SP-A	
SP-B	
SP-C	
SP-D	
Other	

*The phospholipid composition is constant in most mammalian species. Disaturated phosphatidylcholine represents about two thirds of the total phosphatidylcholine. Dipalmitoylphosphatidylcholine makes up the majority species of the disaturated phosphatidylcholine fraction and is the critical molecule for providing the low surface tension.
†There is about 5% neutral lipid, of which the majority is cholesterol and free fatty acids. There is relatively little triglyceride and cholesterol ester.
‡The composition of the surfactant proteins is not known precisely, but on a mass basis, there appears to be more SP-A than SP-D and more SP-A than SP-B and SP-C.

COMPOSITION

Lipids

The critical components of purified lipids are DPPC, unsaturated phosphatidylcholine, phosphatidylglycerol, and the surfactant proteins (Table 9-1).[11] The quantity of saturated phosphatidylcholine is related to the alveolar surface area in a variety of species, and phosphatidylcholine is the dominant chemical constituent present in the surface film at low surface tension.[12] Phosphatidylglycerol is an anionic phospholipid that is thought to be important in the electrostatic and calcium-dependent interactions with the surfactant proteins. A reduction in the percentage of phosphatidylglycerol is the earliest and most sensitive alteration in the composition of surfactant in lung injury. However, the function of phosphatidylglycerol can be replaced by phosphatidylinositol without detectable physiologic consequences in terms of surfactant function.

Proteins

The surfactant proteins can be divided into two distinct groups: the hydrophilic proteins, SP-A and SP-D, and the hydrophobic proteins, SP-B and SP-C. SP-A and SP-D are collagenous glycoproteins that function as calcium-dependent lectins, and for this reasons, these proteins are referred to as *collectins* (Fig. 9-3).

SP-A and SP-D are important components of innate immunity and are not thought to be critical to surfactant function.[10,13–15] The SP-A–deficient mouse has normal lung function, but increased susceptibility to a variety of infectious agents. As described in more detail later, SP-D binds surfactant phospholipids poorly, is found mainly in the lipid-free supernatant, and should not be considered as an integral surfactant protein for physiologic considerations. Both SP-A and SP-D are very important in host defense and are broad-range pattern recognition molecules. Both of these proteins bind to many of the same microorganisms, help clear microbes from the alveolar compartment, and interact with immune effector cells. SP-C and SP-B are important physiologic components of natural surfactant.[16] These proteins are extremely hydrophobic and are intimately involved in the trafficking of phospholipids, stacking of phospholipids in the lamellar body, and the formation and maintenance of the surface monolayer. SP-B is critical for film formation (adsorption) from vesicular lipids, for formation of tubular myelin (a major reservoir of extracellular surfactant), for removing liquid-phase lipids from the monolayer, and for enriching the monolayer in gel-phase phospholipids (DPPC).[17] These aspects of SP-B function are facilitated by interactions with anionic phospholipids, especially phosphatidylglycerol, and are enhanced by SP-A. SP-C is also involved in film formation and creation of the surface reservoir of surfactant lipids, but its effects are not facilitated by SP-A. The precise

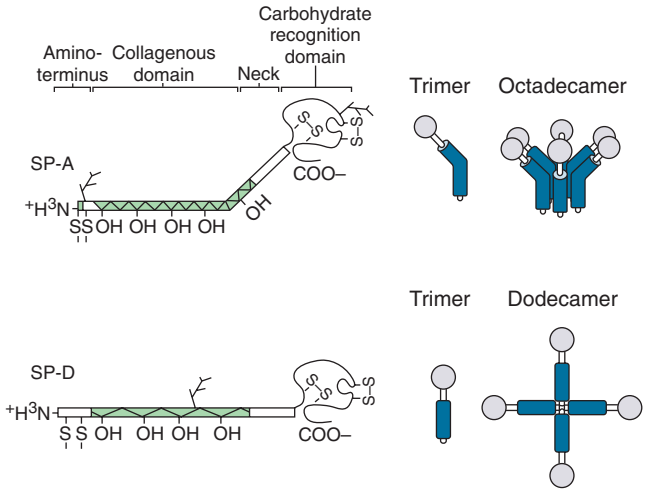

FIGURE 9-3 ■ Structural organization of surfactant proteins A and D (SP-A and SP-D). SP-A and SP-D are collagenous glycoproteins with four important domains. The N-terminal region contains cysteines for intermolecular disulfide bonding to form covalent oligomeric units and has one of the N-linked oligosaccharides in SP-A. The collagen-like domain imparts structural rigidity and elongated molecular structure to both proteins. In SP-A, the collagen region has a kink, which accounts for the bend in the collagen region and the bouquet-like structure of the oligomer. In SP-D, the collagen domain is straight and contains the only N-linked carbohydrate. The neck contributes to the trimeric assembly of polypeptide subunits and spacing for the terminal carbohydrate recognition domain (CRD). The CRD is a globular region of the molecule that plays a major role in the recognition of multiple ligands. In SP-A, the CRD accounts for most of the binding to dipalmitoylphosphatidylcholine vesicles, type II cells, macrophages, and inhaled organisms. The N-linked carbohydrate of SP-A is important for binding to certain microbes, such as influenza virus. In SP-D, the CRD unit is responsible for all the reported interactions with viruses and bacteria. (Adapted from Kuroki Y, Voelker DR: Pulmonary surfactant proteins. J Biol Chem 269:25943–25946, 1994.)

topography of SP-C in the fluid phase of the monolayer and surface-associated bilayers is not known precisely. In mice, a deficiency in SP-B causes a severe respiratory insufficiency and gas-exchange abnormalities, whereas a deficiency in SP-C is not critical for surfactant function. However, SP-C deficiency can lead to chronic inflammatory interstitial lung disease in certain murine strains. SP-B is the one surfactant protein that is critical for surfactant function.

Surfactant Protein A

SP-A was the first surfactant protein identified by its association with surfactant phospholipids. SP-A is a large octadecameric protein with a molecular mass of about 650 kDa.[18] Early studies focused on the role of SP-A in surfactant homeostasis in vitro. The functions of SP-A in vitro include lipid binding and formation of tubular myelin, acceleration of the adsorption of surfactant to the air-liquid interface, and inhibition of surfactant secretion. However, the physiologic importance of these in vitro observations on surfactant regulation has been seriously questioned, because the SP-A–deficient mouse has normal surfactant function.[7,19] Nevertheless, the clearance of surfactant has been reported to be decreased in SP-A–null mice.[20] SP-A binds surfactant phospholipids avidly, especially DPPC, and is critical for the formation of tubular myelin.[6] Over 99% of SP-A in lavage fluid is bound to phospholipid. The current estimate for the concentration of SP-A in rat alveolar lining fluid is 360 μg/mL of total SP-A and 4 to 11 μg/mL of free SP-A.[21] In normal human volunteers, the concentration of total SP-A in alveolar fluid has been calculated to be 180 μg/mL.[22] SP-A may also be important for the function of surfactant during acute lung injury, when a variety of serum factors can inhibit sufactant function, and these effects are partially inhibited by SP-A. However, as demonstrated by the SP-A knockout mouse, SP-A is not essential for normal metabolism and processing of surfactant in vivo.[19]

The major function of SP-A appears to be in innate immunity, in which SP-A binds to a variety of microorganisms, promotes their clearance by phagocytic cells, and directly alters the function of immune effector cells.[9] SP-A like SP-D is a multivalent pattern-recognition molecule and binds to a wide variety of glycoproteins and other ligands. The binding is somewhat promiscuous, has a low affinity, and physiologic effects are likely due to the polyvalent structure of SP-A and the multiple binding sites on cells and organisms. Nevertheless, several putative receptors for SP-A have been identified.[14,23,24] One of the newer functions of SP-A is to serve as a fetal hormone of parturition. Mendelson and colleagues[25] have suggested that the fetal lung secretes SP-A, which activates fetal macrophages that migrate to the uterine wall where they produce IL-1β and initiate labor.

SP-A is localized primarily to the gas-exchange units of the lung and small airways. In rodents, SP-A is found alveolar type II cells and also in nonciliated bronchiolar cells that line the conducting airways. In humans, almost all the SP-A is found in the alveoli, and very little is found in the respiratory epithelium that lines the conducting airways. However, there is SP-A in human tracheal submucosal glands and low-level expression in some nonpulmonary tissues.

Synthesis and Secretion

The gene for SP-A is located on chromosome 10 very near the closely related proteins SP-D and mannose-binding lectin. Humans have two genes for SP-A, which code for proteins with minor amino acid alterations in the collagen domain.[26,26a] Newly synthesized SP-A undergoes a variety of posttranslational modifications that include proteolytic removal of the signal peptide, addition of N-linked carbohydrates, sialylation, acetylation, and sulfation. A number of factors have been reported to increase the synthesis of SP-A, including cyclic adenosine monophosphate (cAMP), keratinocyte growth factor (KGF), and interleukin (IL)-1. Corticosteroids produce a biphasic dose-response with stimulation at low concentrations and inhibition at high concentrations.

Secretion of SP-A from type II cells occurs by two different routes. The dominant route is by direct constitutive secretion independent of lamellar body exocytosis.[27,28] In addition, there is regulated secretion associated with lamellar bodies, in as much as some SP-A is contained within lamellar bodies. Newly synthesized SP-A is secreted directly, and the SP-A found in lamellar bodies is probably derived from recycled SP-A. Most of the intracellular form of SP-A is not heavily glycosylated.

Structure and Function

SP-A is a collagenous glycoprotein with a complex, highly ordered tertiary structure (see Fig. 9-3). The overall organizational structure of SP-A is very similar to serum mannose-binding lectin (MBL) and the complement component C1q. These molecules form a polarized bouquet-like structure composed of 18 monomers that are organized as six trimeric units. The structural domains for several of the properties of SP-A have been determined. As shown in Figure 9-3, the N-terminal cysteines are important in the formation of covalent intermolecular cross-links that stabilize the higher-ordered oligomers. The collagenous region plays a prominent role in the trimerization of monomeric forms of SP-A. The kink in the collagenous portion is due to an additional amino acid that interrupts the gly-X-Y repeats typical of collagen-like domains. The rigid collagenous region provides the overall bouquet-like structure to SP-A. The neck region forms a coiled coil motif and is important for maintaining the structure and stability of the terminal carbohydrate recognition domain (CRD). The C-terminal CRD unit is critical for most SP-A functions and consists of a globular domain that binds carbohydrate and other ligands recognized by SP-A. The structure of the CRD unit is highly conserved in this class of calcium-dependent lectins. The macromolecular structure of SP-A is 20 nm from the N-terminal to the C-terminal CRD unit and across the array of CRD units. Although the carbohydrate moieties of SP-A are not essential for many of its activities, these are the sites for binding to influenza and herpes simplex type 1 virus. The most important details about protein structure come from its crystal structure, which revealed a hydrophobic-binding pocket in the CRD that likely accounts for lipid-binding properties of SP-A.[29]

The relatively normal physiology of mice with genetic deletion of SP-A was unexpected. The observation that surfactant was normal in the SP-A deficient mice was unanticipated in view of the documented effects of SP-A in vitro.[7] However, these SP-A–deficient mice demonstrated the importance of SP-A in host defense for viral and bacterial pathogens. SP-A–deficient mice are more susceptible to infection by group B *Streptococcus*, *Pseudomonas aeruginosa*, *Haemophilus influenza*, respiratory syncytial virus, and *Pneumocystis carinii*.

Binding to Infectious Organisms

SP-A binds to a variety of microorganisms, including viruses, bacteria, mycobacteria, fungi, and *Pneumocystis*.[30] Most of the binding of SP-A to microbial surfaces occurs via the CRD portion of SP-A. These interactions are calcium dependent and inhibited by sugars such as mannose. It has been proposed that SP-A associated with tubular myelin is one of the first barriers for host protection; multivalent SP-A could bind both surfactant lipid in alveolar fluid and inhaled organisms or particles.[31] This might protect the lung from infection and aggregate inhaled particles and microbes to facilitate clearance.

Viruses. SP-A binds influenza, herpes simplex, respiratory syncytial virus, and presumably many more respiratory viruses. SP-A binds influenza and inhibits hemagglutination and infection, although the effect is not as dramatic as with SP-D. SP-A binds to influenza by the terminal sialic acid residues on the N-linked carbohydrate of SP-A. Thus, carbohydrate moieties on both microorganisms and SP-A play a role in the process by which SP-A interacts with pathogens. The SP-A–deficient mouse demonstrates a role for SP-A in respiratory viral infections and its importance in host defense.[32,33]

Bacteria. SP-A binds to both gram-positive and gram-negative bacteria and is thought to be an important component of host defense. SP-A binds to and increases phagocytosis of *Streptococcus pneumoniae,* group A *Streptococcus*, and *Staphylococcus aureus*. SP-A stimulates phagocytosis of opsonized *S. aureus*, but the effect is dependent on the growth conditions of the organism and thereby the chemical composition of their external coat. More recently, SP-A has been reported to bind to peptidoglycan, an important component of the cell wall of gram-positive bacteria. Hence, SP-A may be an important host-defense molecule for gram-positive organisms.

SP-A binds gram-negative bacteria with the rough form of lipopolysaccharide (LPS), aggregates these bacteria, and increases phagocytosis and killing.[34,35] SP-A binds to the smooth variants of *Escherichia coli* poorly. Gram-negative bacteria that colonize the respiratory tract usually display the smooth form of LPS, whereas those that colonize the gastrointestinal tract display rough forms of LPS. SP-A binds the lipid A moiety and not the oligosaccharides of LPS, which is the ligand for SP-D. In addition, isolated SP-A binds to and increases the phagocytosis of *H. influenzae*, *Klebsiella,* and *P. aeruginosa*.[36] In addition, Wu and coworkers[34] demonstrated that SP-A and SP-D could directly kill gram-negative bacteria by increasing their membrane permeability.

Mycobacteria, Fungi, Mycoplasma, and *Pneumocystis.* SP-A enhances the adherence and subsequent phagocytosis of mycobacteria by macrophages. This effect has been attributed to an interaction between the N-linked carbohydrate on SP-A and macrophages and is thought to be due to increased surface expression of the mannose receptor on macrophages.[37] Lipoglycans, especially mannosylated lipoarabinomannan, are important ligands for SP-A on mycobacteria. Weikert and associates[38] reported that SP-A increased the binding and phagocytosis of mycobacteria by rat macrophages and human monocytes and that this interaction occurred through a specific 210-kDa SP-A receptor. In other studies, several different putative SP-A receptors on

macrophages have been described, and these receptors include Toll-like receptor 2 (TLR2), CD14, calreticulin, C1qRp, and signal-inhibitory regulatory protein α (SIRPα) as well as the 210-kDa receptor.[9] The increased phagocytosis of mycobacteria by SP-A may facilitate some killing but also allows mycobacteria to escape to an intracellular replicative environment.

SP-A is also important in host defense against fungal infections, especially *Histoplasma* and *Aspergillus*. Madan and colleagues[39] reported that human SP-A bound to *Aspergillus fumigatus* conidia and enhanced their phagocytosis and killing by human neutrophils and alveolar macrophages. McCormack and coworkers[40] reported that SP-A could directly kill extracellular, but not intracellular, *Histoplasma*. There is no convincing evidence for SP-A in the clearance of fully encapsulated *Cryptococcus neoformans* or *Candida albicans*. SP-A also binds to and inhibits the growth of mycoplasma, although the role of SP-A in clearance and killing of mycoplasma appears to be modest.

SP-A binds to gp120, the major surface glycoprotein of *P. carinii*, but does not clear the infection. Although SP-A binds and stimulates adherence of fully encapsulated *Pneumocystis* to macrophages, SP-A does not enhance phagocytosis by macrophages. Pneumocystis can persist extracellularly in the alveolar space for a long time in the presence of physiologic levels of SP-A.

Interaction with Phagocytic Cells

SP-A has been reported to bind to several receptors on macrophages and to modulate the expression of microcidal factors and TLR2 and 4 and the clearance of apoptotic cells.[9,41,42,42a] The binding of SP-A to alveolar macrophages appears to be specific and not seen with other mononuclear phagocytes as Kupffer cells, resident peritoneal macrophages, or peritoneal macrophages.[43,44] Some have cautioned that the stimulation of inducible nitric oxide synthase (iNOS) and nitric oxide (NO) production in early experiments could be due to endotoxin contamination in the SP-A and SP-D preparations.[45] The studies on direct activation of inflammatory cells is complex and their results depend on the method of SP-A isolation and the state of the inflammatory cells, especially if they have been primed by a cytokine such as interferon gamma. In addition, it is important for in vitro studies to evaluate the effect of SP-A in the presence of surfactant phospholipids to stimulate the in vivo situation, since SP-A may bind surfactant phospholipids with a higher affinity than microbes or inflammatory cells. Many of the effects of isolated SP-A do not occur if the experiments are done in the presence of surfactant phospholipids. Finally, transforming growth factor-β (TGF-β) has also been reported in some preparations of SP-A, which could account for some anti-inflammatory properties.[46]

SP-A appears to suppress the secretion of inflammatory cytokines by macrophages in the normal lung but enhances cytokine production during infection or lung injury. This is sometimes referred to as the inflammatory paradox of SP-A. Gardai and associates[47] formulated an interesting mechanism for these observations. In the normal lung, SP-A interacts with macrophages through its CRD domain and binds to SIRP-α, which in turn suppresses cytokine production. However, during infection, SP-A binds the organism with its CRD domain and interacts with macrophages via its N-terminal domain and the calreticulin/CD91 complex to stimulate the production of inflammatory cytokines. Hence, SP-A can both stimulate and inhibit inflammatory cytokine production in vitro. It is important to recall that in vivo, there is a complex interaction between SP-A, the phospholipids of surfactant, inhaled microbes, and receptors on inflammatory cells. Each has a different binding affinity for SP-A and independent regulation.

SP-A has also been shown to bind to apoptotic cells and to increase their uptake and removal by macrophages.[41] Uptake proceeds through a common receptor complex involving calreticulin and CD91, which is also involved in the uptake of apoptotic cells mediated by C1q or mannose-binding lectin.[41] However, SP-A appears to be less important than SP-D in clearance of apoptotic cells in vivo.

Surfactant Protein B

SP-B is the one surfactant protein that has been demonstrated to be crucial for surfactant function and is thought to be critical in the adsorption and surface spreading of phospholipids.[16,48,49] Mice with homozygous null alleles for SP-B die of respiratory insufficiency shortly after birth, and heterozygotes have impaired surfactant function. SP-B is required for organizing phospholipids in lamellar bodies, for the formation of tubular myelin, and for delivering phospholipids to the alveolar air-liquid interface. SP-B is thought to be important in film formation and in entry of phospholipids into the surface monolayer, when the film is expanded during inspiration. The five amphipathic helices of SP-B are envisioned to lie along the lipid bilayer or surface monolayer.[48] SP-B interacts with phospholipid bilayers by electrostatic interactions between the polar head groups of the phospholipids and its positively charged amino acids and through the nonpolar faces of the amphipathic helices that interact with the phospholipid acyl chains. SP-B is positively charged and has a preference for interacting with negatively charged phospholipids, such as phosphatidylglycerol. This surfactant protein is squeezed out of the monolayer at moderate film pressures (40–45 mN/m) and does not insert directly into the monolayer or lipid bilayers. SP-B can convert lipid vesicles into phospholipid sheets and is likely to be very important in moving lipid into the monolayer with each respiratory cycle.

Mature SP-B is a homodimer composed of two 79–amino acid polypeptide chains linked by disulfide bonds. The monomer has an expected mass of 8.7 kDa and the homodimer, 17.4 kDa. Each monomer has five amphipathic helices that interact with the surface of the monolayer but do not span the monolayer. There are three internal disulfide bridges within the monomer (C8–C17, C11–C71, and C35–C46) and an interchain disulfide at

C48. SP-B is a member of the family of saposin-like proteins that perturb phospholipid bilayers.

As demonstrated in congenital SP-B deficiency in infants and in genetically altered mice, highly structured lamellar bodies do not form in the absence of SP-B.[50,51] In SP-B deficiency, there is also aberrant processing of SP-C that results in the secretion of a partially processed 12-kDa form of SP-C. The SP-B knockout mouse has severe respiratory deficiency at birth, and heterozygotes have impaired surfactant function and susceptibility to lung injury.[50,51] Lamellar body formation may depend on the ability of SP-B to organize and bind with two adjacent lipid bilayers. Secretion of SP-B occurs exclusively as a component of lamellar bodies. In genetically targeted mice with conditional expression of SP-B, reduction of SP-B below 25% of the wild-type level results in respiratory failure.[49] SP-B is found in natural surfactant preparations, although the content may vary from batch to batch and may differ from that found in surfactant isolated from normal animals. SP-B is also found in Clara cells, but the function of SP-B associated with Clara cells is not known.

There is one gene for SP-B that is located on human chromosome 2. The synthesis of SP-B is markedly stimulated by corticosteroids in vitro. This protein undergoes extensive intracellular processing before the mature homodimer is formed. Within the endoplasmic reticulum (ER), the signal peptide is cleaved, and a prepro 42-kd species of SP-B is formed. In multivesicular bodies, general additional proteolytic cleavages occur to remove a 16-kDa amino terminal peptide and a 30-kDa C-terminal peptide. The final processing of SP-B probably occurs within the multivesicular bodies, and the mature homodimer is formed by the time SP-B arrives in the lamellar body.

Surfactant Protein C

SP-C is an extremely hydrophobic protein that is unique to surfactant and alveolar type II cells.[52,53] SP-C is expressed only in the lung and is a highly specific marker for identifying type II cells. However, the precise physiologic function of this protein is not completely understood. The fully processed form of SP-C is a 35–amino acid lipopeptide that has two palmitates attached as thioesters at amino acids C5 and C6. The segment between residues 13 and 28 forms a very hydrophobic α-helix containing aliphatic amino acids, mainly valine. This α-helix is the membrane-spanning portion of SP-C and is extremely stable. In most species, there are two positively charged amino acids, lysine at position 11 and arginine at position 12, which appear to be necessary to move the protein from the ER into the Golgi network, where the palmitoylation occurs. The precise orientation of the palmitates relative to the valine-rich α-helix is not fully resolved, but both regions are probably important for interactions with phospholipid bilayers or monolayers. SP-C can mix with phospholipids and promote spreading and fusion of phospholipids. SP-C inserts into the monolayer and is squeezed out of the surface monolayer only at relatively high film pressures (>55 mN/m). Presumably, SP-C is important in organizing the phospholipids during the respiratory cycle. SP-C is thought to stabilize the surface film and minimize film collapse. Unlike SP-B, SP-C does not appear to interact with SP-A and is not critical for the formation of tubular myelin. SP-C is found in all preparations of natural surfactant, and a recombinant form of SP-C is used in one type of surfactant replacement therapy.

There is one human gene for SP-C that is located on human chromosome 8. Like SP-B, SP-C is synthesized as a larger prepro form of 21 kDa and processed by proteolytic cleavage of both N-terminal and C-terminal fragments. Most of the posttranslational processing occurs before SP-C arrives at the lamellar body. There is apparently some interaction between the processing of SP-B and SP-C, because in hereditary deficiency of SP-B, an aberrantly processed 12-kDa form of pro SP-C accumulates in type II cells and in alveolar fluid. The SP-C promoter has been an important tool for overexpressing a variety of transgenes in type II cells in mice.

The physiologic role of SP-C is still not completely known. In outbred Swiss black mice, SP-C–null mice appear normal until about 6 months of age, at which time they developed chronic pneumonitis and air space enlargement.[54] This demonstrates that SP-C is not absolutely necessary for surfactant function. However, in the 129J strain, mice develop chronic pneumonitis within 3 months.[55] The genetic background and disease-modifying genes are, therefore, likely involved in clinical manifestations of SP-C deficiency and mutations. These observations provide the background for investigating genetic variants in SP-C as a cause of idiopathic interstitial lung diseases, which is discussed later. SP-C mutations produce a misfolded protein that accumulates and causes ER stress in type II cells and chronic interstitial lung disease.

Surfactant Protein D

SP-D is a calcium-dependent lectin and an important component of innate immunity.[9,56–58] Recombinant SP-D has even been proposed as a therapeutic agent in the treatment of pulmonary infections. The gene for SP-D is near the locus of SP-A on human chromosome 10. SP-D is a collagenous glycoprotein with a complex but highly ordered tertiary structure (see Fig. 9-3). Identical monomers of SP-D assemble as trimers and then combine to form the final dodecamer. This produces a large symmetrical cruciform-shaped molecule with a distance of about 100 nm between the terminal CRDs, about five times larger than SP-A. The CRD unit is primarily responsible for binding to surface ligands on microorganisms and provides for the multivalency of the oligomers.

Conceptually, SP-D should be thought of as a protein distinct from the surfactant system. SP-D binds the phospholipids of surface-active material weakly and is mostly soluble in alveolar fluid. However, SP-D does bind two lipids with carbohydrate motifs, phosphatidylinositol and glucosylceramide, but not phosphatidylcholine. The location of SP-D in the lung also suggests that it is not directly involved with the surfactant system. SP-D is

found in ER of type II cells and in the secretory granules of Clara or nonciliated bronchiolar cells but not in lamellar bodies of type II cells or in tubular myelin. Like SP-A, SP-D is highly expressed in conducting airways of rodents but sparsely in the major conducting airways in humans. SP-D is highly expressed in the hyperplastic type II cells present in interstitial lung diseases. SP-D is also present on many other mucosal surfaces.[59]

The phenotype of the SP-D knockout mouse was unexpected from prior in vitro studies. The knockout mouse shows an increase in the extracellular pools of surfactant and an accumulation of large foamy macrophages with excess metalloprotease activity, which results in alveolar wall destruction and subsequent air space enlargement.[60] The implications are that SP-D regulates macrophage function and that an absence of SP-D leads to a reduced clearance of surfactant. SP-D–deficient mice are also susceptible to infection with influenza A virus and *Aspergillus*. In addition, a large number of apoptotic cells are found in the air spaces and lavage fluid of SP-D–null mice, indicating the importance of SP-D in the clearance of apoptotic cells.

Structure and Function

The overall structure of SP-D is similar to that of SP-A, and the primary structure consists of four domains (see Fig. 9-3). The amino terminal segment contains cysteines that form interchain disulfide bonds that cross-link subunits to form covalent oligomeric structures. The adjacent collagen-like region promotes the formation of noncovalent trimers, imparts a rigid longitudinal structure to the molecules, and organizes the spatial distribution of the carboxy terminal CRDs. The coiled-coil motif of the neck forms and contributes to the spacial organization of the CRD domains. The C-terminal CRD domain contains the calcium- and carbohydrate-binding sites. The crystal structure of the CRD and neck region of SP-D has shown a distinct spatial distribution of the three CRDs, has defined the carbohydrate-binding pocket, and has allowed for computer docking studies to demonstrate the importance of specific vinyl hydroxyl groups in sugars for binding to SP-D.[61,62] As in the case of SP-A, the full oligomerization of SP-D appears to play an important role in maintaining biologic potency that may result from specific spatial cross-linking of ligands as well as amplification of relatively weak interactions through multiple binding sites.

Binding to Infectious Organisms

SP-D is an important host-defense molecule and binds a variety of organisms, usually through its CRD domain.[63] In terms of monosaccharide binding, SP-D has a preference for maltose, glucose, and mannose. The binding of SP-D to organisms can be altered by physiologic glucose concentrations, and impaired binding in the presence of glucose may be important in diabetics.[64]

Viruses. SP-D binds influenza A, inhibits hemagglutination, and inhibits infection.[65] It is interesting to note that the annual severity of influenza infections is related to their ability to bind to SP-D[66] and strains with less SP-D binding are more virulent. The binding is related to the N-linked carbohydrate on the influenza viral coat. SP-D has also been shown to bind SARS-CoV spike protein and to inhibit respiratory synctial virus infection. Although studies on the interaction of SP-D with viruses have been reported for only a few viruses, it is likely that SP-D binds to many respiratory viruses. In humans, high concentrations of SP-D would be suspected to be found only in the gas-exchange regions of the lung, whereas in rodents with abundant Clara cells, SP-D is found at high concentrations along conducting airways.

Bacteria. SP-D binds to bacteria and should be considered an important molecule in host defense. SP-D binds both major components of gram-positive cell walls, peptidoglycan and lipoteichoic acid.[57,67] SP-D also binds to LPS and to gram-negative bacteria with the rough form of LPS and aggregates these bacteria. Like SP-A, SP-D binds the smooth variants of *E. coli* poorly. The binding is thought to be due to the interaction of the CRD of SP-D with the core oligosaccharides of LPS moiety of *E. coli*. SP-D binds and increases phagocytosis of nonmucoid *Pseudomonas*, which is a common cause of nosocomial pneumonia.[68] Interestingly, SP-D binds to the unencapsulated forms of *Klebsiella*, whereas SP-A binds to the encapsulated varieties.[69] Hence, SP-A and SP-D can work in partnership in clearance of *Klebsiella*. Although SP-D binds many bacteria, clearance of group B *streptococci* and *H. influenzae* is normal in the SP-D–deficient mice.[70] Presumably, this is due to compensation by SP-A.

Fungi, Mycobacteria, Mycoplasma, and *Pneumocystis.* SP-D is likely important in defense against fungal infections. SP-D binds to *A. fumigatus* conidia and histoplasma and enhances their phagocytosis and killing. SP-D also binds to and agglutinates *Saccharomyces cerevisiae* and the cell wall ligand for binding is beta (1–6) glucan.[71] This binding is inhibited by pustulan, an extremely effective competitive inhibitor of SP-D. SP-D also binds *Alternaria*, a common mold and aeroallergen, and SP-D may be important in clearing a variety of inhaled fungal spores. SP-D agglutinates *Mycobacterium tuberculosis* but inhibits its phagocytosis by human macrophages. Once in macrophages, SP-D promotes phagosome-lysosome fusion and thereby intracellular killing.[72] SP-D also binds *Mycoplasma* and the binding site on *Mycoplasma* appears to be a lipid component of the cell membrane.[73]

The *P. carinii* surface glycoprotein gp120 is a ligand for SP-D, and the binding is calcium dependent and inhibited by glucose and mannose. Although SP-D binds to *P. carinii*, is found in association with the organisms in vivo, and stimulates adherence of the microbe to macrophages, it does not enhance phagocytosis by macrophages. In this case, there is clear association of SP-D with the organism but no evidence of enhanced clearance.

Interactions with Phagocytic Cells

SP-D has been reported to bind to several different receptors on macrophages and to stimulate microbicidal

metabolism, as indicated by the production of reactive oxygen species.[9] Rat SP-D enhances oxygen radical production by alveolar macrophages but not peritoneal macrophages.[74] Surfactant lipids do not alter this effect of SP-D. In general, unlike SP-A, the effects of SP-D are not inhibited by the addition of surfactant phospholipids. However, there remain concerns that in the early studies the stimulation of macrophages by SP-D could be due to endotoxin contamination.[45] Holmskov and coworkers[75] isolated a 340-kDa SP-D-binding protein that is found on the surface of alveolar macrophages and may be a SP-D receptor. Other possible receptors for SP-D include the calreticulin and CD-91 complex, SIRP-α, and CD14.[41,47,76]

SP-D is also involved in the clearance of apoptotic cells, and this has been demonstrated both in vitro and in vivo. The SP-D–deficient mouse has an increased number of apoptotic cells in its lavage fluid and clears instilled apoptotic cells at a reduced rate.[41,70] SP-D binds to apoptotic cells and facilitates their ingestion by macrophages through the calreticulin and CD91 complex.

The interactions of both SP-D and SP-A with organisms and phagocytic cells are complex, and the clear identification of the receptors for these proteins is awaited in order to sort out apparently conflicting observations. The interaction will be affected by the organism, the growth cycle of the organism, the phagocytic cell, and the state of activation of the phagocytic cell as well as the source of SP-A or SP-D and the presence or absence of contaminating endotoxin and TGF-β in the surfactant protein preparation. A clear association of alterations in SP-A and SP-D in host defense in humans has not been reported.

SECRETION AND EXTRACELLULAR PROCESSING OF SURFACTANT

Secretion of the phospholipid components of surfactant has been studied extensively (Fig. 9-4).[77] Turnover studies have demonstrated that the surfactant system is dynamic; 10% to 20% of the surfactant pool is secreted each hour.[78,79] There are several different independent pathways for stimulating secretion that work through different receptors and signaling mechanisms. In vivo secretions are stimulated by hyperventilation or even a single deep breath or sigh. Stretch is an important physiologic stimulation, which signals exocytosis through an elevation of intracellular calcium.[80] In vitro, tetradecanoyl acetate (TPA) and adenosine triphosphate (ATP) greatly stimulate basal secretion. TPA activates protein kinase C directly, and ATP stimulates protein kinase C indirectly via a $P2Y_2$ purinergic receptor and activation of phospholipase C. Agents that stimulate secretion via cAMP-dependent pathways such as β-agonists and cholera toxin stimulate secretion more modestly. Other agents that have been reported to stimulate secretion include calcium ionophores, arachidonate, prostaglandin E_2, vasopressin, endothelin, and serum lipoproteins.

Secretion of surfactant is also under negative control. Inhibitors of secretion in vitro include SP-A and DPPC. In vitro, SP-A inhibits secretion at very low concentrations (~1 μg/mL), and this occurs to a lesser extent in the presence of phospholipid. However, this inhibition of secretion observed in vitro appears not to occur in vivo, because in the SP-A knockout mouse, surfactant secretion and turnover are normal.[19] However, the role of SP-A as a negative regulator of surfactant secretions remains a controversial area. Secretion requires active extrusion of the lamellar body contents, and in vitro SP-A may constrain this final phase of secretion.[81] In vivo secretion is likely highly regulated, and there may be multiple checks and balances such that alteration in one pathway might not alter turnover.

After exocytosis by alveolar type II cells, the secreted lamellar bodies undergo physical rearrangements

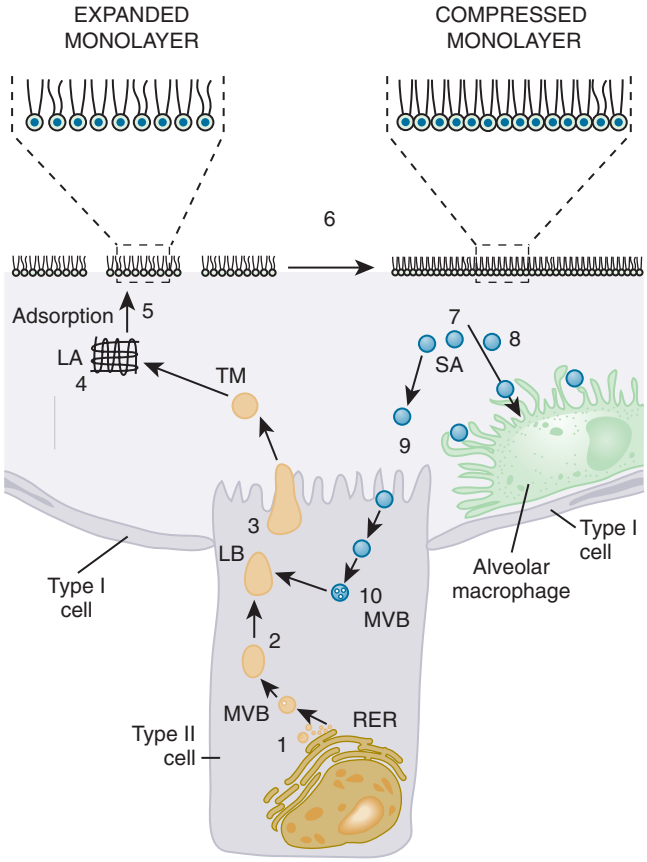

FIGURE 9-4 ■ Metabolic trafficking of surfactant phospholipids. The phospholipids are synthesized in the rough endoplasmic reticulum (RER) and processed in the Golgi network of the alveolar type II cell (*1*). They are transported to the multivesicular bodies (MVB) (*2*), where the first lamellae are formed. These lamellae increase to form lamellar bodies (LB), which are subsequently secreted by exocytosis (*3*). The secreted LB unfolds to form tubular myelin (TM) (*4*) and other large aggregates (LA). These forms adsorb into the expanded surface monolayer (*5*). This is a critical step for producing a low surface tension in the lung. During the respiratory cycle, as the film is compressed during exhalation, the film pressure rises, and a compressed, closely packed monolayer of nearly pure dipalmitoylphosphatidylcholine is formed (*6*). Material is excluded from the monolayer (*7*) and forms small aggregates (SA). Some of these aggregates are ingested by macrophages (*8*), and some are endocytosed by reprocessing by alveolar type II cells (*9* and *10*).

extracellularly (see Fig. 9-2). The initial change is the conversion from the multilamellar state to tubular myelin (see Fig. 9-4). This requires SP-A, SP-B, calcium, and the surfactant phospholipids and can be reproduced in vitro.[6] In lavage samples (LA), surfactant can be isolated by differential centrifugation. These aggregates contain SP-A and SP-B and are composed of tubular myelin, multilamellar structures, and other loose lipid arrays, which are the expected forms of secreted and unraveling lamellar bodies. LA forms adsorb rapidly to the air-liquid interface and can be considered an extracellular reservoir of surfactant. LA can be converted into smaller aggregates (SA), which are much less surface active. These SA are thought to represent surfactant that has left the air-liquid interface and is available to be taken up by type II cells and reprocessed. The conversion of LA to SA is facilitated by an enzyme called convertase that has some of the properties of a carboxylesterase.[82] Although there are at least four routes for the catabolism of surface-active material, the two dominant routes are uptake by type II cells and catabolism by alveolar macrophages.[78] The current estimates are that 25% to 85% of secreted surfactant is recycled by adult type II cells[83,84] and about 15% is catabolized by macrophages. Relatively little pulmonary surfactant goes up the mucociliary escalator, and very little enters the bloodstream or lymphatics. Catabolism of extracellular surface-active material is regulated by granulocyte-macrophage colony-stimulating factor (GM-CSF) and its ability to activate macrophages.[85] Adult idiopathic alveolar proteinosis is caused by an autoantibody to GM-CSF[86,87]; some pediatric forms of alveolar proteinosis are due to mutations in the receptor for GM-CSF.[88,89] The extracellular pool of surfactant, perhaps excess surfactant, appears to be regulated predominantly by alveolar macrophage clearance.

SURFACTANT ABNORMALITIES IN LUNG DISEASE

Primary Surfactant Deficiency of the Newborn

Epidemiology and Clinical Features

The importance of the pulmonary surfactant system in the pathophysiology of the NRDS was first reported by Avery and Mead in the late 1950s.[5] The observation that NRDS was due to a primary surfactant deficiency has been confirmed by the tremendous impact that exogenous surfactant administration has had on infant mortality.

The incidence of NRDS varies with gestational age and birth weight. Approximately 15% of infants born between 34 and 37 weeks of gestational age (<1700 g) develop NRDS, whereas 50% of infants between 30 and 34 weeks of gestational age (<1500 g) and 70% of those born at less than 30 weeks of gestational age (<1250 g) develop this disease. These rates may also be influenced by other factors, including race, gender, socioeconomic status, and maternal health.

Infants with NRDS develop sternal retractions, nasal flaring, tachypnea, and grunting shortly after birth. There is a marked decrease in lung compliance, which is associated with hypoxemia, and diffuse bilateral parenchymal infiltrates. Mechanical ventilatory support usually requires high oxygen concentrations and ventilatory pressures. Even though artificial ventilation and exogenous surfactant have decreased infant mortality, there still exists a major disability rate among the survivors, particularly in the infants of very low birth weight. The most common of these disabilities is bronchopulmonary dysplasia. Accurate fetal lung maturity assessments have led to maternal treatment strategies that have resulted in a decrease in the incidence of NRDS by 10% to 30%. Ultrasonic anthropometric measurements are helpful but do not accurately estimate lung maturity in the third trimester. Amniotic fluid surfactant analysis reliably predicts the risk of NRDS. Pathologic changes typical of NRDS include widespread atelectasis, capillary congestion, microhemorrhage, edema, and hyaline membranes.[5] Mechanical ventilation of these infants has been shown to retard alveolarization and to increase interstitial collagen deposition and bronchial smooth muscle within the lung. As a result, more "protective" ventilatory strategies, including high-frequency oscillation, as well as NO administration, are currently being used.

Treatment

Fujiwara and colleagues[90] reported the first successful use of exogenous surfactant in neonates with NRDS in 1980. Several large clinical trials demonstrated significant improvement in gas exchange, decreased barotrauma, and decreased infant mortality in response to this therapy. Results of these trials have also shown that prophylactic administration of surfactant before the first breath is superior to surfactant given after a period of ventilation. These differences were particularly notable in the infants of very low birth weight (<28 weeks of gestational age). Prophylactic treatment is reserved for infants less than 28 weeks of gestational age. Otherwise, surfactant should be administered once the diagnosis of NRDS is established, usually within 30 minutes after birth. The usual dose of surfactant administered to these infants is approximately 100 mg phospholipid/kg body weight. Although surfactant therapy is very effective for NRDS, approximately 30% of affected infants do not respond to this therapy.

Hereditary Surfactant Protein B Deficiency

Although most cases of NRDS result from immaturity, there are inherited forms specifically due to SP-B deficiency.[91,92] Associated abnormalities include aberrant structured tubular myelin, decreased number of lamellar bodies, and abnormal processing of SP-C. Regardless of gestational age, affected patients develop respiratory distress in the first few days of life that is refractory to all therapy, including surfactant supplementation. Death

eventually ensues in the first few months of life, unless they receive a lung transplant. Although the most common abnormality involves a 1-bp deletion and 3-bp insertion in codon 121 in exon 4, which results in a premature stop codon, other mutations also occur and can lead to respiratory failure. The heterozygotes represent about 1 in 3000 individuals in the general population, would be predicted to have about half the SP-B level, and might be more sensitive to acute respiratory distress syndrome (ARDS). In mice, about 20% of wild-type SP-B is required for normal function. Mice with 50% reduction are more susceptible to acute lung injury. NRDS also results from other deficiencies in surfactant synthesis and assembly. The most common deficiency is the ATP-binding cassette family member A3 (ABCA3), a lamellar body phospholipid transport protein.[93,94]

Hereditary Surfactant Protein C Deficiency and Mutations

Deficiency of SP-C would not be expected to produce acute respiratory failure. In mice, SP-C deficiency causes diffuse nonspecific chronic interstitial pneumonitis over months to years and depends on the genetic strain. A splice site mutation in intron 4 of the SP-C gene produces chronic interstitial lung disease with an autosomal dominant inheritance pattern.[92,95,96] Recently, additional cases of nonspecific interstitial pneumonitis (NSIP) and usual interstitial pneumonitis have been reported with a single gene mutation.[97] This kindred also showed an autosomal dominant inheritance pattern. The hypothesis is that the mutations cause a misfolded SP-C protein, which accumulates and produces ER stress and chronic lung disease.[97a]

Acute Respiratory Distress Syndrome

Early descriptions of ARDS suggested that surfactant abnormalities play an important role in the lung dysfunction observed in these patients. Petty and Ashbaugh[98] recorded abnormal pressure-volume curves in lungs isolated from patients dying of ARDS. Morphologic changes noted in the lung tissue of these patients at autopsy were similar to those of preterm infants suffering from NRDS. The clinical criteria used to diagnose ARDS, including severe hypoxemia, decreased lung compliance, and bilateral infiltrates on chest radiograph, are also similar to those used to diagnose NRDS. As opposed to a primary deficiency of surfactant, however, ARDS is more complex, with many different etiologies and an elaborate inflammatory cascade resulting in lung injury and alveolar edema. The underlying alveolar epithelium is severely damaged in ARDS, whereas the alveolar epithelium is relatively intact at the onset of NRDS.

Surfactant Alterations

Extensive animal studies and several human reports characterizing surfactant alterations in ARDS and acute lung injury have shown a decrease in the percentage of phosphatidylcholine, phosphatidylglycerol, and DPPC and a corresponding increase in phosphatidylinositol, sphingomyelin, and in some cases lysophosphatidylcholine.[99,100] Decreased levels of SP-A and SP-B have also been demonstrated in bronchoalveolar lavage (BAL) samples from patients with ARDS, and surface tension–lowering properties of the isolated surfactant are abnormal.[99] These abnormalities correlated with the severity of ARDS. BAL samples isolated from patients with severe ARDS also show an increase in poorly surface-active small aggregate (SA) and a decrease in large aggregate (LA). In animal models of acute lung injury, there is a severe reduction of surfactant protein gene expression at the onset of respiratory insufficiency.[101]

Mechanisms Leading to Surfactant Dysfunction

With increased alveolar permeability in patients with ARDS, a number of proteins enter the air space and can either alter the structure of surfactant phospholipids and proteins within the bulk phase or directly compete with surfactant molecules for space at the air-liquid interface. Interestingly, this nonstoichiometric inhibition of surfactant by plasma proteins can be overcome in vitro by increasing the concentration of surfactant. This observation provides rationale for administering large doses of exogenous surfactant to patients with ARDS. Other factors inactivating endogenous surfactant include lipid peroxidation of surfactant or perhaps direct oxidation of surfactant, degradation of phosphatidylcholine through phospholipases, and cleavage of surfactant proteins by proteases leaking into the air space. Thrombogenic components leaking into the air space can also coagulate and incorporate surfactant phospholipids into fibrin clots, thereby rendering the surfactant inaccessible to the air-liquid interface. An additional mechanism contributing to surfactant inactivation that has recently been described is an increase in the neutral lipids, primarily cholesterol. Although physiologic levels of cholesterol are essential for organizing the surface film, elevated levels may inhibit surfactant function.[102] Cholesterol is increased in patients with lung injury, and exposure of functional surfactant to this neutral lipid results in a loss of surfactant function.[100] Another mechanism contributing to surfactant dysfunction in ARDS involves the increased conversion of LA into SA. An important factor contributing to this conversion process is the large change in alveolar surface area determined by the size of the tidal volume. Indeed, in vivo studies have shown that increased tidal volumes, but not respiratory rates or positive end-expiratory pressure (PEEP) levels, correlated with an increased conversion of LA into SA,[103] and this was associated with physiologic deterioration. Hence, the deleterious effects of mechanical ventilation on lung function may be mediated, in part, by changes in alveolar surfactant aggregate forms. Minimizing these phasic changes in surface area by means of smaller tidal volumes allows surfactant to be maintained in LA forms and results in improved physiologic outcomes.[103] These findings are supported by clinical trials demonstrating

improved patient outcomes when lower tidal volumes are used in patients with ARDS.[104,105]

Pneumonia

There is increasing evidence that the pulmonary surfactant system plays a role in the pathophysiology of pneumonia. Surfactant or isolated surfactant component enhances macrophage phagocytic activity and migration, suppresses lymphocyte proliferation, decreases mediator release from activated inflammatory cells, and directly enhances both bacterial and viral killing. In addition, pneumonia elicits an inflammatory response that may lead to alveolar edema and an increase in proteins within the air space. These proteins, as well as phospholipases directly secreted from bacteria, may inhibit surfactant function. BAL samples obtained from patients with bacterial pneumonia showed decreased phosphatidylcholine and phosphatidylglycerol levels, as well as decreased SP-A levels.[99]

Experience with administering exogenous surfactant to patients with pneumonia is limited. Animal studies involving mice with viral pneumonitis has shown promising results, and a recent clinical trial in children with respiratory syncytial viral pneumonia demonstrated improved gas exchange, lung mechanics, and length of stay in the intensive care in surfactant-treated patients compared with controls.[106] Further studies are necessary to determine whether there is a role for exogenous surfactant in treatment of severe pneumonia.

Interstitial Lung Diseases

In addition to diseases involving acute alveolar inflammation, surfactant alterations have also been characterized in various interstitial lung diseases. Decreased levels of DPPC and of phosphatidylglycerol and increased levels of phosphatidylinositol have been observed in BAL fluid from patients with idiopathic pulmonary fibrosis (IPF).[107] BAL fluid of patients with IPF reveals reduced levels of SP-A and little change in SP-D.[107–109] The reduction in SP-A in BAL fluid is found in a variety of diffuse interstitial lung diseases. The ratio of SP-A to phospholipid, used to correct for recovery of total surfactant, is reduced in patients with IPF and predicts the subsequent 5-year survival rate among patients with IPF. In addition, Günther and associates[110] demonstrated that surfactant biophysical properties were impaired in IPF.

SP-A and SP-D have also been measured in serum and may serve as biomarkers of lung disease, especially when alveolar epithelial integrity is compromised. Serum concentrations of SP-A and SP-D are increased in patients with alveolar proteinosis, ARDS, and IPF.[108,111,112,112a] Measuring SP-A and SP-D in serum might be useful in the diagnosis of alveolar proteinosis, because the serum levels are quite high, the image on high-resolution computed tomographic scanning is nearly specific, and a biopsy can be avoided. More clinical correlations between serum values of SP-A and SP-D and usual clinical variables are needed to judge their value in the care of patients with interstitial lung disease. A small subset of patients with familial pulmonary fibrosis has been attributed to SP-C mutations. Most of the cases have histopathologic diagnosis of NSIP, but a few have the morphologic features of usual interstitial pneumonia (UIP).[97] Recently, mutations in SP-A2 have been also reported to be associated with interstitial lung disease and lung cancer.[113]

Obstructive Lung Diseases

Surfactant proteins may be synthesized in the peripheral airways and/or transported to the airways via the mucociliary escalator. The role of surfactant as a down-regulator of inflammation and the importance of surfactant in maintaining the openness of conducting airways suggest that surfactant alterations may be important in obstructive lung diseases.[114,115] BAL samples from patients with asthma showed decreased SP-A levels and a normal phospholipid composition.[22] The surface activity of the surfactant was abnormal, which was attributed to the inhibitory effects of proteins recovered in these samples. Studies in animal models of asthma and human studies have shown that pretreatment with exogenous surfactant inhibited subsequent allergic bronchoconstriction.[116,117] Interestingly, mice with an asthmatic response to *A. fumigatus* have been shown to have airway hyperresponsiveness, reduced surface activity in lavage fluid extracts, and reduced SP-B. Instillation of IL-4 reduced SP-B protein levels in lavage.[118] In these murine models of asthma, instillation of SP-D can also mitigate the inflammatory response.[119,120] No surfactant alterations have been demonstrated in patients with chronic bronchitis or emphysema.

Cystic fibrosis is characterized by colonization of both gram-negative and gram-positive bacteria and early airway inflammation. Both SP-A and SP-D are reduced in BAL from patients with cystic fibrosis, and the relative deficiency could contribute to bacteria colonization.[121] Serum SP-D has been reported to be increased in COPD and associated with an increased risk of COPD exacerbations.[121a]

Other Lung Diseases

Alveolar proteinosis is due to decreased clearance of surfactant[121b] (see Chapter 63). Alveolar phospholipids and surfactant proteins SP-A, SP-B, and SP-D are markedly increased in lavage samples from affected patients. SP-A and SP-D are also increased in the sera of these patients.[108,112] Decreased catabolism of surfactant results in an excess accumulation of multilamellated structures within the alveoli. Adult alveolar proteinosis has been shown to be an autoimmune disease produced by an antibody to GM-CSF, which results in decreased macrophage clearance of surfactant.[86,87] Pediatric forms of alveolar proteinosis are due to alterations in GM-CSF signaling, usually due to alterations in the GM-CSF receptor.[88,89] Effective treatment involves removing this material through whole-lung lavage and/or treatment with exogenous GM-CSF.

The ischemia-reperfusion injury associated with lung transplantation results in alterations in pulmonary

surfactant similar to those observed in patients with severe ARDS. Surfactant administered shortly after transplantation and reperfusion results in improved gas exchange in comparison to non–surfactant-treated lungs. Moreover, when surfactant is administered to donor lungs before storage, longer storage times are tolerated (up to 38 hours) with relatively little physiologic dysfunction observed after reperfusion.

Measurement of SP-A and SP-D in pleural fluid might also be useful to distinguish metastatic adenocarcinoma of the lung from other adenocarcinomas or mesothelioma.[122] In addition, surfactant protein gene expression can be used to screen for micrometastases in lymph nodes.[123] In mice with pulmonary adenomas, serum SP-D correlates extremely well with tumor size.[124]

SURFACTANT THERAPY FOR ACUTE RESPIRATORY DISTRESS SYNDROME

Numerous reports have suggested that exogenous surfactant administration may be of benefit in patients with ARDS.[125] To date, a few large multicenter clinical trials have evaluated this therapy and have shown inconsistent and somewhat disappointing results. The protein-free synthetic surfactant colfosceril palmitate (Exosurf) was administered via continuous aerosolization for up to 5 days in 364 patients with severe sepsis-induced ARDS.[126] There were no significant improvements in mortality, oxygenation, duration of mechanical ventilation, or duration of hospitalization in comparison with an aerosolized saline-treated control group. In a subsequent, albeit much smaller trial, the natural bovine surfactant Survanta, which contains some SP-B and SP-C, was administered via intratracheal instillation and compared with a group of patients receiving standard therapy. Surfactant resulted in both improved oxygenation and improved 30-day survival rates.[127] Based on the promising results of this trial, and suggestive preclinical studies, a series of subsequent clinical trials evaluated the efficacy of Venticute, a synthetic preparation containing recombinant SP-C and 50 mg PL/mL. After two phase II trials demonstrated safety of the treatment and improvements in gas exchange and ventilator-free days,[128] two larger phase III studies involving 221 and 227 patients, respectively, were conducted.[129] Although improvements in oxygenation in response to Venticute were shown in both studies, no differences in overall survival were noted in either study. A subgroup analysis, however, showed that patients with direct lung injuries, such as those caused by pneumonia and/or aspiration, had improved outcomes, including survival, when given Venticute. These observations led to a phase III trial assessing Venticute administration in patients with severe, direct lung injuries; however, that trial was stopped in 2008 due to lack of efficacy (personal communication, JFL). Interestingly, in a separate study, a natural, calf lung lavage surfactant call calfactant, was evaluated in pediatric patients with ARDS. This multicenter, randomized, blinded phase III trial included 153 patients ranging in age from infants to adolescents and showed that exogenous surfactant administration resulted in improvements in oxygenation and reduction in mortality (19.5% versus 36%), although the improved survival observed in this study was almost entirely due to the patients given surfactant who had direct lung injuries.[130] Currently, there is a larger phase II study under way evaluating calfactant in a prospective fashion in patients with direct injuries with ages ranging from 1 month to 85 years.

Surfactant Preparation and Dose

In general, animal studies suggest that natural surfactant preparations are superior to synthetic products, mainly due to the presence of hydrophobic surfactant proteins in the former compounds. Unfortunately, resource availability, cost, and the potential for variable composition are limiting factors of the natural products. For these reasons, more effective synthetic preparations are being developed. The newer synthetic compounds, including a novel recombinant SP-C–based surfactant (Venticute) and a SP-B–like peptide-based surfactant (Surfaxin) have been tested in phase I and II trials, and appear to have excellent biophysical activities, although none have shown consistently positive outcomes in Phase III studies to date, as noted earlier.[128] One area of current and future research is the evaluation of exogenous surfactant preparations that may affect bacterial growth and/or host-defense mechanisms. Although none of the commercially available surfactant preparations currently contain the collectins SP-A or SP-D, the addition of these components to exogenous surfactants, and recent studies focused on novel protein components of SP-B and SP-C, or peptoids, that will mimic the function of these proteins but are resistant to degradation, are being evaluated.[131–135]

The ideal dosage and dosing schedules are also unknown and will depend on the preparation used, the nature of the underlying illness, and the method used for delivery. For example, for severe disease with significant inhibition of surfactant function, relatively large amounts of exogenous surfactant will be required. Moreover, if surfactant is administered as a liquid bolus, relatively large dose volumes will be required for a more homogenous distribution.

Surfactant Delivery Methods

Animal studies have shown that surfactant administered via tracheal instillation is optimal if given as a rapid bolus rather than as slow infusion. In some studies, surfactant was administered via bronchoscopic instillation into individual lobes, and significant improvements in gas exchange were observed.[136] When directly compared in an animal model, bronchoscopic instillation was similar to tracheal instillation with regard to surfactant distribution patterns and physiologic outcomes, although the former technique took significantly longer and required a skilled bronchoscopist.[137] On the other hand, bronchoscopic instillation of surfactant associated with a lavage procedure aimed at removing inhibitory compounds from the air space may prove to be effective for some types of ARDS and/or meconium aspiration.[125,138]

Effects of Mechanical Ventilation

Animal studies have shown that the level of PEEP significantly influences the efficacy of surfactant replacement therapy. In addition, higher tidal volumes result in a greater conversion of exogenous LA surfactant forms to inferior functioning SA. The inherent conversion kinetics of a particular surfactant preparation, together with the specific mode of ventilation used, may well influence the duration of clinical response after surfactant is administered. Like endogenous surfactant, ventilatory modes that use smaller tidal volumes appear to be optimal, and when directly compared in an animal model of lung injury, high-frequency oscillation was superior to conventional modes utilizing low tidal volume and high PEEP with respect to physiologic outcomes and surfactant metabolism.[139]

Proposed Surfactant Treatment Strategies

The factors affecting a host's response to exogenous surfactant may all be influenced by the condition of the host's lungs at the time of administration. For example, a patient with severe ARDS would require large doses of a tracheally instilled surfactant to overcome protein inhibition. Another patient with relatively mild respiratory distress may respond to an aerosolized surfactant preparation, inasmuch as protein inhibition would not be as significant and smaller quantities of material would be sufficient. Moreover, the distribution of the injury at this stage would be relatively uniform so that aerosolization would be feasible. Although this early treatment strategy has not been used in humans, there is evidence from animal models of hyperoxia and ischemia-reperfusion that early administration of exogenous surfactant may prevent progressive lung dysfunction. These observations, together with animal data showing that surfactant is altered early in lung injury and in vitro data showing the importance of surfactant in host-defense properties, all provide a good rationale for pursuing early administration of exogenous surfactant in patients at high risk of developing ARDS. Until a reliable, early marker of impending ARDS is available, however, there still exists the problem of potentially treating patients who may not require or benefit from this intervention.

ACKNOWLEDGMENT

We thank Dennis Voelker for the figures on SP-A and SP-D, and Mary Williams for the figure of tubular myelin.

KEY POINTS

- Pulmonary surfactant allows for the low surface tension in the gas-exchange portions of the lung, which prevents atelectasis, decreases the work of breathing, improves oxygenation, prevents alveolar flooding, and helps maintain patency of very small airways.
- SP-B is the only surfactant protein critical to surfactant formation in vivo.
- Mutations in SP-B and SP-C can lead to diffuse lung disease.
- SP-A and SP-D are thought to be important components of innate immunity and bind to both microorganisms and inflammatory cells.
- Surfactant replacement therapy in ARDS improves oxygenation but has not been shown to improve survival.

MECHANISMS THAT CAN IMPAIR THE RESOLUTION OF ALVEOLAR EDEMA

ALVEOLAR FLUID TRANSPORT UNDER PATHOLOGIC CONDITIONS

FUTURE DIRECTIONS

INTRODUCTION

This chapter discusses how the distal lung epithelium regulates lung fluid balance by active ion transport mechanisms across both the alveolar and the distal airway epithelium. Both experimental models of pulmonary edema and clinical studies are considered to illustrate how active sodium and chloride ion transport regulate the resolution of alveolar edema. Some of the material in this chapter has been included in recent reviews.[1,2]

For many years, it was generally believed that differences in hydrostatic and protein osmotic pressures (Starling forces) accounted for the removal of excess fluid from the air spaces of the lung. This misconception persisted in part because some experiments that measured solute flux across the epithelial and endothelial barriers of the lung were done at room temperature[3] and the studies were done in dogs, a species that turned out to have a very low rate of active sodium and fluid transport.[4] Although the removal of interstitial pulmonary edema by lung lymphatics and the lung microcirculation was known for a long time,[5] there was no information on how pulmonary edema was removed from the distal air spaces of the mature lung. New insight on active transport came from clearance of alveolar fluid at the time of birth and the development of culture systems to study pulmonary epithelial cells.

LUNG EPITHELIAL FLUID ABSORPTION

With few exceptions, the general model for transepithelial fluid movement is that active salt transport drives osmotic water transport. This paradigm is also correct for fluid clearance from the distal air spaces of the lung.[6,7] The results of several in vivo studies demonstrated that changes in hydrostatic or protein osmotic pressures cannot account for the removal of excess fluid from the distal air spaces. Furthermore, pharmacologic inhibitors of sodium transport can reduce the rate of fluid clearance in the lungs of several different species, including the human lung.[8] In addition, there is good evidence that isolated epithelial cells from the distal air spaces of the lung actively transport sodium and other ions, resulting in osmotic water absorption of fluid from the distal air spaces of the lung.

The large surface area of the alveoli favors the hypothesis that most fluid reabsorption occurs at the alveolar level, although active fluid reabsorption may occur across all of the different segments of the pulmonary epithelium of the distal air spaces of the lung. The precise contribution of each anatomic segment in the distal air spaces to fluid reabsorption is not firmly established. The distal airway epithelium is composed of terminal respiratory and bronchiolar units containing polarized epithelial cells that have the capacity to transport sodium and

chloride, including ciliated cells and nonciliated cuboidal Clara cells. The alveoli themselves are composed of a thin alveolar epithelium (0.1–0.2 μm) that covers 99% of the air space surface area in the lung and contains thin, squamous type I cells and cuboidal type II cells.[9] The alveolar type I cell covers 95% of the alveolar surface. The close apposition between the alveolar epithelium and the vascular endothelium facilitates efficient exchange of gases but also forms a tight barrier to movement of liquid and proteins from the interstitial and vascular spaces, thus assisting in maintaining relatively dry alveoli.

Ion transporters and other membrane proteins are asymmetrically distributed on opposing cell surfaces, conferring vectorial transport properties to the epithelium. Physiologic studies of the barrier properties of tight junctions in the alveolar epithelium indicate that diffusion of water-soluble solutes between alveolar epithelial cells is much slower than through the intercellular junctions of the adjacent lung capillaries.[10] Removal of large quantities of soluble protein from the air spaces appears to occur primarily by restricted diffusion, although there is evidence for some endocytosis and transcytosis of albumin across alveolar epithelium.[11]

EVIDENCE FOR ACTIVE FLUID TRANSPORT IN THE INTACT LUNG

A substantial number of innovative experimental methods have been used to study fluid and protein transport from the distal air spaces of the intact lung, including isolated perfused lung preparations, in situ lung preparations, surface fluorescence methods, and intact lung preparations in living animals for short time periods (30–240 min) or for extended time periods (24–144 hr). The advantages and disadvantages of these preparations have been reviewed in some detail.[7]

The first in vivo evidence that active ion transport could account for the removal of alveolar edema fluid across the distal pulmonary epithelium of the mature lung was obtained in studies of anesthetized, ventilated sheep.[12] In those studies, the critical discovery was that isosmolar fluid clearance of salt and water occurred in the face of a rising concentration of protein in the air spaces of the lung, whether the instilled solution was autologous serum or an isosmolar protein solution. The initial protein concentration of the instilled protein solution was the same as that of the circulating plasma. After 4 hours, the concentration of the protein had risen from approximately 6.5 g/100 mL to 8.4 g/100 mL, while the plasma protein concentration was unchanged. In longer-term studies in unanesthetized, spontaneously breathing sheep, alveolar protein concentrations increased to very high levels. After 12 and 24 hours, the alveolar protein concentrations increased to 10.2 and 12.9 g/100mL, respectively.[13] The overall rise in protein concentration was equivalent to an increase in distal air space protein osmotic pressure from 25 to 65 cm H_2O. Because the epithelial barrier was intact and thus prevented protein leak or a rapid protein absorption occurs in the lung, the only way that the protein concentration could have risen was if water had been removed (i.e., absorbed).

Other studies in the intact lung have supported the hypothesis that removal of alveolar fluid requires active transport.[14] For example, elimination of ventilation to one lung did not change the rate of fluid clearance in sheep, thus ruling out changes in transpulmonary airway pressure as a major determinant of fluid clearance, at least in the uninjured lung.[15] Furthermore, if active ion transport was responsible for fluid clearance, then fluid clearance should be temperature-dependent. In an in situ rat lung preparation, fluid clearance was inhibited by low temperature.[16] Similar results were obtained in ex vivo human lung studies,[8] in which hypothermia inhibited sodium and fluid transport.

Additional evidence for active ion transport was obtained in intact animals with the use of amiloride, an inhibitor of sodium uptake by the apical membrane of alveolar epithelium and distal airway epithelium. Amiloride inhibited 40% to 70% of basal fluid clearance in sheep, rabbits, rats, guinea pigs, and mice and in the human lung.[1] Amiloride also inhibited sodium uptake in distal airway epithelium from sheep and pigs.[17] To explore further the role of active sodium transport, experiments were designed to inhibit Na^+,K^+-ATPase. It has been difficult to study the effect of ouabain in intact animals because of cardiac toxicity. However, in the isolated rat lung, ouabain inhibited greater than 90% of fluid clearance.[18] Following the development of an in situ sheep preparation for measuring fluid clearance in the absence of blood flow, it was reported that ouabain inhibited 90% of fluid clearance over a 4-hour period.[14] Other investigators also established the likely role of active fluid transport for removal of fluid from the fetal lung.[15]

ION TRANSPORT IN ALVEOLAR AND DISTAL AIRWAY EPITHELIAL CELLS

The success in obtaining nearly pure cultures of alveolar epithelial type II cells from rats made it possible to study the transport properties of these cells and relate the results to the findings in the intact lung studies. The initial studies showed that, when type II cells were cultured on a nonporous surface such as plastic, they would form a continuous confluent layer of polarized cells after 2 to 3 days.[19,20] Interestingly, after 3 to 5 days, small domes of fluid could be appreciated below which the substratum was detached by the formation of the domes. The domes were thought to result from active ion transport from the apical to the basal surface, with water following passively, because they were inhibited by the replacement of sodium by another action or by pharmacologic inhibitors of sodium transport, such as amiloride and ouabain. More detailed information on the nature of ion transport across alveolar type II cells was obtained by culturing these cells on porous supports and mounting them in Ussing chambers and measuring short-

circuit current (Isc) and ion flux under voltage clamp conditions.[1,19,21]

The coordinated role of apical and basolateral sodium transport has been studied in several in vitro studies. Sodium ions that enter the epithelial cells at the apical membrane are pumped out of the cells at the basolateral membrane by the Na^+,K^+-ATPase enzyme. Because of the continuous pumping, sodium chemical potential is lower inside the cell. The entry step is passive, and sodium flows down a chemical potential gradient through specialized pathways, where basolateral transport requires energy to move ions against the gradient. Because of the pump activity, potassium electrochemical potential is larger inside the cell, and potassium leaks through the basolateral membrane and is then recycled by the Na^+,K^+-ATPase. The pathways for sodium entry into alveolar type II cells are numerous. Amiloride blocked dome formation[19,20] and decreased Isc in the in vitro studies,[21] a finding that supported the critical importance of sodium uptake through an amiloride-sensitive pathway in the apical membrane of alveolar epithelial cells. As already discussed, the efficacy of amiloride as an inhibitor of fluid clearance in the intact lung was demonstrated in several in vivo studies, although the fraction of amiloride-sensitive transport was as low as 40% to 50% in some lung preparations, particularly the rat and the human lung. The amiloride-insensitive sodium influx may be represented in vivo in part by the Na^+-glucose cotransport. A detailed discussion of the pharmacologic, biophysical, and molecular bases for fluid clearance across the alveolar and distal airway epithelium is available in other reviews.[1,22]

The role of the alveolar type I cell in vectorial fluid transport in the lung is unknown, although several investigators have tried to assess the potential contribution of the alveolar type I cell to vectorial fluid transport. On the basis of studies in freshly isolated type I cells, it is known that these cells have a high osmotic permeability to water with expression of aquaporin-5 on the apical surface.[23] Recent studies of freshly isolated alveolar type I cells from rats demonstrated that these cells express the Na^+,K^+-ATPaseα_1- and α_2-subunit isoforms.[24,25] In the same study, there was evidence for Na^+,K^+-ATPase α_1-subunit expression on the basolateral surface of the alveolar epithelial type I cells in situ in the rat lung. In addition, there is evidence for expression of all the subunits of the epithelial Na^+ channel (ENaC) in freshly isolated alveolar type I cells as well as in situ in the rat lung.[26] Finally, there is some evidence that ^{22}Na uptake can be partially inhibited by amiloride in freshly isolated rat alveolar type I cells, although definitive studies of cultured, polarized type I cells have not yet been achieved. Recent data demonstrate that the alveolar epithelial type I cells express a multitude of sodium transporting proteins, ENaC, cyclic nucleotide–gated sodium channels (CNG), and the Na^+,K^+-ATPase.[27] In addition, the cells express chloride transporters, that is, the cystic fibrosis transmembrane regulator (CFTR), and thus have the ion transporters necessary to participate in vectorial ion transport and clearance of alveolar fluid.[27a]

The alveolar epithelium comprises 99% of the surface area of the lung, a finding that suggests that removal of edema fluid from the lung might primarily occur across the alveolar epithelium. However, it has been demonstrated that the distal airway epithelium also actively transports sodium, a process that depends on amiloride-inhibitable uptake of sodium on the apical surface and extrusion of sodium through a basolateral Na^+,K^+-ATPase.[1,17] Clara cells actively absorb and transport sodium from the apical to the basal surface.[28] In addition, there are new data on the possible role of CFTR in upregulating cyclic 3′,5′-adenosine monophosphate (cAMP) fluid clearance (see next section, "Regulation of Lung Epithelial Fluid Transport"). This information provides support for a possible role of distal airway epithelia in fluid clearance, because CFTR is expressed abundantly in distal airway epithelial cells as well as in alveolar epithelial cells. Thus, even though their surface area is limited, a contribution from distal airway epithelia to the overall fluid transport is probable, especially as cells from the distal airway epithelium primarily transport salt from the apical to the basolateral surface. Figure 10-1 provides a schematic diagram of our current understanding of the location of ion transporters in the distal airway and alveolar epithelium that are responsible for vectorial fluid transport or net distal air space fluid clearance.

There are also new data confirming the importance of ENaC for alveolar fluid clearance using RNA interference (RNAi) against the αENaC subunit.[29] In those studies, inhibition of αENaC expression by specific small interfering RNA (siRNA) against αENaC attenuated the amiloride-sensitivity of both normal and stimulated alveolar fluid clearance, thus demonstrating the importance of ENaC.

REGULATION OF LUNG EPITHELIAL FLUID TRANSPORT

This section considers how the rate of vectorial fluid transport across the distal pulmonary epithelium can be increased by catecholamine or cAMP-dependent mechanisms. The potential relevance of these mechanisms under pathologic conditions is evaluated in the section "Alveolar Fluid Transport under Pathologic Conditions," later in this chapter.

Studies in newborn animals indicated that endogenous release of catecholamines, particularly epinephrine, may stimulate reabsorption of fetal lung fluid from the air spaces of the lung.[14,30,31] In most adult mammalian species, stimulation of β_2-adrenergic receptors by either salmeterol, terbutaline, or epinephrine increases fluid clearance.[32–35] This stimulatory effect occurs rapidly after intravenous administration of epinephrine or instillation of terbutaline into the alveolar space, and is completely prevented by either a nonspecific β_2-receptor antagonist (propranolol) or, in rats, by a specific β_2-antagonist.

The increased fluid clearance by β_2-agonists can be prevented by amiloride or RNAi against αENaC, indicating that the stimulation is related to an increased

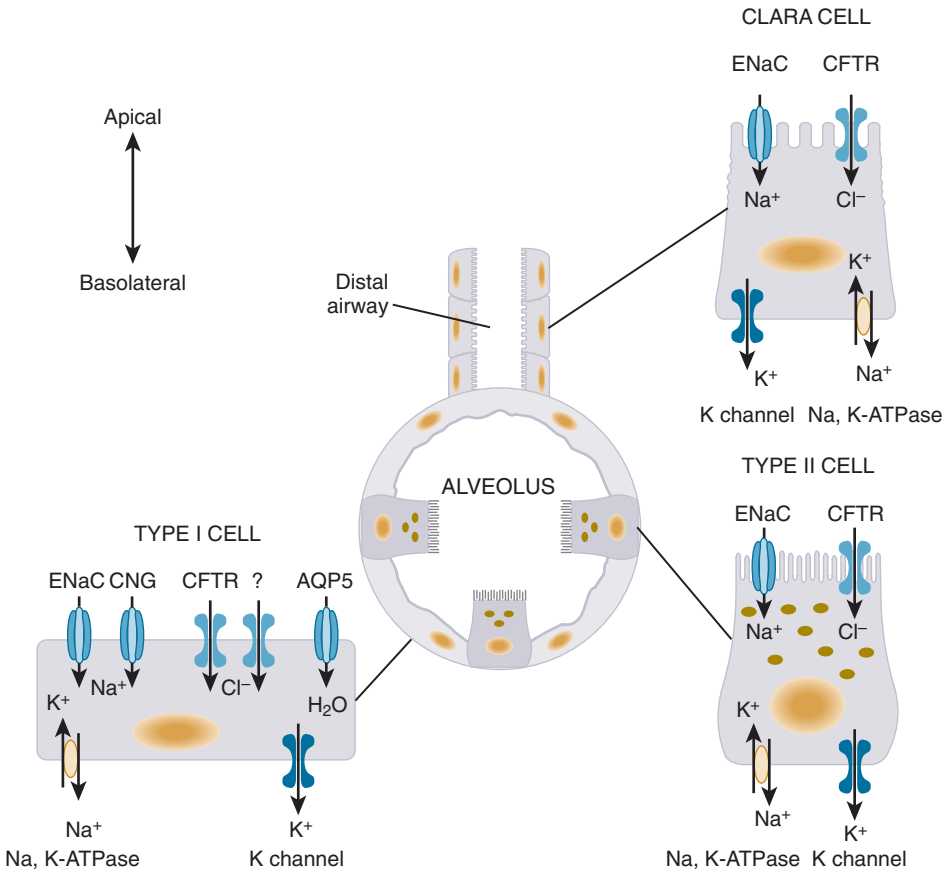

FIGURE 10-1 ■ A schematic diagram of the distal pulmonary epithelium that is relevant for salt and water transport. CFTR, cystic fibrosis transmembrane regulator; CNG, cyclic nucleotide–gated sodium channel; ENaC, epithelial Na^+ channel; AQP5, aquaporin-5. (Modified from Matthay MA, Folkesson HG, Clerici C: Lung epithelial fluid transport and the resolution of pulmonary edema. Physiol Rev 82:569–600, 2002.)

transepithelial sodium transport.[29,35] In anesthetized ventilated sheep, terbutaline-induced stimulation of fluid clearance was also associated with an increase in lung lymph flow, a finding that reflected increased removal of some of the alveolar fluid volume to the interstitium of the lung.[32] Although terbutaline increased pulmonary blood flow, this effect was not important, because control studies with nitroprusside, an agent that increased pulmonary blood flow, did not increase fluid clearance. Other studies have demonstrated that β-adrenergic agonists increased fluid clearance in rat, dog, guinea pig, and mouse as well as human lung.[1] The presence of β_1- and β_2-receptors on alveolar type II cells has been demonstrated in vivo by autoradiographic and immunochemistry techniques.[1]

It has been difficult to quantify the effect of catecholamines on the rate of alveolar fluid clearance and edema resolution in humans.[36] However, studies of fluid clearance in the isolated human lung have demonstrated that β-adrenergic agonist therapy increases fluid clearance, and the increased fluid clearance can be inhibited with propranolol or amiloride.[8] Subsequent studies suggested that long-acting lipid-soluble β-agonists may be more potent than hydrophilic β-agonists in the ex vivo human lung.[35] The magnitude of the stimulatory effect is similar to that observed in other species, with a β-agonist–dependent doubling of fluid clearance over baseline levels. These data are particularly important because aerosolized β-agonist treatment in some patients with pulmonary edema might accelerate the resolution of alveolar edema (see section "Alveolar Fluid Transport under Pathologic Conditions").

What has been learned about the basic mechanisms that mediate the catecholamine-dependent up-regulation of sodium transport in the lung? Based on in vitro studies, it was proposed that an increase in intracellular cAMP resulted in increased sodium transport across alveolar type II cells by an independent up-regulation of the apical sodium conductive pathways and the basolateral Na^+,K^+-ATPase. Proposed mechanisms for up-regulation of sodium transport proteins by cAMP include augmented sodium channel open probability,[1,37] increases in Na^+,K^+-ATPase α-subunit phosphorylation, and delivery of more ENaC channels to the apical membrane and more Na^+,K^+-ATPases to the basolateral cell membrane.[1]

Although most experimental studies have attributed a primary role for active sodium transport in the vectorial transport of salt and water from the apical to the basal surface of the alveolar epithelium of the lung, the potential role of chloride, especially in mediating the cAMP-

mediated up-regulation of fluid clearance across distal lung epithelium, has been the subject of a few recent studies. One older study of cultured alveolar epithelial cells concluded that vectorial transport of chloride across alveolar epithelium occurs by a paracellular route under basal conditions and perhaps by a transcellular route in the presence of cAMP stimulation.[38] Another study of cultured alveolar epithelial type II cells suggested that cAMP-mediated apical uptake of sodium might depend on an initial uptake of chloride.[39] A more recent study of cultured alveolar type II cells under apical surface–air interface conditions reported that β-adrenergic agonists produced acute activation of apical chloride channels with enhanced sodium absorption.[40] However, the results of these studies were considered to be inconclusive by some investigators,[41] partly because the data depend on cultured cells of an uncertain phenotype. Furthermore, studies of isolated alveolar epithelial type II cells do not address the possibility that vectorial fluid transport may be mediated by several different epithelial cells, including alveolar epithelial type I cells as well as distal airway epithelial cells.

In order to define the role of chloride transport in the active transport of salt and water across the distal pulmonary epithelium of the lung, one group has used in vivo lung studies to define the mechanisms and pathways that regulate chloride transport during the absorption of fluid from the distal air spaces of the lung.[42] This approach may be important because studies in several species, as already discussed, have indicated that distal airway epithelia are capable of ion transport and that both ENaC and CFTR are expressed in alveolar and distal airway epithelia.

Both inhibition and ion substitution studies demonstrated that chloride transport was necessary for basal fluid clearance. The potential role of CFTR under basal and cAMP-stimulated conditions was tested using intact lung studies in which CFTR was not functional because of failure in trafficking of CFTR to the cell membrane, the most common human mutation in cystic fibrosis (Δ1F508 mice). The results supported the hypothesis that CFTR was essential for cAMP-mediated up-regulation of isosmolar fluid clearance from the distal air spaces of the lung, because fluid clearance could not be increased in the Δ1F508 mice either with β-agonists or with forskolin, unlike in the wild-type control mice.[42] Additional studies using pharmacologic inhibition of CFTR in both mouse and human lungs with glibenclamide supported the same conclusion, namely that chloride uptake and CFTR-like transport seemed to be required for cAMP-stimulated fluid clearance from the distal air spaces of the lung.[42] Glibenclamide can also inhibit potassium channels so the inhibitory effects may not be specific for CFTR, but the Δ1F508 mouse studies have provided more direct evidence. Although the absence of CFTR in the upper airways results in enhanced sodium absorption, the data in these studies provide evidence that the absence of CFTR prevents cAMP–up-regulated fluid clearance from the distal air spaces of the lung, a finding that is similar to the results from studies on the importance of CFTR in mediating cAMP-stimulated sodium absorption in human sweat ducts.[43] Because CFTR is distributed throughout the distal pulmonary epithelium in distal airway epithelium as well as at the alveolar level in the human lung,[44] the data also suggest that the cAMP-mediated up-regulated reabsorption of pulmonary edema fluid may occur across distal airway epithelium as well as at the level of the alveolar epithelium. Finally, additional studies indicated that the lack of CFTR results in a greater accumulation of pulmonary edema in the presence of a hydrostatic stress, thus demonstrating the potential physiologic importance of CFTR in up-regulating fluid transport from the distal air spaces of the lung.[42] There is new evidence that functional CFTR chloride channels are present in adult rat alveolar epithelial type II cells based on whole cell patch-clamp experiments.[45] In addition, new data demonstrated expression of CFTR in both alveolar type I and II cells,[27,27a] as well as using a novel CFTR specific inhibitor, $CFTR_{Inh\text{-}172}$, in human lungs again demonstrated the importance of CFTR and chloride transport for cAMP-driven fluid absorption.[46]

In the last few years, several interesting catecholamine-independent mechanisms have been identified that can up-regulate fluid transport across the distal air spaces of the lung as well as in cultured alveolar type II cells. Hormonal factors such as glucocorticoids can up-regulate transport by transcriptional mechanisms, whereas thyroid hormone may work by a posttranslational mechanism. Some growth factors can work by either transcriptional or direct membrane effects, or by enhancing the number of alveolar type II cells. For example, keratinocyte growth factor (KGF) is a potent mitogen for alveolar type II cells. Administration of KGF (5 mg/kg) into the distal air spaces of the rat lung increases fluid clearance by 66% over baseline levels.[47] Other investigators have shown that KGF can enhance sodium and fluid transport in normal and injured rat lungs.[48,49] KGF may also work by enhancing the expression of sodium transport proteins.[50] There is also evidence that a proinflammatory cytokine, tumor necrosis factor-α (TNF-α), can rapidly up-regulate sodium uptake and fluid transport. The effect of TNF-α is amiloride inhibitable in both rats and isolated A549 human cells.[51,52] Finally, serine proteases can regulate the activity of ENaC and potentially increase fluid clearance across the distal airway epithelium. These catecholamine-independent mechanisms are explored in more detail in one review.[1]

MECHANISMS THAT CAN IMPAIR THE RESOLUTION OF ALVEOLAR EDEMA

Several mechanisms have been identified that can impair fluid transport from the distal air spaces of the lung. This section considers three conditions that have relevance to human disease: hypoxia, the use of anesthetics, and the presence of reactive oxygen and nitrogen species. The next section reviews mechanisms that impair fluid transport under specific pathologic conditions.

Hypoxia may occur during residence or recreation at high altitudes and under a variety of pathologic conditions associated with acute and chronic respiratory disease. Therefore, it is important to understand the effect of hypoxia on the ion and fluid transport capacity of the lung epithelium. The effect of hypoxia under in vivo conditions has been studied primarily in rats. In anesthetized rats, as well as in isolated perfused lungs, hypoxia decreased alveolar liquid clearance by inhibition of the amiloride-sensitive component.[53,54] The effect of hypoxia could not be explained by transcriptional effects on ENaC or Na^+,K^+-ATPase. The results suggested a post-translational mechanism such as a direct change of sodium transporter protein activity or transport to the plasma membrane. This latter hypothesis was supported by the normalization of fluid clearance by a cAMP agonist (terbutaline), which appears to increase the trafficking of sodium transporter proteins from the cytoplasm to the membrane.[55,56] Direct evidence for this mechanism in hypoxic alveolar epithelial type II cells was demonstrated for ENaC[57] as well as for an inhibitory effect of hypoxia on Na^+,K^+-ATPase activity in isolated A549 cells.[58]

In alveolar epithelial cells, the halogenated anesthetics affect sodium and fluid transport at the physiologic level as well as on a cellular level. In the rat, halothane and isoflurane decrease fluid clearance by inhibition of the amiloride-sensitive component. This effect was rapidly reversible after cessation of halothane exposure.[59] In vitro, exposure to a low concentration of halothane (1%) for a short time (30 min) induced a reversible decrease in Na^+,K^+-ATPase activity and amiloride-sensitive ^{22}Na influx in rat alveolar type II cells.[60] The mechanisms whereby halothane induced a decrease in sodium transport protein activity have not been yet elucidated, but they are not related in vitro to a decrease in intracellular adenosine triphosphate content or to a change in cytosolic free calcium. Taken together, these observations suggest that halogenated anesthetics may interfere with the clearance of alveolar edema.

Lidocaine is widely used in patients with acute cardiac disorders and has also been recently implicated as a possible cause of pulmonary edema following liposuction. In experimental studies in rats, either intravenous or intra-alveolar lidocaine reduced fluid clearance in rats by 50%.[61] Because lidocaine did not inhibit ENaC when expressed in oocytes, it seems that the inhibitory effect on vectorial fluid transport was primarily on the basal surface of alveolar epithelial cells, either through an effect on the activity of Na^+,K^+-ATPase or through an indirect effect via blockade of potassium channels, a well-known property of lidocaine. The effect of lidocaine was also completely reversible with β_2-agonist therapy.[61]

Under several pathologic conditions, in response to proinflammatory cytokines, activated neutrophils and macrophages can localize in the lung and migrate into the air spaces of the lung, and release reactive oxygen species by the membrane-bound enzyme complex nicotinamide adenine dinucleotide phosphate oxidase and nitric oxide (NO) via the calcium-insensitive inducible form of NO synthase. NO decreased Isc across cultured rat type II cells without affecting transepithelial resistance. NO also inhibited 60% of amiloride-sensitive Isc across type II cell monolayers following permeabilization of the basolateral membrane with amphotericin B.[62] NO reacted with superoxide ($\cdot O_2$) to form peroxynitrite ($ONOO^-$), a potent oxidant and nitrating species that directly oxidizes a wide spectrum of biologic molecules, such as DNA constituents, lipids, and proteins.[22] Boluses of peroxynitrite (0.5–1 mM) delivered into suspensions of freshly isolated type II cells from rabbits decreased amiloride-inhibitable sodium uptake to 68% and 56% of control values, respectively, without affecting cell viability. Some investigators reported that products of macrophages, including NO, can down-regulate sodium transport in fetal distal lung epithelium stimulated with endotoxin.[63] The data indicate that oxidation of critical amino acids residues in ENaC protein is probably responsible for this effect. This evidence matches well with other studies that have shown that protein nitration and oxidation by reactive oxygen and nitrogen species have been associated with diminished function of a variety of important proteins present in the alveolar space, including surfactant protein A.[64]

There is also new evidence that transforming growth factor-β_1 decreases expression of ENaC and alveolar epithelial sodium and fluid transport by an ERK 1/2-dependent mechanism in both primary rat and human alveolar type II cells.[65]

ALVEOLAR FLUID TRANSPORT UNDER PATHOLOGIC CONDITIONS

Fluid clearance from the distal air spaces of the lung has been measured in mechanically ventilated patients with acute respiratory failure from pulmonary edema as well as in several animal models designed to simulate clinically relevant pathologic conditions.

Studies of fluid clearance have been done in intubated, ventilated patients by measuring the concentration of total protein in sequential samples of undiluted pulmonary edema fluid aspirated from the distal air spaces of the lung with a standard suction catheter passed through the endotracheal tube into a wedged position in the distal airways of the lung.[36,66,67] This method for measuring fluid clearance in patients was adapted from the method for aspirating fluid from the distal air spaces of the lung in experimental studies in small and large animals.[7,32] The clinical procedure has been validated in patients by demonstrating that there is a relationship between fluid clearance and the improvement in oxygenation and the chest radiograph.[36,67]

In patients with severe hydrostatic pulmonary edema, there was net fluid clearance in the majority during the first 4 hours after endotracheal intubation and the onset of positive-pressure ventilation.[66] The rate of fluid clearance was 14%/hr in 38% of the patients. Overall, 75% of the patients had intact fluid clearance. There was no significant correlation between the levels of fluid clearance and endogenous plasma levels of epinephrine,

although twice as many of the patients with intact fluid clearance received aerosolized β-adrenergic therapy as did those with impaired fluid clearance; this difference did not reach statistical significance, perhaps because the total number of studied patients was modest. In a recent study of congestive heart failure in rats, it was demonstrated that β-adrenergic stimulation increased alveolar fluid clearance and that type II cell hyperplasia was likely responsible for the stimulation.[66a]

The majority of patients with increased permeability edema and acute lung injury have impaired alveolar epithelial fluid transport, a finding that is associated with more prolonged respiratory failure and a higher mortality (Fig. 10-2). In contrast, a minority of patients can remove alveolar edema fluid rapidly, and these patients have a higher survival rate.[36,67] These results indicate that a functional, intact distal lung epithelium is associated with a better prognosis in patients with acute lung injury, thus supporting the hypothesis that the degree of injury to the distal lung epithelium is an important determinant of the outcome in patients with increased permeability pulmonary edema from acute lung injury.

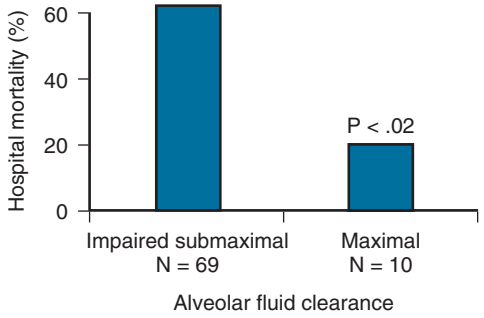

FIGURE 10-2 ■ Hospital mortality is increased in patients with acute lung injury or the acute respiratory distress syndrome with impaired fluid clearance. Impaired fluid clearance (<14%/hr) was compared with those with maximal fluid clearance (<14%/hr). The columns represent percent hospital mortality in each group. Hospital mortality of patients with maximal fluid clearance was significantly less ($P < .02$). N, number of patients. (Data from Ware LB, Matthay MA: Alveolar fluid clearance is impaired in the majority of patients with acute lung injury and the acute respiratory distress syndrome. Am J Respir Crit Care Med 163:1376–1383, 2001.)

What are the mechanisms that may impair fluid clearance from the air spaces of the lung in patients with acute lung injury? As already explained, alveolar hypoxia can depress alveolar epithelial fluid transport. Also, viral or bacterial lung infection can depress alveolar fluid transport, either by interfering with normal ion transport or by inducing apoptosis or necrosis of the distal lung epithelium. There are also some clinical data indicating that a decrease in fluid clearance may be associated with higher levels of nitrate and nitrite in pulmonary edema fluid, a finding that supports the hypothesis that nitration and oxidation of proteins essential to epithelial fluid transport may occur in some patients with lung injury, further depressing their ability to remove alveolar edema fluid.[64] Recent data suggest that elevated levels of the receptor for advanced glycation end-products (RAGE) may be a marker for alveolar type I cell injury and predict a reduced rate of clearing pulmonary edema fluid.[67a]

FUTURE DIRECTIONS

Recent progress demonstrates that it is feasible to quantify the rate of edema reabsorption from the distal air spaces of the lung in ventilated, critically ill patients with acute pulmonary edema. In conjunction with progress in experimental studies of lung fluid balance under clinically relevant pathologic conditions, further studies should be done to test the potential role of catecholamine-dependent and -independent therapies that might enhance the resolution of clinical pulmonary edema. Recent experimental data in a rat model of acute lung injury indicates that β_2-adrenergic agonist therapy can decrease lung endothelial permeability, increase alveolar fluid clearance, and decrease pulmonary edema when given after lung injury had developed.[68] The feasibility of delivering of therapeutic concentrations of aerosolized β-adrenergic agonist therapy to the distal air spaces of ventilated patients has been demonstrated.[69] Therefore, clinical trials are being conducted to test the potential value of this therapy for enhancing the resolution of pulmonary edema and improving clinical outcomes.[70]

KEY POINTS

- The distal conducting airways and alveolar surface are lined with epithelial cells that provide a tight barrier to protect the distal airspaces for gas exchange.
- The primary mechanism for reabsorption of excess alveolar fluid is active vectorial sodium and chloride transport.
- The best understood transporters are ENaC and CFTR.
- The resolution of alveolar edema is driven by active ion transport and can be up-regulated by cAMP stimulation.
- Alveolar fluid transport is impaired in patients with acute lung injury.

THERAPEUTIC IMPLICATIONS

INTRODUCTION

When animals migrated from sea to land, gills were exchanged for lungs, thus increasing the surface area for gas exchange, and the respiratory exchange organ (lungs) was relocated deep within the thorax. This new apparatus required a connection from the areas of gas exchange in the alveoli to the external environment, which was provided by the airways. The airway epithelium is exposed to a wide array of environmental invaders, such as microbes and other inhaled irritants. The epithelium developed an early system for responses to the "invaders" as a first line of defense. Normally, when inhaled microbes deposit on the epithelial surface, the epithelium responds via a signaling cascade to trap and clear the invaders. The secretion of a thin layer of mucus plays an important role in the protection of the host, and this is normally accomplished without symptoms or significant pathologic changes. However, in chronic inflammatory airway diseases, overexuberant pathologic responses occur, impairing rather than protecting the host.

Mucous hypersecretion in large conducting airways leads to cough and excessive sputum production. Mucous hypersecretion also occurs in small peripheral airways, which become plugged. However, this peripheral plugging produces few or no symptoms early. Furthermore, no effective therapy is yet available. Therefore, this chapter focuses on mucus, mucins, and the effects of their hypersecretion. It is hoped that wide recognition of the effects and mechanisms of mucin hypersecretion will lead to important therapeutic progress.

COMPONENTS OF MUCUS

Mucus secretion normally plays a protective role in the epithelium. Airway mucus is a complex mixture of proteins and liquids and includes a sol phase composed of water and electrolytes.[1,2] Mucus contains water (95%), most of which is bound in a viscoelastic gel containing mucins.[3,4] The gel-forming mucins in mucus are high-molecular-weight glycoproteins that are key components of mucous cells and are rich in carbohydrates.[5] Mucin oligosaccharides are joined by an initial α_0-glycoside linkage of *N*-acetylgalactosamine to the hydroxyl moieties of serine or threonine of the mucin protein backbone.[6] Mucins produced intracellularly are packed tightly within granules. During exocytosis (secretion), the cells

secrete their granule contents in a condensed form, and the secreted mucins undergo rapid hydration to form a gel with unusual viscoelastic properties that allow the gel to interact with cilia to affect mucociliary clearance and effective cough. Various mucins may have very different biophysical properties, and future studies are needed to characterize these properties and their potential pathophysiologic implications. Currently, approximately 19 mucin (MUC) genes have been cloned. They are divided into two groups: membrane-associated– and gel-forming–secreted mucins.[7,8] Of the secreted mucins, two are especially prominent in inflammatory airway diseases: MUC5AC in airway goblet cells,[9–12] and MUC5B in submucosal gland mucous cells.[10,11,13,14]

CHARACTERISTICS OF NORMAL AIRWAY MUCINS IN HEALTHY INDIVIDUALS

Gel-forming mucins are produced by mucous tubules in submucosal glands in the large conducting airways and in goblet cells located in the surface epithelium in both large and small airways. MUC5AC is the predominant mucin produced by the surface epithelium[15] and by airway epithelial cells in culture.[12,16] The submucosal glands are normally small.[17] In the normal surface epithelium, goblet cells are sparse[12,18,19] but present at all levels, decreasing in number peripherally, presumably reflecting less contact of peripheral airways with environmental particulates. Pathogen-free animals also have few goblet cells in the airway epithelium.

On the surface of the airways is a periciliary sol phase, above which the mucous gel floats. The contracting cilia propel the mucous blanket mouthward, along with trapped environmental particles that have deposited on the epithelial surface. In addition, in the large conducting airways, clearance is assisted by cough. Interestingly, the cough receptors are preferentially located at the bifurcation of the airways,[20] adjacent to the gland ducts that exit on the epithelial luminal surface. The colocalization of cough receptors at sites of gland secretion on the airway surface facilitates cough-induced clearance. Activation of the cough receptors has been shown to stimulate submucosal gland secretion via vagal efferent nervous cholinergic pathways; these nerves also innervate airway smooth muscle in the conducting airways, and blockade of their efferent cholinergic pathways is the basis of anticholinergic therapy in chronic obstructive airway disease. The gland secretion that accompanies cough assists in the entrapment of deposited particulates and in their clearance from the major conducting airways.

MUCOUS HYPERSECRETORY DISEASES AND THEIR CLINICAL CONSEQUENCES

A variety of chronic inflammatory airway diseases are associated with mucous hypersecretion, and the stimuli involved may vary. For example, allergic factors are involved in asthma (see Chapter 38), genetic abnormalities dominate cystic fibrosis (CF; see Chapter 41), and chronic obstructive pulmonary disease (COPD; see Chapter 39) is linked closely to the inhalation of toxic components of cigarette smoke. Regardless of the variety of etiologies, the similarities that exist in cellular responses (such as mucous hypersecretion) among these various disease states suggest that some common mechanisms are likely to exist that could be useful in therapy.

The clinical manifestations of mucous hypersecretion depend, at least in part, on the anatomic location of the hypersecretory process. Hypersecretion of mucins by submucosal glands in proximal airways is associated with excessive sputum production.[21] Cough (described in Chapter 29) ensues because of the colocalization of the cough receptors and the gland duct openings.

Because of the large cross-sectional area of the conducting airways, obstructive plugging of these airways is rare. In contrast, the peripheral airways do not contain glands nor do they contain cough receptors to produce symptoms. Conversely, mucous hypersecretion in peripheral airways is due to secretion from goblet cells on the epithelial surface. The small diameters of the airways increase their tendency to become obstructed in many ways: First, secretion of mucins results in mucin hydration, which increases the volume more than a thousandfold.[22] Because of their small diameters, peripheral airways are more likely to become obstructed by mucin degranulation than are larger airways. In addition, chronic inflammation is associated with an increase in the volume of the epithelium, which occupies a larger percentage of the airway lumen than in healthy airways, thus exaggerating the obstructive effects of mucous hypersecretion. Contraction of airway smooth muscle adds to the narrowing, further exaggerating the effects of mucous hypersecretion. This is shown schematically in Figure 11-1. Mucous plugging may be the result of local hypersecretion by the peripheral airways themselves. However, it is also possible that mucus is aspirated retrograde into the periphery. Retrograde contamination of peripheral airways by bacteria-containing mucus (e.g., in intubated patients in the intensive care unit) could play a role in perpetuating chronic bacterial infection.

In spite of the fact that chronic progressive mucous plugging is common in chronic inflammatory airway diseases such as COPD,[23] CF,[18] and acute fatal asthma,[24–28] the detection of peripheral mucous plugging is very difficult.

IMPORTANCE OF MUCOUS HYPERSECRETION IN CHRONIC INFLAMMATORY AIRWAY DISEASES

In healthy subjects, mucous secretion is involved in innate immune defense of the host (see Chapter 13). These host responses defend against inhaled “invaders” (e.g., microbes, other inhaled irritants) efficiently, usually without obvious interference with function. However, in various chronic inflammatory airway diseases, there is evidence of abnormal inflammatory responses, which are believed to be importantly involved in the

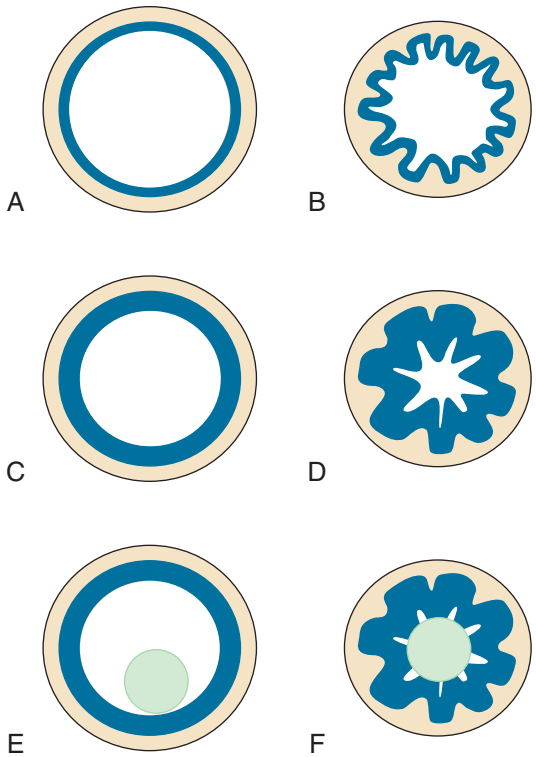

FIGURE 11-1 ■ Schematic representation of the potential impact of goblet cell hyperplasia and mucous plugging on small airway obstruction. In normal individuals, the surface epithelium covering small airways contains few goblet cells and is composed of a thin layer of epithelial cells. **A** and **B**, Normal, thin epithelium contributes little to luminal narrowing both when airway smooth muscle is relaxed (**A**) and when smooth muscle shortening occurs (**B**). **C** and **D**, In various airway inflammatory diseases (e.g., acute asthma, chronic obstructive pulmonary disease, and cystic fibrosis), epithelial cell hyperplasia is present in small airway epithelium, resulting in epithelial thickening. **C**, When airway smooth muscle is relaxed, thickened epithelium contributes little to airflow limitation. **D**, However, because the thickness of the airway wall (composed of epithelium, lamina propria, muscle, and adventitial compartments) is an important determinant of airflow limitation, when smooth muscle shortening occurs, hyperplastic epithelium is predicted to contribute to airflow obstruction. **E** and **F**, When hyperplastic goblet cells release mucins in the airway lumen, swelling of secreted mucins during hydration may result in mucous obstruction. **F**, The contribution of mucous secretions to airflow limitation is likely to be increased when smooth muscle shortening occurs. Thus, both goblet cell hyperplasia and mucous obstruction in small airways are predicted to contribute significantly to the airflow limitation that occurs in chronic inflammatory airway diseases. (Redrawn from Burgel PR, Montani D, Danel C, et al: A morphometric study of mucins and small airway plugging in cystic fibrosis. Thorax 62:153, 2007.)

pathophysiology of the diseases. Thus, whereas secretion of mucus normally plays a protective role in host defense, hypersecretion plays an important role in the pathophysiology of various chronic airway diseases. Below is a brief review of studies of mucous hypersecretion in CF, asthma, and chronic bronchitis/COPD. Other airway diseases can also cause mucous hypersecretion (e.g., bronchiectasis).

Cystic Fibrosis

CF, a life-shortening genetic disorder, is described in detail in Chapter 41. Mucous plugging has long been known to play a major role in the pathophysiology of the disease, but the extent and characteristics of plugging have long escaped analysis. It is of interest to understand why knowledge of peripheral airway disease is so limited: First, peripheral airways are too small to be visualized through a bronchoscope. Second, radiologic techniques have inadequate resolution to detect plugged airways. Biopsy material has been limited because of technical limitations. Finally, the peripheral airways are numerous (see Chapter 1), so obstruction of a large number of peripheral airways is required to cause clinically recognizable airway obstruction (see Chapter 24). Various investigators have reported that mucins contribute to the pathophysiology in CF.[10,29,30] A biopsy study of conducting airways in CF showed an increase in goblet cell size and an enlarged submucosal gland volume.[17] In a quantitative analysis of CF lungs removed at the time of lung transplantation, Burgel and coworkers[18] reported that in CF, most small airways contained extensive plugging, whereas control lungs contained only rare plugs (Fig. 11-2). Plugging was also present in small, noncartilaginous airways (Fig. 11-3). Pulmonary function studies in these CF patients prior to transplantation were indicative of severe airway obstruction, and the authors suggested that the extensive peripheral airway plugging contributed to the loss of lung function. In the airways with plugs, there was extensive goblet cell hyperplasia, with mucins streaming into the luminal plugs. These studies indicate that CF patients with late-stage disease and severe airway obstruction have extensive peripheral airway plugging, which contributes to the advanced obstruction present and the need for transplantation.

Although mucins play a role in the production of mucous plugs, other components (e.g., neutrophil products) including DNA and extravasated blood products (such as albumin) also contribute. It should be noted that the observation that mucin production is increased in CF and that mucins were seen streaming into lumens obstructed by plugs does not necessarily imply that CF epithelial cells have increased responsiveness to mucin production in CF, but only that in the area of plugs there are stimuli (e.g., *Pseudomonas* bacteria) that effectively stimulate production and secretion of mucins.

In CF, Burgel and coworkers[18] noted that the staining for mucins occupied approximately 20% of the plugged lumen volume, indicating that mucins contributed to the plugs but that other molecules were also importantly present. Neutrophils were also conspicuous in the plugs. Voynow and colleagues[31] reported that elastase, a product secreted by neutrophils, causes the degradation of mucin MUC5AC. Davies and associates[32] reported findings that suggested that one airway mucin (MUC5AC) is more vulnerable to proteolytic degradation than the other (MUC5B). The findings reported by Burgel and coworkers[18] confirmed this opinion. The prominent presence of neutrophils in plugged airways suggests the possibility that neutrophil-mediated effects could be

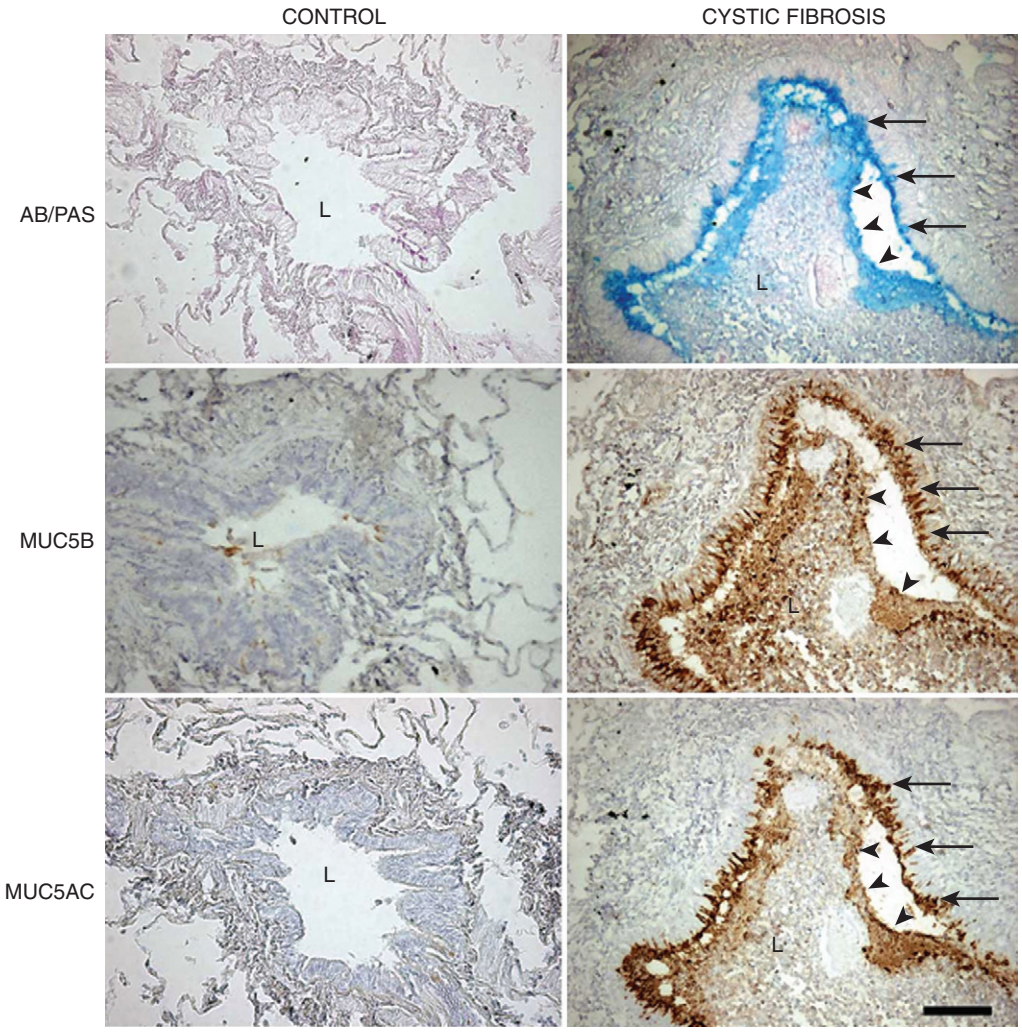

FIGURE 11-2 ■ Mucous glycoconjugates and mucins in airway lumens of controls and patients with cystic fibrosis. Representative photomicrographs. Sections containing small airways in a typical control subject (*left panels*) and in a patient with cystic fibrosis (*right panels*) were stained with Alcian blue/periodic acid–Schiff (AB/PAS) for mucous glycoconjugates, blue staining (*upper panels*) or with antibodies to mucin MUC5B (*brown staining; middle panels*) and MUC5AC (*brown staining, lower panels*). In the control subject, the airway lumen (L) is empty; no staining for AB/PAS, MUC5B, or MUC5AC is observed in the lumen or in the epithelium. In the patient with cystic fibrosis, the airway lumen is obstructed by a plug containing mucous glycoconjugates (AB/PAS), MUC5B, and MUC5AC only at the periphery of the plug (*arrowheads*), adjacent to the epithelium. Staining for mucins is absent in the center of the plug. Goblet cells in the epithelium are stained positively with AB/PAS and with MUC5AC and MUC5B antibodies (*arrows*). (Original magnification ×100; *bar* = 100 μm.) (From Burgel PR, Montani D, Danel C, et al: A morphometric study of mucins and small airway plugging in cystic fibrosis. Thorax 62:153, 2007.)

involved in proteolytic inactivation of secreted mucins. Many other molecules may also be components of mucous plugs. For example, albumin is a normal component of blood, but in states of inflammation with increased vascular permeability, albumin is reported to move from the vascular lumen to the airway lumen. Albumin is a plasma protein that can move across the endothelial surface via multiple mechanisms.[33] When albumin is present in renal tubular epithelial cells, it activates epidermal growth factor receptors (EGFRs) and causes the production of inflammatory mediators.[34] If albumin has similar actions in airways, perhaps in diseases with increased vascular permeability, albumin might play a role in activating EGFR and leading to mucous hypersecretion.

Asthma

In normal healthy subjects, airway mucins are sparse,[19] and only a thin layer of mucus exists on the airway luminal surface. Healthy subjects produce little sputum. However, in patients with asthma, a history of sputum overproduction is associated with an accelerated decline in maximal expiratory airflow.[35]

Sputum production is a frequent symptom of asthma and contributes to asthma morbidity. Turner-Warwick and Openshaw[36] reported that 77% of asthma patients had a history of sputum production, and 56% reported maximum sputum production at the peak of an asthma attack. Goblet cell numbers are increased even in mild asthma.[12] Mucous hypersecretion causes plugging,

especially in peripheral airways, which may not cause symptoms early. Widespread mucous hypersecretion was reported in fatal asthma by Cardell and Pearson in 1959[24] and was confirmed by other studies.[25–28] Thus, sputum secretion and cough, symptoms of hypersecretion in large airways, are common in asthma. Mortality in acute asthma is associated with mucous plugging, which is presumed to be a major cause of death. An example of mucous plugging in fatal asthma is shown in Figure 11-4.

In experimental models of allergic airway disease, mucous hypersecretion has been reported. For example, allergic sensitization by ovalbumin in rats increased mucin production in the airway epithelium.[37]

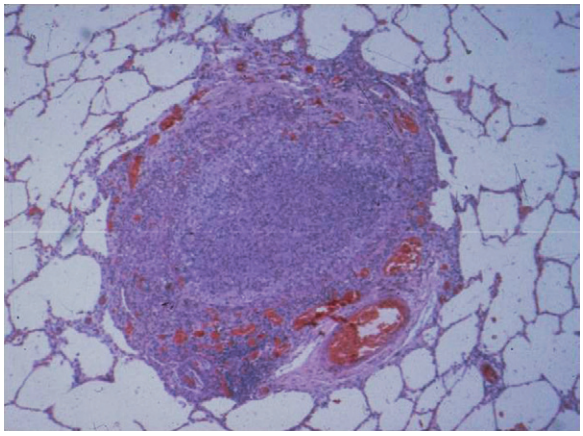

FIGURE 11-3 ■ Mucin plug in terminal bronchiole in a patient with cystic fibrosis. This section was stained with AB/PAS. The plugged bronchiole is surrounded by alveoli.

Chronic Bronchitis and Chronic Obstructive Pulmonary Disease

Mucous hypersecretion has often been considered to be an annoying but otherwise benign component of airway diseases associated with smoking. To understand the effects of mucin overproduction in chronic bronchitis and COPD, the anatomy of mucin-containing cells in airways is helpful. Submucosal glands are located in the large conducting airways but not in the peripheral, noncartilaginous airways. These glands are normally small and produce only small volumes of mucus. In tobacco-associated disease, the glands become enlarged and are capable of producing copious secretions. These secretions are cleared in the sputum, assisted by cough. If disease is limited to the large airways and airway obstruction is not prominent, symptoms of cough may disturb the patient but deterioration of lung function may not be conspicuous. Conversely, mucous hypersecretion in the peripheral airways (especially the noncartilaginous airways) is derived from goblet cells that form in the surface airway epithelium, where hypersecretion can cause airway obstruction. However, mucous secretions in the periphery are not detected early, so peripheral airways remain a relatively silent zone! Hogg and coworkers[23] and others were long convinced that peripheral airway changes occur early in the evolution of COPD. Many tests designed to diagnose peripheral airway obstruction have been devised (see Chapter 24), but these tests have not proved selective.

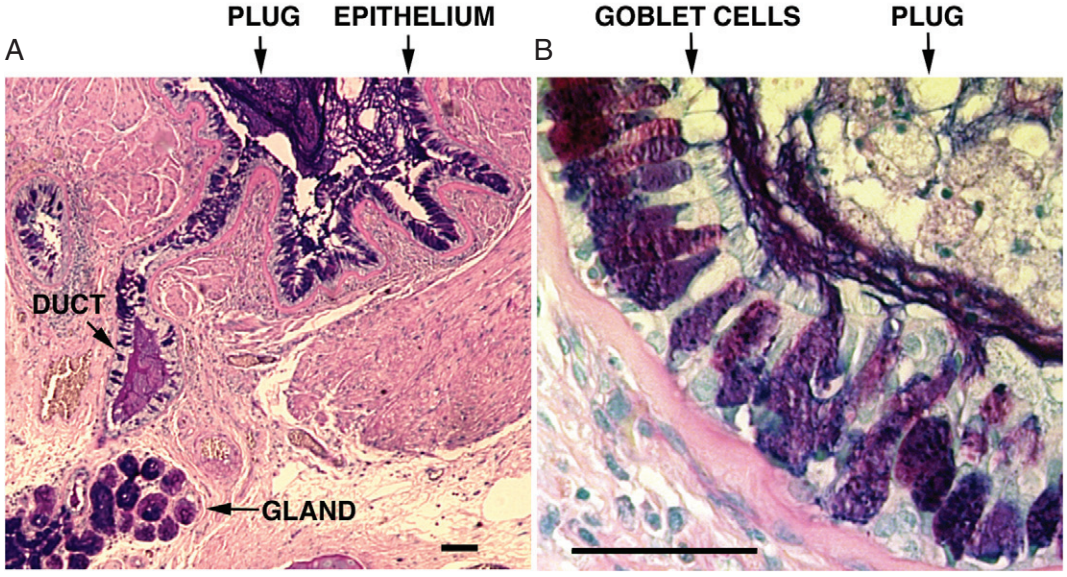

FIGURE 11-4 ■ Mucous hypersecretion in fatal asthma. **A**, AB/PAS staining for mucous glycoconjugates in a proximal airway section in a patient with fatal asthma. The airway lumen is plugged (PLUG) with mucus. The epithelium (EPITH.) shows marked goblet cell metaplasia. The submucosal gland (GLAND) has intense staining for mucous glycoconjugates and releases its contents into a gland duct (DUCT) that is filled with AB/PAS-stained material. **B**, Another AB/PAS-stained section of airway epithelium in the same patient at higher magnification. Although goblet cells (GC) here remain intact, mucus can be seen streaming from the luminal tips of the goblet cells into the lumen. The lumen is filled with mucus. Both scale *bars* = 50 μm.

In 2004, Hogg and coworkers[23] performed a quantitative assessment of small airways in surgically resected lung tissue in patients with COPD with different degrees of airway obstruction. The progression of COPD was strongly associated with an increase in inflammatory mucous exudates in the lumens of small airways. In addition, they reported an increase in the volume of tissue in the airway wall, which potentiates the effects of luminal plugging. Thus, in COPD, as well as in CF and in acute severe asthma, obstruction of peripheral airways plays a major role in the pathophysiology of the disease. Previous limited attempts at intervention are due to multiple factors: (1) most physicians associate mucous hypersecretion with large airways, where mucus can be visualized, and where the patients have complaints (cough and sputum production); (2) obstruction of the peripheral airways generally is not associated with symptoms early, decreasing the level of awareness; (3) peripheral airways are relatively inaccessible because of the limitations of present methodologies.

EPITHELIAL SIGNALING PATHWAYS RESPONSIBLE FOR MUCIN PRODUCTION IN AIRWAYS

The previous sections describe the characteristics of airway mucins (in "mucus") in airway diseases including CF, acute severe asthma, and COPD, where potentially lethal effects of mucous hypersecretion by obstruction of peripheral airways ("mucous plugging") are documented. Here the signaling pathways for mucin production are reviewed.

Early Studies of Mucins

Chronic airway diseases have long been associated with mucous hypersecretion. The gel-forming mucins, which are large-sized glycoproteins, became recognized as being responsible for the major characteristics of mucus. Cloning of mucin genes (reviewed by Rose and colleagues[38]) provided tools for studying mucin regulation. In the 1990s, intense research on mucins began, and many stimuli were shown to produce mucins in airway epithelial cells. Based on the newly available cell and molecular tools, rapid advances began to clarify the pathways involved in mucin production. In 1998, Li and associates[29] reported that *Pseudomonas* bacteria stimulate epithelial mucin production via a Src-dependent Ras/Raf/MAPK pathway.

Epidermal Growth Factor Receptor Activation Stimulates Mucin Production in Airways

Many of the stimuli that induce mucin production in airways such as microbes and cigarette smoke are derived from the environment and are inhaled, depositing on the airway epithelial surface. Takeyama and coworkers[37] hypothesized that receptors on the surface of the airway epithelium could be candidates for epithelial signaling, resulting in mucin production that occurs in response to the deposition of the inhaled foreign particulates. Epidermal growth factor (EGF), an EGFR ligand, was discovered by Cohen,[39] and subsequently, his group expanded the understanding of EGF and its receptor EGFR, focusing on epithelial cell proliferation and cancer. EGFR is a 170-kDa membrane glycoprotein that is activated by multiple ligands.

Takeyama and coworkers[37] hypothesized that epithelial responses to inhaled microbes such as *Pseudomonas* are initiated on the epithelial luminal surface, where the microbes are deposited, by activation of EGFR. The authors discovered that activation of EGFR by its ligands (such as EGF and transforming growth factor-α [TGF-α]) causes mucin production in cultured human airway epithelial cells, an effect that is prevented by EGFR inhibition. They confirmed these results in rats in vivo; they also found that ovalbumin sensitization increases MUC5AC mucin.

Perrais and colleagues[40] confirmed that EGFR ligands activate EGFR to produce mucins. They reported that the downstream pathways include a Ras/Raf/MAP kinase cascade. Subsequent reports identified EGFR as a key target for mucin synthesis/goblet cell metaplasia in response to multiple stimuli in vitro and in vivo (for a representative list, see Table 11-1).

TABLE 11-1. Examples of Stimuli That Induce Mucin Synthesis In Vitro or In Vivo by Epiderma Growth Factor Receptor Activation in Airways

In Vitro Experiments
- Bacterial products
  - *P aeruginosa* supernatant[45]
  - Lipopolysaccharide (LPS)[45,46]
  - Lipoteichoic acid (LTA)[63]
- Phorbol 12-myristate 13-acetate (PMA)[46]
- Cigarette smoke[64]
- Inflammatory cells
  - Neutrophils[16]
  - Eosinophils[65]
- Serine proteases
  - Human neutrophil elastase[55]
  - Human airway trypsin-like protease[66]

In Vivo Experiments
- T helper 2 (Th2) cells
- Antigen (ovalbumin)[37]
- Interleukin-13 (IL-13)[67]
- Mechanical damage of epithelium[68]
  - Cigarette smoke[64]
  - Leukotrienes[69]

Metalloproteases Cleave Membrane-Bound Epidermal Growth Factor Receptor Ligands to Produce Mucins

Airway epithelial cells themselves synthesize EGFR ligands in the airway epithelium[41] as transmembrane precursors that can be cleaved by metalloproteases, releasing soluble active growth factors.[42] In 1999, Dong and associates[43] reported that general metalloprotease inhibitors prevent the effects of EGFR proliferation in proportion to the release of the membrane-bound EGFR ligand TGF-α, and they concluded that the soluble ligand was responsible for the effects of EGFR activation. Prenzel and coworkers[44] similarly reported that a general metalloprotease inhibitor prevented EGFR ligand release and subsequent EGFR activation. These papers were the first to implicate cleavage of EGFR ligands by metalloprotease(s) in EGFR surface signaling. Subsequently, Kohri and colleagues[45] linked *Pseudomonas* bacterial supernatant to mucin production. EGFR activation was required, but the mode of EGFR signaling in the airway epithelium was unclear.

Tumor necrosis factor α–converting enzyme (TACE) is a member of the ADAM family of proteases. It is bound to the luminal surface of the airway epithelium. Shao and associates[46] recognized that TACE was capable of cleaving membrane-bound EGFR proligands (as shown previously).[47] Shao and associates[46] showed that *Pseudomonas* and their product lipopolysaccharide (LPS) increase mucin production in human airway epithelial cells, an effect that was reported to be EGFR-dependent and associated with the cleavage and release of the membrane-bound EGFR ligand TGF-α. Selective knockdown of TACE prevented the sequence leading to mucin production, establishing TACE as important in autocrine signaling involved in mucin production. These results established the role of TACE in the autocrine activation of EGFR and in mucin production in airways. Subsequently, many different stimuli were reported to cause mucin production via autocrine EGFR signaling by the airway epithelium. Other metalloproteases have also been reported to be involved in epithelial signaling. Because of the importance of the cleavage step in ligand-dependent EGFR activation, further exploration of various proteases in mucin production is recommended.

Roles of Reactive Oxygen Species in Airway Epithelial Mucin Production

Excess production of reactive oxygen species (ROS) is known to cause cell damage in chronic inflammatory diseases,[48] but ROS scavengers are also reported to inhibit interleukin-8 (IL-8) production.[49]

Several studies have contributed to the understanding of the role of ROS in epithelial signaling and mucin production. Thus, ROS stimulation (e.g., with H_2O_2) activates EGFR[50,51] and results in mucin production.[16]

Dual oxidase-1 (DUOX1) was found in human airway epithelial cells and was reported to generate ROS.[52,53] Shao and Nadel[54] suggested that DUOX1 could release ROS and thereby activate TACE. They used human neutrophil elastase (HNE) as the stimulus, because HNE had been previously reported to produce mucin via EGFR ligand-dependent activation.[55] Shao and Nadel[54] reported that HNE induced TACE activation, TGF-α release, and mucin expression, effects that were inhibited by ROS scavengers, implicating ROS in the response. Knockdown of DUOX1 expression with small interfering RNA prevented the responses. Furthermore, the PKC-δ/PKC-θ inhibitor rottlerin prevented the effects of HNE, suggesting that DUOX1 plays a critical role in mucin production via PKC-δ/PKC-θ-DUOX1-ROS–TACE-proligand-EGFR cascade. The scheme is shown diagrammatically in Figure 11-5. It is of interest that DUOX1 may release ROS in a limited cell compartment adjacent to TACE, thus producing a signal in defense of the host without harmful effects on epithelial cell viability. In fact, DUOX1 is now recognized to play a role in other epithelial defensive responses such as wound healing.[56] Activation of DUOX1 stimulates the production of the chemokine IL-8.[57] It is hoped that future studies in various epithelia will evaluate the importance of ROS and other aspects of the proinflammatory cascade in a variety of epithelial-based diseases, both inflammatory and malignant.

ROS liberated by inflammatory cells recruited to the epithelium may also play roles in mucin production. Thus, neutrophils recruited to the airways and activated are known to produce ROS.[58,59] When neutrophils were isolated from blood and activated and the neutrophil supernatant was added to human airway epithelial cells, the cells became EGFR phosphorylated and increased mucin synthesis occurred, effects that were shown to be due to EGFR phosphorylation.[16] However, neutrophils can also produce large amounts of ROS that may cause DNA damage and death of epithelial cells.[60] Thus, at low concentrations, molecules such as ROS produced by inflammatory cells can induce defensive responses such as mucin production, whereas higher concentrations can be destructive to the epithelium.

Because ROS appears to play important roles in mucin production, and because only limited studies of ROS-induced modulation exist, further examination of ROS effects on epithelial cell signaling are in order.

Toll-like Receptors

Multiple stimuli activate airway epithelial cell receptors and produce defensive responses. (For a discussion of innate immune responses, see Chapter 13.) Here we focus on mechanisms of mucin production. Because of their importance in studies performed on mucin production, Toll-like receptors (TLRs) are included here. Recognition of inhaled stimuli by the airway epithelium was initiated with studies of inhaled microorganisms. Recognition of pathogens is mediated by a set of germline-encoded receptors called "pattern recognition receptors," which recognize conserved molecular patterns shared by large groups of microorganisms. An important group of these receptors were discovered in fruit flies (so-called Toll receptors). When they were found in mammals, they were called "Toll-*like* receptors" (TLRs).[61]

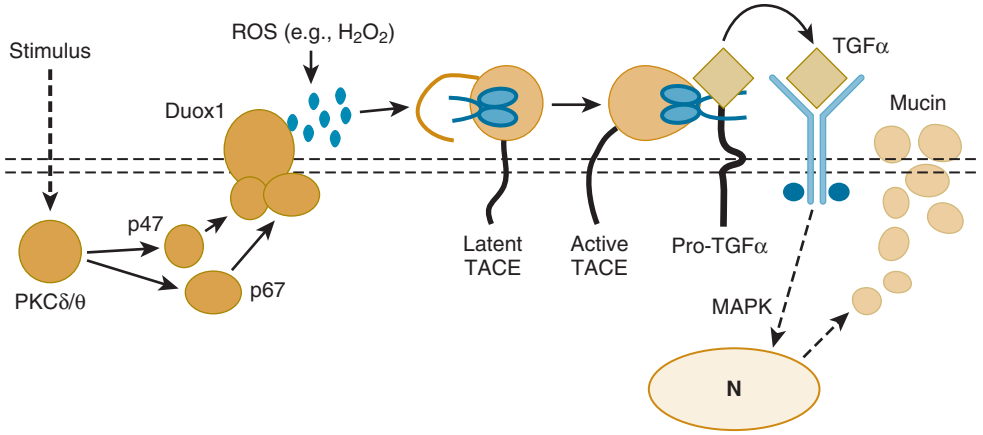

FIGURE 11-5 ■ Diagrammatic scheme of epidermal growth factor–dependent cascade that causes mucin production. Deposition of a stimulus on the airway epithelium activates an epithelial receptor (not shown), activates protein kinase C (PKC) isoforms PKCδ and PKCθ, which recruit cytosolic components (e.g., $p47^{phox}$) to plasma membrane (*double-dotted lines*) to join dual oxidase-1 (DUOX1) to form an active enzyme system for generating reactive oxygen species (ROS; e.g., H_2O_2; represented by *dark dots*). ROS activate the latent form of tumor necrosis factor-α–converting enzyme (TACE), which has an inhibitory prodomain (represented by a *curved line*) covering its catalytic domain (represented by *scissors*), removing the prodomain and exposing the catalytic domain to cleave pro-transforming growth factor-α (TGF-α; *yellow diamond with a dark tail*) into soluble TGF-α (*yellow diamond without a tail*), which binds to and activates epidermal growth factor receptor (EGFR), initiating mitogen-activated protein kinase signaling to the nucleus (*arrow* to nucleus), leading to mucin gene expression and mucin protein production. (Redrawn from Shao MX, Nadel JA: Dual oxidase 1–dependent MUC5AC mucin expression in cultured human airway epithelial cells. Proc Natl Acad Sci U S A 102:767, 2005.)

Early studies of TLRs were convincing in showing that these receptors are responsible for many of the pathophysiologic features of microbes. For example, the outer membranes of gram-negative bacteria contain the glycolipid LPS, which is responsible for many of the pathophysiologic features of these bacteria and is due to stimulation of TLR-4. Subsequently, many TLRs have been described in mammalian cells, including the airway epithelium. The discovery of TLRs provides a mechanism for microbes to bind to the host epithelium, and thus invade. Viral binding to these receptors is important for the entry of many viruses into epithelial cells and consequent multiplication. This binding is also an important sensing device, allowing the epithelium to detect the presence of the microbe and thence to initiate signaling that provides defensive responses. For example, multiple TLRs are involved in signaling responses to the effects of various viruses on IL-8 and vascular endothelial growth factor (VEGF) production.[62] These results show that multiple TLRs play roles in airway epithelial cell responses by activating EGF receptors via a complex epithelial cell cascade.

THERAPEUTIC IMPLICATIONS

The subject of deposition and clearance is discussed in Chapter 12, where effects of hypersecretion and inadequate clearance are discussed. Mucous hypersecretion occurs in the large conducting airways, where it causes cough and sputum secretion. In peripheral airways, hypersecretion can completely obstruct airway lumens. A most serious problem associated with mucous hypersecretion is peripheral mucous plugging. The peripheral airways remain a "silent zone" in the lungs, and novel methods are needed for adequate evaluation of these airways. Here, we have reviewed signaling pathways involved in mucin production. Multiple molecules are involved in the signaling process, providing multiple potential targets for therapy.

KEY POINTS

- Mucous hypersecretion is common in chronic inflammatory airway diseases (e.g., CF, chronic bronchitis and COPD, and asthma).
- In large conducting airways, hypersecretion is associated with cough and excess sputum production.
- In peripheral airways, hypersecretion is generally asymptomatic early but can lead to widespread plugging, incapacitation, and death.
- Many environmental microbes and other irritants stimulate mucin production by stimulating airway epithelial TLRs.
- A well-characterized epithelial surface pathway provides signals that induce mucin production and are candidates for therapy of mucous hypersecretion.

ENVIRONMENTAL AEROSOLS

INTRODUCTION

The human lung has a large surface area, which for an average size person approximates half a doubles tennis court, thus maximizing the approximation and apposition of capillaries and alveolar tissue. Whereas this design optimizes gas exchange, it also has the intrinsic risk of exposing the delicate alveolar tissues to potentially noxious particles that may be present in the ambient air. There are various safeguards against the danger posed by inhaled particles. The first line of defense is that the configuration of the nasopharynx and serial branching of the airways causes particles to deposit proximal to the more vulnerable alveolar structures.[1,2] Second, if an insoluble particle deposits in the lung, there are processes by which it can be cleared from the airways or alveoli. There are also specific antimicrobial and antioxidant defenses, but these latter topics are beyond the scope of this chapter. Clearance of insoluble particles that deposit in the ciliated airways is achieved by mucociliary clearance.[3] The particles are trapped in a mucous blanket, which is then transported proximally by the beating of cilia. If the cilia are not functioning optimally or if the quantity/quality of the airway mucus is abnormal, the mucus and its entrapped particulates can be cleared by cough clearance. Particles that deposit distal to the ciliated airways are removed by alveolar clearance, mainly

by macrophages ingesting the particles and transporting them to regional lymph nodes.

The branching structure of the airways is a barrier not only to noxious environmental aerosols but also to therapeutic aerosols. However, the application of the principles of deposition facilitates the design of therapeutic aerosol development.[4] Therapeutic aerosols are given for two indications. The vast majority of these aerosols are prescribed for the treatment of respiratory disease, but there is increasing interest in availing of the lungs' large surface area to deliver nonrespiratory drugs via the lung as aerosols, usually peptides that cannot be given by oral route.

DEFINITION AND DESCRIPTION OF AN AEROSOL[1,2]

An *aerosol* can be defined as a system of solid particles or liquid droplets that can remain dispersed in a gas, usually air. Naturally occurring aerosols, as well as those emitted by clinical aerosol generators, almost always contain a wide range of particle sizes. Because the aerodynamic behavior of an aerosolized particle is critically influenced by its mass, it is important to be able to precisely describe the size distribution of aerosolized particles. In clinical studies, the mass median aerodynamic diameter (MMAD) and the geometric standard deviation (σg) are often used to characterize the dimensions of an aerosol. When the mass distribution of particles in an aerosol is fractionated and the cumulative particle distribution plotted as a lognormal distribution on probability paper, it often approximates a straight line. However, recent studies of clinical aerosols have indicated that nebulized particles are often not lognormal in distribution.[5] The MMAD represents the point in the distribution above which 50% of the mass resides, expressed as the diameter of a unit density (1 g/cc) sphere having the same terminal settling velocity as the aerosol particle in question, regardless of its shape and density.

The lognormal plot is convenient because, if linear, it defines a statistically "normal" distribution and the data can be described accurately by the MMAD and the standard deviation alone. For a lognormal distribution, one standard deviation is called the "geometric standard deviation" or σg. The σg is the ratio of the size at 84% (or 16%) to the MMAD and is an indicator of the variability in particle diameters. If the particle size varies over a wide range ($\sigma g > 1.2$), it is described as having a *polydisperse* particle distribution; if the particles are of similar size ($\sigma g < 1.2$), the particle distribution is described as *monodisperse*. Monodisperse aerosols are usually encountered only in research studies where specialized generators are used to create such aerosol.[6] For clinical aerosols that are not lognormal and are widely polydisperse, it is best to relate deposition studies to the entire distribution of particles and avoid focusing on simple descriptive terms like the MMAD and σg.[5,7]

The definition of the mass median diameter (MMD) is the same as that of the MMAD except that the data are not normalized to unit density.

PRINCIPLES OF DEPOSITION

The fraction of inhaled particles that deposit (as opposed to being exhaled) is called the "deposition fraction."[1,2] The likelihood that a particle will deposit in a particular airway depends on the interaction of three factors: the physical characteristics of the particle (e.g., mass, shape), the gas flow in which the particle is transported (the patient's breathing pattern[8] and any velocity impacted to the particle by a propellant), and the airway anatomy (especially the presence of airway obstruction[9]). In general, the greater the mass, the faster the velocity, and the narrower the airway, the greater the predisposition of the particle to deposit by a process called "inertial impaction." Inertial impaction is the dominant mechanism by which particles deposit in the nasopharynx and more proximal airways and describes the process by which a particle fails to follow the air stream in which it is suspended, thereby impacting on an obstacle instead of circumventing it. The probability of a particle undergoing inertial impaction (I) can be estimated using the following equation:

$$I = \alpha(V_t V_a \sin\theta / gR \quad (1)[1]$$

where V_t is the settling velocity of the entrained particle V_a = air stream velocity, θ = angle required to circumvent the obstacle, and R = airway radius. The settling velocity (defined in Equation 2) increases as particle size increases. This equation applies to situations in which laminar flow predominates. The presence of turbulent nonlaminar flow will tend to further increase impaction. Particles that fail to deposit in proximal airways by inertial impaction can deposit in peripheral airways and alveoli by a process called gravitational sedimentation.

Gravitational sedimentation is the process by which a particle accelerates under gravity until it reaches a terminal settling velocity (V_t), which is determined by the equation[1]

$$V_t = (\rho - \sigma) g d^2 / 18\gamma \quad (2)$$

where σ = density of air, γ = viscosity of air, ρ = density of particle, d = diameter of particle, and g = acceleration due to gravity. Therefore, for a given velocity, the greater the aerodynamic mass of an aerosol, the shorter the time it will remain suspended the air stream. Gravitational sedimentation is the main mechanism by which particles (0.5–5.0 μm in diameter) deposit in the peripheral regions of the lung.

Sedimentation is critically dependent on the patient's breathing pattern.[8] If there is a breath-hold before exhalation, particles are more likely to sediment; without a breath-hold, particles are more likely to be exhaled rather than deposited. It has also been suggested that alveolar volume may affect deposition fraction (larger air spaces require more time for sedimentation).

Very small particles (<0.2 μm) can deposit by diffusion.

The diffusion coefficient of a particle (D) can be expressed[2] as

$$D = kT / 3\pi\eta d \quad (3)$$

where k is the Boltzman constant, T is the temperature in Kelvin, η is the gas viscosity, and d is particle diameter.

These tiny particles are rarely important in therapeutic aerosols, but in inhalation toxicology studies, these particles can be produced by combustion and may be clinically relevant, even though they tend to be transient due to the tendency to agglomeration. In addition, manmade nanoparticles, which are of increasing interest in electronics and biomedical research, would, if inadvertently inhaled, be likely to deposit by diffusion (discussed later under "Environmental Aerosols").

Particles between 0.2 and 0.5 μm in diameter tend to be too small to deposit efficiently by sedimentation and yet too large to deposit efficiently by Brownian diffusion and tend to be exhaled rather than deposited in the lung.[1,2]

MEASUREMENTS OF PARTICLE SIZE

Evaluation of Aerosol Particle Size

Particle size is an important factor in determining whether a particle will undergo nasopharyngeal deposition, airway deposition, or alveolar deposition.[10] Particle size is usually measured by light scattering or cascade impaction. Light scattering measurement is based on the principle that there is differential scattering of polarized light by particles of different sizes. In cascade impaction, particles at a set flow rate go through a series of apertures of decreasing diameter and impact on a series of plates if they fail to follow the air stream. Cascade impactors with high flow rate (e.g., 28 L/min) devices were originally designed for environmental sampling of ambient air to collect 100% of the emitted dose. They have been adopted as the method of choice for monitoring quality control in a manufacturing plant for aerosol delivery. Cascade impaction has an advantage over light scattering in that it facilitates the correlation of different methods of quantifying the distribution of the active drug (e.g., chemical analysis of drug on each plate compared with radioactive label or weight).

However, measuring the emitted dose of aerosol using a high-flow cascade impactor is not ideal for predicting how an aerosol will perform in clinical practice. While low-flow cascade impactors sample only some of the output, they more closely duplicate in vivo conditions.[5,11,11a]

Application of In Vitro Measurements of Particle Size to Clinical Studies[5,7,11]

Particle size data obtained with different techniques are not necessarily interchangeable. Meaningful comparisons of the sizes of clinical aerosols, especially those produced by a pressurized metered-dose inhaler (MDI; which emits high-velocity particles), should be compared only if obtained with identical techniques. Nevertheless, despite the technical difficulties encountered in measuring the size of polydisperse clinical aerosols, some investigators have established that, when used with appropriate caution, data obtained by in vitro measurement of particle size do provide useful predictive data for subsequent clinical studies.[5,7,11]

The classic studies of the influence of particle size on lung deposition were performed with solid nonhygroscopic monodisperse aerosols.[6] In contrast, pharmaceutical aerosols tend to be polydisperse liquid droplets with the active pharmaceutical ingredient (as well as in some cases pharamaceutically inactive excipients such as preservatives and freon) being either in solution or suspended as micronized particles. Droplets can change size by exchanging water with either the dry carrier gas or the humid environment of the upper airway.[2,12] While some drug ingredients are hygroscopic and some diluent solutions are hypertonic, both of which could lead to an increase in particle size based on some theoretical models, the clinical significance of such changes is not known with certainty. It has been reported that hypotonic saline aerosols were associated with a slightly more peripheral deposition pattern on gamma scintigraphy compared with hypertonic saline aerosols.[13] Measuring the particle distribution of wet aerosols is difficult because the particles can be affected by ambient humidity. Therefore the predictive value of cascade impaction data from aqueous aerosols for in vivo deposition (e.g., for upper airway deposition as measured by gamma scintigraphy) is strongly dependent on the specific technique used for cascade impaction.[11a]

GENERATION OF THERAPEUTIC AEROSOLS[4]

There are three common ways in which therapeutic aerosols can be generated. First, the patient's inspiratory airflow may aerosolize a micronized dry powder (dry powder inhalers) Second, micronized particles are suspended in a volatile pressurized liquid that vaporizes when at atmospheric pressure, thus imparting velocity to the emitted particles. The third approach is to apply a dispersal force to a liquid and generate droplets, which are then inhaled by tidal breathing. The generation of the dispersal force can be as simple as using a compressed air source attached to a narrow orifice to generate a Venturi (i.e., jet nebulizer) or by more complex vibrating membranes and meshes. Figure 12-1 shows examples of commercial aerosol devices.

Dry Powder Devices[4,14,15]

Because dry powder inhaler aerosols are generated by the patient's inspiration, they are by definition coordinated with inspiration. The inspiratory flow rate tends be rapid and thus predisposes to extrapulmonary deposition. In optimizing design of new devices, there is a need to minimize resistance to flow so that weak and

FIGURE 12-1 ■ Examples of commercial aerosol devices. *From upper left, clockwise:* A pressurized metered-dose inhaler (pMDI; Proventil HFA, Schering-Plough, Kenilworth, NJ); a jet nebulizer and compressor (Pari, Midlothian, VA); a multidose dry powder inhaler (Diskus, GlaxoSmithKline, Research Triangle Park, NC); a single-dose dry powder inhaler (HandiHaler, Boehringer Ingelheim, Ridgefield, CT); a vibrating mesh nebulizer synchronized with breathing pattern (I-Neb, Philips/Respironics, Pittsburgh, PA); a valved-holding chamber (Forest Laboratories, St. Louis, MO), used in association with a pMDI.

tachypneic patents will be able to generate a threshold flow rate. Furthermore, it is desirable that the emitted dose should not vary significantly with changes in inspiratory flow so that intersubject dosing remains consistent. For high-potency drugs, lactose is often used as an excipient bulking agent. Devices can be single-dose devices in which a capsule of powder is perforated in the device (Spiriva HandiHaler, Boehringer Ingelheim, Ridgefield, CT), multidisk with individual doses wrapped in foil blisters (Advair/Seretide Diskus, GlaxoSmithKline, Research Triangle Park, NC), or multidose metered reservoir (Pulmicort Flexhaler, Astra Zeneca, Wilmington, DE,). For dry powder devices to maintain reproducible dosing over time, it is critical that the powder be protected from moisture. Despite these technical challenges, the design of dry powder inhalers has greatly improved and the devices described previously perform at high levels of efficiency and reproducibility.

A newer version of the dry powder device involves the incorporation of the drug particles into microspheres for more precise control of dose and particle size. This approach has been pioneered in the use of development of inhaled insulin.[16]

Pressurized Metered-Dose Inhalers[4,17–21]

Pressurized MDIs using chlorofluorocarbon propellants have been used in clinical practice for 50 years and remain the most popular method of administering short-acting rescue inhalers and inhaled corticosteroids. They are portable and discrete. The velocity of the emitted particles, however, requires that for adequate lung deposition, there must be precise coordination with a patient's respiration. Studies have shown that actuation technique is suboptimal in most patients. Even with optimal technique, 80% of the emitted dose may deposit on the pharynx and can cause local irritation. In addition, some orally bioavailable medications cause significant systemic exposure from swallowed medication. Valved holding chambers reduce pharyngeal deposition because high-velocity particles impact on the inside of the chamber and if the chamber has valves, the need for

precise coordination with respiration is obviated. For young children, a face mask can be used in conjunction with a valved holding chamber. Unfortunately, registration studies for MDI medications are almost always performed without a holding chamber because manufacturers do not want their product's prescription tied to a specific holding chamber. To make the chambers more acceptable to patients, effective small-volume chambers (140 mL) and collapsible chambers have been developed.

For the past decade, there has been a phase-out program for chlorofluorocarbon-containing pressurized MDIs because of concerns about the impact of chlorofluorocarbons on the environment. Short-acting β-agonists and corticosteroid pressurized MDIs have been reformulated using hydrofluoroalkane as a propellant. The U.S. Food and Drug Administration mandated that these new hydrofluoroalkane-containing pressurized MDIs have performance standards at least equal to existing chlorofluorocarbon-containing pressurized MDIs. While this task has been far more difficult and expensive than anticipated, the last remaining chlorofluorocarbon-containing pressurized MDIs were removed from the U.S. market in early 2009.

Jet Nebulizers[22]

The ubiquitous small-volume jet nebulizer is the mainstay of bronchodilator delivery in hospitalized patients and patients at the extremes of age. These devices are cheap and require little patient cooperation. In addition, they are useful for delivering medications that have a relatively large treatment mass such as antibiotics. Generation of the driving pressure requires either a tank of pressurized gas or an electric compressor. Although the manufacturers of compressors have made these devices more portable, they are far from convenient for ambulatory patients. In addition, nebulizers tend to take 10 to 20 minutes to deliver a single treatment, which negatively impacts adherence. Most generic nebulizers are inefficient and deliver less than 10% of the nebulizer charge to the lung. The remainder is left in the nebulizer chamber as dead volume, lost through the expiratory port because the device generates aerosol throughout the respiratory cycle, or deposited in the extrapulmonary upper airway because most of the emitted dose is contained in large, poorly respirable particles.

New Developments in Aerosol Delivery Systems[22–26]

Manufacturers have made enhancements in nebulizers. Internal recycling baffles reduce emitted particle size. Expiratory filters have been added for potentially hazardous aerosols to reduce collateral exposure. Significant enhancements in drug delivery by nebulizers are possible by coordinating nebulization with inspiration (e.g., "breath actuation") that essentially turns the nebulizer off during expiration. Another improvement in efficiency is called "breath enhancement," which utilizes the patient's inspiratory flow through the nebulizer to increase drug delivery (e.g., LC Star, Pari, Germany; Ventstream, Medicaid, Bognor Regis, UK).[24]

The newer devices include the AKITA (Activaero GMBH, Geunden, Germany), AER_X (Aradigm, Hayward, CA), eFlow (Pari, Midlothian, VA), I-neb (Philips/Respironics, Pittsburgh, PA), and On Q (Nektar, San Carlos, CA). Each device employs unique proprietary technologies that distinguish them from the traditional devices. Some tend to be more precise in their coordination with breathing patterns of individual patients (Akita, I-neb, AERx); they usually have a lower dead volume in the nebulizer chamber, a greater fraction of particles in the respirable range (i.e., <5 μm) and shorter treatment times. They eschew bulky compressors, use either vibrating mesh or crystal, or extrude the liquid through tiny holes or a combination of both vibration and microextrusion. They vary in their durability and the relative ease by which they can be cleaned between treatments.

Recently, the design of aerosol delivery systems has combined slow and deep inspiration with direct mechanical feedback to the patient for particles of relatively large MMAD. As discussed earlier, a "slow" inspiration reduces particle inertia and allows inhalation of particles that would otherwise deposit in the oropharynx during tidal breathing and will thus minimize oropharyngeal deposition.

PRINCIPLES OF ASSESSMENT OF DELIVERY SYSTEMS[22,23]

Assessing effects of an aerosolized drug requires the understanding of three major factors: the aerosol delivery system, the quality of the aerosol produced, and the quantification of deposition within the lungs. The latter measurement is performed in vivo and is time consuming and costly and involves some degree of risk and uncertainty to the patient. The other two components of the aerosol delivery process can be well characterized and studied in vitro. The field of aerosol delivery has advanced significantly in the last 10 years such that device characteristics and aerosol behavior can be significantly optimized on the bench before exposure to patients.

The Inhaled Mass

Figure 12-2 depicts a simple in vitro setup for measuring the quantity of aerosol produced by a nebulizer. An absolute filter that captures the aerosolized particles has replaced the mouthpiece. This system does not require an understanding of nebulizer function from first principles. Because the nebulizer is attached to a breathing device (Harvard pump, Harvard Apparatus, South Natick, MA), the conditions of delivery such as routine tidal breathing can be duplicated. The quantity of drug captured on the inspiratory filter represents the amount that passes the lips of the patient. To distinguish this quantity from a "dose" or deposited drug, the term *inhaled mass*

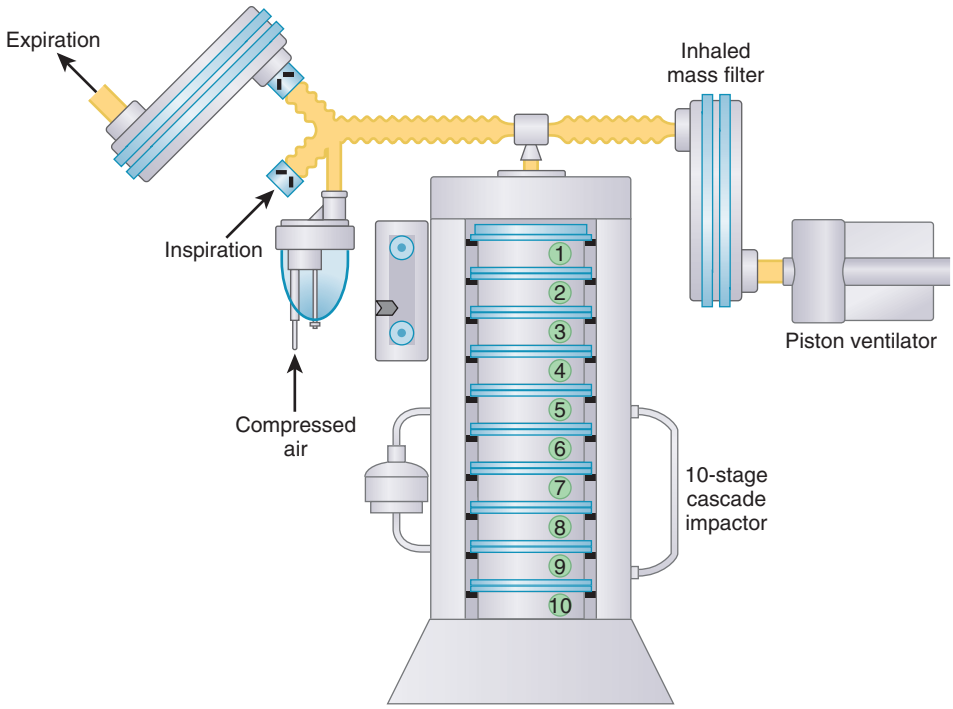

FIGURE 12-2 ■ The technique for bench measurements of inhaled mass and particle distribution: breathing pattern defined by settings on piston ventilator. Particles presented to "patient" (the ventilator) are captured on the inhaled mass filter. In separate experiments, the cascade impactor measures inspired aerosol. (Redrawn from Smaldone GC: Drug delivery via aerosol systems: concept of "aerosol inhaled." J Aerosol Med 4:229–235, 1991, with permission.)

has been coined. The *inhaled mass* represents "delivery" of drug to the patient constrained by conditions that should mimic actual clinical delivery.

Deposition

The term *deposition* begins to imply a "dose" to the patient. The term *deposition* needs to be further refined in a given situation (e.g., oropharyngeal versus parenchymal deposition, or central versus peripheral deposition within the lung). Each of these terms may be important depending upon the disease entity to be treated. Obviously, the measurement of deposition requires an in vivo experiment. However, deposition can be related to parameters that are measured in vitro as shown in Equation 4:

$$\text{Deposition} = \text{aerosol inhaled} - \text{aerosol exhaled} \quad (4)$$

Because the term "aerosol" is a little vague with respect to drug activity, Equation 4 can be rewritten as

$$\text{Deposition} = \textbf{\textit{inhaled mass}} - \text{exhaled mass} \quad (5)$$

Bench models are useful in identifying the parameters that define the *inhaled mass* for different devices and experimental conditions (Equation 5).[11] Investigators have developed protocols to test the output in vitro in ways that more closely replicate clinical practice. For example, bench testing of jet nebulizers can incorporate a piston ventilator to duplicate breathing patterns of spontaneously breathing patients or a ventilator circuit and endotracheal tube to duplicate aerosol delivery in the setting of mechanical ventilation. These in vitro protocols can be used to evaluate aerosolization protocols in ways that can optimize pulmonary drug deposition in subsequent clinical studies. For example, in patients undergoing mechanical ventilation, the brand of nebulizer, humidification, ventilator settings, and nebulizer volume fill are factors that can be optimized in vitro before proceeding to clinical studies.[27,28]

Because pulmonary anatomy is an important determinant of drug deposition, in vitro studies are a useful adjunct but not a substitute for clinical deposition studies. Clinical deposition studies are used to acquire two types of data: quantization of the mass of an inhaled drug deposited in the patient and an evaluation of regional distribution in the patient. Deposition can be divided into extrapulmonary deposition versus pulmonary deposition, whereas pulmonary deposition can be further subdivided into deposition in central airways versus peripheral airspaces. Gamma scintigraphy can be used to acquire both types of data. A radiotracer (usually technetium) is mixed with the study drug and aerosolized and inhaled. The drug deposition images on the gamma camera are superimposed on an outline of the patient's lung (obtained by a separate radioactive gas study[22,30] or a transmission image from an external standardized radioactive source[31]). Quantification of lung deposition can be obtained by expressing the radioactivity detected in the lungs to the radioactivity charge in the nebulizer. One must correct for the attenuation of radioactivity by the patient's body habitus using the transmission image. It is

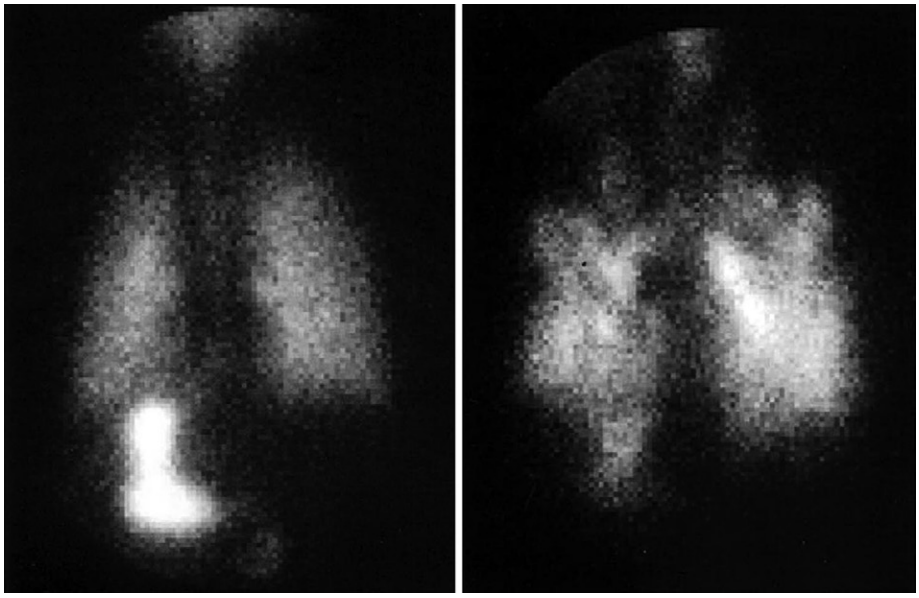

FIGURE 12-3 ■ Scans from patients with cystic fibrosis: *Left,* A 9-year-old boy with 48% upper airway (stomach) deposition. *Right,* A 31-year-old woman demonstrating a more peripheral but patchy distribution. also necessary to confirm with a cascade impactor that the distribution of radiotracer and drug is identical throughout the range of particle sizes.[27]

There are other methods of measuring drug deposition that do not require gamma scintigraphy. A mass balance technique uses filters placed near a patient's mouth to measure the first amount inhaled and the amount exhaled, with the difference being what was deposited in the patient.[22,30] Pharmacokinetic approaches include comparison of blood levels of aminoglycosides obtained after an intravenous calibration standard to blood levels obtained after inhalation[32] or the urinary concentrations of pentamidine after inhalation.[33,33a] Oral charcoal can be used to block the absorption of swallowed pharyngeal deposited drug so that blood levels will be due entirely to drug absorbed through lung deposition and absorption.[14]

STRATEGIES TO OPTIMIZE DEPOSITION OF THERAPEUTIC AEROSOLS[19]

The determinants of aerosol deposition apply to both therapeutic and environmental inhaled particles. To optimize deposition of therapeutic aerosols, a number of strategies have been developed based on these principles, which are now discussed.

Getting Particles Past the Oropharynx

In clinical studies, predicting penetration of aerosol beyond the oropharynx and subsequent lung deposition is a major criterion for device selection. Deposition estimations are often based on particle size measurements defined by in vitro characterization of the aerosol produced by a given device. During tidal breathing, most investigators would expect aerosols below 5 μm to be deposited primarily in the lungs (the "fine particle fraction"). Conventional aerosol delivery devices (jet nebulizer, pressurized MDI, and dry powder inhaler) emit particles with a wide range of sizes and velocities. It is estimated that the combined effect of particle size, particle inertia, and the geometry of the oropharynx result in upper airway deposition ranging from 30% to 90% of the total deposition in the patient. Only nebulizers producing particles with particularly small MMAD (e.g., AeroTech II, Biodex, Shirley, NY; MMAD, 1.0 μm) bypass the upper airways (5% oropharyngeal deposition in adults).[34] In children, the smaller oropharyngeal airways make the task more difficult.[35] Thus, the demands placed on traditional devices can be overwhelming if the drug must efficiently bypass the upper airways (Fig. 12-3).

Control of Breathing Pattern and Aerosol Deposition

In normal subjects, the pattern of breathing is the most important factor affecting aerosol delivery and deposition. How the patient breathes affects the performance of the device, the penetration of particles past the oropharynx,and the deposition within the parenchyma. Earlier studies suggested that much of the variation in parenchymal deposition was related to differences in airway geometry between subjects. However, variability in deposition between subjects appears well controlled if the pattern of breathing is controlled. Figure 12-4 depicts data from 11 subjects inhaling 2.6-μm monodisperse particles. The fraction of particles depositing in the lung can be closely related to the period of breathing. In simplified form, points near the origin of the horizontal

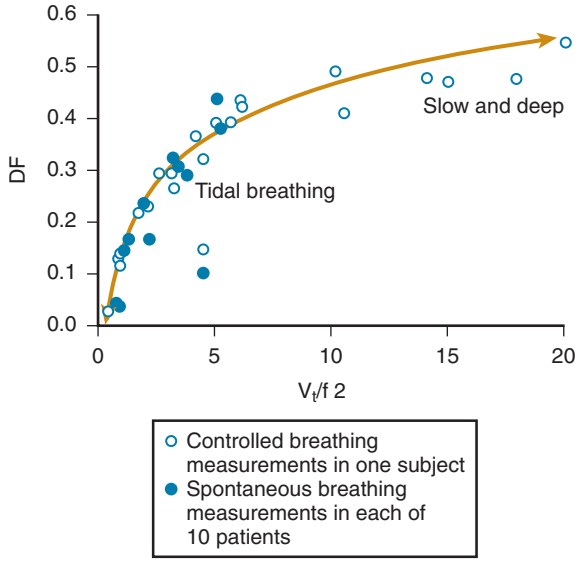

FIGURE 12-4 ■ Effect of breathing pattern on deposition; from 1 subject during controlled breathing (*filled circles*); from 10 patients during spontaneous breathing (*open circles*; data for 2.6-μm monodisperse particles). Breathing pattern was defined by a relationship that represents a measure of the period of breathing (tidal volume divided by breathing frequency squared or V_t/f'^2). Typical "tidal breathing" parameters found near origin, "slow and deep" inspirations away from the origin. (Modified from Bennet WD, Smaldone GC: Human variation in the peripheral airspace deposition of inhaled particles. J Appl Physiol 62:1603–1610, 1987, with permission.)

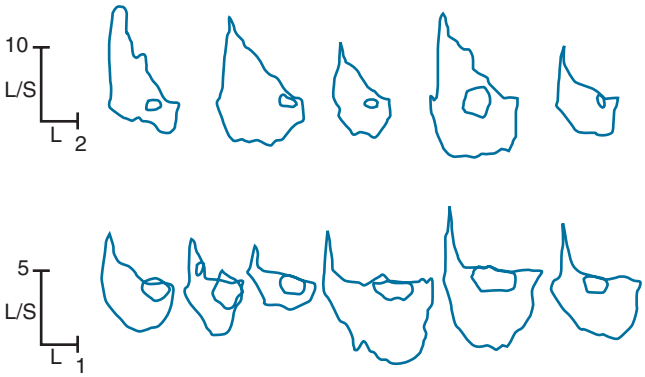

FIGURE 12-5 ■ Tracings of maximal flow and tidal flow versus volume for normal subjects (*upper panel*) and patients with severe obstructive lung disease (*lower panel*). Note the change in the sensitivity of the axes (ordinate: flow range from 0–10 or 0–5 L/S; abscissa: volume range from 0–2 or 0–1 L, respectively). *Lower panel*, For the patients, tidal loops are superimposed on maximal flow volume curves. (Modified from Smaldone GC, Messina M: Flow-limitation, cough and patterns of aerosol deposition in humans. J Appl Physiol 59:515–520, 1985, with permission.)

axis represent normal tidal volumes and frequencies. As tidal volume increases and breathing frequency decreases, the time of inspiration is prolonged (e.g., "slow and deep inspiration"). The curve depicted in Figure 12-4 represents maximum deposition with a slow and deep inspiration for particles of 2.6 μm. The curve would be shifted upward with deposition approaching 100% for larger particles.

Expiration and Problems with Aerosol Deposition

In normal subjects, those particles that do not deposit during inspiration are largely exhaled completely. Particles that pass through the oropharynx during inspiration enter the central airways and traverse them without difficulty because lobar and segmental bronchi are generally widely patent during inspiration. Then the particles enter alveoli with a few depositing by sedimentation, and like cigarette smoke, the bulk of the aerosol begins to be exhaled. Deposition is controlled by sedimentation in small airways and is influenced by local geometry and, to a strong degree, by the residence time (period of breathing).

In obstructive lung disease, maximal expiratory flows are diminished. With moderate disease, maximal flows can be superimposed on tidal breathing; as the disease progresses, maximal flows can be reduced even further. Therefore, it is common to observe that patients are often breathing on their maximal expiratory flow volume curves even during quiet tidal breathing[36] (Fig. 12-5). In these patients, flow-limiting segments exist in the same airways found in normal subjects during forced expiration, but in these patients, they form during every tidal breath. In patients with obstructive lung disease, the promotion of deposition in the peripheral lung poses a significant challenge as deposition of aerosol is enhanced during expiration at sites of flow limitation (Fig. 12-6). Based on these physiologic considerations, peripheral deposition of aerosol in these subjects would be favored by using a system that combines a slow prolonged inspiration (to promote deposition by settling) with a breath of long enough duration to minimize the particles available to the airways during expiration.

For many aerosol applications, inhaling particles "slowly and deeply" solves the problems outlined previously. A slow inhalation will minimize oropharyngeal deposition. "Slow" inspiration reduces particle inertia and allows inhalation of larger particles that would have deposited in the oropharynx during tidal breathing. This concept has been exploited in physiologic studies of mucociliary clearance in the distal airways utilizing particles as large as 6 μm.[37] More recently, commercial applications of these principles have combined slow and deep inspiration with direct mechanical feedback to the patient for particles of relatively large MMAD, resulting in more efficient delivery to the more distal airways (Fig. 12-7).[38]

Deposition and Dose versus Response[39–41]

For conventional bronchodilators and steroids, the dose and response are not critical for clinical efficacy because most delivery systems provide drug to the patient on the flat portion of the dose-response curve. Safety of most preparations is enhanced because of the high potency of most drugs and a high threshold for toxicity. The

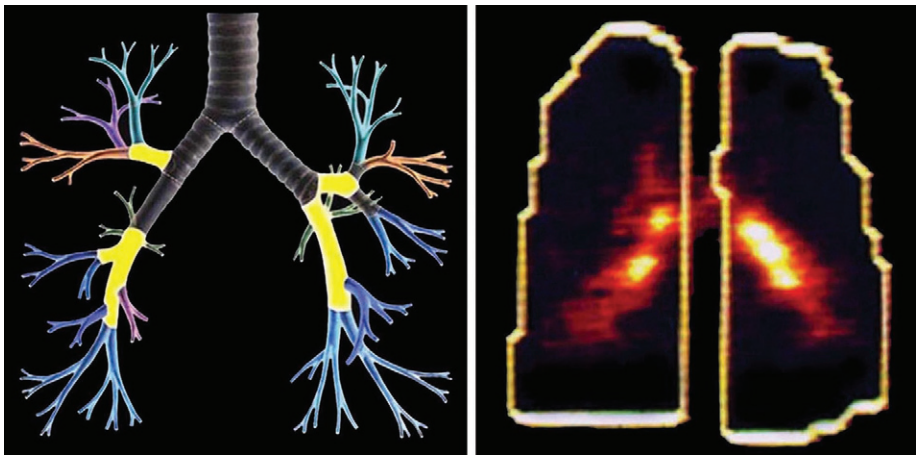

FIGURE 12-6 ■ Sites of flow-limiting segments in humans (*left panel*), corresponding deposition image in patient with severe chronic obstructive pulmonary disease (COPD; posterior view) with maximal expiratory flow volume curve superimposed on tidal loop (as shown for patients in *lower panel* of Figure 12-5). Particle deposition occurs preferentially at sites of flow-limiting segments. (Redrawn from Smaldone GC: Advances in aerosols: Adult respiratory disease. J Aerosol Med 19:36–46, 2006, with permission.)

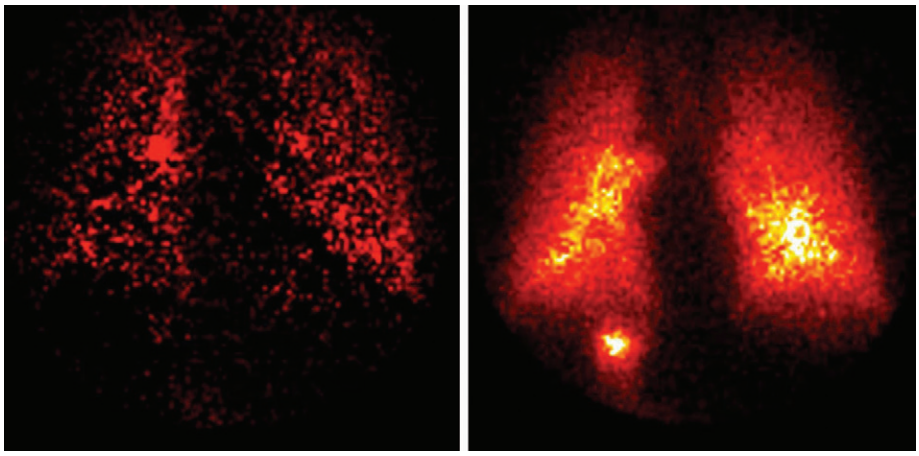

FIGURE 12-7 ■ Effect of slow and deep breathing on aerosol delivery and deposition. Deposition scans from normal subject following breathing from I-neb, a breath-actuated vibrating nebulizer (particles generated only during inspiration): *Left,* Following 20 breaths of normal tidal breathing. *Right,* Scan repeated after 3 breaths of very slow and deep inspiration (~7 sec/breath, see Fig. 12-1). For slow and deep breathing, deposition was 50 times more efficient per breath, a combination of enhanced delivery and more efficient deposition (unpublished data).

situation for bronchodilators and steroids may not carry over to newer drugs. For example, aerosolized cyclosporine used in the treatment of lung transplant rejection has recently been shown to significantly reduce mortality.[39] In vivo measurements of deposition have been related to clinical effects (dose vs. response). Figure 12-8 shows gamma camera images of individual patients from an early study assessing the effects of inhalation of aerosolized cyclosporine aerosol.[40] Analysis of cyclosporine deposition was related to clinical effects as shown in Figure 12-9. After institution of aerosolized cyclosporine therapy in patients with persistent acute rejection, pulmonary function improved (after 3 mo of therapy) as illustrated by increases in forced inspiratory volume in 1 second (FEV_1). However, there was a suggestion of a dose-response relationship with those patients receiving less than 20 mg of drug per allograft having minimal response.[40] A similar situation will exist for systemically absorbed drugs such as insulin where the dose to the lung parenchyma will be critical in patient management. Although clinical studies have shown that aerosolized cyclosporine appears to be effective overall in a population of patients,[39] the data from individual patients in Figure 12-9 suggest that conventional aerosol delivery systems leave some patients at risk for inadequate dosing, while others may be overdosed and exposed to potential toxicity.

ADDITIONAL FACTORS INFLUENCING DEVELOPMENT OF THERAPEUTIC AEROSOLS

In addition to efforts to bypass the oropharynx and optimize lung deposition, other factors influence the design

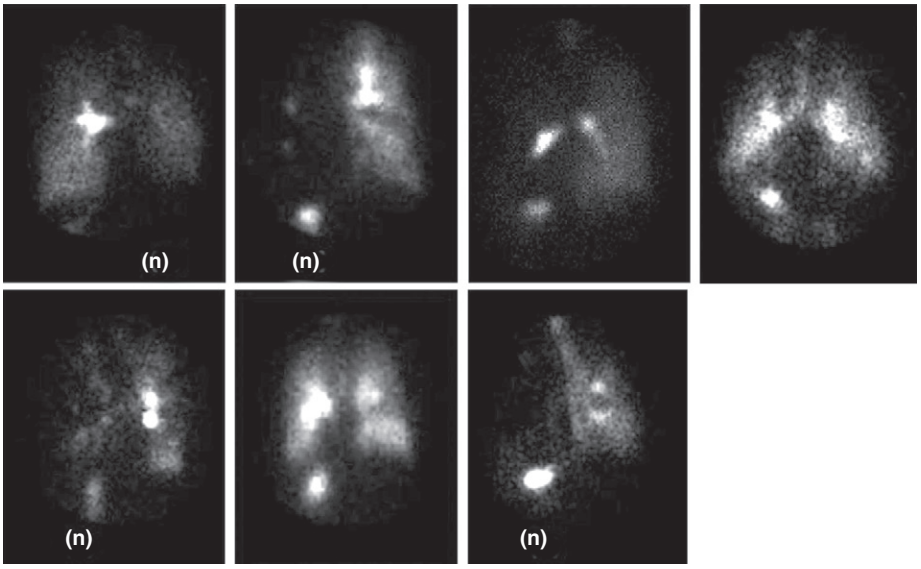

FIGURE 12-8 ■ Deposition of aerosolized radiolabeled cyclosporine aerosol. Lung images from seven patients with single- or double-lung transplants ("n" indicates native lungs). There was considerable variation in regional particle deposition (data from these images applied to Figure 12-9). (Modified from Smaldone GC: Advances in aerosols: Adult respiratory disease. (Redrawn from Iacono AT, Smaldone GC, Keenan RJ, et al: Dose-related reversal of acute lung rejection by aerosolized cyclosporine. Am J Respir Crit Care Med 155:1690–1698, 1997, with permission.)

of therapeutic aerosols. Some of these factors are disease related and others relate to specific populations.

Asthma[41–45]

One of the most important features of the commercial formulations of inhaled corticosteroids, the mainstay of maintenance therapy of asthma, is reduced oral bioavailability.[41–43] Many delivery systems for inhaled corticosteroids have high levels of oropharyngeal deposition (up to 80% with pressurized MDIs and dry powder inhalers), and it is crucial that when this oropharyngeal deposited drug is subsequently swallowed, its systemic exposure be kept as low as possible. The oral bioavailability of beclomethasone as one the oldest of the inhaled corticosteroids is about 20%, fluticasone is about 1%, and mometasone less than 1%. A newer drug, ciclesonide, does not become activated until it deposits in lung tissue.[43] However, even if there is no oral bioavailability, systemic exposure can still occur because of inhaled corticosteroids being absorbed directly into the lung after deposition. It appears that alveolar deposition may give rise to more systemic exposure because particles depositing in ciliated airways are subject to mucociliary clearance and because the barrier to diffusion may be more permeable in the alveolar air spaces than the airway. There are some pharmacodynamic data that suggest when fluticasone is administered to both normal subjects and asthmatics, the normal subjects are more susceptible to hypothalamic-pituitary-adrenal (HPA) axis suppression. This finding is most likely due to the more proximal deposition in the asthmatic subjects because of reduced airway caliber.[44] Most pharmaceutical manufacturers have therefore tried to target airway deposition over alveolar deposition. This appears reasonable because asthma is thought to be an airways disease. Some investigators, however, have suggested that there may be an alveolar inflammatory component in asthma, thus suggesting that alveolar deposition may be beneficial.[45] Nonetheless, this remains a minority viewpoint. Targeting of the airways in asthma is complicated by the polydisperse nature of therapeutic aerosols. Making average aerosol diameter smaller reduces oropharyngeal deposition but increases the amount of alveolar deposition. A low oral bioavailability is more important for polydisperse aerosols with larger MMADs in order to minimize systemic exposure from swallowed drug. Systemic exposure to inhaled corticosteroids can lead to

short-term growth suppression in children, decreases in bone mineral density, and possibly an increase in cataracts.[41–43] Whereas the potential role of inhaled corticosteroids in prevalence of cataracts is confounded by concomitant use of intermittent systemic corticosteroids, smoking, and ultraviolet light exposure,[46] an epidemiologic study from Australia that controlled for use of systemic and ocular steroid use found an association between inhaled steroids and the prevalence of cataract.[47] Cataracts could be theoretically due to inadvertent spraying of aerosol into the eyes in addition to systemic exposure.

While the search continues for the ideal method of delivery for inhaled steroids to patients with asthma, advances in drug design, formulation, and delivery now provide a wider array of options to the clinician. However, no delivery system can be considered to be intrinsically superior to all others. The delivery system should be judged instead by its ability to optimize the pharmacokinetic properties of the drug, most notably oral bioavailability, and by its suitability for the target subpopulation of asthmatics.[4]

Cystic Fibrosis

Antimicrobials are inhaled for the treatment of cystic fibrosis, for example, tobramycin, aztreonam, and polymyxin. Antibiotics usually require the aerosolization of several hundred milligrams of medication. Jet nebulizers or vibrating mesh devices are usually required to deliver such a large mass of medication. Aminoglycosides, when given systemically, have poor penetration and are limited by renal and ototoxicity. Inhalation of tobramycin, for example, can result in sputum levels two orders of magnitude higher than those associated with systemic delivery. For the purposes of inhalation, tobramycin was reformulated without the preservative present in the intravenous preparation.[48] Aztreonam was reformulated with a lysine side chain for inhalation instead of the methionine side chain found in the intravenous formulation, in order to reduce the risk of airway irritation.[49]

For patients with cystic fibrosis, antimicrobials and mucolytics (recombinant DNase and hypertonic saline) have been shown to be of benefit.[50] The multiplicity of inhaled treatments, however, is likely to have a negative impact on patient adherence and therefore creates the need to explore the use of devices with shorter treatment duration in order to improve adherence.

Delivery of Inhaled Medications to Young Children

Asthma is common in children and delivery of aerosols poses special challenges. The need for cooperation and coordination with breathing pattern and the need to generate a threshold inspiratory flow in children means that those younger than 4 years old cannot use a dry powder inhaler. Children 6 years and older can use a pressurized MDI, but under that age, a pressurized MDI should be used in association with a valved holding chamber because children have difficulty coordinating actuation with the respiratory cycle.[51] Face masks can be incorporated with holding chambers and jet nebulizers for children younger than 4. After age 6 years, children can be taught how to use a pressurized MDI without a spacer, although the use of spacers should continue to be encouraged.

For young children with asthma, nebulized treatment with a suspension of budesonide is an effective and well-tolerated alternative.[52] It should be noted that nebulizers tend to be less effective at aerosolizing suspensions than solutions, and clinicians are advised to prescribe budesonide only with the brand of nebulizers used in the clinical trials of this product.

Young children usually require a face mask to be used with either a nebulizer or a valved holding chamber. Recent studies suggest that clinically relevant in vitro modeling should include mimicking a child's breathing pattern and placing the face mask on a model of a child's face.[53] Using such a model, nebulizers appear to result in less variability in inhaled mass compared with the valved holding chamber. For a pressurized MDI used with a valved holding chamber, leaks around the face mask limit the exchange of tidal air with air in the chamber, thereby reducing the inhalation of aerosol by the patient. For nebulizers operated with compressors, the face mask can be kept filled with particles in spite of leaks because the compressor flow can exceed the minute ventilation of the child.[54] However, the very leaks that may preserve delivery to nebulizers result in deposition of drug on the face and in the eyes.

Recent experiments have indicated that deposition on the face and particularly in the eyes can be minimized if masks are designed such that linear velocity in the region of the leaks near the bridge of the nose is reduced. As can be seen in Figure 12-10, with such a modified face mask, deposition on the eyes and face was markedly reduced, while drug delivery to the patient (*inhaled mass*) was preserved.[53] Subsequent in vivo experiments confirmed the model's predictions[55] (Fig. 12-11). Even though the incidence of cataract in children receiving inhaled corticosteroids is very low, there is epidemiologic evidence linking inhaled steroid use in adults to an increased risk of cataract.[47]

Delivery of Therapeutic Aerosols to the Nasal Mucosa[56–58]

Corticosteroids, antihistamines, cromoglycate, and decongestants are inhaled nasally to treat rhinitis. These formulations use large particle sizes to maximize nasal deposition. For children who use inhaled corticosteroids for perennial rhinitis, formulations with low oral bioavailability such as fluticasone, mometasone, and ciclesonide are preferable to reduce the risk of growth suppression.

Among an increasing list of aerosolized medications that are being used to treat diseases of the nasal mucosa are corticosteroids, cromolyn, anticholinergics (ipratroprium bromide), saline, and decongestants. The particle

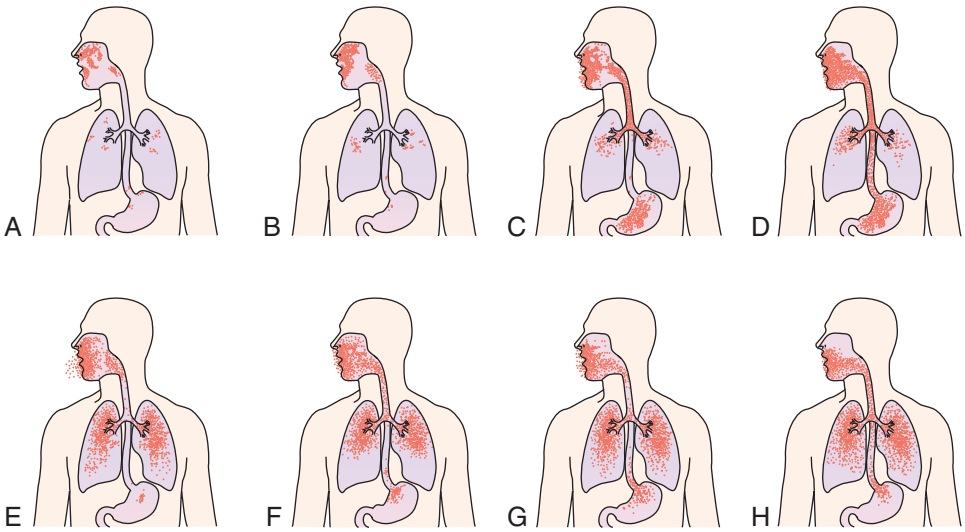

FIGURE 12-11 ■ Drug deposition of radiolabeled salbutamol in a young child: **A,** Inhaling from a pressurized metered dose inhaler/spacer through a non-tightly fitted facemask. **B,** Inhaling from a nebulizer through a non–tightly fitted face mask. **C,** Inhaling from a pressurized metered-dose inhaler/spacer through a tightly fitted face mask, screaming during inhalation. **D,** Inhaling from a nebulizer through a tightly fitted face mask, screaming during inhalation. **E** and **F,** Inhaling from a pressurized metered-dose inhaler/spacer through a tightly fitted face mask, quietly inhaling. **G** and **H,** Inhaling from a nebulizer through a tightly fitted face mask, quietly inhaling. Deposition on the face is apparent especially for the tight-fitting masks. (A-H, Redrawn from Erzinger S, Schuepp KG, Brooks-Wildhaber J, et al: Facemasks and aerosol delivery in vivo. J Aerosol Med 20(Suppl):S78–S84, 2007, with permission.)

size of nasal aerosols tends to be larger than pulmonary inhalers. Manual pumps that produce large, relatively low velocity particles are being used as an alternative to high-velocity, freon-based pressurized MDIs. There are isolated reports of nasal perforation occurring with high-velocity inhalers,[56] and patients should be advised to direct the spray in the direction of the ipsilateral ear and away from the nasal septum. In addition, actuating the inhaler against the lateral wall of the nares reduces the risk of epistaxis (caused by irritating the septum by medial orientation) or headache (caused by stimulating the olfactory nerve by a vertical delivery. In severe allergic sinusitis, the mucosa may be so congested that a short course of systemic corticosteroids may be needed

to allow penetration of aerosolized therapy. Prolonged use of topical decongestant sprays may lead to rebound hyperemia and intractable nasal congestion. In certain cases, systemic administration of decongestants may be preferable.

Intranasal corticosteroids are an effective therapy for seasonal and perennial rhinitis. While regular use of such an agent has been shown to lead to short-term growth suppression in children, it appears that this complication can be prevented by the use of a formulation with a low oral bioavailability (e.g., mometasone).[57,58]

Aerosol Delivery during Mechanical Ventilation[27,28,59–61]

Bronchodilators are used to treat patients with airway obstruction as they undergo mechanical ventilation. There is also interest in delivering topical antimicrobial therapy in patients with purulent tracheobronchitis. The dose delivered to this setting can be highly variable and subtherapeutic delivery can occur without optimizing certain factors. Humidification (temporary discontinuation of humidification doubles delivered dose through reduced rain out of medication), coordination with respiratory cycle, and the appropriate selection of delivery system can impact delivered dose. If optimized, consistent delivery can occur at doses that approximate those delivered in spontaneously breathing subjects.[27,28] Using such optimized delivery techniques in critically ill patients with ventilator-associated tracheobronchitis, aerosolized antibiotics decrease ventilator-associated pneumonia and other signs and symptoms of respiratory infection, facilitate weaning, and reduce bacterial resistance and use of systemic antibiotics.[59]

Aerosolized β-sympathomimetic agents are an essential component of the treatment of status asthmaticus. Such delivery is complicated if the patient is undergoing mechanical ventilation. Recent studies, however, have identified ways in which such delivery can be optimized. The use of pressurized MDI is feasible provided certain conditions are met.[60] For example, it is necessary to use a spacer/holding chamber when using a pressurized MDI in this setting. Not all holding chambers are equivalent in efficiency and different brands are not necessarily interchangeable. In contrast to the treatment of spontaneously breathing patients, delivery during mechanical ventilation must be synchronized with respiration. It is essential that a dose-escalation protocol be employed because doses far in excess of those used for maintenance therapy may be needed. Hence, efforts to obtain objective evidence on response to treatment (e.g., peak airway pressure, dynamic compliance) and toxicity (tachycardia, arrhythmias) should be sought. In endeavoring to maximize delivered doses, however, it must be remembered that the efficiency of pressurized MDI delivery decreases significantly if the interval between serial actuations is less than 1 minute and if the synchronization with the respiratory cycle is suboptimal.[61]

In conclusion, once technical factors have been identified and optimized, efficient delivery of aerosolized medications to patients undergoing mechanical ventilation is readily attainable.[28]

DIAGNOSTIC RADIOAEROSOLS

In this chapter, we primarily discuss the use of radioaerosols as research tools to measure lung deposition and mucociliary clearance. However, radioaerosols are also used in clinical practice.

The radiolabeled ventilation-perfusion scan is an important clinical tool for detection of pulmonary emboli. Perfusion is measured by injecting radiolabeled macroaggregates of protein that impact in capillaries while ventilation is evaluated by a radioactive gas or aerosol. Discrepancies between perfusion abnormalities and ventilation abnormalities are used to assess pulmonary emboli. The measurement of ventilation should ideally be performed by the use of radioactive gas (xenon or krypton). However, the use of these agents has significant disadvantages. Xenon has a relatively long half-life and needs to be trapped after exhalation. Krypton, in contrast, has a very short half-life and per-patient costs are high. In response to these concerns, technetium-labeled aerosols were developed on the assumption that if ventilation were absent from a lung region, then aerosol deposition would not occur in that region. In general, that assumption is true if submicron aerosols are inhaled, but it must be remembered that aerosol behavior is not identical to that of a gas.[62] For example, patients who are tachypneic with high inspiratory flows and who have airway obstruction will have central "hot spots" due to deposition by impaction.[36] This limits the use of these techniques in certain patient groups.

MUCOCILIARY CLEARANCE AND DISEASE

Inhaled particles that deposit in the ciliated airways are trapped in a blanket of mucus. Mucus is transported proximally by the rhythmic beating of the cilia (a fast, forward-power stroke and slower, backward-recovery stroke) to the pharynx where it is swallowed, a process called "mucociliary clearance."[3] The percentage of ciliated respiratory epithelial cells is highest in the tracheal and lobar bronchi and decreases progressively in more distal airways. Secretory cells are also more numerous in proximal airways. Goblet cells produce thick carbohydrate-rich secretions, while other cells produce more serous secretions. Diseases such as chronic bronchitis and bronchiectasis are associated with increased numbers of goblet cells in more distal airways. Airway secretions are also produced by submucosal glands. The latter are lined by mucinous and serous epithelial cells and become hypertrophic and hyperplastic in chronic bronchitis and other types of chronic airway inflammation.

Secretory dysfunction is common in many diseases but the pathophysiology of the dysfunction varies signifi-

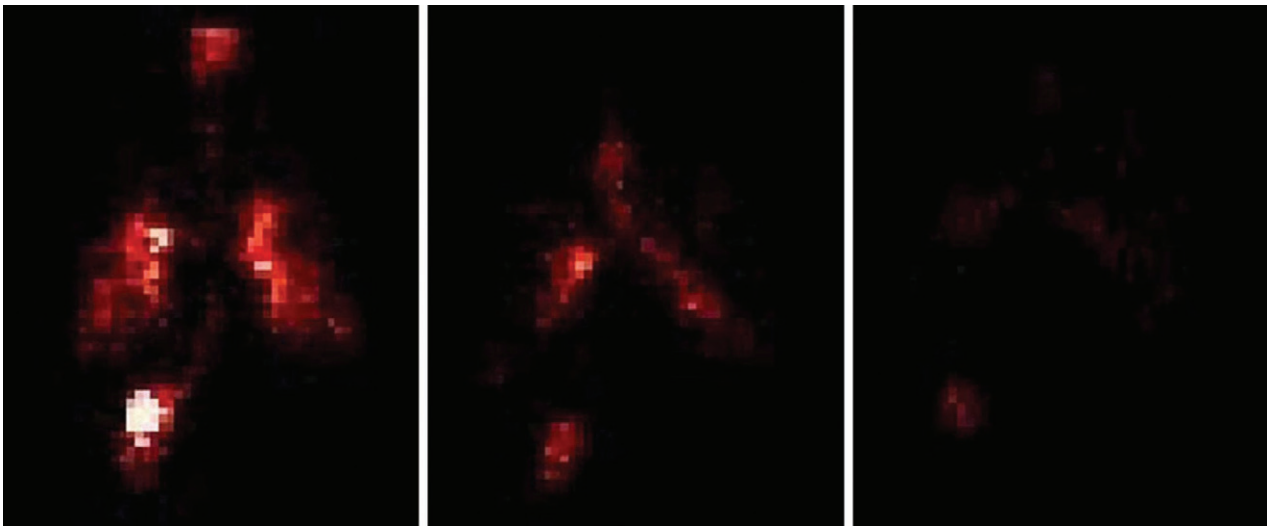

FIGURE 12-12 ■ Mucociliary clearance measured with the gamma camera. Serial scintigraphic images of the lungs, airways and oropharynx. *On the left* at 0 min, central airways activity is apparent (note esophagus and stomach outlined from swallowed oropharyngeal deposition), 60- and 120-min images seen (*middle* and *right*), most activity is cleared from the lungs in 120 min.

cantly. Mucociliary clearance can be impaired by intrinsic defects in ciliary function, which can be congenital (ciliary dyskinesias) or acquired (tobacco-smoking, influenza). Mucociliary clearance impairment can also be due to changes in the quantity and composition of airway secretions (chronic bronchitis, cystic fibrosis). When the mucociliary apparatus is significantly impaired, secretions can be cleared predominantly by cough clearance.

Mucociliary clearance in healthy subjects is usually completed within 24 hours of deposition.[3] The mucous path can be followed using radiolabeled aerosols (Fig. 12-12). Particles that deposit on ciliated airways containing ^{99m}Tc, bound to a molecule that prevents absorption into the circulation, will follow the clearing mucus. Particles deposit in proximal airways by inspiratory impaction (larynx, main stem, lobar and segmental bronchi). Extrapulmonary deposited particles will be swallowed and appear in the gamma scintigraphy as stomach "hot spots" overlying the left lower lung field. The interpretation of mucociliary clearance studies is complex and, in order to compare rates of mucociliary clearance between subjects or even to compare a series of studies in one subject, it is essential to consider a number of important variables.

The most important parameter affecting the rate of mucociliary clearance in healthy subjects is the initial pattern of particle deposition. We have already discussed the factors that determine this pattern and how it can be quantified (e.g., the specific central-to-peripheral ratio). The relevance of the initial pattern is that particles that are deposited in the central airways will be cleared more rapidly into the pharynx than more distally deposited particles. Therefore, if a normal subject with a central pattern of deposition is studied, the rate of mucociliary clearance will be faster than if it had been studied using a more peripheral initial deposition pattern. In addition, the fastest rates of mucous transport in normal subjects are believed to be in the trachea with a progressive decrease through more distal generations with the most peripherally deposited particles in the alveolar region not accessible to mucociliary clearance. Based on these principles, for data to be compared between studies, the initial pattern of deposition must be standardized.

Primary ciliary dyskinesia is a congenital disorder of the dynein arms of the cilia.[3] The normal cilium has nine pairs of dynein peripheral arms and two central pairs. Each pair consists of an inner and outer dynein arm. A variety of defects result in loss of the ciliary movement. The normal ciliary beat has a rapid forward stroke and a slower return stroke. In the absence of the ciliary movement, there will be mucous stasis and these patients develop bronchiectasis and sinusitis. In males, this can also lead to infertility due to immotile spermatozoa. There are associated abnormalities of visceral organs, situs inversus, and dextrocardia.

Cystic fibrosis, the most common fatal single gene genetic disease in Europe and North America, is associated with severe bronchiectasis.[3] The most persuasive causative theory is that the mucus is dehydrated and less easy to clear because of defective chloride channel (cystic fibrosis transmembrane receptor).[63] Hypertonic saline, when administered to the airways of patients with cystic fibrosis, creates an osmotic gradient that draws water into the airway lumen. Trials are underway to see if blocking epithelial sodium channels in the presence of hypertonic saline could increase water content of mucus. Epithelial sodium channel blockers are analogues of the amiloride molecule. While inhaled amiloride can block epithelial sodium channel receptors, its brief half-life at the airway epithelium limits its clinical effectiveness and leads to a search for newer agents with more favorable pharmacokinetics. Alternatively, stimulation of calcium-dependent chlorine channel with uridine triphosphate analogues can also increase airway hydration. The airway secretions in cystic fibrosis not only contain mucus secreted by the airway but also consist, predominantly,

of DNA and actin from dead neutrophils and recombinant DNase, administered by inhalation to facilitate clearance of secretions.

In chronic bronchitis. there is hypertrophy and hyperplasia of the submucosal glands as well as an increase in the number of goblet cells and the presence of goblet cells in more distal airways compared to normal. It appears that the mucous versus serous component increases and exacerbates the solid phase increases even more. This in effect means that the mucous layer is relatively dehydrated.[63,64]

In patients who die of status asthmaticus, the airways at autopsy are filled with inspissated mucus. Clearance of radiolabeled mucus is severely impaired in patients with status asthmaticus but recovery of mucociliary clearance occurs within weeks.[65]

Impairment of radiolabeled mucociliary clearance may be an index of disease severity in asthma,[65,66] chronic obstructive pulmonary disease (COPD),[67] and cystic fibrosis.[68] Serial measurements of mucociliary clearance can be useful in measuring pharmaceutical enhancement of mucociliary clearance both acutely and at a steady state, for example, the acute and sustained effects of hypertonic saline in cystic fibrosis.

In conclusion, mucociliary clearance is impaired in asthma, chronic bronchitis/COPD, cystic fibrosis, non–cystic fibrosis-bronchiectasis, and primary ciliary dyskinesia. Cough clearance augmented by physical therapy and other mechanical interventions (flutter valves, vibration vests) provides some treatment, but pharmaceutical interventions are limited. In asthma, there is improvement in mucociliary clearance and in sputum volume using guafenesin, but the data are sparse. In cystic fibrosis, benefits of DNAse are based on clinical data not mucociliary clearance.[50,69] β-Agonists increase mucociliary clearance after a single dose, but sustained enhancement on mucociliary clearance with β-agonists has yet to be demonstrated.[69] The epithelial sodium channel inhibitors show promise but clinical benefits are yet to be proven.[62,63]

ALVEOLAR CLEARANCE

Particle solubility affects clearance in alveoli. Soluble particulates may be absorbed through the thin membrane of the peripheral air spaces.[3,70,71] Insoluble particulates, however, tend to be phagocytosed by alveolar macrophages. Their metal content influences the free radical generating properties of the particle and can promote inflammation, especially as the particle is delivered to the lysosomes. Lysosomes have a very low pH designed to kill microorganisms but the low pH may promote solubility of transition metals such as ferrous iron and therefore be proinflammatory.

Responses to preexisting inflammation may be important because cells that are primed by one type of inflammation (e.g., by tobacco smoke or endotoxin) may be more reactive to a second stimulus from an inhaled particulate. Inhaled dose is important and excessive exposure can lead to overloading of alveolar macrophages, which can be proinflammatory even with relatively nonreactive particulates.[71] Macrophages migrate to regional lymph nodes and some particles are characterized by a distinctive adenopathy (e.g., silicosis and its eggshell calcifications).

ENVIRONMENTAL AEROSOLS

An appreciation of the principles of aerosol deposition and clearance is essential to both understanding the epidemiology of illness associated with exposure to environmental aerosols and in the development of rational strategies to reduce the impact of those exposures. This is a complex subject that overlaps with topics covered in several other chapters in this book. The impact of exposure to an aerosol depends on a number of factors, some of which are self-evident, and others that are less apparent. These factors include the total mass of particulates in the air, the size distribution, the shape and surface area of particles, the chemical composition of the particles, the level of ambient turbulence, the airway anatomy and breathing patterns of exposed individuals, and the immune response to inflammatory or infectious agents.[71,72] Exposure of rodents to high doses of low-toxicity, poorly soluble particulates results in pulmonary inflammation,[72] and impairment of alveolar clearance,[73] and an increased tendency to develop tumors.[72] It is, however, not yet clear if it is appropriate to extrapolate from high-dose rodent exposures to the determination of rational exposure thresholds for humans.[72] Unfortunately, it appears that in vitro exposure of cell cultures to environmental particulates correlates poorly with in vivo animal exposures.[74,75]

In December of 1952 in London, England, 4000 excess deaths were attributed to smog. This disaster had a huge impact on public health policy and led to efforts to reduce the impact of air pollution. At the time, it was assumed that it was the total concentration of particulates that was the most important determinant of mortality. However, retrospective analysis of stored autopsy specimens suggested that exposure to fine particulates and metals may have been more important than the total mass of exposure.[76] The increased emphasis on particle size was supported by a series of urban epidemiologic studies that found correlations between daily concentrations of particulates and mortality. Using data from urban sampling devices that can measure the amount of particles less than 10 μm in diameter (PM_{10}), it was demonstrated that even small increases in PM_{10} produced an increase in acute death rates.[77] Interestingly, it was cardiovascular deaths that seemed to dominate over respiratory death, leading to speculation that the deposition of particles in the lung could activate proinflammatory cascades. Later studies, using even more sophisticated samplers, found a correlation between mortality and fluctuations in the $PM_{2.5}$, fine particles less than 2.5 μm in diameter.[78] More recent research has focused on even smaller particles between 1 and 100 nm.[79] When these occur in the atmosphere, usually as result of combustion, they are referred to as ultrafine particles. When they are

manufactured in the semiconductor, pharmaceutical, or chemical industries, they are referred to as nanoparticles, even though their dimensions are also 1 to 100 nm. In contrast to ambient ultrafine particles, which tend to be polydisperse, nanoparticles are more monodisperse. Measuring particle size distributions in the nano spectrum requires more sophisticated techniques than conventional particles. Spectrophotometry, atomic force microscopy, and complex light scattering techniques have been developed to make these measurements. As particles approach the nano range, their behavior can be very different from the same material in bulk. Both ultrafine and nanoparticles can deposit by diffusion, have a very high deposition fraction, and are small enough to pass between epithelial cells in the lung and cause systemic toxicity. Surface area may become more important than mass. Metals may lose their malleability and become hard. For example, titanium is a relatively inert and nontoxic substance when inhaled as a typical respirable aerosol (0.5–5 μm particle size) but exposure to titanium particles within the nano range result in marked cytotoxicity and proinflammatory effects in the lungs of rats. These effects have led to calls for tighter regulation of nanoparticle manufacture and distribution of nanomaterials.

Application of the principles of aerosol deposition can reduce exposure to infectious or toxic environmental aerosols. For example, dust mite fecal aerosols tend to be large and have a relatively rapid settling velocity.[80] However, the energy imparted by a ceiling fan can prolong their residence time and facilitate their inhalation; hence, asthmatic patients are advised to eschew the use of ceiling fans in their bedrooms. Pulmonary tuberculosis is an infection spread exclusively through the inhalation of infected droplet nuclei that are present in ambient air.[81] The placement of a face mask on patients with suspected tuberculosis would intercept cough-generated aerosols by impaction before they have the opportunity to dry and settle in the air where they can remain ambient for hours. Individuals who wish to avoid inhaling ambient infected tuberculous aerosols need to wear tight-fitting masks such that all their inspired air is filtered by the mask because the aerosols are small enough to follow the air stream and pass around loosely fitting masks. Most naturally occurring aerosols have sufficient large particles to be filtered by the nose and the branching structure of the large central airways. Some aerosols, however, pose particular dangers. Asbestos fibers, despite being relatively large, can deposit in small peripheral air spaces because their cylindrical structure allows them to follow the air stream to the lung periphery.[82] As discussed previously, ultrafine aerosols pose an additional danger if inhaled. They can pass between the protective epithelial cells of the lung and cause systemic toxicity. Deposition of environmental aerosols are affected by particle size and shape, but also by breathing pattern; generation of aerosols by workers who are performing manual labor and have increased inspiratory flow rates and minute ventilation can result in increased lung-deposited dose. While larger particles have low peripheral deposition, these particles can nevertheless be hazardous because of their mass. For example, after the attack on the World Trade Center, particles greater than 50 μm were deposited in peripheral air spaces because they were present in very high concentrations in the air for hours after the collapse of the towers. Consequently, New York City firefighters who responded to the disaster site on the day the towers collapsed had significantly higher rates of lung injury than those who reported on day 2.[83] The toxicity of inhaled inorganic particles is complex and beyond the scope of this text. Factors influencing toxicity include the metal content of particles, especially transitional metals such as iron, which may influence free radical generation. It has been suggested that free radical generation may be greater in particulates that are freshly generated before they are oxidized by the air, thus potentially increasing the danger to workers who grind inorganic material.[84]

The most important indoor toxic environmental aerosol is tobacco smoke, a topic covered elsewhere in this text. However, some of the principles of aerosol delivery and deposition are useful in explaining some of the epidemiologic associations with different types of cigarettes.[85,86] Despite marked differences in "smoking-machine" generated concentrations of tar, cigarettes marked as medium-tar, low-tar ("lite"), and ultralow-tar ("ultralite") are associated with similar incidences of lung cancer. (High-tar unfiltered cigarettes are associated with an even higher incidence of lung cancer.) The explanation for this paradox appears to lie in part with the standardized smoke generator (ventilation holes in the "lite" cigarettes that dilute the machine- generated smoke may be occluded by human lips). However, a more important factor may be that people tend to inhale the smoke of the "lite" cigarettes more deeply and deposit carcinogenic particulates in the more distal airspaces. This latter theory is supported by the observation of a relative increase in the incidence of more peripheral adenocarcinomas relative to more central squamous carcinomas following the introduction of "lite/ultralite" cigarettes to the U.S. market where they now hold an 80% market share.[86]

In conclusion, further progress in understanding of the role of environmental aerosols in health and disease will be dependent on the collaboration of several disciplines, and an appreciation of the principles of deposition and clearance by the participating investigators should facilitate interdisciplinary communication and cooperation.

KEY POINTS

- The likelihood that a particle will deposit in an airway depends on the physical characteristics of the particle, the gas flow transporting the particle, and the airway anatomy. The greater the mass, the faster the flow, and the more narrow the airway, the greater the potential for inertial impaction.
- Particle deposition by sedimentation is dependent on a subject's breathing pattern. Breath-holding before exhalation increases deposition by sedimentation.
- Holding chambers reduce pharyngeal deposition and reduce the need for precise coordination to get the full dose.
- Most traditional jet nebulizers are inefficient and deliver less than 10% of the drugs to the lung.
- In normal subjects, the pattern of breathing is the most important factor affecting aerosol drug delivery to the lungs.
- Making the average aerosol diameter smaller reduces oropharyngeal deposition but increases the alveolar deposition, which may increase systemic absorption.
- Compared to parenteral therapy, medicines can be delivered by aerosol in greater concentration to the target organ, the lung, with fewer side effects.
- Directing the jet of high-velocity nasal sprays to the ipsilateral side avoids the side effects of headache when directed vertically and epistaxis when directed medially.
- Mucociliary disorders can be inherited and acquired. They can result from structural ciliary changes or changes in the composition or quantity of the mucus.
- Environmental aerosols, especially the fine particulates, result in excess acute deaths, often from cardiac causes.

SYSTEM INTEGRATION

INTRODUCTION

The immune system is broadly conceptualized as having two separate but interconnected arms. In evolutionary terms, the *innate immune arm* is an older and more primitive system that has developed to provide early host defense against viruses, fungi, and bacteria. The fundamental basis of innate immunity is a system for pathogen detection that relies on the recognition of a range of pathogen-associated molecular patterns (PAMPs) that include complex lipids, carbohydrates, unmethylated CpG DNA sequences, and double-stranded RNAs. PAMPs are recognized by a series of secreted, cell surface and intracellular pattern recognition receptors (PRRs) that promote the recognition, phagocytosis, and killing of many microbes. In addition, recognition of PAMPs by PRRs initiates inflammation, which, in turn, leads to the recruitment of phagocytes, which kill and degrade microbes, promote the repair of damaged tissues, and assist in the restoration of tissue function. Though some organisms, for example, sea urchins, have evolved a system of host defense based exclusively on the innate immune system,[1] mammals and higher animals have evolved an *adaptive immune system* that differs from the innate immune system by its exquisite antigenic specificity. The adaptive immune system is also distinguished from its innate counterpart by the development of immunologic memory, thereby allowing a more rapid response to repeated exposure to previously encountered microbes and antigens. The initiation of adaptive immunity and the execution of some of its effector mechanisms are also dependent on the innate immune system. Thus, both the innate and the adaptive immune systems exist in a classic symbiotic relationship to provide optimal defense of the lung and other organs and tissues.

The broad concepts of innate and adaptive immunity outlined previously have evolved to protect most organs and tissues from *microbes*, a term we use to include bacteria, yeasts, fungi, protozoa, multicellular parasites, and viruses. However, most organs and tissues, including the lung, have adapted or evolved additional mechanisms to tailor the immune system to their own specific needs. The lung epithelium has a surface area approximately the size of a tennis court and represents the largest epithelial surface in the body. With an average respiratory rate of 15 breaths/min and an average tidal volume of 500 mL, the lungs are exposed to over 10,000 L of ambient air/day. The air that we breathe is a complex mixture of gases and particulates that can contain pollutants, oxidants, inorganic and organic dusts, pollens, toxins, bacteria and their constituents (e.g., bacterial endotoxin, lipopolysaccharides [LPS]), and viruses. In addition, the airways and gas-exchange surfaces of the lung can be exposed by aspiration to acidic gastric contents as well as to infected mucus from the nasal sinuses. Thus, all surfaces of the respiratory tract from the nasal passages to the alveoli are constantly exposed to a spectrum of harmless, harmful, and pathogenic agents, raising the important question of how the lung differentiates between what is harmful and what is essentially harmless.

Like the gut, the lung has evolved discriminative mechanisms to both suppress unwanted and potentially

harmful responses to harmless materials and retain the ability to vigorously activate innate and adaptive immunity when encountering harmful microbes and stressors. The overall goal of this chapter is to review current concepts of innate immune responses in the lung and their underlying mechanisms. Multiple cell lineages participate in innate protection of the lung, and many share similarities in the way they recognize and respond to microbes and other harmful agents. Therefore, we have organized the chapter into four broad sections. First, we provide an overview of lung innate immunity and its fundamental components. Second, we discuss general mechanisms of innate immune recognition. Third, we review innate lung cells and the effector mechanisms they utilize. Fourth, we discuss how these systems and mechanisms are integrated. Throughout the chapter, we also discuss how the innate immune system primes the adaptive immune system as a prelude to the chapter on adaptive immunity (see Chapter 14).

OVERVIEW OF THE COMPONENTS OF LUNG INNATE IMMUNITY

The innate immune system provides protection to the lungs against a diverse spectrum of inhaled particles and antigens that range from harmless nonmicrobial particles (e.g., dusts and pollens) to harmful pathogenic microbes (e.g., *Mycobacterium tuberculosis*). To accomplish the range of protection, the lungs have evolved multiple mechanisms to survey and respond to inhaled particles based primarily on their size and physicochemical properties, especially the presence and absence of PAMPs. As illustrated in Figure 13-1, innate immune protection in the lung can be broadly divided into considerations of (1) the conducting airways and (2) the gas-xchange surfaces of the alveoli. At the cellular level, innate protection is afforded by the coordinated functions of airway and alveolar epithelial cells, resident macrophages and

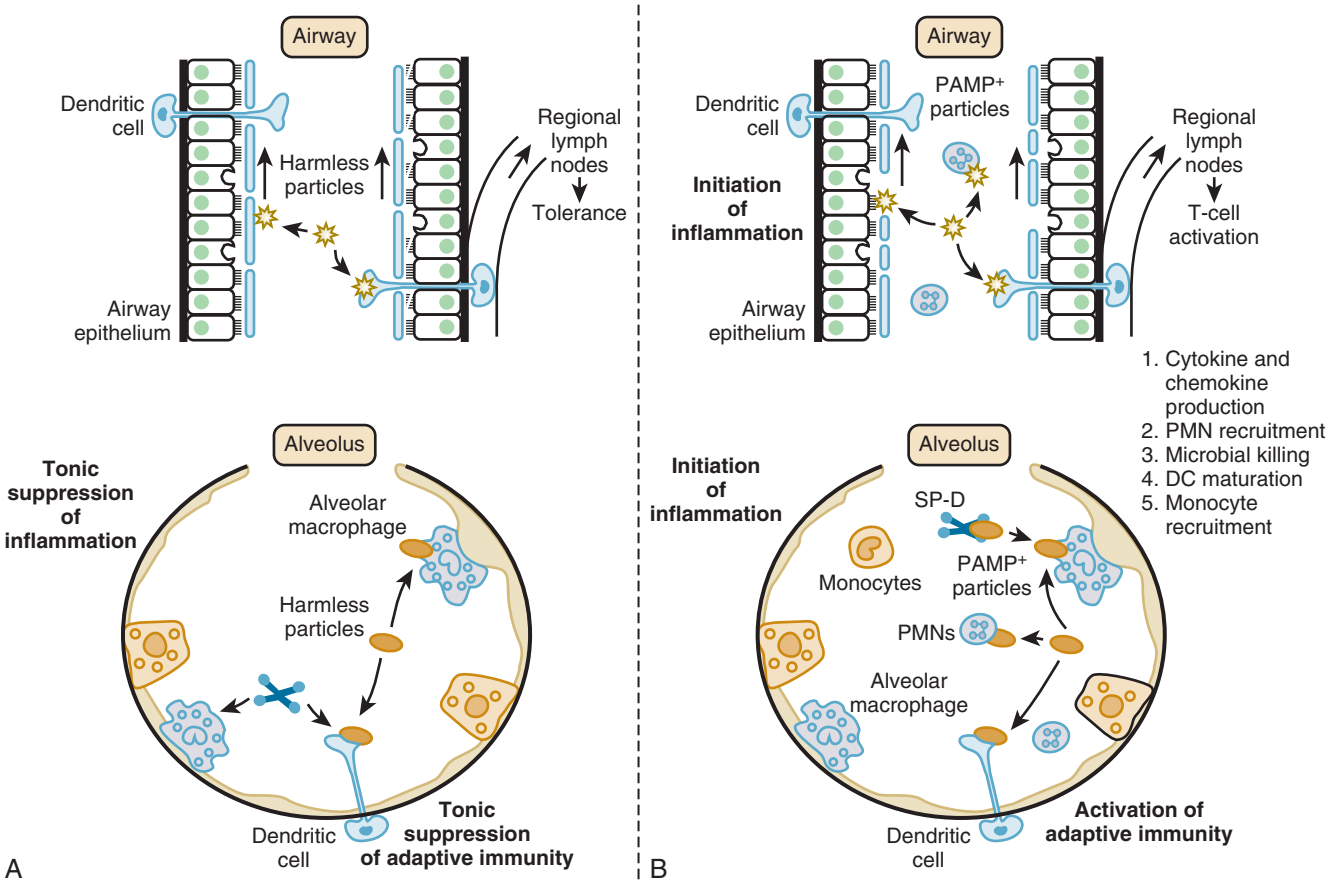

FIGURE 13-1 ■ Overview of innate immune protection in the conducting airways and alveoli of the lung. **A**, In the absence of pathogen-associated molecular patterns (PAMPs), that is, in the steady state, the airways are protected by mucus that captures harmless particulates and transports them along the mucociliary escalator. Dendritic cells also capture particles, traffic to regional lymph nodes, and promote tolerance to commonly inhaled antigens. Also in the absence of PAMPs, the alveoli are maintained in an anti-inflammatory and immunosuppressed state to prevent unwanted inflammation and immune activation toward commonly inhaled particles and antigens. **B**, Innate immunity is activated in the presence of PAMPs. PAMPs stimulate airway epithelial cells to express chemokines, cytokines, and lipid mediators that attract neutrophils (polymorphonuclear leukocytes [PMNs]), which, in turn, kill PAMP-expressing microbes. Airway dendritic cells response to PAMPs by maturing, migrating to regional lymph nodes, and stimulating T-cell proliferation. A similar program is activated in the alveoli upon PAMP detection by alveolar macrophages, alveolar epithelial cells and dendritic cells, resulting in the initiation of inflammation and activation of adaptive immunity.

dendritic cells (DCs), and recruited neutrophils (polymorphonuclear leukocytes [PMNs]), monocytes, and DC precursors.

Though often underestimated, an important component of airway host defense resides in the anatomic structure and epithelial cell lineages of the tracheobronchial tree. Air turbulence created by the nasal passages and the cartilaginous segmentation of the trachea and large airways ensures that particles in excess of 10 μm in diameter are deposited on the mucus-coated surfaces of the nose, pharynx, trachea, and descending airways. In turn, mucus, its ensnared particulates, and dissolved solutes are constantly wafted toward the pharynx by the coordinated beating of ciliated airway epithelial cells where their removal is aided by coughing, sneezing, and swallowing. In addition to the biophysical properties of mucus in innate host defense of the airways, the gel and pericellular liquid phases also contain an array of antimicrobial peptides and proteins, antioxidants, antiproteases, as well as specific immunoglobulin A (IgA) antibodies (Table 13-1), all of which are maintained at a modestly acidic pH (pH 6.6).[2] Principal among airway antimicrobial peptides in humans are salt-sensitive cysteine-rich cationic β-defensins and the cathelicidin, LL-37/hCAP-18.[3–7] β-Defensin-1 is constitutively secreted by airway epithelia and accumulates in airway surface liquid at microgram per milliliter concentrations.[8] Other β-defensins and LL-37/hCAP-18 are inducibly expressed following exposure to LPS and other proinflammatory mediators.[9–11] Antimicrobial proteins including lactoferrin and lysozyme are also present in airway epithelial secretions and contribute to the maintenance of normal airway sterility.[12,13]

The conducting airways are lined with ciliated and secretory epithelial cells that serve a key role in initially evaluating the surfaces of large particles with which they come into contact. In addition, a network of DCs resides throughout the airway epithelium and continuously samples the airway lumen (see Fig. 13-1). DCs are particularly abundant in the trachea and large conducting airways where most large particulates are deposited. In the absence of PAMPs, DCs capture airway antigen and migrate to regional lymph nodes where they induce $CD4^+$ and $CD8^+$ T-cell tolerance to harmless inhaled antigens.

In contrast to large particles, particles smaller than 5 μm in diameter are able to descend the entire tracheobronchial tree and lodge at bronchiolar-respiratory duct junctions or deposit onto the surfactant-rich surfaces of the alveoli. While sharing many similarities with innate protection of the airways—for example, the presence of antioxidants, antiproteases and antimicrobial enzymes—additional innate protection of the alveoli is afforded by the presence of resident alveolar macrophages and the lung specific collectins, surfactant protein A (SP-A) and SP-D (see Fig. 13-1). In addition to expressing Toll-like receptors (TLRs), resident alveolar macrophages express scavenger receptors that participate in the phagocytosis of microbial and nonmicrobial particles. SP-A and SP-D are secreted PRRs and are capable binding to microbial PAMPs, leading to opsonization and phagocytosis by alveolar macrophages and intraseptal DCs, which then either crawl into the airways and move up the mucociliary escalator or migrate to regional lymph nodes, respectively. In the absence of PAMPs, resident alveolar macrophages also play an important role in suppressing inflammation and adaptive immunity, thereby protecting the alveoli from unwanted responses to harmless inhaled particulates. SP-A and SP-D also play a key role in suppressing inflammation in the absence of PAMPs through tonic signaling effects on resident alveolar macrophages. Thus, the innate immune system not only protects the lungs from harmful microbes but also prevents inflammation, injury, and activation of the adaptive immune system in the steady state and in response to harmless inhaled particulates.

Next, we must consider how the airways and alveoli respond to the presence of potentially harmful microbes. As illustrated in Figure 13-1, resident airway and alveolar macrophages, DCs, and airway and alveolar epithelial cells are capable of recognizing different PAMPs through their repertoires of cell surface and intracellular PRRs, and by interaction of PAMP-bound secreted PRRs with specific receptors on epithelial cells, macrophages, and DCs. In turn, these interactions induce signaling responses that activate nuclear factor-κB (NF-κB), activator protein-1 (AP-1), and other key transcriptional switches to promote the expression of an array of innate response genes (Table 13-2). These gene products collectively promote the migration of PMNs and monocytes from the pulmonary circulation into the air spaces, facilitate changes in endothelial and epithelial permeability to facilitate inflammatory cell transmigration into the airspaces, and initiate the expression of specific genes involved in microbial killing. In addition to the activation of PMN and macrophage-dependent killing mechanisms, airway and alveolar DCs also respond to PAMPs, and following microbial phagocytosis, they undergo a process of maturation followed by migration to regional lymph

Transcription of most of these genes is initiated by the activation of NF-κB and/or AP-1. Activation of NF-κB is initiated by most PRRs and involves the activation of IκB kinase. AP-1 is activated by MAPKs, especially JNK and p38. Activation of MAPKs also results in transactivation of NF-κB, and so activation of both pathways is usually required for optimal expression of genes involved in innate immunity.

nodes (see Fig. 13-1). During this process, ingested microbial products are digested, captured by major histocompatibility complex (MHC) class II molecules, and displayed on the DC plasma membrane together with co-stimulatory molecules such as CD40, CD80 and CD86 for effective presentation to naive $CD4^+$ and $CD8^+$ T-cells. Following activation and expansion in regional lymph nodes, effector $CD4^+$ and $CD8^+$ T-cells then migrate back to the site of microbial infection to augment specific host defense through their ability to activate macrophages and other effector cells by producing interferon-γ (IFN-γ), tumor necrosis factor-α (TNF-α), and other cytokines that increase host antimicrobial defenses.

In summary, innate immune mechanisms involving the airway and alveolar epithelium, secreted antimicrobial enzymes, PRRs and peptides, mucus and mucociliary transport, and resident macrophages and DCs protect the lung against inhaled microbial and nonmicrobial particulates to maintain lung sterility and health. In addition, in the steady state, the innate immune system actively suppresses inflammation and promotes tolerance to commonly inhaled harmless particulates. Above a certain threshold and upon sensing the presence of PAMPs, additional mechanisms are activated to protect the lungs by promoting inflammation and adaptive immunity and by establishing communication and cooperation between these systems. We should note that, although it is convenient to think of these events separately, it seems reasonable to suppose that in normal healthy individuals, responses to harmless nonmicrobial particulates and harmful microbes are occurring simultaneously, and silently, to maximally sustain lung health and protection.

INNATE RECOGNITION IN THE LUNG

With this broad overview of the key elements in innate host defense of the lung and their connections to adaptive immunity, we now consider in more detail how microbes are recognized by resident and recruited lung cells. For this purpose, we specifically focus on the mechanism of recognition by PRRs that are expressed by epithelial cells, macrophages, and DCs or are present in airway or alveolar surface liquids.

Secreted Pattern Recognition Receptors

Secreted PRRs have evolved to serve as bridges between certain PAMPs and specific receptors for these molecules. In the lung, secreted PRRs have particularly important roles in innate protection of the alveolar surfaces.

Collectins

The collectins are a family of secreted PRRs of which SP-A and SP-D are uniquely expressed in the distal lung.[14] All members of the collectin family are characterized by the presence of an N-terminal collagen-like domain, a coiled neck domain, and a globular C-type lectin domain that interacts with microbial PAMPs. SP-A and SP-D interact with a variety of PAMPs and stimulate microbial phagocytosis, the production of reactive oxidant species, the activation of NF-κB and AP-1 and the expression of proinflammatory cytokines.[15,16] Several studies have shown that activation of a proinflammatory response occurs when PAMP-bound SP-A and SP-D interact with macrophages via their collagenous tails through CD91.[17-19] Consistent with these findings, SP-A–deficient and SP-D–deficient mice have increased susceptibility to pulmonary infection with *Pseudomonas aeruginosa* and *Staphylococcus aureus*,[20,21] emphasizing the important contribution of these lung-specific collectins to innate lung host defense.

The lung is remarkable in that it maintains sterility of the alveolar surfaces while actively suppressing unwanted and potentially harmful inflammatory responses to harmless inhaled materials. Several studies have shed new light on this issue by revealing an additional role for SP-A and SP-D in the tonic suppression of lung inflammation. When initially created, SP-D–deficient mice were found to have increased numbers of foamy, activated alveolar macrophages and increased lung injury, suggesting that SP-D may somehow tonically suppress lung macrophage activation and lung inflammation.[22] As illustrated in Figure 13-2, some studies also suggest that in the steady state, that is, in the absence of PAMPs, SP-D and SP-A interact with alveolar macrophages via their globular head groups and signal via signal inhibitory regulatory protein-α (SIRPα) to tonically suppress proinflammatory responses.[19] Thus, SP-A and SP-D, through their ability to interact under different circumstances with CD91 and

SIRPα, play a pivotal role in the maintenance of the anti-inflammatory environment of the alveoli under steady-state conditions, while promoting an inflammatory and innate response when microbes are sensed. Interestingly, other studies also suggest that lipid and phospholipid constituents of surfactant significantly contribute to maintenance of the anti-inflammatory environment of the alveoli.[23]

Complement

The complement system functions as a pattern recognition system as well as a bridge to adaptive immunity through its ability to recognize repetitive structures on some microbes, and the Fc region of IgG and IgM antibodies. Complement activation is important in lung innate immunity because it promotes the opsonization of microbes and the generation of the potent chemotactic factor C5a, which, in turn, assists in the recruitment of phagocytic cells. Complement components of the classical, alternative, and mannose-binding lectin activation pathways are present in lung airway and alveolar fluids[24–26] and are synthesized by alveolar type II cells, macrophages, and DCs.[13,27–29] Many microbes can directly activate the alternative complement pathway, resulting in the covalent attachment of C3b to the microbial cell wall. Microbes expressing cell wall–associated mannose-rich polysaccharides can also bind mannose-binding lectin and activate the mannose-binding lectin pathway to promote C3b attachment to the microbial cell wall. Phagocytic cells, especially macrophages, PMNs, and DCs, express various receptors for C3b and C3bi and, together with other receptors, phagocytose and kill complement-opsonized microbes.

Pentraxins and Other Secreted Pattern Recognition Receptors

The pentraxins, including C-reactive protein, serum amyloid P, and pentraxin 3, also recognize PAMPs on microbes and activate the complement system to assist in their removal by phagocytic cells.[30,31] Similarly, ficolins promote phagocytosis and complement activation by binding to the gram-positive bacterial cell wall components *N*-acetylglucosamine and lipoteichoic acid.[32]

Cellular Pattern Recognition Receptors

Different families of PRRs have evolved to enable the host to sense the presence of PAMPs in extracellular, endosomal, and cytoplasmic compartments in each of the lineages involved in lung innate immunity (Fig. 13-3). Key among the transmembrane cell surface and endosome-associated PRRs is the TLR family that is widely expressed on epithelial cells, macrophages, PMNs, and DCs. Members of the scavenger receptor family are primarily expressed on macrophages; whereas C-type lectin receptors are mainly expressed on DCs. Cytoplasmic PRRs are composed of nucleotide-binding and oligomerization domain (NOD)–like receptors (NLRs) of the NOD and neuronal apoptosis inhibitor protein (NACHT) leucine-rich domain and pyrin-containing protein (NALP) families and RNA helicases of the retinoic acid–inducible gene (RIG) family. Each of the cytoplasmic PRRs has evolved as a strategy to alert the host of the presence of PAMPs within the cytoplasm, as often occurs during the intracellular replication of facultative bacteria and viruses.

Plasma Membrane and Endosomal Pattern Recognition Receptors

Toll-like Receptors. TLRs are widely expressed throughout the body and are represented on airway and alveolar epithelial cells, macrophages, PMNs, and DCs.[33–36] Thirteen TLRs have been described in mice (TLR1-13) and 10 in humans (see Fig. 13-3). Although the ligands and biologic function of TLR10-13 remain unclear, significant progress has been made in understanding the functions and downstream signal transduction pathways of TLR1-9.[37–40] TLRs can be divided into those expressed on the cell surface (TLR1, 2, 4, 5, 6, and 11) and those expressed in intracellular compartments (TLR3, 7, 8, and 9). TLRs also recognize endogenous ligands called danger-associated molecular patterns (DAMPs) including heat shock proteins, low-molecular-weight hyaluronan, heparin sulfate, fibronectin, high mobility group-1 protein, and low-density lipoproteins (LDLs). Recognition of DAMPs by TLRs and other PRRs is usually associated with the initiation of noninfectious inflammation. Surface TLRs recognize a wide variety of PAMPs, while intracellular TLRs mainly recognize nucleic acid–based PAMPs. TLRs not only recognize their individual cognate PAMPs but also combine with other TLRs to form heteromeric complexes that recognize a broader range of PAMPs.[40–42] For example, TLR1 associates with TLR2 to recognize microbial lipopeptides,[43] TLR2 and TLR4 recognize the LPS-LPS-binding protein (LBP)/myeloid differentiation protein-2 (MD-2) complex when presented by CD14, and TLR2 recognizes broad patterns of lipoproteins in concert with either TLR1 and TLR6.[44] TLR5 recognizes flagellin and is particularly important in the response of airway epithelial cells to *P. aeruginosa* infection. Similarly, TLR6 can functionally associate with TLR2 to recognize a variety of microbial lipopeptides and peptidoglycan from gram-positive bacterial cell walls.[45]

In contrast to TLR1, 2, 4, 5, 6, and 11, TLR3, 7, 8, and 9 are not highly expressed at the cell surface but are expressed intracellularly in endosomal and endoplasmic reticulum membranes.[37–40] Intracellular destruction of ingested microbes results in the release of nucleic acids into the phagosome lumen. The ligand-binding regions of TLRs3, 7, 8, and 9 are also all expressed on the luminal side of the endosomal membrane. TLR3 recognizes viral double-stranded RNA and induces the production of type I IFNs (IFN-α/β).[46] In turn, type I IFNs play a vital role in antiviral immunity and in DC maturation.[47] TLR7 recognizes single-stranded RNA from viruses, whereas TLR9 recognizes unmethylated CpG-motifs in microbial DNA.[48,49] Synthetic ligands for TLR7 and 8, such as resiquimod and imiquimod, have been used therapeutically in the treatment of virally induced skin infections and skin tumors. is also believed to be a direct result of their ability to activate skin DCs to produce type I IFNs.[50]

Scavenger Receptors. The first macrophage scavenger receptor (SR) was described by Goldstein and coworkers in 1979[51] and Brown and colleagues in 1980[52] and was shown to bind and internalize acetylated-LDL. Since then, multiple SRs have been identified and shown to play diverse roles in the phagocytosis of a variety of particles and molecules ranging from bacteria to lipids (see Fig. 13-3). The SR family comprises eight classes (A-H) of which class A (SR-A) and class B (SR-B) are primarily involved in innate immunity through their ability to recognize and promote phagocytosis of a wide range of bacteria. Members of the SR-A and SR-B subfamilies are abundantly expressed on macrophages and DCs but do not appear to be expressed by airway or alveolar epithelial cells. This is in keeping with the notion that during exposure to inhaled microbes and particles, the lung epithelium has evolved mechanisms to respond to PAMPs by promoting inflammation but not to engage in phagocytosis, leaving this activity to professional phagocytes.

Class-A SRs are homotrimeric type II transmembrane proteins (extracellular C-terminal). SR-A exists as two splice variants (SR-AI and SR-AII) of a single gene and has been shown to recognize LPS, lipoteichoic acid, double-stranded RNA, and unmethylated CpG DNA sequences, suggesting that it may function in the recognition of PAMPs. However, studies with intact bacteria suggest that its primary function is to promote the phagocytosis of a range of nonopsonized bacteria including *S. aureus*, *Steptococcus pneumoniae* and *Escherichia coli*.[53] SR-A–deficient mice have increased susceptibility to systemic infections with *S. aureus* and *Listeria monocytogenes*[54,55] and pulmonary infections with *S. pneumonia*.[56] A second and equally important class-A SR involved in nonopsonic phagocytosis of bacteria is macrophage receptor with collagenous structure (MARCO). Initial studies suggested that MARCO has limited expression in splenic and lymph node macrophage subpopulations but was not expressed in lung macrophages.[57] However, later studies indicated that MARCO expression is induced following PAMP recognition, particularly by CpG DNA and LPS, and by proinflammatory cytokines such as TNF-α.[58,59] Studies in MARCO-deficient mice have also revealed its importance in innate pulmonary host defense against *S. pneumoniae*.[60] Furthermore, down-regulation of MARCO by IFN-γ increases susceptibility to *S. pneumoniae* in mice and may contribute to pulmonary bacterial pneumonias that occur following influenza infections.[61] MARCO is also thought to be a major receptor for unopsonized bacteria on human alveolar macrophages.[62] Interestingly, MARCO has also been implicated in the phagocytosis of inorganic dusts by pulmonary macrophages.[63,64] MARCO may also play a role in dampening pulmonary inflammation because MARCO-deficient mice exhibit increased lung inflammation in response to exposure to environmental stimuli such as crystalline silica and inhaled oxidants.[65,66]

Class-B SRs are primarily represented in the lung by CD36. CD36 is expressed on monocytes, macrophages, DCs, and vascular endothelium but does not appear to be expressed on airway or alveolar epithelial cells.[67–69] Like class-A SRs, CD36 has been implicated in PAMP recognition, especially lipoteichoic acid,[70] and in the phagocytosis of *S. aureus*.[71,72] However, whereas CD36 deficiency in mice results in impaired host defense against *S. aureus*,[70] naturally occurring genetic deficiency of CD36 in humans is associated with impaired responses to oxidized LDLs and the development of a metabolic syndrome–like state rather than a pulmonary phenotype.[73]

C-Type Lectin Receptors. In additional to their presence in the secreted PRRs SP-A and SP-D, C-type lectin domains are widely incorporated in a family of cell surface receptors that play an important role in the function of DCs and macrophages (see Fig. 13-3). As with SRs, C-type lectin receptors (CLRs) do not appear to be expressed on airway and alveolar epithelial cells. CLRs recognize high-density carbohydrate-based PAMPs on microbial cell walls and viral coats. Carbohydrate binding can be divided into mannose and galactose specificity.[74] Type I CLRs include dendritic and thymic epithelial cell-205 (DEC-205) and macrophage mannose receptor (MMR), and type II CLRs include dendritic cell-specific intracellular adhesion molecule (ICAM-3) grabbing nonintegrin (DC-SIGN) and dectin-1. As is discussed, studies in mice bearing targeted disruptions of CLR genes have emphasized their importance in innate host defense and particularly in DC maturation and antigen presentation.

DEC-205 is type 1 transmembrane receptor protein found on a variety of DC subsets, macrophages, and thymic epithelial cells.[75] The natural carbohydrate ligands of DEC-205 remain largely uncharacterized though the receptor has been shown to induce the endocytosis of experimental antigen-anti-DEC-205 receptor complexes and promote their delivery to endosomes prior to antigen processing and presentation. When DCs are treated with the antigen-anti-CD205 fusion protein alone, they induce tolerance to the antigen by deleting specific $CD4^+$ and

FIGURE 13-2 ■ Pulmonary collectins, especially surfactant protein A (SP-A) and SP-D, play a key role in suppressing inflammation in the absence of PAMPs, while stimulating inflammation in the presence of PAMPs. **A,** Structure of pulmonary collectins. **B,** The importance of SP-D in tonic suppression of lung inflammation is illustrated by the spontaneous proinflammatory phenotype of SP-D–deficient mice. **C,** Tonic suppression of inflammation is mediated by the binding of collectins to signal-inhibitory regulatory protein α (SIRPα) via their head groups, whereas activation of inflammation is mediated when PAMP-bound collectins interact with CD91 via their collagenous tail regions. (**A,** Adapted from Wright JR: Immunoregulatory functions of surfactant proteins. D NOD-like receptors (NLRs)

$CD8^+$ T-cells and by promoting the development of T-regulatory (T_{Reg}) cells.[76] In the presence of an inflammatory stimulus, DCs exposed to the antigen-anti-DEC-205 fusion proteins promote long-lived immunity mediated by Ag-specific $CD4^+$ and $CD8^+$ T-cells.[77,78] Antigens delivered by targeting DEC-205 may be presented in association both with MHC class II molecules and by cross-presentation with MHC class I molecules.[79–81] Furthermore, a recent study showed that DEC-205 mediates the uptake of self-antigens via the endocytosis of apoptotic cells, thereby providing a possible mechanism for the cross-presentation of self-antigens resulting in the induction of both central and peripheral tolerance.[82]

Dendritic cell-specific receptor-1 (dectin-1) was initially thought to be a DC-specific CLR but was later shown to be expressed on macrophages, monocytes, PMNs, and some T-cell subsets.[83,84] Dectin-1 specifically recognizes β-(1,3)- and β-(1,6)-linked glucans[85] and is thought to play a key role in the nonopsonic phagocytosis of a number of pathogenic yeasts, fungi, and bacteria by macrophages and DCs.[86] Ligation of dectin-1 also stimulates the production of an array of proinflammatory cytokines, oxidants, and lipid mediators following recruitment of the Syk tyrosine kinase to the cytoplasmic tail of the receptor.[87–91] Dectin-1 also stimulates the proliferation of $CD4^+$ and $CD8^+$ T cells and serves as a costimulatory molecule.[83,92] In DCs, dectin-1 synergizes with TLR2 to induce TNF-α and interleukin (IL)-12 production but also promotes the production of IL-2 and IL-10 independent of the TLR2 pathway in a Syk kinase–dependent manner.[88] Recent studies have also begun to define the complex nature of the host's ability to recognize and clear foreign elements via dectin-1.[87] Whereas signals derived from dectin-1 can directly activate macrophages and DCs, the signaling patterns generated also influence the pattern and direction of DC activation through complex integrated signals derived from other systems such as TLRs.

DC-SIGN is also a type II CLR,[93,94] but differs from dectin-1 by its specificity for microbial mannose-rich carbohydrates.[93,95–97] Ligation of DC-SIGN activates Raf-1 kinase signaling and enhances TLR-induced cytokine expression.[98,99] DC-SIGN also mediates DC trafficking and DC–T-cell interactions through its ability to interact with ICAM-3 and ICAM-2, respectively. DC-SIGN is also expressed on the surface of a subset of peripheral blood and lung BDCA-2^+ plasmacytoid DCs (pDCs) and resident alveolar macrophages.[100] Interestingly, increased expression of DC-SIGN by alveolar macrophages has been reported in response to stimulation with IL-13, suggesting a possible role for DC-$SIGN^+$ cells in the pathogenesis of type 2 T helper (Th2)–mediated lung diseases.[100]

Cytoplasmic Pattern Recognition Receptors

Nucleotide-Binding and Oligomerization Domain–like Receptors. In humans, NLRs are a family of 22 intracellular PRRs that have evolved to sense PAMPs in the cytoplasm of most cells. Cytoplasmic PAMPs recognized by NLRs include bacterial peptidoglycans and flagellin from gram-positive and gram-negative bacteria as well as microbial toxins such as *Bacillus anthracis* lethal factor.[101–103] Earlier, we briefly introduced DAMPs as a collection of nuclear and cytoplasmic molecules including high mobility group box-1 (HMGB1), adenosine triphosphate (ATP), nicotinamide adenine dinucleotide (NAD^+), and adenosine that are released following tissue injury.[104] Though not technically DAMPs, recent studies have also shown that uric acid and crystalline silica are also sensed by NLRs and, like PAMPs, initiate noninfectious inflammatory responses.[105–107] In turn, the recognition of cytoplasmic PAMPs and DAMPs by NLRs activates an array of signal transduction pathways that lead to the activation of NF-κB and the consequent production of proinflammatory cytokines. NLRs also induce the assembly of intracellular protein-protein complexes called inflammasomes,[108–111] which stimulate IL-1β production and initiate several different forms of programmed cell death, including apoptosis, necrosis, pyroptosis, and pyronecrosis.[112]

NLRs are characterized by the presence of three functional domains: a C-terminal leucine-rich repeat domain (LRR), a core NOD or NACHT domain, and an N-terminal effector-binding domain consisting of either a pyrin-domain (PYD), a caspase activation and recruitment domain (CARD), or a baculovirus inhibitor of apoptosis protein repeat domain (Bir). NLRs are divided into subfamilies based on protein structure and include the NALPs (NACHT leucine-rich domain and pyrin-containing protein), NODs, CIITA (class II transactivator), IPAF (interleukin 1β-converting enzyme [ICE]-protease activating factor), and NAIP (neuronal apoptosis inhibitor protein) subfamilies.[113] More information about NLR structure and function is available in several recent reviews.[101,102,108,112–118]

NLRs may also play a role in the maturation of immature DCs after exposure to PAMPs or cytokines.[109] The precise mechanisms by which NLR signaling occurs is an area of intense investigation, but studies show that NLRs participate in the formation of three distinct inflammasomes including the NALP1-, NALP3- and IPAF-containing inflammasomes.[102,108] Although the role of

NLRs in a variety of human disorders has been characterized, the complete role of these molecules in lung homeostasis and defense is not yet fully understood.

Retinoic Acid–Inducible Gene-1–like Receptors. The last group of cytoplasmic PAMP sensors is the retinoic acid–inducible gene (RIG)-1–like receptors that have evolved to detect the presence of RNA from RNA viruses and replicating DNA viruses. Three family members, RIG-I, myeloma-differentiation associated gene 5 (MDA5), and laboratory of genetics and physiology 2 (LPG2), have been identified. All three family members contain a central ATPase and RNA-helicase domain and a C-terminal regulatory domain. The N-terminus of RIG-I and MDA5 contains a CARD domain (as recently reviewed by Nakhaei and associates).[119] RIG-1 has been shown to recognize viral RNA sequences from several viruses and is involved in the response of lung epithelial cells to influenza virus.[120,121] In contrast, MDA5 has been shown to respond to poly [I:C] and picornoviruses.[122] Upon sensing viral RNA sequences, RIG-like family members activate NF-κB and interferon regulatory factor (IRF) signaling pathways to promote the expression of type I IFNs and proinflammatory cytokines,[123] thereby inducing and augmenting host and lung innate immunity. This area of innate immunity is rapidly evolving, and it is likely that RIG-like receptors will be found to affect other areas of innate and adaptive immunity. Indeed, a recent study has implicated RIG-1 in lung tumor metastasis.[124]

Summary

Collectively, secreted, plasma membrane, endosomal, and cytosolic PRRs provide remarkable flexibility in innate protection of the lung. In the descending airways, plasma membrane PRRs, especially TLRs, are poised to sense PAMPs but are generally unable to phagocytose PAMP-containing microbes. However, TLR signaling in airway epithelial cells results in the production of proinflammatory mediators, especially chemokines and cytokines that call in PMNs and macrophages to the site of PAMP detection to enable microbial clearance. In addition, intraepithelial DCs constantly sample the airway lumen to maintain immunologic tolerance to commonly encountered antigens that do not express PAMPs while remaining poised to activate the adaptive immune system once PAMPs are sensed. It seems reasonable to suggest that in the steady state, responses to inhaled particulates and microbes occur continuously, but silently. The alveoli are also protected by epithelial cells, DCs, and resident alveolar macrophages that also sense PAMPs via plasma alveolar PRRs. However, two additional levels of protection exist. First, secreted PRRs, especially SP-A and SP-D, protect the alveolar surfaces by tonically suppressing unwanted inflammation in the steady state, while remaining poised to stimulate innate responses in the presence of PAMPs. Second, resident alveolar macrophages express an additional array of PRRs, especially SRs that promote the phagocytosis of microbes and other particulates. In the next section, we discuss how ligation of these various PRRs activate and regulate innate host defense responses in lung cells.

EFFECTOR MECHANISMS

Many cell lineages are committed to maintaining sterility and innate protection of the respiratory tract, and in this section we discuss the three broad cell types involved in protection in the steady state, namely (1) airway and alveolar epithelium, (2) macrophages and DCs, and (3) PMNs, which though not an abundant cell type in the steady state are rapidly recruited to augment lung phagocyte numbers once the presence of PAMPs is detected.

Epithelium

The lung epithelium has an important role in host defense against microbes that pass through the glottis to reach the conducting airways and gas-exchange parenchyma. The conducting airways of the lower respiratory tract are lined by ciliated columnar epithelial cells down to the terminal airways and respiratory bronchioles, which are nonciliated. In contrast, the alveolar epithelium consists of flattened type I epithelial cells that form most of the alveolar surface and type II cuboidal epithelial cells that produce surfactant and surfactant-related proteins and project into the subepithelial structures of the lungs. The classic antimicrobial defense mechanism in the conducting airways is the mucociliary system, which moves microbes deposited on the airway epithelial surface upward and out of the lungs. In addition to this physical removal system, the airway and alveolar epithelium participate actively in the innate defense of the lungs, with the major goal of protecting the critical gas-exchange surface from microbial invasion.[125] The mucociliary system provides for the removal of all particles that deposit on the airway epithelium, and the clearance times in the trachea and proximal airways are measured in minutes. The cilia on the epithelial surface beat in coordinated waves, directing the movement of particles upward toward the larynx. Epithelial cell activation is not required for optimal ciliary beating, although beat frequency can be speeded by β-agonists and slowed by opiates and other drugs.[126]

The normal constituents of airway epithelial fluid contribute to the initial inactivation of microbial particles on the airway surface (see Table 13-1). The major antibacterial components include lysozyme, lactoferrin, and β-defensins, but others are also present in lower concentrations. Lysozyme is lytic to bacterial cell walls and has broad activity. Lactoferrin binds iron, reducing its availability for microbial metabolism. The defensins have antimicrobial activity for gram-positive and gram-negative bacteria, fungi, mycobacteria, and some viruses.[127] The first member of the β-defensin family was actually identified as an expressed protein in bovine trachea.[128]

The mucociliary system and antimicrobial constituents of airway epithelial fluid can be thought of as constitutive host defenses, because they do not depend on specific microbial recognition mechanisms and do not need activation. However, the airway and alveolar epithelium also participate in innate immune mechanisms in that they express bacterial recognition molecules

common to innate immune cells and can be induced to produce an array of proinflammatory mediators that recruit leukocytes into the airways directly through the airway and alveolar epithelial walls. Airway and alveolar epithelial cells express PRRs and sense bacteria on the epithelial surface by the same TLR-dependent mechanisms used by leukocytes.[115] Among these are CD14, TLR-1, -2, -4, -6, and -9.[33,129,130] Signaling through PRRs on epithelial cells enhances the production of antimicrobial defensins by airway epithelial cells. For example, bacterial products such as LPS acting through TLR4 stimulate the release of β-defensins from human airway epithelial cells,[131] although the effect is much less than in macrophages, because human airway epithelial cells express very low amounts of the key TLR4 cofactor, MD-2.[132] Similarly, proinflammatory cytokines produced during innate immune responses, such as TNF-α, IL-1β and IFN-γ, amplify the production of β-defensins by airway epithelial cells in culture.[8,133]

In addition to defensins and other microbicidal proteins, bacterial products stimulate the airway epithelium to produce chemotactic signals that recruit inflammatory cells into the airways, and endogenous cytokines also stimulate airway and alveolar epithelial cells to amplify leukocyte migration. Bacterial LPS stimulates ciliated airway epithelial cells to produce CXC and CC chemokines, which recruit PMNs and monocytes, respectively, into the airway lumen.[131] Airway epithelial cells also produce IL-1β, IL-6, IL-8, RANTES (regulated on activation, normal T-cell expressed and secreted), granulocyte-macrophage colony-stimulating factor (GM-CSF), and transforming growth factor-β (TGF-β), in addition to other proinflammatory cytokines.[125] As with other cells involved in innate immunity, cytokine production in airway epithelial cells occurs via the activation of transcription factors NF-κB and NF-IL-6, among others.[134] Interestingly, noninfectious environmental agents like ozone,[135] asbestos,[136] diesel exhaust particles,[137] and air pollution particles[138] all lead to NF-κB activation in airway epithelial cells under experimental conditions, which is typically followed by IL-8 production and release. Airway epithelial cells also recognize unmethylated bacterial DNA by TLR9, leading to NF-κB activation and production of IL-6, IL-8, and β_2-defensin in the airways.[139] Unlike airway epithelial cells, alveolar epithelial cells do not respond directly to LPS but produce chemokines in response to TNF-α and IL-1β secreted by alveolar macrophages, which have encountered bacteria or their products in the alveolar spaces.

Studies with transgenic mice provide further support for the critical role of the lung epithelium in innate immunity and microbial defense. Skerrett and coworkers[140] showed that mice expressing a dominant negative IκB construct in distal airway epithelial cells, preventing NF-κB activation, have impaired airway PMN recruitment in response to inhaled LPS. This finding supports the importance of bacterial recognition by distal airway epithelial cells in vivo and shows that epithelium-derived cytokines produced by the NF-κB pathway probably are just as important as macrophage-derived cytokines in driving innate inflammatory responses in the airways and alveolar spaces. Hajjar and colleagues[140a] produced bone marrow chimeras in which either myeloid (leukocytes) or nonmyeloid (epithelial) cells lacked MyD88, a key adapter molecule required for signaling via all TLRs except TLR3. The mice lacking MyD88 (and, therefore, deficient TLR signaling) in nonmyeloid cells including the airway and alveolar epithelium had markedly impaired clearance of *P. aeruginosa*, whereas mice with or without MyD88 in myeloid cells had normal and equivalent bacterial clearance. This surprising result further supports the important role of the airway and alveolar epithelium in bacterial recognition and clearance from the lungs, a role that is perhaps equivalent to that of resident and recruited leukocytes.

Innate immune responses in the airway epithelium can generate or influence adaptive responses, because recognition of β-(1,3)-glucan in house dust mites stimulates the production of CCL20, a chemokine that recruits immature DCs into the airways.[141] The airway epithelium can directly influence the function of lung DCs, inducing adaptive Th2 responses that are thought to be important in the pathogenesis of asthma, and LPS responses in the airway epithelium are involved in some DC-driven Th2 cell responses.[142] Airway epithelial cells produce thymic stromal lymphopoietin, GM-CSF, IL-1β, IL-25, IL-33, and osteopontin, all of which activate DCs.[143]

An emerging concept is that deliberate stimulation of innate immunity in the airways and air spaces produces broad enhancement of antimicrobial defenses. Exposure of mice to a crude extract of nontypable *Haemophilus influenzae* bacteria via aerosol initially stimulated innate immunity and then protected the mice from lethal infection with *S. pneumoniae*.[144] This was associated with enhanced production of lysozyme, lactoferrin, and defensins in the lungs. Similarly, exposure to this crude bacterial extract protected mice from *S. aureus*, *P. aeruginosa*, and the fungus *A. fumigatus*.[145] Thus, prestimulation of innate immune mechanisms in the airway and perhaps alveolar epithelium enhances the antimicrobial activity and host defense of the lungs against a broad array of bacteria and fungi. The implication is that deliberate low-level stimulation of innate immunity in the lungs could be used as a protective strategy, but the emerging recognition of the important role of lung epithelial innate immunity in stimulating and regulating adaptive immune mechanisms raises the possibility that such a strategy might have unexpected effects.

Thus, innate immune mechanisms in the airways stimulate endogenous defenses by enhancing production of airway defensins and other antimicrobial products, by stimulating PMN and monocyte recruitment into the airways to augment antimicrobial defenses, and by setting the stage for DCs and Th2-mediated adaptive immune responses that could be important in the pathogenesis of allergic lung diseases.

Neutrophils

PMNs serve as the immediate effector arm of the innate immune system.[146,147] PMNs are produced from progenitor cells in the bone marrow, circulate for a short time

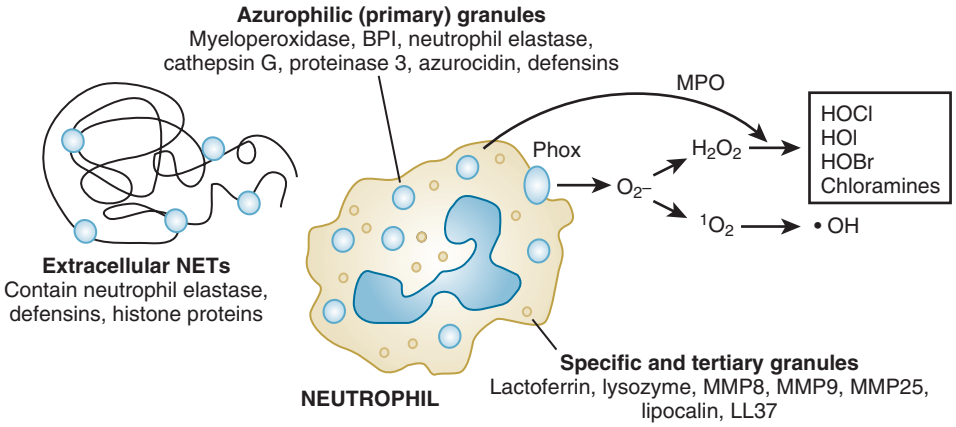

FIGURE 13-4 ■ Neutrophils use several mechanisms to kill microbes. (Mofified from Nathan C: Neutrophils and immunity: Challenges and opportunities. Nat Rev Immunol 6:173–182, 2006.)

in the bloodstream, and migrate to sites of tissue inflammation in response to signals produced by local innate immune mechanisms. The marrow progenitor cells that produce PMNs also produce monocytes, which mature into tissue macrophages and DCs. Mature PMNs are released from the marrow in response to granulocyte colony-stimulating factor (G-CSF) and other stimuli and circulate for up to 6 to 8 hours. The bone marrow releases between 10^9 and 10^{10} PMNs each day, and marrow release can increase severalfold in response to acute signals from the lungs and other tissues. PMNs contain several different kinds of cytoplasmic granules, which contain an array of proteins (Fig. 13-4). Small specific granules serve as a source of new membrane and fuse with the leading edge of the cell during migration. Primary (azurophilic) granules contain myeloperoxidase, which accounts for the green color of pus, bacterial permeability-increasing protein (BPI), PMN elastase, matrix metalloproteinases (MMPs), other proteinases, and defensins.

Circulating PMNs are spherical, with a diameter of approximately 8 μM, and must deform to make their way through the capillary microcirculation in the lungs and other organs. PMNs bear surface adhesion molecules that recognize carbohydrate and protein moieties expressed on activated endothelial cells. In the systemic circulation, PMNs migrate into tissue through postcapillary venules in a four-step process: weak adherence to the venular endothelium, rolling along the endothelial surface, arresting on the endothelial surface, and migration between endothelial junctions into tissue in response to local chemotactic gradients.[148] This paradigm is different in the lungs, where the pulmonary capillaries slow the transit of PMNs because of the small cross-sectional capillary diameter.[149,150] This produces a reservoir of capillary PMNs that are poised to respond directly to signals from the innate immune system in the air spaces. When bacteria or their products such as gram-negative LPS circulate in the bloodstream, PMNs undergo activation with cytoskeletal rearrangements that cause stiffening,[151] promoting increased entrapment of PMNs in the pulmonary capillaries.

When innate immunity is activated in the lungs, chemotactic factors are produced by resident alveolar macrophages and activated epithelium, which create soluble and tissue-fixed gradients that recruit PMNs into the alveolar spaces. Leukotriene B_4 (LTB_4) is a product of arachidonic acid metabolism in alveolar macrophages that produces an immediate and short-lived soluble gradient that recruits PMNs into the air spaces but dissipates within minutes.[152,153] Release of LTB_4 is followed closely by the release of IL-8, a chemotactic cytokine (chemokine) that binds to heparin residues on tissue matrix, creating a tissue reservoir that promotes long-lived gradients.[154,155] IL-8 is the dominant member of a group of CXC chemokines, which also include GRO-α, -β, and -γ, and ENA-78. The CXC chemokines have a C-X-C sequence at the N-terminus, which provides PMN specificity, and an N-terminal ELR peptide sequence, which is important in chemotactic receptor binding. The CXC chemokines recruit PMN to sites of inflammation, whereas chemokines with the CC N-terminal sequence recruit monocytes. IL-8 and related chemokines probably reach the endothelial luminal surface by diffusion from alveolar fluids, and bind to endothelial cell surface glycosaminoglycans to create a fixed local signal that guides PMNs sequestered in pulmonary capillaries into the air spaces. Whereas PMNs bear a single receptor for LTB_4, they express two different receptors with differing affinity for IL-8. The low-affinity receptor (CXCR2) is thought to localize PMNs at sites of inflammation, whereas the high-affinity receptor (CXCR1) is thought to guide PMN migration into tissues. The low-affinity receptor is shed from the surface of circulating PMNs in sepsis.[156] PMNs also have receptors for the complement component C5a and for formylated peptides produced by bacteria in the air spaces, so that endogenous as well as exogenous signals attract PMNs to sites of inflammation. The diversity of chemotactic stimuli recognized by PMNs promotes the formation of combinatorial gradients that guide PMN migration toward localized sites of inflammation in the lungs and other tissues.[157]

In the systemic circulation, PMN migration into tissues depends on the integrin CD11/CD18 on the PMN surface

recognizing the counterligand ICAM-1 on the endothelial surface. In the lungs, however, CD18-dependent and -independent mechanisms exist and the signals that determine whether or not PMN migration depends on CD18 are not clear.[158] For example, PMN migration into the lungs in response to *E. coli* and *P. aeruginosa* is CD18-dependent, whereas neutrophils do not require CD18 to emigrate into the air spaces in response to *S. pneumonia*. TNF-α and IL-1β appear to direct CD18-dependent migration, whereas IFN-γ is more important for CD18-independent emigration. Selectins like VLA-4 (very late antigen-4) and PECAM-1 (platelet–endothelial cell adhesion molecule-1) do not appear to regulate CD18-independent migration.

Under normal circumstances, PMN emigration is not associated with injury to the endothelial or epithelial barriers that separate the plasma compartment from the air spaces in the lungs. Endothelial cells undergo reversible contraction in response to thrombin and other inflammatory stimuli, opening endothelial junctions and allowing the passage of leukocytes. The alveolar epithelium is a much tighter barrier, and PMNs reach the air spaces with only minor and transient changes in epithelial permeability.[159,160] During migration, the spherical PMNs in the bloodstream change shape and small specific granules fuse with the leading edge of the cell membrane, providing new membrane material bearing specific adhesion molecules. PMNs in the air spaces are polarized, which is an initial sign of activation, but contain the full complement of primary azurophilic granules containing myeloperoxidase and defensins.[160] Metabolic studies of PMNs in rabbits with pneumococcal pneumonia and humans with bronchiectasis have shown that in these models, most PMN activation occurs in the air spaces and not during emigration into the lung.[161,162] However, when endothelial activation is intense, or when PMN activation signals are present within the circulation, PMNs become preactivated and migration can be associated with damage to the endothelial and epithelial barriers, with increased permeability pulmonary edema.[163]

Once in the air spaces, PMNs ingest bacteria and fungi that have been opsonized by complement and immunoglobulins that accumulate in the air spaces at sites of inflammation. PMNs contain a series of effector mechanisms to kill bacteria and fungi, including oxidant production, microbicidal proteins in primary azurophilic granules, and extracellular traps. As microbes are recognized and the phagosome begins to form, the subunits of a nicotinamide adenine dinucleotide phosphate, reduced form (NADPH) oxidase are assembled in the cell membrane and the cell undergoes a respiratory burst, in which an electron is transferred to molecular oxygen to form superoxide anion, which is reduced again to form hydrogen peroxide (H_2O_2). This happens on the invaginating phagosomal membrane, focusing oxidants on the contents of the developing phagosome. As the phagosome forms, the primary granules fuse with the phagosomal membrane, adding myeloperoxidase and cationic antimicrobial peptides to the phagolysosome. Myeloperoxidase catalyzes the formation of hypochlorous acid from H_2O_2 and a halide, typically chloride (Cl^-) because of its high concentration in the cellular environment. Hypochlorous acid is a highly reactive oxidant that oxidizes methionines, tyrosines, and other amino acids on proteins, killing the microbe.

In addition to their presence in airway surface liquid, PMN primary azurophilic granules also contain high concentrations of defensins.[127,164] Human neutrophil proteins (HNP)-1, -2, and -3 are α-defensins, so named because of the pattern of disulfide bonding in the tertiary structure of the proteins, and are abundant in azurophilic granules of PMNs. HNP-1 and -2 make up approximately 90% of the defensin proteins in PMNs. When defensins are added to the phagolysosomal space, they attach to negatively charged microbial membranes via electrostatic interactions and are thought to form lytic pores in the microbial cell wall. PMN defensins have antimicrobial activity for gram-positive and gram-negative organisms, fungi, and some viruses. Defensins are most active under conditions of low ionic strength and lose activity with increasing concentrations of salt or plasma proteins, which interfere with electrostatic interactions between the cationic defensins and the anionic microbial surface.[127] This has been proposed as a contributing factor for the pathogenesis of chronic airway infection in cystic fibrosis.[165] In addition to their antimicrobial activity, members of the defensin family participate directly in innate and adaptive immunity, because they stimulate IL-8 production by epithelial cells and modulate the responses of T-cells and immature DCs.[164,166,167]

When phagocytosis is appropriately regulated, microbial killing occurs within the protected environment of the PMN phagolysosome. However, at sites of intense inflammation, PMNs release superoxide anion, H_2O_2, and granular contents directly into the extracellular environment, leading to oxidant formation in the alveolar spaces with oxidation of structural proteins in the alveolar walls and intracellular proteins in leukocytes and the accumulation of defensins and other granular contents in the alveolar spaces.[168] These extracellular products contribute to indirect tissue injury by PMNs.

In addition to killing intracellular microbes using oxidants, chlorination, and antimicrobial peptides, as a final act, PMNs can project uncoiled nuclear DNA into the surrounding environment to form NETs (neutrophil extracellular traps) that ensnare and destroy bacteria[169,170] (Fig. 13-5). NET formation depends on the initial respiratory burst of the PMN and leads to the death of the PMN in a process that is distinct from apoptosis and necrosis.[171] The PMNs of patients with chronic granulomatous disease, which lack a functional membrane NADPH oxidase, do not form NETs with appropriate stimulation.[171] A variety of proinflammatory stimuli activate NET formation, including LPS and IL-8. C5a triggers NET formation in PMNs after priming with IFNs or GM-CSF. Some microbes, including *S. aureus*, *E. coli*, *P. aeruginosa*, and *M. tuberculosis*, directly stimulate NET formation by PMNs. The extracellular DNA mesh contains cationic proteins embedded in the negatively charged DNA net, including histones, defensins, and cathelicidin,

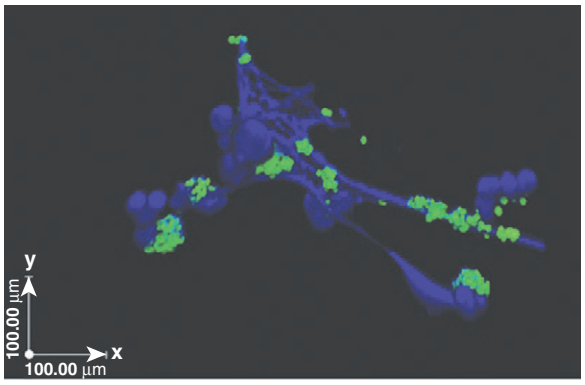

FIGURE 13-5 ■ Neutrophils can kill microbes by propelling uncoiled DNA into the surrounding environment. These have been termed neutrophil extracellular traps (NETs). FIGURE 13-6 ■ Apoptotic PMN (*arrowheads*) being ingested by a lung macrophage in the bronchoalveolar lavage (BAL) of a patient with acute respiratory distress syndrome (ARDS). (From Matute-Bello G, Liles WC, Radella F, et al: Neutrophil apoptosis in the acute respiratory distress syndrome. Am J Respir Crit Care Med 156:1969–1977, 1997.)

which kill enmeshed bacteria. Similar extracellular traps are produced by eosinophils and mast cells, but unlike PMNs, eosinophils apparently survive NET formation. NET formation thickens secretions at sites of inflammation, creating a viscous pus that contains enmeshed microbes. As might be expected, some bacteria produce extracellular enzymes that degrade DNA NETs, including *S. pyogenes* (DNase Sda1/2) and *S. pneumoniae* (DNase EndA).[172,173] The mechanisms by which NETs are cleared from the air spaces during resolution of inflammation are not clear.

PMNs have an important role in signaling the activation of adaptive immunity. In rabbits with tuberculous pleurisy, PMNs were the first cells into the infected pleural space and were found to produce chemotactic factors that direct the subsequent wave of monocyte recruitment, which characterizes the full inflammatory reaction to *M. tuberculosis*.[174] PMN granule proteins cathepsin G and azurocidin are chemoattractants for mononuclear cells, which mature into macrophages and DCs at sites of inflammation, and neutrophil-derived CC chemokines recruit DCs.[175,176] PMNs release limited amounts of TNF-α and IFN-γ, which regulate macrophage, T-cell, and DC activation and maturation; however, the large numbers of PMNs at sites of inflammation can bring the concentrations of these PMN-derived cytokines into biologically relevant ranges. PMNs also produce CXCL-10 (IP-10, IFN-γ–inducible protein-10), which is a chemoattractant for natural killer cells and Th1 cells.[177]

At the same time that PMNs participate in and intensify inflammation in tissue, they also produce signals that control and begin the resolution of inflammation. PMNs, like macrophages and endothelial cells, release the secretory leukocyte protease inhibitor (SLPI), which inhibits PMN elastase.[178] After migration into tissues, PMNs produce lipoxins from membrane arachidonic acid, which inhibit PMN recruitment, superoxide anion generation, and NF-κB activation and enhance the uptake of apoptotic PMNs by macrophages.[179] PMN-derived oxidants inactivate proteases and other proteins at sites of inflammation.

PMNs and their products are cleared largely by macrophages during the resolution of inflammation. PMNs die primarily by apoptosis, necrosis, or NET formation. Apoptosis is a highly regulated form of cell death and is mediated by a series of intracellular caspases.[180,181] Apoptosis occurs via two major pathways: ligation of membrane death receptors, principally Fas/CD95 and TNFRI (p55), and mitochondrial stress that results in the release of cytochrome c into the cytoplasm. PMNs undergoing apoptosis express phosphatidylserine on the outer leaflet of the cell membrane and undergo nuclear chromatin condensation and cell shrinkage. Apoptotic PMNs are recognized via the CD36 receptor on macrophages and rapidly ingested, so that large numbers of apoptotic PMNs are usually not seen (Fig. 13-6). Macrophages that ingest apoptotic PMN produce TGF-β and IL-10, which have anti-inflammatory effects. This process results in the clearance of PMNs and their residual intracellular contents and dampening of inflammation. PMNs that are not ingested by macrophages undergo secondary necrosis with release of remaining intracellular contents into the inflammatory environment. When intracellular ATP levels fall to critically low levels, PMNs die by necrosis, with loss of membrane integrity, cytoplasmic swelling, and discharge of intracellular contents into the extracellular environment. Intracellular components are recognized as danger signals by macrophages, some of which have been included as "alarmins," or DAMPs.[182] DAMPs include the nuclear protein HMGB1, granular antimicrobial peptides, and other intracellular products. Macrophages that recognize these danger signals produce IL-1β, TNF-α, IL-8, and other proinflammatory cytokines, initiating or perpetuating inflammatory responses. Some PMNs recovered from the lungs of patients with acute respiratory distress syndrome (ARDS) have features of apoptosis, with small cytoplasmic features and nuclear pyknosis, whereas many have features of necrosis, including severe degranulation, membrane blebbing,

and cytoplasmic swelling. The signals that govern the balance between necrosis and apoptosis are incompletely understood.

Thus, PMNs are important effector cells in innate immunity, ideally designed to circulate through the body and accumulate rapidly at tissue sites of acute inflammation. Under normal circumstances, they arrive in tissue ready to ingest and kill microbes, then go quietly away by programmed cell death. PMN-derived signals regulate local inflammation and stimulate adaptive immune responses, providing a broader role for PMNs in host defense.

Mononuclear Phagocytes

The concept of the mononuclear phagocyte system as a functionally and phenotypically heterogeneous system of mononuclear phagocytes distributed throughout the body was developed in the 1960s and 1970s through a series of insightful studies pioneered by van Furth and Cohn[183] and Volkman and Gowans.[184] The central concept is that resident macrophages in all organs and tissues are derived from progenitor cells in the bone marrow. In turn, progenitor cells give rise to circulating blood monocytes and are recruited into organs and tissues where they differentiate into macrophages, thereby maintaining macrophage homeostasis. Heterogeneity in macrophage function and phenotype is thought to be an adaptive response to microenvironmental cues at the sites to which they have been recruited. For instance, in the lung, exposure to pulmonary surfactants and a high oxygen tension in the alveoli programs macrophages to express unique effector functions not seen in other organs. In response to additional needs during inflammation or infection, monocyte production in the bone marrow increases, thereby enabling increased monocyte recruitment to affected tissues.

In 1973, Steinman and Cohn[185] characterized a population of antigen-presenting cells in mouse spleen and, based on their morphology, coined the name *dendritic cells (DCs)*. Since the late 1980s, a vast array of monoclonal antibodies against monocytes, macrophages, and DC cell surface antigens has been developed and used in an attempt classify monocyte/macrophages and DCs as separate lineages. The issue is confusing for many reasons but particularly because macrophages exhibit many of the functions and antigenic markers of DCs, and vice versa. Indeed, in a recent position paper, David Hume[186] suggested that it is artificial to separate monocytes/macrophages and DCs into separate lineages and that the functional and antigenic divergence between these populations should be considered in the context of the known heterogeneity that occurs within the mononuclear phagocyte system. The issue of using cell surface markers to separate macrophages and DCs is particularly relevant in the lung, where CD11c is expressed at high levels on resident alveolar macrophages, interstitial macrophages, and DCs (as reviewed by Hume[186]). In addition, much of our initial understanding of the functions of resident lung mononuclear phagocytes came from studies conducted without the use of extensive cell surface marker panels or lineage tracing technologies. Thus, although it is clear that the cells described in many studies are mononuclear phagocytes, it is sometimes difficult to classify them further.

As illustrated in Figure 13-7, pulmonary mononuclear phagocytes can be broadly thought of as three overlapping subpopulations: (1) resident macrophages of the airway, alveolar surfaces, and alveolar interstitium, (2) monocytes that marginate in the lung microvasculature and are recruited into the air spaces in response to innate activation, and (3) resident and recruited DCs of the airways and lung parenchyma. In this section, we focus on the localization and innate immune functions of each group of cells.

Resident Macrophages

Resident airway and alveolar macrophages reside in the mixed environment of epithelial lining fluid and ambient inhaled air, whereas resident interstitial macrophages are located within the interstitial tissue or alveolar septae. Morphometric analyses indicate that the number of interstitial macrophages in normal lung is between one tenth and one half of the total number of alveolar macrophages.[187,188] Unlike resident alveolar and airway macrophages that can be obtained by bronchoalveolar lavage, interstitial macrophages can be obtained only by using tissue dispersion techniques. Consequently, considerably less is known about the biology and function of interstitial macrophages than about resident alveolar macrophages, especially in humans. In addition, interpreting current and past studies can be difficult because artifacts in cell phenotype and function can be introduced as a consequence of the tissue dispersion approach or by in vitro exposure to trace amounts of contaminating PAMPs during isolation. Despite these caveats, interstitial macrophages are thought to share many functional similarities with resident alveolar macrophages.

Functions of Resident and Interstitial Alveolar Macrophages. The primary functions of resident alveolar macrophages are (1) to dispose of inhaled microbes and particulates, (2) to clear pulmonary surfactant, and (3) to tonically suppress the development of inappropriate inflammatory and immune responses. Resident alveolar macrophages are capable of phagocytosing a wide spectrum of harmless and harmful microbes and other particulates. Under basal conditions, most ingested phagocytosed particulates are enclosed within phagosomes, which ultimately fuse with lysosomes, leading to their degradation by an array of acid-pH optimum hydrolytic enzymes. Some inhaled microbes (e.g., *M. tuberculosis*) and some environmental particulates (e.g., crystalline silica) are resistant to this process and become sequestered in secondary lysosomes where they remain for the lifespan of the macrophage. Most of these latter cells probably crawl into the airways and are cleared via the mucocilliary escalator, although a few probably migrate to regional draining lymph nodes, where their ultimate fate is uncertain.[189,190] Some particle-laden macrophages may remain in the lung for extended periods of time before either dying and releasing their particle burden, thereby rendering it available for phagocytosis

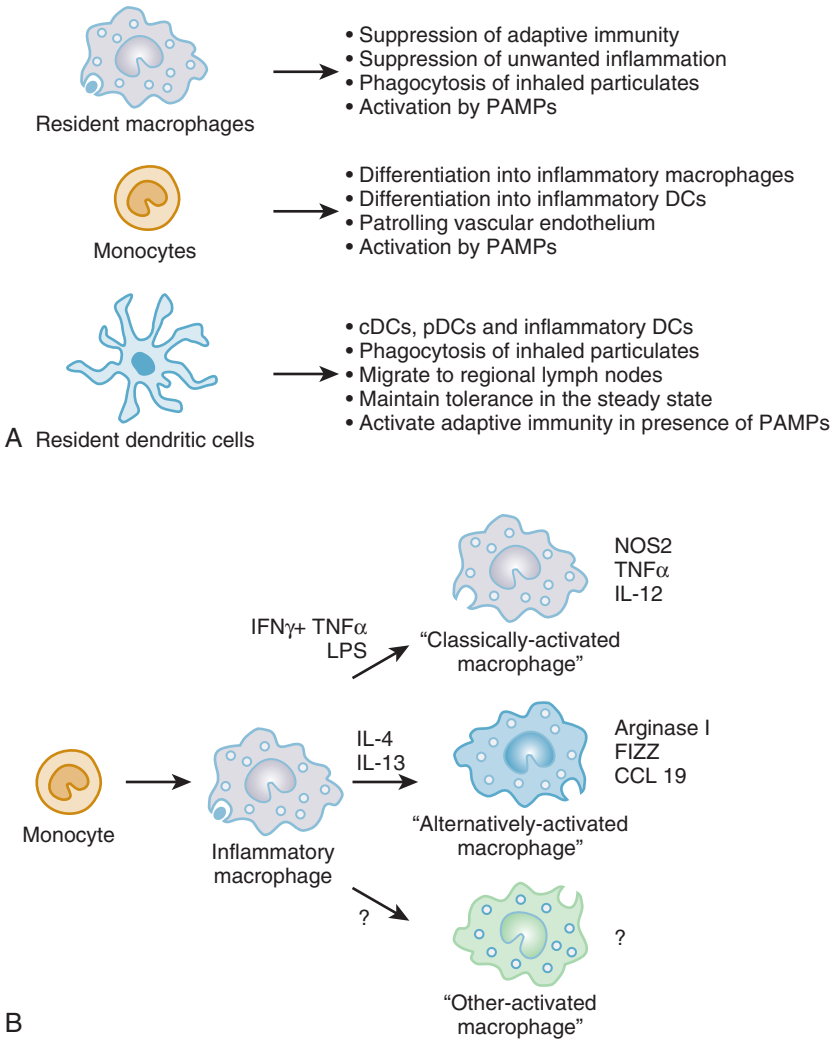

FIGURE 13-7 ■ **A,** In the steady state, lung mononuclear phagocytes can be considered to include: (i) resident macrophages of the alveoli and alveolar septae, (ii) marginating monocytes of the lung microvasculature, and (iii) resident dendritic cells. Each of these subsets exhibits overlapping and unique functions. **B,** Macrophages display distinct patterns of gene expression in response to type 1 T helper cells (Th1) and Th2 type cytokines and PAMPs. Prototypical are so-called classically and alternatively activated macrophages. It is likely that macrophages can exhibit a diverse repertoire of other states.

by other macrophages, or undergoing apoptosis and being cleared by other phagocytes.

Resident alveolar macrophages also actively contribute to the normal homeostasis of pulmonary surfactant. This point is most clearly emphasized in patients with pulmonary alveolar proteinosis (PAP), a disorder characterized by the accumulation of proteinaceous and lipid-rich surfactant in the alveoli leading to impaired gas exchange. A fundamental characteristic of the disorder is the finding that alveolar macrophage numbers are reduced, and those that are present are inefficient in clearing pulmonary surfactant.[191,192] Several studies have shown that PAP is associated with the development of autoantibodies against GM-CSF,[191–193] emphasizing the importance of GM-CSF in the activities of resident alveolar macrophages.

Last, resident alveolar macrophages play a critically important role in tonic suppression of alveolar inflammation and adaptive immunity. Based in part on studies by Maclean and associates,[194] the concept has evolved that the lung can deal with inhaled microbes and particulates until a certain threshold burden is reached. The threshold is, in part, determined by the phagocytic capacity of alveolar macrophages. Once the threshold is exceeded, microbes and other particulates are phagocytosed by resident DCs that "snorkel" through tight junctions of the alveolar epithelium to sample the alveolar compartment. Consistent with this concept, studies have shown that depletion of alveolar macrophages with liposome-encapsulated clodronate augments antigen presentation by pulmonary DCs, which in turn augments adaptive immune responses to intratracheal antigens.[195,196] Other studies have shown that resident alveolar macrophages suppress the functions of natural killer (NK) cells and plasma cells.[197,198]

The ability of resident alveolar macrophages to suppress inflammation and T-cell responses is specific to these cells and is not a characteristic of macrophages obtained from other locations or peripheral blood.[199–201] These findings suggest that the alveolar microenvironment may play an important role in the development of suppressive activity by resident alveolar macrophages. As noted earlier, the pulmonary collectins SP-A and SP-D inhibit PAMP-dependent production of proinflammatory cytokines through their interaction with SIRPα.[19] In addition, TGF-β, produced by alveolar macrophages and

activated at the surface of alveolar epithelial cells by the integrin αvβ6, has been shown to basally suppress alveolar inflammation.[202,203] Other studies have emphasized the importance of IL-10, prostaglandin E_2 and nitric oxide in the tonic suppression of alveolar inflammation and adaptive immunity.[204,205] Together, these studies suggest that resident alveolar macrophages have several mechanisms that actively suppress alveolar inflammation and the antigen-presenting activity of interstitial DCs, while remaining poised to reverse this response upon appropriate stimulation.

The tonic suppressive activity of alveolar macrophages can be relieved in several different ways. One mechanism involves exceeding the threshold phagocytic capacity of resident alveolar macrophages, thereby allowing microbes to interact with other lung cells, for example, pulmonary DCs or alveolar epithelial cells, which respond to PAMPs and other molecules by producing proinflammatory cytokines. Indeed, GM-CSF and TNF-α have been shown to reverse tonic suppression of adaptive immunity in vivo.[206] A second mechanism involves alveolar macrophages themselves. Here, PAMP recognition by the globular head groups of SP-A and SP-D enables lung collectins to interact with macrophages via calretiulin and CD91.[19] In contrast to the suppressive signal initiated when SP-A and SP-D interact with macrophages via SIRPα in the absence of PAMPs, CD91 signaling leads to the production of proinflammatory cytokines, which then augment inflammation and the recruitment of PMNs and monocytes. Thus, as summarized in Figure 13-7, resident alveolar macrophages are capable of suppressing inappropriate alveolar inflammation and adaptive immune responses to commonly encountered antigens. However, mechanisms exist to overcome this suppression to allow the recruitment of inflammatory cells, especially PMNs and monocytes, and to promote adaptive immunity.

Recruitment of Mononuclear Phagocytes

Bone-marrow–derived progenitor cells differentiate into monocytes, macrophages, and all DC subsets.[207–209] Two subsets of human and mouse circulating blood monocytes have been described that give rise to either resident macrophages or inflammatory macrophages and conventional DCs (cDCs).[210,211] In humans, these monocyte subsets are characterized as $CD14^{hi}CD16^{+}$ and $CD14^{lo}CD16^{+}$ monocytes.[212] The corresponding mouse subsets are defined as $CCR2^{hi}Ly6c^{hi}(Gr\text{-}1^{hi})CX_3CR1^{lo}$ and $CCR2^{lo}Ly6c^{lo}(Gr\text{-}1^{lo})CX_3CR1^{hi}$. Mouse $CCR2^{hi}$ and human $CD14^{hi}CD16^{+}$ monocytes are recruited to inflammatory sites in a CCR2-CCL2 (MCP-1)–dependent manner where they differentiate into inflammatory macrophages and cDCs. In contrast, $CD14^{lo}CD16^{+}$ human monocytes and $CCR2^{lo}$ mouse monocytes are considered as "resident" monocytes that patrol the lung microvasculature and contribute to the marginated monocyte pool.[213] This subset also expresses high levels of fractalkine receptor (CX_3CR1) and following interaction with fractalkine (CX_3CR1L) expressed on the luminal face of vascular endothelial cells, they transmigrate into tissues and differentiate into macrophages.[210,211] More information about the mechanisms of monocyte, macrophage, and DC migration can be found in several reviews.[214,215]

Functions of Recruited Monocytes and Macrophages. In contrast to resident alveolar macrophages, recruited monocytes and macrophages have important proinflammatory and host-defense activities including (1) microbial killing and (2) amplification of inflammation. Monocytes and macrophages kill microbes with reactive oxygen species and reactive nitrogen species. Superoxide anion (O_2^-) is mainly produced by the phagocyte NADPH oxidase.[216] Like PMNs, monocytes subsequently convert O_2^- into additional reactive oxygen species in a myeloperoxidase-dependent fashion,[217] but as they differentiate into macrophages, intracellular myeloperoxidase content declines and additional reactive oxygen species (e.g., hydroxyl radical [OH^-] are formed by the Fenton reaction.[218]

The generation of reactive oxygen species is critical to host defense against commonly encountered and pathogenic bacteria. Patients with chronic granulomatous disease and mice bearing a targeted disruption of the $p47^{phox}$ component of the NADPH oxidase[219,220] are deficient in their ability to control pulmonary and other infections.[219–222] However, inappropriate production of reactive oxygen species by macrophages (and other inflammatory cells) can result in epithelial injury that can lead to fibroproliferation as can be seen with survivors of ARDS and patients with idiopathic pulmonary fibrosis, asbestosis, or silicosis.[223–225] Thus, whereas reactive oxygen species play a vital role in the protection of the lung against microbes, inappropriate production in response to nonmicrobial particulates and pollutants including cigarette smoke[226] can result in a spectrum of injury to the airway and alveolar epithelium. Nitric oxide (NO) produced by inducible nitric oxide synthase (iNOS or NOS2) also contributes to macrophage-mediated microbial killing and epithelial injury following condensation with O_2^- to form peroxynitrite.[227,228] Whereas the importance of NO in microbial killing of *L. monocytogenes* and *M. tuberculosis* has been clearly demonstrated in mice,[229] the role of NO in host defense in humans is less clear.

Recruited monocytes and macrophages also amplify inflammation through the production of cytokines, chemokines, and lipid mediators. Studies conducted in the late 1970s indicated that macrophages hydrolyse arachidonyl-containing phospholipids in response to exposure to a variety of TLR agonists through the actions of cellular and secreted phospholipase A2 enzymes (PLA_2s).[230–233] The hydrolysis of arachidonyl-containing phospholipids by PLA_2s results in the formation of (1) lyso-phosphatidylcholine that, upon acetylation, leads to the production of platelet-activating factor (PAF)[234] and (2) arachidonic acid that serves as a substrate for the production of all eicosanoids (as reviewed by Riches and coworkers[235]).

PAF is produced within minutes of exposure of macrophages to TLR agonists and has broad proinflammatory activities that promote PMN recruitment, bronchoconstriction, and vasodilation. PAF also primes PMNs,

monocytes, and macrophages for enhanced production of proinflammatory cytokines in response to PAMPs.[236,237] Arachidonic acid is oxidized to prostaglandin E_2 (PGE_2), PGD_2, PGI_2 and thromboxane A_2 by cyclooxygenase-1 (COX-1) and COX-2, and these prostaglandins have important roles in the regulation of vascular tone and in the feedback inhibition of macrophage effector functions.[238] The principal leukotriene produced by macrophages is LTB_4, which is synthesized following TLR engagement and represents the major immediate PMN chemotactic factor produced in the lung prior to chemokine expression.[152,239]

Whereas the production of lipid mediators contributes to aspects of early lung inflammation, the production of cytokines and chemokines by macrophages and epithelial cells is necessary for the optimal recruitment of inflammatory cells and for their activation. The human chemokine family consists of four closely related subfamilies that have been classified on the basis of the presence and pattern of conserved cysteine residues and have been designated C, CC, CXC, and CXXXC families (as reviewed by Kunkel and coworkers[240] and Keane and Streiter[241]). The CXC and CC families are critical to the development of pulmonary inflammation. Members of the CXC family containing the ELR motif stimulate PMN chemotaxis, whereas family members that lack the ELR motif (e.g., CXCL10) are produced in response to IFN-γ and help regulate angiogenic responses.[242,243] In contrast, CC family members are involved primarily in the recruitment and activation of mononuclear cells. Macrophages are capable of producing CXC chemokines, especially IL-8, in the settings of acute and chronic lung inflammation in patients with bacterial pneumonia, ARDS, idiopathic pulmonary fibrosis, bronchiolitis obliterans with organizing pneumonia, and cystic fibrosis.[244–247] In addition, CC chemokines, such as macrophage inflammatory protein (MIP)–1α, are produced by macrophages in interstitial lung diseases.[248,249]

In addition to the programmed responses discussed previously, recruited monocytes differentiate into macrophages, which are capable of further differentiation. Based on earlier work in which different PAMPs were found to induce the expression of distinct patterns of macrophage gene expression,[29,250–252] the concept evolved that different patterns of gene expression could be induced in response to the conditions or stimuli that prevail at the sites to which macrophages have been recruited.[253,254] For example, exposure of macrophages to Th1 cytokines and LPS induces a pattern of gene expression characterized by increased expression of IL-12, IL-23, TNF-α, NOS2 and reduced expression of IL-10 and arginase. This response has been called "classic macrophage activation."[254] In contrast, exposure to Th2 cytokines, including IL-4 and IL-13, leads to a different pattern of gene expression characterized by increased synthesis of arginase, FIZZ, CCL19 and reduced expression of NOS2, a response often referred to as "alternative macrophage activation."[254] Defining these responses as distinct "phenotypes" can be useful in thinking about how macrophages participate in innate immunity and effector cells in the adaptive immune response (see Fig. 13-7). However, it is also more complicated than some of the simplistic schemes that have been proposed because there are often overlapping patterns of gene expression in response to other stimuli. Thus, it may be more appropriate to think about these adaptive responses as further evidence of the diversity of macrophage function. Regardless of these semantic issues, diversity in PAMP and stimulus-induced patterns of gene expression by macrophages contribute greatly to their diverse roles in innate protection of the lungs, lung cancer, repair, fibrosis, and microbial elimination.

In summary, macrophages play key roles in the maintenance of lung homeostasis through their abilities to suppress unwanted inflammation and immune responses to harmless, commonly encountered inhaled materials. However, they remain constantly poised to respond to harmful inhaled microbes and other substances. Part of this response involves calling in additional support through the recruitment of circulating blood PMNs and monocytes. In turn, recruited monocytes can differentiate into macrophages, which can then express appropriate responses to microenvironmental cues that they sense in the site to which they have been attracted.

Dendritic Cells

DCs represent an important group of phagocytic and antigen-presenting cells that act as a bridge between the innate and the adaptive immune systems. In the lung, DCs have been shown to form an extensive intra- and subepithelial network throughout the respiratory tract (Fig. 13-8). DCs are particularly abundant in the nose, trachea, large airways, and alveolar septae.[255–263] These cells continuously sample the airway and alveolar lumen by extending and retracting bulbous dendritic projections through the epithelium into the airway and alveolar lumen.[264,265] After encountering antigens and particulate matter in the airway, DCs then leave the epithelium and traffic into regional lymph nodes where they deliver stimulatory or tolerogenic signals to naïve T-cells.[266,267] This trafficking occurs constitutively in the steady state, and as such, lung DCs can be considered transient

FIGURE 13-8 ■ Airway dendritic cells exist as an interdigitating network within the epithelium and below the basement membrane. The section was stained for major histocompatibility complex (MHC) class II. (From Vermaelen K, Pauwels R: Pulmonary dendritic cells. Am J Respir Crit Care Med 172:530–551, 2005.)

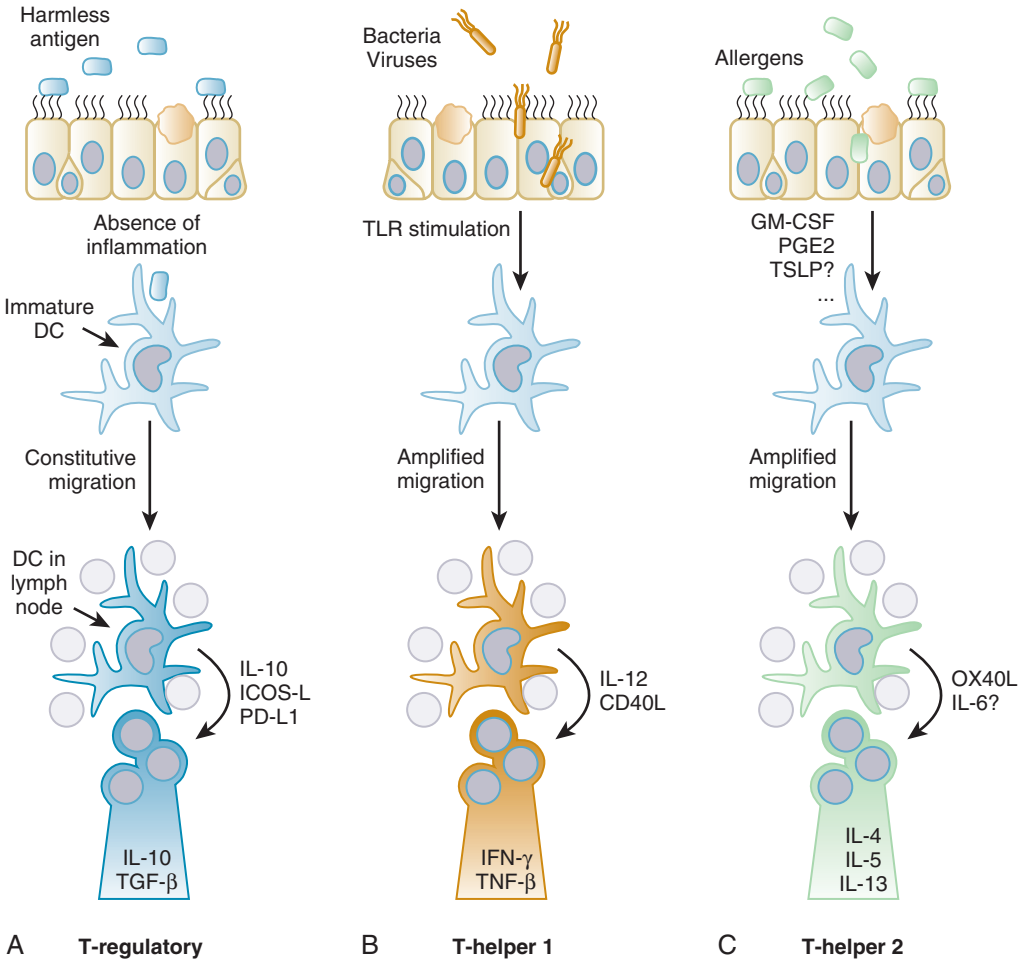

FIGURE 13-9 ■ Resident lung dendritic cells are capable of inducing the activation of CD4⁺ T-regulatory cells, as well as Th1 and Th2 CD4⁺ T-cells. (Redrawn from Vermaelen K, Pauwels R: Pulmonary dendritic cells. Am J Respir Crit Care Med 172:530–551, 2005.)

residents that are continuously replenished by bone marrow–derived precursors in the blood.[259,268,269]

Newly recruited resident DCs have an immature phenotype characterized by the expression of high levels of MHC class II and low levels of co-stimulatory molecules. These cells serve as the body's primary professional antigen-presenting cells that activate and initiate the clonal expansion of antigen-specific T-cells. DCs continually endocytose soluble and particulate materials that enter the respiratory tract. If these materials contain PAMPs, DCs will undergo a maturation program associated with the up-regulation of co-stimulatory molecules (such as CD40, CD80, and CD86), activate the expression of genes for cytokines and growth factors that promote naïve T-cell activation, and traffic to the regional lymph node (Fig. 13-9). Even in the absence of PAMPs, these DCs will not fully mature but will still traffic to lymph nodes. In the lymph nodes, DCs present MHC-peptide antigen complexes to T-cell receptors (TCRs) on naïve T-cells. TCR engagement by MHC-peptide complexes, in the presence of cytokines and co-stimulatory molecules expressed by DCs, leads to T-cell activation and expansion. The absence of the cytokines or co-stimulatory molecule engagement leads to the development of immunologic tolerance to the presented antigens (see Fig. 13-9). This is similar to the situation that occurs in the course of normal tissue turnover or following sterile injury, where DCs encounter and present self-antigen through their ability to phagocytose apoptotic cells and membrane vesicles generated by fragmenting apoptotic cells. In the absence of PAMPs, MHC-restricted presentation of self-antigens to naïve T-cells results in the delivery of a tolerogenic signal by self-antigens (see Fig. 13-9).

The ingestion of materials in the presence of PAMPs activates a program of DC maturation associated with the down-regulation of endocytic and phagocytic activities, the up-regulation of antigen-processing machinery, the up-regulation of co-stimulatory molecules expression, especially CD40, CD80, and CD86,[260,266,270] and the activation of genes encoding cytokines and growth factors that promote downstream naïve T-cell activation and maturation into T-effector cells,[271,272] which recirculate to the original site of PAMP activation to augment the development of adaptive immunity. With this general overview of DC function as a background, we now discuss in more detail the function and control of the multiple DC subsets represented in the lung. We focus largely on mouse lung DC subsets, because most

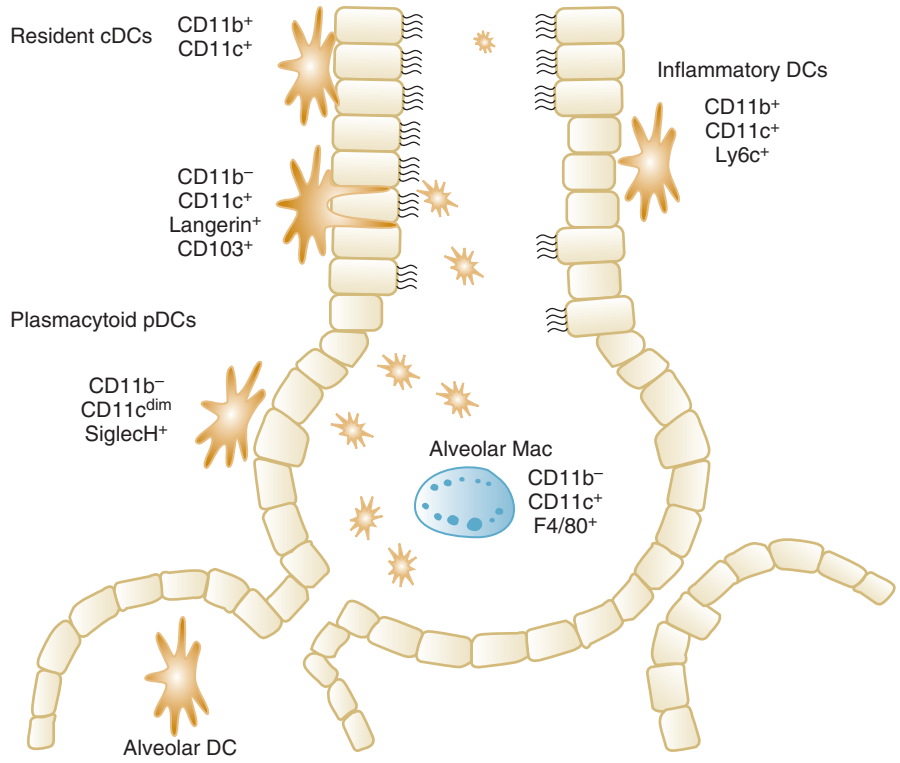

FIGURE 13-10 ■ Three major subsets of dendritic cells (DCs) exist in mouse lung: resident conventional DCs (cDCs), plasmacytoid DCs (pDCs) and inflammatory DCs. Each subset can be defined by the expression of distinct patterns of cell surface antigens recognized by monoclonal antibodies. (Redrawn from GeurtsvanKessel CH, Lambrecht BN: Division of labor between dendritic cell subsets of the lung. Mucosal Immunol 1:442–450, 2008.)

of the current knowledge has been developed in this species.

Mouse and Human Lung Dendritic Cell Subsets. Studies using cell surface markers, particularly CD11c and CD8α, initially suggested that DCs arose from both myeloid and lymphoid precursors that were thought to give rise to a bewildering array of DC subsets.[273] Recent studies in mice, however, suggest that DCs can be grouped into three major subsets, namely plasmacytoid DCs (pDCs), conventional DCs (cDCs), and inflammatory DCs (Fig. 13-10). pDCs are characterized by the presence of TLRs 7 and 9 and expression of the cell surface marker Siglec-H. They also secrete abundant quantities of type I IFNs in response to TLR ligation by PAMPs. Many TLR7 and TLR9 agonists are viral products, and their ability to stimulate type I IFN secretion by DCs is an important component in the early antiviral response. Typically, pDCs are present in low numbers in lung tissues in the steady state but are rapidly recruited into the lung when viral PAMPs are detected. Like other DCs, pDCs can also process antigens, traffic to regional lymph nodes, and participate in antigen presentation to naïve T-cells. In addition, pDCs can also restrain the activity of cDCs, thereby controlling both inflammation and the induction of adaptive immunity.

cDCs are the archetypal antigen-presenting DC and can be subdivided into migratory cDCs and lymphoid tissue resident cDCs. As their name implies, lymphoid tissue resident cDCs reside in spleen and lymph nodes and respond to antigens delivered by draining afferent lymphatic vessels. Migratory cDCs also have classic antigen-presenting functions but transiently reside in the airway epithelium and alveolar septae before migrating to regional draining lymph nodes via afferent lymphatics. Migratory cDCs extend their dendritic processes through the airway and alveolar epithelial tight junctions to capture, process, and present inhaled antigens in association with MHC class II molecules. Upon migration to lymph nodes, migratory cDCs present MHC-peptide antigen complexes and co-stimulatory molecules to naïve T cells.

In contrast to migratory cDCs and pDCs, inflammatory cDCs are absent from lymphoid and peripheral tissues under steady-state conditions. However, in response to local activation of innate immunity, peripheral blood monocytes home to sites of inflammation and/or infection and differentiate into inflammatory cDCs in response to specific cytokines, especially GM-CSF and Flt3 ligand.[208,209] The functions of inflammatory DCs are similar to those of migratory cDCs.

It is now recognized that all DCs and monocytes arise from a single myeloid progenitor cell called the macrophage and DC precursor (MDP).[274] The MDP differentiates to yield common DC precursor cells (CDPs) and monocytes. Whereas monocytes differentiate into macrophages, both monocytes and the CDPs can give rise to DCs. The CDPs can further differentiate into preconventional DCs (pre-DCs) and pDCs, whereas monocytes can

give rise to inflammatory DCs. In view of these findings, it has been suggested that the earlier classification of DCs into lymphoid DCs and myeloid DCs should be abandoned.[275]

Based on cell surface marker expression, mouse lung contains two major subsets of cDCs. All mouse lung cDCs express high levels of MHC class II proteins and the integrin CD11c, but the two subsets are differentiated by the presence or absence of CD8α (see Fig. 13-10). They can be further subdivided by the presence or absence of CD11b and/or langerin (see Fig. 13-10). Langerin$^+$ cDCs, which resemble Langerhans cells of the skin, exist together with langerin$^-$ subsets within the epithelium of the trachea and large airways.[260,276] The langerin$^+$ cDC subset also expresses CD103 and low levels of CD11b whereas the langerin$^-$ cDC subset is CD11b^{hi}CD103$^-$.[266] Ly-6C^{hi} blood monocyte progenitors give rise to both the Ly-6C^{hi} and Ly-6C^{lo} circulating monocyte subsets.[277,278] The Ly-6C^{lo} blood monocyte develops into the CD11b^{hi}CD103$^-$ lung DCs whereas the Ly-6C^{hi} blood monocytes develop into the CD11b^{lo}CD103$^+$ lung DCs.[212,279] Additional cDC subsets are found within the submucosa of the trachea and large airways. These cells are typically CD103$^-$CD11b^{hi}CD11c^{hi} and are efficient antigen-presenting cells. Though less well characterized, cDCs of the lung parenchyma are generally characterized as being CD11c^{hi}CD11b^{lo}CD8α$^-$CD205$^+$ Several excellent reviews on mouse lung DC subsets are available.[280,281]

Studies of human lung DC subsets are limited by difficulties in the availability of tissue samples, and as is the case for interstitial macrophages, there is always the possibility that methods for isolating DCs from lung tissue samples can activate and/or alter DC surface marker expression thereby introducing artifacts to the analysis. Human lung DCs are distinguished from resident alveolar macrophages by their expression of MHC class II, especially human leukocyte antigen (HLA)–DR4. In addition, human resident alveolar macrophages are highly autofluorescent whereas lung DCs exhibit low autofluorescence.[282] Human lung DCs can be distinguished from other myeloid and lymphoid cells by the absence of T-cell, B-cell, NK-cell, monocyte, and granulocyte lineage markers. MHC class II$^+$ DCs are found in normal human airway epithelium, lung parenchyma, and visceral pleura[256] and a langerin$^+$ DC subset is present in bronchioles.[283] Like the mouse, large numbers of DCs are present in alveolar septae.[255,258] Five subsets of pulmonary cDCs have been found in human lungs. Demedts and colleagues[284] identified three DC subsets in normal human lung specimens (Table 13-3). These include a CD1a$^+$MHCII$^+$BDCA-1 (blood dendritic cell antigen-1) cDC subset, another cDC subset that expresses BDCA-3$^+$ and CD11c$^+$, and a pDC subset that expresses BDCA-2$^+$ and CD123$^+$.[285] A fourth langerin$^+$ cDC subset is associated with airway mucosal epithelium. A fifth CD103$^+$Langerin$^+$CD11b^{lo} subset that express tight junction proteins, claudin 1, claudin 7, and zona occludins-2 resides beneath the basal lamina of both human and mouse mucosal epithelium.[284–287]

Inflammatory DCs arise by recruitment of blood monocyte and differentiation in response to activation of innate immune mechanisms. Inflammatory cDCs initially retain monocyte markers and are characterized as CD11c^{hi}CD11b^{hi}Ly6C^{hi}. Based on their ability to produce TNF-α and NOS2, these cells have also been called Tip-DCs,[288] though as noted earlier, this is also a property of macrophages, leading to the suggestion that DCs are really part of the broader mononuclear phagocyte system.[186]

DC, dendritic cell; MHC, major histocompatibility complex.

Functions of Lung Dendritic Cells. Lung DCs have the remarkable ability to change their phenotype upon exposure to PAMPs and other "danger" signals.[289,290] The maturation of immature lung DCs results in functional changes that "polarize" the DC subset. The term "polarization" is used here to indicate that the antigen-exposed DC subset acquires the ability to ultimately skew naïve T cells to become Th1, or Th2 (or possibly even Th17 or T_{Reg} cells). The ability to leave the epithelial barrier and migrate to regional lymph nodes is mediated in part by the expression of matrix MMP-9, and mice lacking MMP-9 fail to develop allergic airway inflammation.[291] When immature DCs are activated by chemokines they also down-regulate inflammatory chemokine pathways and traffic into draining lymph nodes by up-regulating CCR7. The CCR7 ligands, CCL19 and CCL21, are expressed on peripheral lymphatic endothelium and lymph node stromal cells. This mechanism serves to guide DCs from nonlymphoid into lymphoid tissues. The use of chemokines, chemoattractant receptors, selectins, and their ligands tightly regulates the migration of pDC and cDC subsets to, from, and within lung tissue. These various interactions have been reviewed by Springer[214] and Bromley and associates.[215]

Within draining regional lymph nodes, mature DCs that arrive from the lung are capable of delivering pathogen-specific signals to naïve T-cells. The further differentiation of these activated T-cells into functional T-cell subsets is driven by specific patterns of DC- and T-cell–derived cytokines that induce a fully mature T-cell response. These patterns of cytokines then sustain T-cell activation and downstream T-cell skewing.[289] For example, IL-12, IL-13, and IL-27, type 1 IFNs, and ICAM engagement drives the polarization of naïve T-cell into the Th1 phenotype. In contrast, CCL2 and OX40 ligand

promotes Th2 phenotype polarization, whereas IL-10 and TGF-β promote T_{Reg} development. The patterns of T-cell cytokine production that develop after exposure to a pathogen are relatively specific to that pathogen and determine in large part the resultant DC subset–driven T-cell response. This mixture of signaling molecules includes pro- and anti-inflammatory cytokines, reactive oxygen species, chemokines, eicosinoids, heat shock proteins, extracellular matrix proteins, and endogenous molecules such as histamine and PGE_2 that polarize the T-cell phenotype. However, T-cell polarization is not fixed and can change based on alterations in these signaling patterns, which can occur during the maturation of the host response to a pathogen. Nevertheless, in general, the concept that antigens plus PAMPs polarize lung DCs toward antigen-specific T-cell immunity whereas antigens alone polarize lung DCs toward antigen tolerance[292] appears to be correct. A major benefit of the ability of lung DCs to recognize and clear material present in inhaled air is to maintain efficient oxygen exchange in the lung. Even with chronic exposure, either the majority of harmless antigenic materials are eliminated and fail to trigger lung inflammation or they generate antigenic tolerance.[293] In this way, the lung both removes harmless substances from the airway and maintains tolerance to some antigens that are encountered daily by breathing while at the same time ensuring that the lung does not mount an inflammatory or immune response that could result in lung damage.

Most inhaled materials are exhaled.[294] Materials that are sampled by airway DCs are directed to intracellular compartments, resulting in the processing and presentation of their associated antigens and ultimately leading to the activation of naïve T-cells.[294–296] Endocytosed antigenic proteins are degraded into peptides and become associated with MHCII molecules within endolysosomal compartments that later fuse with the endplasmic reticulum. Antigen processing results in the generation of complexes consisting of antigenic peptides bound to MHC class I or class II molecules (MHCIp or MHCIIp). These complexes can engage naïve T-cell TCRs, which is followed by polarization of these T-cells into Th1, Th2, Th17, or T_{Reg} subsets.[297,298] DCs also present lipid antigens to naïve T-cells in complexes with the MHC-like molecule CD1. Both MHCII and CD1 molecules traffic within the same endosomal compartments where they are loaded with either peptides or lipids, respectively.[299] There are recent helpful reviews on the regulation and assembly of CD1-lipid, MHCIp, and MHCIIp complexes.[300,301] With the exception of viral antigens that are synthesized within the infected cell and host-derived intracellular antigens, extracellular antigens that ultimately become associated with MHCI initially gain entry to the DC via endocytosis or phagocytosis, but must escape the endosome. Once in the cytosol, these antigens are processed by the proteosome where they gain access to the transporter of antigenic peptide and endoplasmic reticulum. Subsequently, these antigens are degraded into peptides and then loaded into MHCI molecules to form MHCIp complexes for transport to the DC's surface.[302–305] Pinocytic uptake of exogenous antigens and phagocytosis of apoptotic cells that contain exogenous antigens (or even phagocytosis of exosomes, small vesicles released by apoptotic cells) promote entry of antigens into the cytosolic pathway and peptide loading into MHCI molecules for cross-presentation of MHCIp complexes to naive T-cells.[306,307]

Lung DCs can process and present viral antigens through phagocytosis of infected epithelial cells and cross-presentation. These cells also stimulate antiviral immunity via their ability to secrete antiviral type I IFNs (especially pDC), activate naïve Th lymphocytes, and induce T-effector memory cell responses.[308–310] The further differentiation of these activated T-cells into functional T-cell subsets is discussed in detail in Chapter 14.

SYSTEM INTEGRATION

The innate and adaptive immune systems have evolved to protect the lungs from harm by environmentally acquired microbes and other inhaled substances as well as from host-derived harmful stressors such as unwanted inflammation and inappropriate activation of adaptive immunity. A core concept is that innate immune protection in the lungs is not a consequence of individualized responses of individual cells but, rather, represents coordinated responses and collective cooperation between many resident and recruited lung cell types. These coordinated events result in maintenance of sterility of the airways and gas-exchange units, tolerance to harmless inhaled substances and self-antigens, and vigilance to respond to harmful microbes and substances. In addition, innate immune mechanisms assist in the rapid resolution of injury and restoration of lung homeostasis and function.

From the nose to the alveolus, the respiratory epithelium, interdigitating DCs, and resident and recruited macrophages have evolved exquisite, diverse, and overlapping mechanisms to distinguish between harmful and harmless. In its simplest form, this distinction is achieved by sensing the presence of microbial PAMPs. In the absence of PAMPs, the epithelium remains largely ignorant of inhaled particulates, whereas "snorkeling" DCs continuously sample the airways and alveoli for particles, antigens, and apoptotic cells to phagocytose, degrade, and present antigen to lymph node resident naïve $CD4^+$ and $CD8^+$ T-cells, thereby maintaining tolerance to harmless commonly encountered antigens and self-antigens. Similarly, resident macrophages phagocytose and dispose of particulates that reach the alveoli, while tonically maintaining an anti-inflammatory and immunosuppressive environment through the production of anti-inflammatory cytokines, especially TGF-β and IL-10, and eicoansoids such as PGE_2.

Integration of innate functions is dependent on cell-cell communication. In some settings, communication is fostered by proximity, as DCs exist as a network within airway epithelium and contact each other through tight junctions; whereas resident alveolar macrophages use integrins to communicate with alveolar epithelial cells.

In other settings, cell-cell communication is mediated through the secretion of a vast array of cytokines and lipid mediators, which can act in autocrine or paracrine fashions. Thus, different cell lineages can communicate with each other and among themselves. Communication between different cell types also plays an important role in the coordination of innate immunity and in the activation of adaptive immunity. For example, the finding that experimental or genetic depletion of resident alveolar macrophages results in the induction of alveolitis and lung injury, and diminishing tolerance to inhaled antigens,[311,312] emphasizes the importance of resident alveolar macrophages in suppressing inflammation and the activation of adaptive immunity. Integration of innate immunity in the lung is also associated with "coordinated burden sharing." For example, airway goblet cells and submucosal glands produce mucus, whereas ciliated epithelial cells propel mucus and entrapped particulates toward the pharynx. Similar coordinated burden sharing is exhibited by airway epithelial cells, which are poorly phagocytic but are highly capable of sensing PAMPs and calling in PMNs and monocytes, which in turn are highly phagocytic and microbicidal and eliminate an array of microbes. Together, these integrated systems have evolved to provide the lungs with maximum protection against harmful microbes while minimizing harmful responses against harmless inhaled substances. The net result is an exquisite system for protecting the gas-exchange parenchyma of the lungs, which is critical for survival.

KEY POINTS

The following is a brief summary that will help readers navigate the complex literature in this rapidly evolving, expanding, and important field of investigation:

Innate Immunity

- A primitive system of host defense system broadly based on the recognition of repetitive structures on microbes called "pathogen-associated molecular patterns" (PAMPs) by "pattern recognition receptors" (PRRs) expressed on lung cells.

Components of Lung Innate Immunity

- Airway epithelium
  - Tracheal and large airways are protected by mucus, which traps large inhaled particulates that are then transported to the pharynx by muciliary transport.
  - Airway surface liquid contains antibacterial proteins (e.g., lysozyme, lactoferrin) and peptide (e.g., defensins).
  - Airway epithelial cells respond to PAMPs by producing chemokines, cytokines, and lipid mediators, which recruit PMNs and monocytes.
- Alveolar epithelium
  - Alveoli are protected by SP-A and SP-D, which serve as microbial opsonins.
  - SP-A and SP-D also serve to suppress unwanted inflammation and adaptive immune responses to commonly encountered antigens.
- Neutrophils
  - Recruited to the airways and alveoli when airway and alveolar epithelial cells detect PAMPs.
  - Phagocytose and kill microbes by combined oxidative and nonoxidative mechanisms.
- Macrophages
  - Resident cells of the airway and alveolar lumen.
  - Suppress unwanted alveolar inflammation and adaptive immunity in the steady state.
  - Activated by PAMPs to amplify inflammation via the production of chemokines, cytokines, and lipid mediators.
  - Phagocytic cells capable of removing a wide range of microbial and nonmicrobial inhaled particulates.
- Dendritic cells
  - Three kinds of DCs, pDC, cDC, and inflammatory DC.
  - cDCs transiently reside in the airways and alveolar septae.

continued

KEY POINTS—CONT'D

- cDCs constantly sample airway and alveolar lumen contents by phagocytosis.
- In absence of PAMPs, immature cDCs traffic to regional lymph nodes and promote tolerance to inhaled antigens.
- In presence of PAMPs, cDCs mature, express co-stimulatory molecules, and activate effector T-cells.
- Depending on the mix of signals they receive, cDCs can polarize Th1, Th2, Th17, or T_{Reg} cell development

Integration of Innate Immunity

- The cell lineages of innate lung immunity collaborate to promote optimal responses to perceived danger signals (primarily PAMPs) while maintaining tolerance to inhaled antigens in the steady state.

Cytotoxic T-Cell Reactions in the Lung

INTRODUCTION

The human immune system consists of many different cell types and organs that have evolved to destroy or control potentially harmful foreign substances. The immune response is essential for survival because it constitutes the principal means of defense against infection by pathogenic microorganisms, including those that enter through, and reside in, the respiratory tract. The immune response is also critically involved in pathologic processes of the lung and upper respiratory tract. This chapter provides an understanding of the adaptive (or acquired) immune response, which depends on the specific recognition of antigens by T and B lymphocytes. Immune recognition is highly specific for a particular pathogen, and yet an individual's immune cells can collectively respond to an almost unlimited number of foreign antigens. The molecular mechanisms underlying this specificity and diversity are unique to the immune system. The adaptive immune response also changes after successive encounters with the same pathogen. For example, memory of an antigen allows the immune response to occur faster and in greater magnitude compared with the initial encounter. This chapter also describes how primary and secondary immune responses are regulated by complex cellular interactions and the release of particular types of soluble mediators. Antigen-specific immune responses are also regulated and augmented by nonspecific inflammatory cells of the immune system, such as dendritic cells, macrophages, neutrophils, eosinophils, and mast cells.

COMPONENTS OF THE IMMUNE SYSTEM: OVERVIEW

All of the cells of the immune system arise from pluripotent hematopoietic stem cells through two main lines of differentiation that give rise to the lymphoid lineage and the myeloid lineage.[1] Specificity within the immune system is primarily provided by lymphocytes. The two major categories of lymphocytes are T cells, which are derived from bone marrow stem cells and primarily develop in the thymus, and B cells, which develop in the bone marrow in adult humans. A third population of lymphocytes is natural killer (NK) cells.

Lymphocytes and other cells of the immune system express a large number of different molecules on their surfaces. Some of these markers can be used to separate cells with different functions or to distinguish cells at particular stages of differentiation. Monoclonal antibodies to many different cell surface markers have been produced, and a systematic nomenclature has been

developed. The CD ("cluster of differentiation" or "cluster determinant") system provides a basis by which monoclonal antibodies that bind to the same surface molecule are grouped together, and the CD number is used to indicate the specific molecule recognized. Tables 14-1, 14-2, and 14-3 provide a partial list of surface antigens, particularly those mentioned in this chapter. The markers are partially grouped based on the cell type expressing them. It may be necessary to refer to this list of molecules throughout this chapter.

T cells are distinguished by the presence of the T-cell receptor for antigen (TCR).[2–4] Most T cells express a receptor composed of an α and a β chain, whereas a much smaller subset expresses a structurally similar receptor composed of a γ and a δ chain. Both receptors are associated with a complex of polypeptides, the CD3 complex, which provides a transmembrane signaling function and allows TCR engagement to be coupled to cellular activation. T cells expressing αβ TCRs can be divided into $CD4^+$ and $CD8^+$ T-cell subsets. $CD4^+$ T cells primarily recognize antigens presented by major histocompatibility complex (MHC) class II molecules. $CD8^+$ T cells primarily recognize antigens presented by MHC class I molecules. Functionally, T cells can be divided into several major subsets. For example, T helper cells may interact with B cells and help them to survive and divide, make antibody, and become memory B cells. T helper cells also may interact with cytotoxic T cells or with phagocytic cells and help them destroy intracellular pathogens. Different subsets of T helper cells can be distinguished by the pattern of cytokines that they secrete during an immune response. T helper cells are generally encompassed within the $CD4^+$ T-cell subset. Another subset of T cells is responsible for destruction of cells that have become infected by virus or other intracellular pathogens. These cells are called "cytotoxic T cells" and usually express the CD8 phenotypic marker. Although not clearly distinguished by phenotypic markers, separate subsets of T cells, within both the $CD4^+$ and the $CD8^+$ subsets, have been termed "T regulatory (or suppressor) cells" because they down-regulate immune responses.

TABLE 14-1. Selected Cell Surface Markers of Human T Cells

Cell Surface Markers	Identity/Function
TCR for antigen	Interacts with peptide/MHC complex on antigen-presenting cells
CD2	Binds to LFA-3; involved in co-stimulation and adhesion
CD3	T-cell signaling complex
CD4	Identifies T-cell subset with helper function; interacts with MHC class II molecule
CD8	Identifies T-cell subset with cytotoxic function; interacts with MHC class I molecule
CD25	α chain of IL-2 receptor; expressed on activated T cells and on a subset of regulatory $CD4^+$ T cells
CD28	Binds B7-1 (CD80) and B7-2 (CD86); co-stimulatory molecule involved in T-cell activation
CD45	Phosphatase involved in cellular activation and differentiation; different isoforms (CD45RA, CD45RO) mark naive versus previously activated T cells and stages of activation
CD62L	L-selectin; involved in lymphocyte adhesion; levels mark naive versus memory cells
CD69	Activation marker
CD95 (Fas)	Fas; receptor involved in apoptosis
CD95L (Fas ligand)	Ligand for Fas; involved in T-cell–mediated killing
CD152 (CTLA-4)	Binds to B7-1 (CD80) and B7-2 (CD86); involved in down-regulation of TCR signaling
CD154 (CD40 ligand)	Ligand for CD40; important for T-cell activation and T-cell–dependent B-cell activation
CD134 (OX40), CD137 (4-1BB), ICOS, PD-1	Additional co-stimulatory molecules in the TNF or CD28 family; involved in T-cell activation and regulation

CTLA-4, cytotoxic T lymphocyte antigen-4; ICOS, inducible co-stimulator; IL-2, interleukin-2; LFA-3, lymphocyte function antigen-3; MHC, major histocompatibility complex; PD-1, programmed cell death-1; TCR, T-cell receptor; TNF, tumor necrosis factor.

TABLE 14-2. Cell Surface Markers of Human B Cells

Cell Surface Markers	Identity/Function
BCR for antigen	Immunoglobulin molecules; recognizes antigen
CD5	Binds to CD72; regulation of cell proliferation/activation; identifies B1a cell subset
CD19	B-cell coreceptor subunit; involved in co-stimulation
CD20	B-cell marker
CD21	Complement receptor type II; B-cell coreceptor subunit; marks certain B-cell subsets; EBV receptor
CD22	Adhesion molecule; involved in B-cell activation
CD23	Identifies B-cell subset; low-affinity receptor for IgE
CD40	Binds CD40L; involved in T-cell–dependent B-cell activation
CD79a (Ig-α)	Involved in B-cell activation; signaling through BCR
CD79b (Ig-β)	Involved in B-cell activation; signaling through BCR
CD80 (B7-1)	Binds CD28 and CD152 (CTLA-4) on T cells
CD86 (B7-2)	Binds CD28 and CD152 (CTLA-4) on T cells

BCR, B-cell receptor; CD40L, CD40 ligand; CTLA-4, cytotoxic T lymphocyte antigen-4; EBV, Epstein-Barr virus; Ig, immunoglobulin.

TABLE 14-3. Other Cell Surface Markers of General Interest

Cell Surface Markers	Distribution	Identity/Function
CD1	Thymocytes, subset of lymphocytes, antigen-presenting cells	MHC class I–like molecule; involved in presentation of nonpeptide antigens
CD11a	Leukocytes	α chain of LFA-1; associates with CD18; interacts with ICAM-1; involved in adhesion and migration
CD11b	NK cells, monocytes, granulocytes	α chain of CR3; adhesion molecule
CD11c	Monocytes, granulocytes	α chain of CR4; adhesion molecule; identifies dendritic cells
CD14	Granulocytes, monocytes	Receptor for LPS/LPB complex; myeloid differentiation antigen; cell activation
CD16	NK cells, monocytes	FcγRIII; low-affinity receptor for IgG; involved in ADCC
CD18	Leukocytes	β chain of β_2 integrin molecules, including LFA-1, CR3, and CR4
CD29	Leukocytes	β chain of β_1 integrin molecules, including VLA1–VLA6
CD32	B cells, monocytes, granulocytes	FcγRII
CD35	B cells, subset of NK cells, monocytes, granulocytes	CR1
CD45	Leukocytes	Leukocyte common antigen; phosphatase; involved in cell signaling
CD46	Broad distribution	Membrane cofactor protein; regulates complement activation
CD54 (ICAM-1)	Broad distribution	Binds LFA-1; adhesion molecule
CD56	NK cells	Neural cell adhesion molecule
CD58 (LFA-3)	Broad distribution	Binds CD2; adhesion molecule; involved in cell signaling

ADCC, antibody-dependent cellular cytotoxicity; CR, complement receptor; ICAM-1, intercellular adhesion molecule-1; IgG, immunoglobulin G; LFA, leukocyte function antigen; LPB, LPB binding protein; LPS, lipopolysaccharide; MHC, major histocompatibility complex; NK, natural killer; VLA, vascular leukocyte adhesion molecule.

B cells are identified by the expression of surface immunoglobulin (Ig) or antibody molecules, which represent their specific B-cell receptor for antigen (BCR). Analogous to the CD3 complex on T cells, BCRs are also linked to accessory molecules, Ig-α (CD79a) and Ig-β (CD79b), which are required for cellular activation after antigen interaction.[5] After differentiation, B cells can develop the ability to produce high levels of antibody (soluble Ig). B cells also express a large number of other surface markers that are critically involved in their function and interaction with T cells. For example, most B cells express MHC class II molecules that allow them to present antigen to T helper cells. Other B-cell surface molecules are listed in Table 14-2.

A third population of lymphocytes is probably best defined as those cells that do not express either TCR or Ig and mostly includes NK cells.[6] A large proportion of this subset contains numerous electron-dense granules and is recognized morphologically as large granular lymphocytes. Markers on these cells are frequently shared with T cells (e.g., CD2 and CD8) or cells of the myelomonocytic series, for example, the integrin molecule CD11b or the low-affinity receptor for IgG (FcγRIII or CD16). NK cells appear to play an important role in the initial (innate) host defense against infection and tumor cells. Similar to certain phagocytes, they also have the capability to destroy target cells or pathogens, which have been coated with specific antibody, via a process known as "antibody-dependent cellular cytotoxicity."

The myeloid lineage consists primarily of monocytes (macrophages) and neutrophils, which provide nonspecific inflammatory mediators and phagocytic function. These cells are critically involved in the nonspecific component of the inflammatory response (see Chapters 13 and 16). In addition, macrophages and certain other nonlymphoid cells, such as dendritic cells, are specialized to present antigens to T cells and, thus, also contribute to specific immune responses.

The cells involved in the immune response are organized into tissues and organs. Primary lymphoid organs are the major sites of lymphopoiesis, in which stem cells and their committed precursor cells differentiate into lymphocytes and acquire specific functions. In humans, T lymphocytes mainly develop in the thymus, and B lymphocytes develop in the fetal liver and adult bone marrow. In the thymus, T-cell differentiation also includes acquiring the ability to recognize foreign antigens in the context of self-MHC molecules and the elimination of self-reactive cells (self-tolerance). B-cell acquisition of self-tolerance during development appears to take place in the bone marrow.

Differentiated lymphocytes migrate to secondary lymphoid organs that include lymph nodes, spleen, and mucosa-associated lymphoid tissues, such as the tonsils, lymph nodes of the respiratory tract, and Peyer's patches of the gut. These tissues provide an environment for lymphocytes to interact with each other, with antigen-presenting cells and other accessory cells, and with foreign antigens. The immune response occurs mostly within these secondary lymphoid organs, and lymphocytes migrate through the blood and lymph from one lymphoid organ to another and to nonlymphoid tissues. For example, foreign antigen exposure in the lung usually involves the movement of antigen to surrounding lymph nodes, where the specific immune response by T and B cells occurs. Generation of a cell-mediated immune response or antibody response allows

antigen-specific effector T cells or specific antibodies, respectively, to travel back to lung tissue for a direct assault on foreign antigens.

Under normal conditions, there is a continuous active flow of lymphocyte traffic through the lymph nodes. About 1% to 2% of the lymphocyte pool recirculates each hour, allowing a large number of antigen-specific lymphocytes to potentially come into contact with their appropriate antigen. Recirculating lymphocytes leave the blood and enter the lymph node through specialized postcapillary venules, known as high endothelial venules (HEVs). Specific interacting receptors on lymphocytes and HEV cells allow for this homing process to occur. Lymphocytes return to the circulation by way of afferent lymphatics that pass via the thoracic duct into the left subclavian vein. Lymphocytes also enter mucosa-associated lymphoid tissues, such as the tonsils and Peyer's patches, via HEVs. The recirculation and trafficking of memory and effector T and B cells is tightly regulated, determined by unique combinations of adhesion molecules and chemokines.[7] For example, certain lymphocytes may preferentially migrate across HEVs into intestinal lymphoid tissues (either Peyer's patches or mesenteric lymph nodes) or into respiratory tract tissues or may specifically home to the peripheral lymph nodes or the spleen.

Separate combinations of cell-surface adhesion molecules and chemokines allow activated lymphocytes and other leukocytes to migrate into nonlymphoid tissues, especially during inflammation and in response to the release of inflammatory cytokines.[7] The difference in trafficking patterns for nonactivated (resting) versus activated lymphocytes is striking and emphasizes the importance of particular adhesion molecules in the control of lymphocyte migration.

IMMUNE RECOGNITION

B Cells and Antibodies

Structure of Immunoglobulin and the B-Cell Receptor for Antigen

Immunoglobulin molecules, or antibodies, are a group of glycoproteins that act as BCRs. These molecules can also be secreted in large quantities by activated B cells and plasma cells. Figure 14-1 shows the basic structure of an Ig molecule. Each Ig molecule is bifunctional—one region (Fab) binds to antigen, and a different region (Fc) mediates various effector functions, such as binding to host tissues (via their cell surface Fc receptors) and binding to and activating the first component of the classic complement system.

The basic structure of all Ig molecules involves two identical light polypeptide chains and two identical heavy polypeptide chains linked together by disulfide bonds (see Fig. 14-1A). The isotype (class or subclass) of an Ig molecule is determined by its heavy chain type. There are five Ig classes—IgG, IgM, IgA, IgD, and IgE—corresponding to the γ, μ, α, δ, and ε heavy chain types. In humans, there are four IgG subclasses, IgG1 to IgG4. There are major differences in the structure and main functions of these different Ig classes and subtypes.

In Figure 14-1B, the IgG molecule is shown as an example of basic antibody structure. Each chain is composed of a series of globular regions or domains. Each domain encompasses about 60 to 70 amino acids and has an internal disulfide bond. The site of antigen binding is the amino (NH_2)-terminal domain for both the heavy (H) and the light (L) chains. This domain is characterized by remarkable sequence variability and is referred to as the variable region of the heavy and light chains (V_H and V_L region, respectively). The combination of V_H and V_L forms the antigen-binding site, and there are two such sites per IgG molecule (see Fig. 14-1B). The rest of each polypeptide has a relatively constant structure. The constant domain of the light chain is termed the C_L region, whereas the heavy chain has three constant domains: C_H1, C_H2, and C_H3. The hinge region, located between the C_H1 and C_H2 domains, provides flexibility and independence to the two antigen-binding sites. In both μ and ε heavy chains, there is an additional constant domain between C_H1 and C_H2, resulting in a total of four constant domains.

The greatest variability in antibody molecules occurs in the V_H and V_L domains, and these domains are responsible for the specificity in antigen binding.[8,9] Within the variable domains (see Fig. 14-1C), certain short segments show exceptional variability and are called "hypervariable regions." These regions are also referred to as "complementarity-determining regions" (CDRs) because they are directly involved in the binding to antigen. In both the V_H and the V_L regions, there are three CDRs (CDR1-CDR3) with intervening segments referred to as "framework regions" (see Fig. 14-1C). As discussed later, CDR3 (a component of the polypeptide V region) is formed by parts of the V (variable), D (diversity), and J (joining) gene segments. Variation within the V_H and V_L regions distinguishes one antibody molecule from another and is referred to as *idiotype* or *idiotypic variation*.

Genetic Mechanisms Involved in the Formation of the B-Cell Receptor Repertoire

Proteins are assembled by putting together functional regions, each coded by a gene segment. Most genes coding for a protein have a characteristic structure in which stretches of nucleotides (exons) encode the sequence of the protein. Exons are separated by noncoding regions (introns) (Fig. 14-2A). The entire stretch of deoxyribonucleic acid (DNA) is transcribed into a primary ribonucleic acid (RNA) transcript. Enzymes splice out the noncoding intron sequences to yield the mature messenger RNA segment, which is much shorter than the primary transcript. This messenger RNA is translated into protein on ribosomes. Preceding each gene that codes for a cell surface protein is a leader (L) sequence (at the 5′ coding end). The leader sequence codes for a signal peptide involved in the intracellular transport of the polypeptide chain, after which this polypeptide piece is removed. Figure 14-2B shows the corresponding structure of a rearranged Ig heavy chain

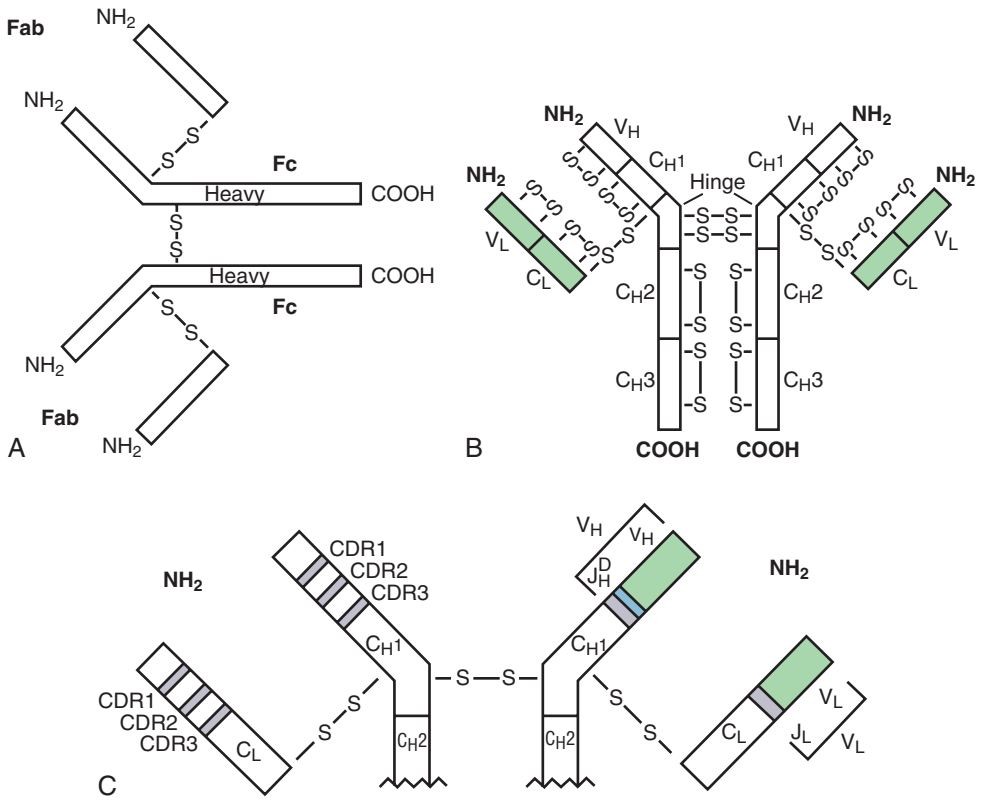

FIGURE 14-1 ■ The structure of immunoglobulin (Ig) molecules. **A,** Basic Ig structure with two heavy chains and two light chains linked together by disulfide bonds. The Fab region is involved in antigen binding, whereas the Fc region mediates various effector functions. **B,** Increasing detail of IgG molecule showing domains of both heavy and light chains. Each domain has an internal disulfide bond. The sites of antigen binding involve the NH_2-terminal domains of both the heavy and the light chains and are referred to as the *variable regions* (V_H and V_L, respectively). The rest of each chain has a relatively constant structure (C_H and C_L domains). **C,** Close-up of the antigen-binding variable regions. On the left, the complementarity-determining regions (CDRs) are *shaded* because they are the most variable components and are most involved in actual antigen binding. The CDRs are separated by intervening segments referred to as framework regions. On the right, the Ig polypeptide regions are correlated with the Ig gene segment (exons) that encode the variable region. Note that CDR3 corresponds to the $V_H/D_H/J_H$ junctional region of the rearranged heavy chain gene and the V_L/J_L junctional region of the rearranged light chain gene. (Adapted from MKSAP in the Specialty of Rheumatology. Philadelphia: American College of Physicians, 1993, p 6.)

gene. Note that each of the protein domains is encoded by an exon, which is separated by noncoding introns.

The BCR repertoire and the Ig molecules are characterized by enormous diversity. The principal genetic mechanisms that are used to generate this diversity include (1) genetic recombination of gene segments to form a functional Ig gene, (2) combinatorial diversity of heavy and light chain matching, and (3) somatic mutation of rearranged genes.[8-10] Another major force in shaping the antibody repertoire has been termed *receptor editing*, which allows receptors with self-reactive potential to be modified by additional recombination events during B-cell differentiation.[11,12]

Figure 14-3A illustrates the principle of genetic recombination for an Ig gene.[8,9] In this case, one of several variable (V) region gene segments (normally separated upstream from the constant [C] region gene segments on the same chromosome) can be linked to a single C region gene segment by genetic recombination. The combining of gene segments, rather than the existence of a single gene coding for every individual antibody molecule, considerably reduces the amount of genetic information required to encode many different antibody molecules. In Figure 14-3B, the different gene segments that encode a κ light polypeptide chain are shown. Note that in this case, a V region rearranges proximal to a J segment, which is linked to the C region segment. Rearrangement of κ or λ light chain genes involves V, J, and C region gene segments (Fig. 14-3A; see also Fig. 14-1C). In the formation of a functional heavy chain gene, a successful rearrangement of gene segments includes one V, one D, and one J region segment linked to a C region segment (compare Figs. 14-1C and 14-3B).

During genetic recombination, additional variability is provided by a process known as *junctional diversification*. When two gene segments are brought together during rearrangement, precise linking does not occur. Instead, some nucleotides are inserted or deleted randomly at the junctional site. This introduces new codons, and therefore new amino acids, into the junctional sequence. If an incorrect number of junctional nucleotides are added or deleted, functional molecules will

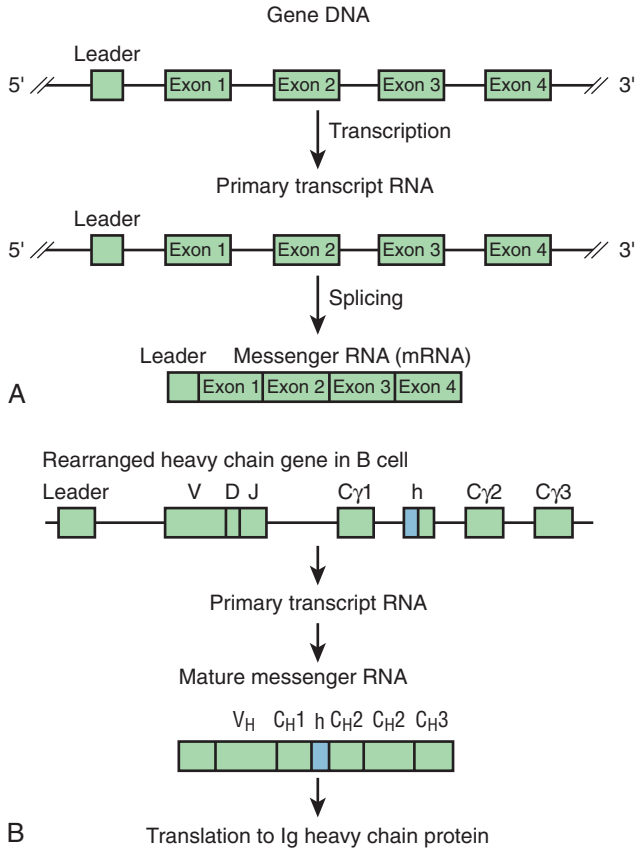

FIGURE 14-2 ■ Genes encoding Ig molecules. **A,** Characteristic structure of genes encoding a membrane protein. Note that the exons code for discrete structural regions of the protein, for example, an external domain, a transmembrane region, and a cytoplasmic tail. **B,** Corresponding structure of a rearranged IgG heavy chain gene. The leader-V region segment of DNA was initially located upstream on the same chromosome and has rearranged proximal to the DJ segment, which is proximal to the IgG Cγ exons. Processing of the primary transcript brings all of the coding regions together in the messenger RNA molecule for translation of the protein. (Adapted from MKSAP in the Specialty of Rheumatology. Philadelphia: American College of Physicians, 1993, p 7.)

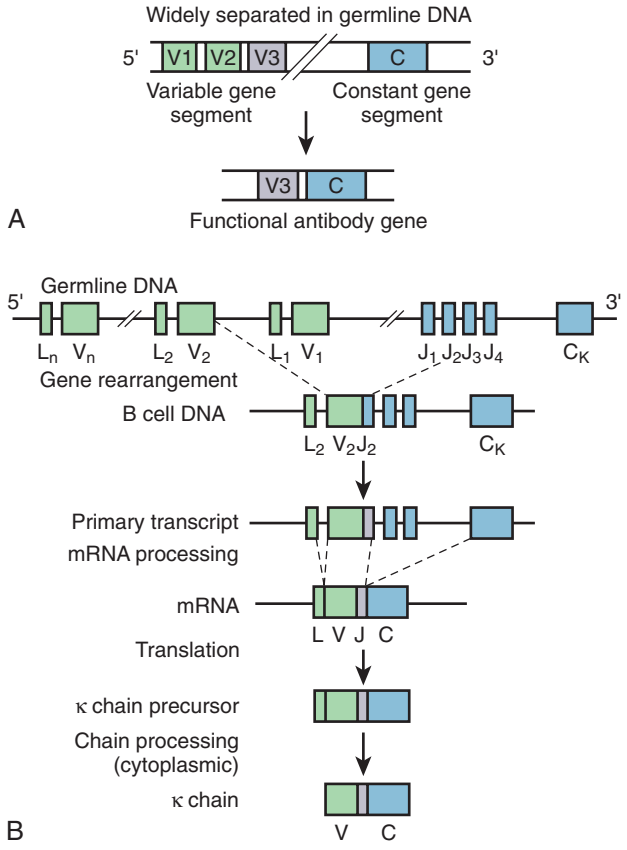

FIGURE 14-3 ■ Principles of genetic recombination. **A,** In the germline DNA, the V region segments are located upstream from the D, J, and C segments on the same chromosome. Recombination, which occurs only in lymphocytes, brings the V gene segments in proximity to the downstream segments. **B,** In the B cell, rearrangement of gene segments separated in the germline DNA allows for the formation of a functional immunoglobulin light chain gene (compare with Fig. 14-1C). mRNA, messenger RNA. (Adapted from MKSAP in the Specialty of Rheumatology. Philadelphia: American College of Physicians, 1993, p 8.)

not be encoded, because the rest of the gene will be "out of frame" or a "stop" sequence will be introduced. Junctional diversity occurs in the hypervariable CDR3 region of the molecule (see Fig. 14-1C).

In general, a single B cell usually expresses an Ig molecule of only one antigen specificity, composed of one heavy chain molecule and one light chain molecule. Even though there are two chromosomal copies of the heavy chain genes in each cell, only one is usually functionally expressed. This phenomenon of using genes on only one parental chromosome is known as *allelic exclusion*. Once a functional rearrangement of heavy chain genes has occurred on one parental chromosome, rearrangement of heavy chain genes on the other chromosome is mostly prevented. If the first rearrangement is not successful, the second one can occur. Allelic exclusion for light chain genes takes place in a similar fashion.

All of the genetic events described earlier occur before the B cell encounters its antigen. Further diversification of the B-cell (or antibody) response occurs after interaction with antigen by a process known as *somatic mutation*, primarily involving point mutations in the hypervariable regions of the V regions.[9,10] Somatic mutation can be viewed as "fine tuning" of the antibody response, occurring after the primary response to a stimulus and during the development of memory B cells. It is, therefore, mostly observed during a secondary immune response. Somatic mutation allows for the production of antibodies with higher affinity for antigen, that is, the ability to bind more strongly to an antigen. Although the mutations occur randomly, B cells with high affinity are selectively expanded (referred to as *affinity maturation*) because the stronger binding allows preferential stimulation by the target antigen, especially when concentrations of the antigen are limiting. Somatic mutation is closely tied to isotype switching, and T-cell help is almost always present. Somatic

mutation usually takes place at the site of T-cell–B-cell interaction in the germinal centers of lymph node or spleen.

Isotype Switching and Function of the Different Immunoglobulin Classes

As described earlier, one B cell usually makes antibody of a single specificity that is fixed by the nature of V_LJ_L and $V_HD_HJ_H$ rearrangements. During the lifetime of this cell, however, it can switch from making an IgM molecule to producing a different class of antibody, such as IgG or IgA, while retaining the same antigenic specificity. This phenomenon is known as *class switching* or *isotype switching*.[9,13]

Figure 14-4 shows the predominant mechanism by which a B cell switches from production of surface IgM to secretion of an IgG, IgA, or IgE molecule. The mechanism involves further DNA rearrangement (a process unique to Ig heavy chain genes), linking rearranged VDJ gene segments with a different heavy chain C region gene segment downstream. The switch (S) region is a stretch of repeating sequences 5′ to the C region that allows a VDJ unit (previously linked to the Cμ region gene segment) to rearrange to another C region downstream. In the process, the intervening DNA is deleted. The B cell, therefore, cannot return to IgM production. As described later, this form of class switching generally occurs after the B cell is stimulated by antigen and frequently is dependent on factors released by T helper cells. In Figure 14-4, it is noted that the Cδ region has no 5′ S region, and therefore the mechanism of class switching described previously is not used so a cell can express IgD on its surface. Another mechanism by which a B cell can express different isotypes is referred to as *alternative RNA splicing*. This mechanism is especially important for mature B cells to be able to express both surface IgM (μ chain) and IgD (δ chain) before B-cell stimulation. Alternative RNA splicing is also used when a B cell secretes IgM rather than expresses surface IgM.

The primary function of an antibody is to bind antigen. In some cases, this has a direct effect, for example, by neutralizing a toxin molecule. However, the interaction of antibody with antigen is usually not sufficient unless secondary effector functions are used.[9] For example, the antibody-antigen complex may activate the complement system, which may cause direct damage to the target or may attract inflammatory cells to the site of infection or injury. The activation of complement also allows inflammatory cells to bind antibody-coated molecules or antibody-coated cells via complement receptors.

Each class of secreted Ig has a different set of functions (Table 14-4).[9,14] IgG is the major antibody of secondary immune responses and is most important for obtaining effective immunization to various toxins, toxoids, and certain extracellular pathogens. IgG accounts for 70% to 75% of the total Ig pool and is the major Ig class in normal human serum. It also crosses the placenta and confers immunity to newborns and neonates for the first few months of life. The interaction

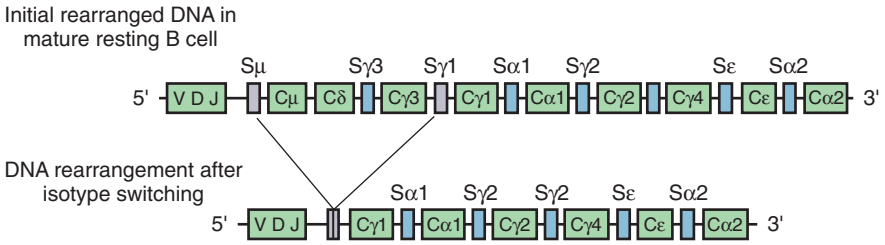

FIGURE 14-4 ■ Genetic mechanisms involved in Ig isotype switching. *Top,* The initial rearrangement of Ig heavy chain gene segments has already taken place in the B cell to put the V region proximal to the D, J, and Cμ segments. This latter genetic region contains other constant region gene segments farther downstream, including Cδ, various Cγ and Cα gene segments, and Cε. In the process of T-cell–dependent B-cell activation in the germinal centers, the B cell is signaled to undergo isotype switching to allow high-rate secretion of an IgG1 antibody. *Bottom,* This is accomplished by additional DNA rearrangements to allow the VDJ unit to rearrange to the Cγ1 segment downstream. The intervening DNA is deleted.

TABLE 14-4. Properties and Functional Characteristics of Immunoglobulin Classes and Subclasses

Effector Function	IgM	IgD	IgG1	IgG2	IgG3	IgG4	IgA	IgE
Mean serum levels (mg/mL)	1.5	0.04	9	3	1	0.5	2.1	0.00003

Ig, immunoglobulin.

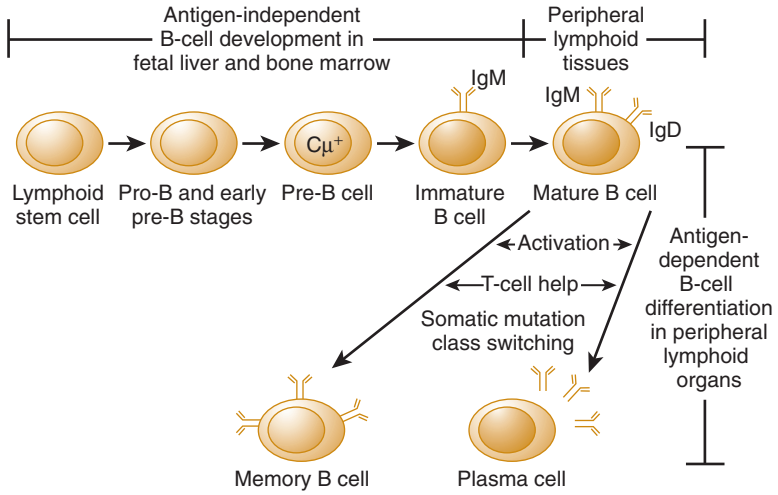

FIGURE 14-5 ■ B-cell development. Antigen-independent differentiation of the B cell in the adult bone marrow is shown from left to right. Pro-B and early pre-B stages involve the rearrangement of Ig heavy chain D-J and V-DJ gene segments and transient expression of a pre–B-cell receptor (BCR). Subsequent rearrangement of Ig light chain genes in the later pre-B cell allows for the development of a BCR-expressing immature B cell. The interaction of the mature naive B cell with antigen in the germinal centers of peripheral lymphoid organs and in the presence of T-cell help allows for somatic mutation of the Ig genes (affinity maturation), isotype switching, generation of B cells that are capable of high-rate IgG secretion, and generation of memory B cells.

of IgG antibodies with antigen can have numerous consequences, including precipitation, agglutination, complement activation, and various cellular effector functions via IgG (Fcγ) receptors.[9,14–17] Although not described at this time, an understanding of these processes is necessary to appreciate how IgG antibodies mediate the elimination or inactivation of pathogens and IgG-coated cells and how antibodies cause various types of immunopathologic processes. There are four IgG subclasses, with IgG1 and IgG3 being most effective at fixing complement and therefore activating complement-mediated effector functions. In addition, the structure of IgG3 is characterized by an elongated hinge region, which may account for its enhanced biologic activity.

IgM is the predominant early-secreted antibody, frequently seen in primary immune responses. IgM is important for effective responses to antigenically complex infectious organisms, especially those with polysaccharide-containing cell walls. IgM antibodies may also be extremely effective at precipitation, agglutination, and complement activation after binding to antigen. Secreted IgM is usually found as a pentamer of the basic (four-domain) Ig unit. Polymerization is facilitated by the binding of the heavy chain tailpieces to a J (joining) peptide.

IgA plays a major role in mucosal immunity and is the predominant Ig in secretions such as saliva and tracheobronchial secretions. Secretory IgA exists mainly in dimeric form and contains a secretory component, which is synthesized by epithelial cells and facilitates transport into secretions as well as protection from proteolysis. Secretory IgA is involved in the prevention of microbial adherence to mucosal cells and in the agglutination of microorganisms. IgA provides the first line of defense against a variety of pathogens.

IgE is scarce in the serum. Its major importance relates to its ability to bind to FcεR1 receptors on mast cells and basophils, and cross-linking of IgE bound to these cells results in cellular activation, degranulation, and release of mediators involved in allergic responses, such as histamine and various leukotrienes.[18] IgE plays a role in immunity to parasites, but in developed countries, it is more commonly associated with allergic responses and allergic diseases, such as hay fever and asthma (see Chapter 38).[19]

B-Cell Development

B cells are produced in the specialized microenvironments of the fetal liver and the adult bone marrow.[20] Figure 14-5 provides an overview of B-cell development, correlating the phenotype of a cell with antigen interactions and the various molecular events described earlier. Development of the stem cell through pro-B, pre-B, and immature B-cell stages occurs in the adult bone marrow. Early steps involve the expression of recombinase enzymes (e.g., recombination activating genes RAG-1 and RAG-2), rearrangement of Ig heavy chain DJ and VDJ gene segments, and transient expression of a pre–B-cell receptor.[20–22] The later pre–B cell is characterized by cytoplasmic μ heavy chain expression. The subsequent rearrangement of light chain genes allows for the expression of surface IgM (the BCR). Immature B cells express surface IgM, whereas mature naive B cells (present in the peripheral lymphoid tissues) usually express surface IgM and IgD. The rearrangement of variable region gene segments that allows for B-cell development in the bone marrow is independent of any antigen interaction and is relatively random. A number of growth and differentiation factors are required to drive B cells through the early stages of development in the bone marrow, and receptors for these factors are expressed on the developing B cells at various stages. Interleukin (IL)-3 and IL-7, for example, appear to be especially important in the early stages of B-cell development.[23,24]

After migration from the bone marrow, the life span of mature naive B cells is limited unless there is contact of the BCR with antigen. The interaction of B cells with foreign antigen occurs in the peripheral lymphoid tissues, particularly in the germinal centers of lymph nodes and spleen.[25] The interaction with antigen, in the setting of T-cell help, results in the generation of memory B cells and cells that secrete a large amount of Ig. This frequently involves class switching and somatic muta-

tion, which allows a secondary antibody response to generate antibodies of a different isotype with higher affinity for the stimulating antigen. These latter processes usually take place in the presence of factors released from T helper cells.

B-cell repertoire formation in the bone marrow is mostly random, and B cells with self-reactivity are generated. Negative selection of cells capable of strongly binding to self-antigens is an important part of B-cell development. This process of B-cell self-tolerance appears to involve both deletion (elimination) and functional inactivation (anergy) of self-reactive cells.[26] A separate mechanism has been described in which B cells with specificity for self-antigens can modify their receptors through a process called *receptor editing*.[11,12] These self-reactive B cells undergo a reversible arrest of development and appear to re-initiate light chain gene rearrangements to alter their BCR. If a B cell fails to successfully edit its BCR, it is destined for cell death (apoptosis). Immature B cells in the bone marrow appear to be capable of receptor editing, whereas mature B cells in the peripheral lymphoid tissues normally lose this ability to reexpress functional recombinase enzymes and to initiate a new round of Ig gene rearrangements.

Immunoglobulin Interactions with Antigen

An antigen is a molecule or molecular complex recognized by B cells or T cells. The term *immunogen* usually refers to a substance capable of eliciting an immune response, and therefore, it must also be capable of being recognized as an antigen. An antigen (e.g., a protein molecule) is usually much larger than the small region fitting into the combining site of an Ig molecule or the peptide piece recognized by a TCR. This smaller region is frequently referred to as an *antigenic determinant* or *epitope*. In a protein, a B-cell epitope can theoretically be constructed in two ways—as a continuous or a discontinuous epitope. In a continuous epitope, the amino acid residues are part of a single uninterrupted sequence, whereas in a discontinuous epitope, residues are not contiguous in the primary structure but are brought together by the folding of the polypeptide chain. Because this kind of epitope requires a special conformation of the antigen, it is frequently referred to as a "conformational epitope."

B cells and T cells usually recognize different parts of an antigen. B cells and their secreted Ig molecules most commonly recognize unprocessed or "native" antigens. These antigens have maintained their native configuration, and most of the epitopes are usually of the discontinuous or conformational type. In general, only a minor component of a B-cell response is directed to small linear peptide regions of the antigen. Studies indicate that epitopes recognized by B cells are not randomly distributed throughout the antigen, but rather reside in regions with particular structural features. One important feature is "accessibility," because epitopes normally must be on the outer surface of a protein and must even be able to protrude from an antigen's globular surface to be able to interact with the BCR.

T Cells and Antigen-Presenting Cells

In contrast to B cells, T cells recognize processed pieces of a protein antigen, which are presented to the TCR by MHC molecules on the surface of antigen-presenting cells.[3,4]

T-Cell Receptors

The TCR shows important structural similarities with Ig molecules (Fig. 14-6).[2] The αβ TCR is expressed by at least 90% of peripheral blood T cells. Essentially, all $CD4^+$ T cells and most $CD8^+$ T cells express this form of the TCR. A small percentage of αβ-expressing T cells have a double-negative ($CD4^-$, $CD8^-$) phenotype. As shown in Figure 14-6, each chain consists of two extracellular (external) Ig-like domains anchored into the plasma membrane by a transmembrane region and a short cytoplasmic tail. Similar to Ig molecules, the outer NH_2-terminal domain of each chain constitutes the variable region. Outside of the transmembrane region, the two chains are covalently linked together by disulfide bonds. The short cytoplasmic tail is consistent with the fact that the αβ heterodimer itself is not capable of transmitting a signal to the inside of the cell after receptor engagement. As discussed later, this function is accomplished by the CD3 complex of polypeptides and other signaling proteins that are associated with the TCR.

The γδ TCR is an alternative form of TCR that is similar in overall structure to the αβ receptor.[27] Although some γδ cells express CD8, most are $CD4^-$, $CD8^-$ (double negative). CD8 expression is largely confined to those

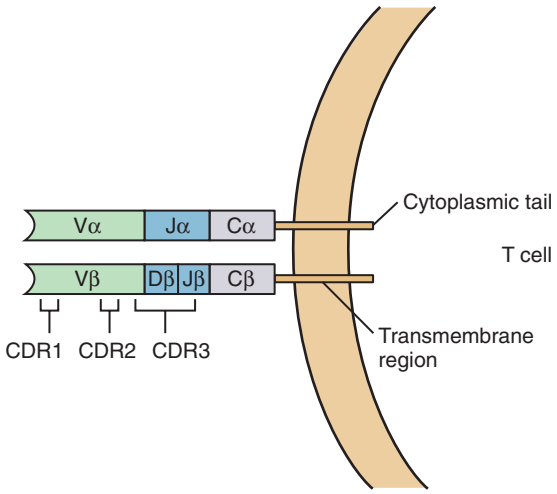

FIGURE 14-6 ■ The T-cell receptor (TCR) α and β chains indicate the regions encoded by different TCR gene segments. The positions of the CDRs of both the β and the α chains are also shown. These are the most variable parts of the TCR and the most important for TCR binding to peptide/major histocompatibility complex. CDR1 and CDR2 of both the α and the β chains are encoded within the variable region genes. CDR3 is formed by the rearrangement of V, D, and J gene segments of the β chain and V and J segments of the α chain and is encoded by the distal part of the V region segment through part of the J segment. The different parts of the TCR are not drawn to scale.

γδ cells residing in the small intestine. The γδ TCR is also expressed in association with the CD3 complex. Although γδ T cells form a minor proportion of the T cells in the thymus and secondary lymphoid organs, they are abundant in various intraepithelial populations, such as in the skin, intestines, and lung.[27,28]

Genetic Mechanisms Involved in T-Cell Receptor Structure and T-Cell Receptor Repertoire Formation

Genes encoding the TCR are organized similarly to Ig genes.[2,29] Figure 14-7 shows the germline organization of the TCR α and β chain gene complexes. In a manner similar to that described previously for B cells, rearrangement of gene segments, junctional diversity, and combinatorial joining of the two chains is responsible for the diversity of the TCR repertoire. However, in contrast to B cells, TCR genes do not undergo somatic mutation. Thus, nearly the entire TCR αβ repertoire is formed during T-cell development in the thymus and before any interaction with antigen. Because the T-cell repertoire is shaped to recognize self-MHC antigens, it is believed that extrathymic somatic mutation might too frequently result in deleterious self-reactive T cells. Thus, the absence of somatic mutation may protect against this potentially serious possibility.

Similar to B cells, T cells also show allelic exclusion for functional gene rearrangements. Thus, if one chromosome undergoes a functional rearrangement such that a functional polypeptide is produced, genes on the other parental chromosome are usually prevented from rearranging. Allelic exclusion is more complete for the β chain than for the α chain, and a small percentage of T cells express two functional TCR α chains (each paired with one β chain) and, therefore, two potential TCR specificities. However, in general, the great majority of mature T cells express only one αβ TCR and, therefore, only one specificity. This specificity does not change during the lifetime of a T cell.

The components of the αβ TCR heterodimer are shown in Figure 14-6, and the ribbon backbone structure of the Vα and Vβ portions of a human TCR are shown in Figure 14-8.[3,4,30,31] The upward-pointing loop structures are the CDRs. These regions are the most variable part of the TCR α and β chains and are most important for binding of the TCR to peptide/MHC complex. The CDR1 and CDR2 regions of the α chain and β chain are encoded within the germline *TCRAV* and *TCRBV* gene segments, and variability in their sequences distinguishes the different V region subfamilies. There are about 25 different Vβ (*TCRBV* gene) human subfamilies, which include about 50 functional gene segments, and about 40 to 50 different Vα (*TCRAV*) gene segments. The most diverse part of the β chain is the CDR3, which is formed during the rearrangement of *TCRB* gene segments and is encoded by the 3′-end of the V region, the diversity (D), and the joining (J) region gene segments (see Fig. 14-7). The expressed α chain gene (*TCRA*) is formed similarly, although there is no diversity (D) gene segment (see Fig. 14-7A). Just as in the rearrangement of Ig genes, random nucleotide additions and deletions as the TCR junctional

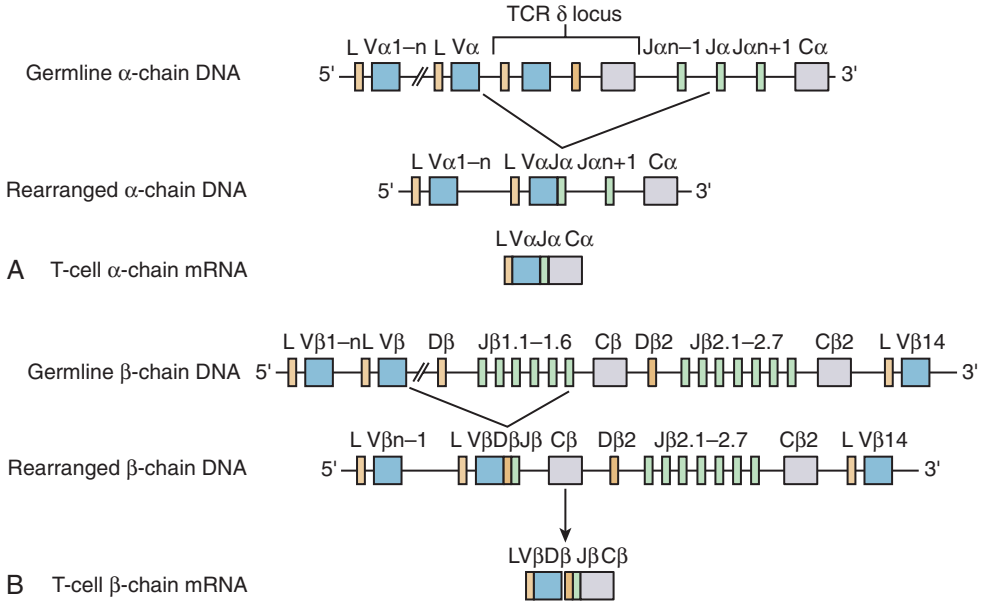

FIGURE 14-7 ■ Rearrangement of genes encoding the TCR. **A,** In the germline TCR α chain gene complex, before any rearrangement in T cells, approximately 40 to 50 Vα gene segments are located upstream of the multiple Jα and Cα gene segments. Within the TCR α chain locus is the TCR δ gene complex (expressed in γδ T cells), which is deleted when Vα genes are rearranged. During T-cell development, Vα genes are rearranged to downstream Jα gene segments to form a functional α chain gene. This process is similar to that described for immunoglobulin gene rearrangements. Expression of RNA and RNA processing allows for generation of TCR α chain messenger RNA (mRNA). **B,** A similar process allows for rearrangement of TCR β chain genes in the pre–T cell during T-cell development. In both **A** and **B**, nucleotide additions and deletions at the margins of the rearranging segments are not shown (see text).

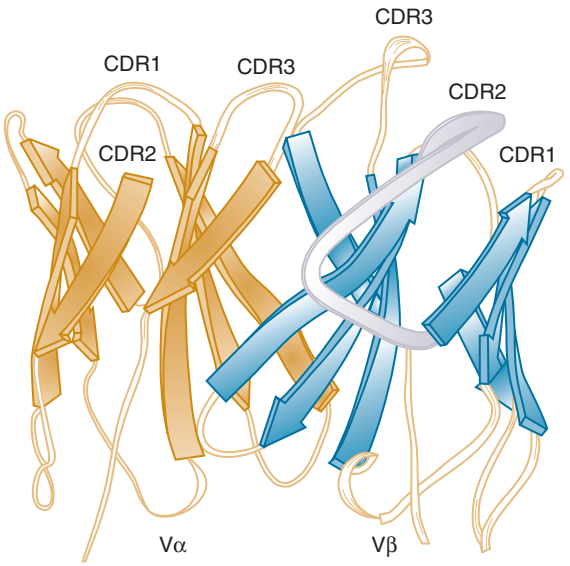

FIGURE 14-8 ■ A ribbon backbone structure of the Vα and Vβ portions of a human TCR. The upward-pointing loop structures are the CDRs. These regions are the most variable part of the TCR α and β chains and are most important for TCR binding to peptide/major histocompatibility complex. The CDR1 and CDR2 regions of the α chain and β chain are encoded within the germ-line TCRAV and TCRBV gene segments, respectively. The highly variable CDR3 region is formed by the rearrangement of V, (D), and J gene segments. Junctional nucleotide substitutions and deletions at the margins of rearrangement add to the potential diversity of the CDR3 region. (Adapted from Kotzin BL, Kappler J: Targeting the TCR in rheumatoid arthritis. Arthritis Rheum 41:1907, 1998.)

region gene segments join together create additional diversity. The CDR3 is the most important part of the TCR for direct interaction with peptide/MHC complexes.

Antigen-Presenting Cells and Molecules of the Major Histocompatibility Complex

There are two major varieties of MHC molecules (and genes) involved in the presentation of antigens to T cells.[32] MHC class I molecules include human leukocyte antigen (HLA)-A, HLA-B, and HLA-C molecules. MHC class II molecules include the HLA-DR, HLA-DQ, and HLA-DP molecules. Class I molecules are expressed on nearly all nucleated cells. In contrast, class II molecules have a limited distribution and are normally present only on cells involved in antigen presentation to T cells, including dendritic cells, macrophages, B cells, and thymic epithelial cells. The limited expression of class II antigens in different tissues may be extremely important in preventing various types of autoimmune reactions. After activation or after exposure to certain cytokines, such as interferon-γ (IFN-γ), other human cell types such as activated T cells and epithelial cells can express class II molecules.

The general structures of the two classes of MHC molecules are shown in Figure 14-9. For MHC class I antigens, the α chain (encoded within the MHC) is complexed to beta$_2$-microglobulin (encoded outside the MHC). As discussed later, the α chain is highly polymorphic (variable between individuals), whereas beta$_2$-microglobulin is invariant. The extracellular portion of the α chain is divided into three domains: α1, α2, and α3. The outer α1 and α2 domains represent the polymorphic components of the molecule, and the α3 domain is relatively constant. MHC class II molecules are composed of an α and a β chain, both of which are encoded within the MHC. The NH_2-terminal domains of

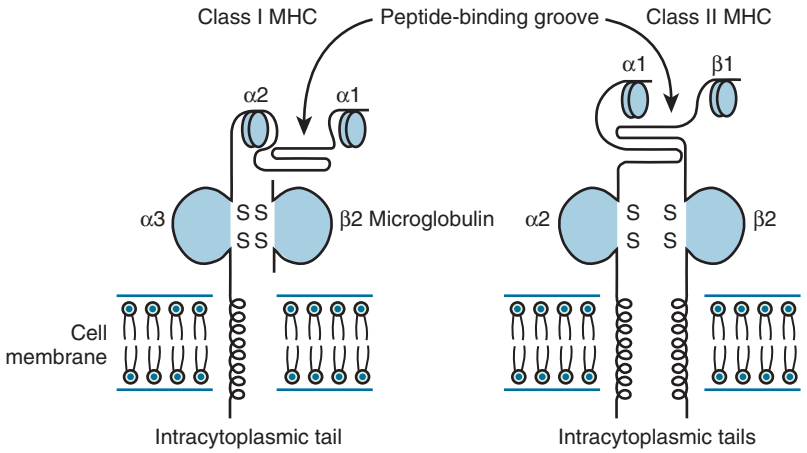

FIGURE 14-9 ■ Comparison of the composition of class I and class II major histocompatibility complex (MHC) molecules. The class I MHC α chain is variable (polymorphic) among different individuals. It is expressed with beta$_2$-microglobulin, which is encoded outside the MHC region, and does not differ among different individuals. The class II MHC molecules are composed of α and β chains. For HLA-DR molecules, only the β chain is variable, whereas for the HLA-DQ and HLA-DP molecules, both the α and the β chains are encoded by polymorphic alleles. In class I MHC molecules, the peptide-binding region is formed between the α1 and the α2 domains, which are polymorphic. The peptide-binding region of class II MHC molecules is formed between the α1 and the β1 domains of the α and β chains, respectively.

each chain (α1 and β1 domains) represent the polymorphic regions of the molecule and are important in antigen presentation, whereas the α2 and β2 domains are relatively constant.

MHC class I and class II molecules have been crystallized and their structures have been elucidated, providing remarkable insight into how antigenic peptides are bound and presented to T cells.[3,4,33–36] In Figure 14-10A, the peptide-binding pocket or groove of a class I molecule is viewed from the top, showing the surface that is contacted by a TCR. MHC class I pockets can usually only bind peptides of 8 to 10 amino acids, which are bound in a typical extended conformation with both the NH_2 terminus and the carboxy (COOH) terminus anchored in the peptide-binding groove. In the case of MHC class II, the peptide-binding groove is formed by the interaction of the NH_2-terminal domains of the α and β chains (see Fig. 14-10B). The structure of MHC class II allows peptides of varying lengths to bind because both ends of the peptide are free, and the peptide shown in the figure has the typical polyproline-like extended helical conformation seen in all class II MHC-bound peptides.

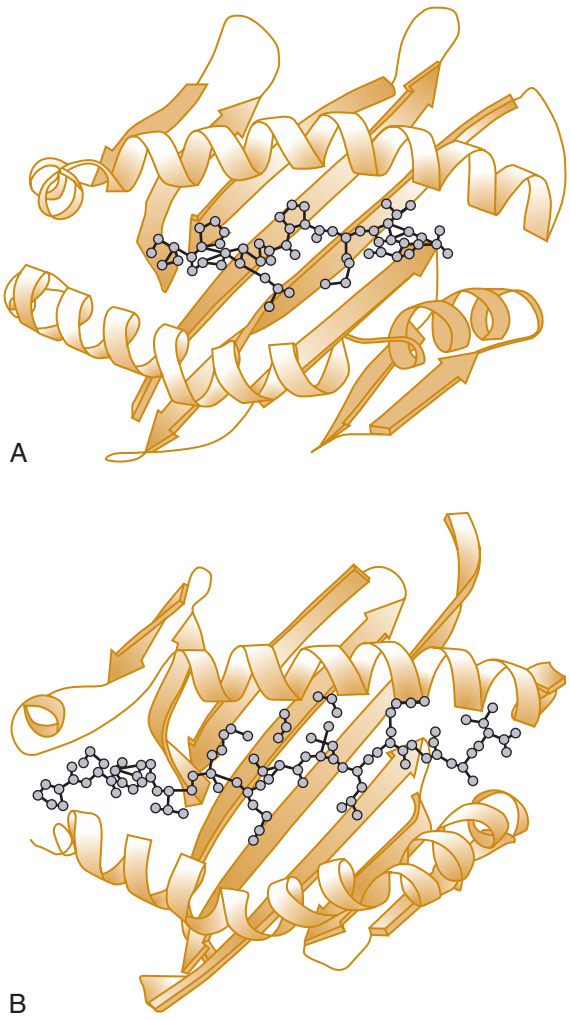

FIGURE 14-10 ■ Structure of the MHC/peptide complexes. **A,** A schematic view of a MHC class I binding groove with peptide. The peptide is shown in ball-and-stick representation. In class I molecules, the peptide is usually of fixed length (~9 amino acids) and bound such that the NH_2 and COOH termini are both anchored in the peptide-binding groove. **B,** A schematic view of a MHC class II (HLA-DR1) molecule with bound peptide in the groove. The peptide is shown in ball-and-stick representation. The peptide has the typical polyproline extended helical conformation seen in all class II bound peptides. The structure of class II allows peptide of varying lengths to bind because both ends of the peptide are free and can extend out of the groove on both sides. (From Jones EY: MHC class I and class II structures. Curr Opin Immunol 9:76–77, 1997.)

The aforementioned structural studies have important implications for understanding the interactions between the peptide/MHC complex and TCRs. For example, changes in amino acid residues on the floor of the peptide-binding pocket (which are covered up by the peptide) will likely affect peptide binding but not TCR binding directly. Amino acid residues on the α-helices facing into the groove are similarly likely to affect peptide binding, whereas residues facing up are candidates for interacting directly with the TCR.

Genetics and Nomenclature for the Human Leukocyte Antigen System

A description of the genetic organization of the MHC is important for understanding the basis for the association of certain HLA genes with disease.[32,37,38] The entire HLA region spans approximately 3.6 megabases and encompasses greater than 200 genes, many of which have important roles in the immune system. Figure 14-11 shows the general organization of class I, II, and III genes on human chromosome 6. The region located between the HLA-DR and HLA-B loci includes genes for complement (C) components (factor B, C2, C4A, and C4B) and genes encoding certain cytokines, such as tumor necrosis factor (TNF).

The combination of closely linked MHC genes on the same chromosome is referred to as the *MHC haplotype*; genes of the entire complex determine the haplotypes.[32] At many of the loci, there are multiple alternative forms (alleles) of a gene that can be inherited. For example, over 690 HLA-A, 1100 HLA-B, 690 HLA-DR, 95 HLA-DQ, and 130 HLA-DP alleles with official names are characterized at this time.[39] Allele numbers for the class II genes continue to increase with new molecular biologic typing techniques. Within the class II region (see Fig. 14-11), the DRA gene (encoding the DR α chain) is not polymorphic, and therefore, all of the allelic polymorphism is determined by DRB (DR β chain) gene variability. The DRB1 gene determines the DR1 to DR18 specificities; the DRB3 and DRB4 genes determine the DR52 and DR53 specificities, respectively. Within DQ, both the DQA1 and the DQB1 genes are polymorphic, and both contribute to DQ variability.

Because they are closely linked, MHC genes are frequently inherited as a unit (referred to as a *haplotype*).[32] Furthermore, meiotic recombination is unusual for certain regions within the MHC; for example, recombination is rare between the DRA and the DQA1 loci and

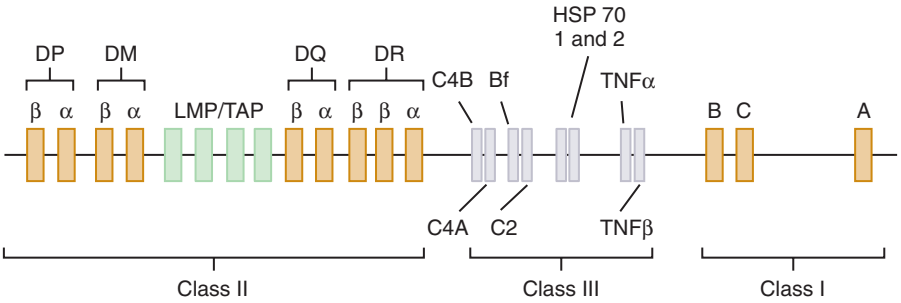

FIGURE 14-11 ■ Overview of the human leukocyte antigen (HLA) gene complex. The class I, II, and III regions of the gene complex are shown. In the class I region are the HLA-A, HLA-B, and HLA-C α chain genes. In the class II regions are the HLA-DR, HLA-DQ, and HLA-DP genes for the α and β chains. This region also contains the DM and LMP/TAP (transporters associated with antigen processing) genes, which encode molecules involved in the processing and transport of peptides to be presented with MHC molecules. The class III region in humans is located between the class I and class II regions and includes complement factors 4A (C4A) and 4B (C4B), factor B (Bf) of the alternate complement pathway, tumor necrosis factor-α and -β (TNF-α and TNF-β), and heat shock protein-70 (HSP70).

is much more common between the DQ and the DP regions. Therefore, in different ethnic populations, certain DR and DQ alleles appear to be inherited together to form part of a stable haplotype. Those associated DR and DQ alleles are inherited in linkage disequilibrium (e.g., DR3 and DQ2 [*DQA1*0501, DQB1*0201*] or DR4 and DQ8 [*DQA1*0301, DQB1*0302*] in whites).[40] On some chromosomes, certain HLA-B, class III, DR, and DQ gene alleles have been maintained as a unit, inherited in linkage disequilibrium, and are referred to as *extended haplotypes*. One extended haplotype associated with autoimmune diseases, such as systemic lupus erythematosus and type 1 diabetes, includes the alleles A1, B8, DR3, and DQ2.[40]

Presentation and T-Cell Recognition of Antigens

In contrast to B cells, T cells recognize processed peptides of a foreign antigen that are complexed to MHC molecules on antigen-presenting cells. Because of the process of thymic selection for self-MHC recognition, there is little capability for T cells to recognize intact or native protein antigens. $CD4^+$ T cells generally recognize peptides complexed to class II MHC molecules, whereas $CD8^+$ T cells interact with peptide/class I MHC molecules.[2–4,32] The purpose of this relatively complex antigen-presentation process may be to focus the T-cell response onto cells. For example, it is much easier for a T cell to kill a virus-infected cell before the pathogen has the opportunity to multiply than it is to kill individual virus particles. The class I MHC molecules, therefore, focus the cytotoxic T-cell response on cells infected with intracellular organisms, whereas free infectious particles are the targets of antibodies. Recognition of free (extracellular) organisms by T cells would only distract these cells from carrying out their true function of killing the infected targets. Class II MHC molecules similarly focus the delivery of T-cell help on the relevant antigen-specific B lymphocytes that eventually produce antibodies. Recognition of antigen only on the surface of MHC class II–expressing cells also allows for a system by which the activation of $CD4^+$ T cells can be closely regulated (see later discussion).

Peptide-containing MHC class I and class II molecules on the surface of antigen-presenting cells serve as ligands for engaging TCRs of $CD8^+$ and $CD4^+$ T cells, respectively. In order to effectively present antigenic peptides, antigen-presenting cells must be capable of performing at least two functions: (1) processing and displaying parts of antigens together with MHC molecules on their cell surface and (2) providing the other accessory signals necessary for T-cell activation. The second function is discussed later. Antigen processing refers to the series of steps that generate these peptide fragments, load them onto MHC molecules, and allow expression of the peptide/MHC complex on the cell surface.[41] MHC class I molecules are loaded with peptides derived from endogenously synthesized proteins in the endoplasmic reticulum, whereas MHC class II molecules are loaded with peptides derived from extracellular proteins in a specialized endosomal vesicle. Major differences exist in the manner in which endogenous and exogenous foreign antigens are prepared and presented to T cells (Table 14-5).[41–49]

All intracellular proteins can serve as sources of peptides for MHC class I molecules.[42–46] Endogenous foreign antigens are usually viral products that are synthesized within the cytoplasm. Some of the viral molecules produced in the cytoplasm are degraded into peptides by a multi-subunit proteasome complex. Transporters of antigenic peptides (TAP-1 and TAP-2) are required for the transport of peptides into the endoplasmic reticulum, where the association with class I molecules takes place. For stable expression on the cell surface, the MHC class I heavy chain and beta$_2$-microglobulin dimer must properly assemble with a peptide inserted into the MHC class I binding groove. This process occurs predominantly in the endoplasmic reticulum (ER) and is orchestrated by multiple ER-resident chaperone and accessory molecules that facilitate peptide loading and stabilization of the complex. After complete assembly of the MHC class I/peptide complex, it is transported to the surface via normal secretory pathways. On the cell

TABLE 14-5. Major Histocompatibility Complex Class I versus Class II Pathways of Antigen Presentation to T Cells

Characteristic	MHC Class I	MHC Class II
Expression	Nearly all nucleated cells	Antigen-presenting cells (B cells, macrophages, dendritic cells, thymic epithelial cells)
Responding cells	$CD8^+$ T cells	$CD4^+$ T cells
Peptides	~9 amino acids	~16–24 amino acids
Source of peptides	Endogenous antigens	Extracellular antigens
Site of peptide generation	Cytoplasm	Phagolysosome, endosome
Proteolytic mechanism	Cytosolic proteasome complex	Endosomal enzymes
Peptide loading compartment	Endoplasmic reticulum	Novel endosome (MHC II compartment)
Transport of MHC to loading area	Already in endoplasmic reticulum	Invariant chain acts as chaperone to carry to MHC compartment
Transport of peptide to loading area	Transporters associated with antigen	Fusion of vesicles processing (TAP-1 and TAP-2)
Loading of peptide into MHC	Complex of calreticulin, TAP-1/TAP-2, tapasin, and ERp57	HLA-DM–mediated release of CLIP and binding of new peptide
Transport of MHC/peptide complex to cell surface	Secretory pathway	Tubular transport

CLIP, class II–associated invariant chain peptide; HLA, human leukocyte antigen; MHC, major histocompatibility complex; TAP, transporter of antigenic peptide.

surface, the complex is recognized by a $CD8^+$ T cell, such as a cytotoxic T cell. In theory, because all cells appear to possess the processing apparatus, any class I–expressing cell can present antigen to a $CD8^+$ cytotoxic effector cell. However, antigen-presenting cells that are capable of activating resting $CD8^+$ T cells are more specialized.

Foreign antigens recognized by $CD4^+$ T cells are usually exogenous antigens that come from outside of the antigen-presenting cell (see Table 14-5).[47–49] In order for such an exogenous antigen to be presented to a $CD4^+$ T cell, it must be taken up (endocytosed or phagocytosed) and processed by an antigen-presenting cell, usually a B cell, macrophage, or dendritic cell. It is degraded into peptides in phagolysosomes. MHC class II molecules are bound to invariant chain immediately after their synthesis in the ER. A segment of invariant chain called class II–associated invariant chain peptide (CLIP) prevents premature binding of peptides in this intracellular compartment.[49] Transport to a multivesicular and multilamellar late endosomal compartments, called the MIIC compartments, allows for dissociation of CLIP and loading with peptide fragments. A nonclassic MHC class II–like molecule, HLA-DM, facilitates the release of CLIP and subsequent binding of other peptides to the empty MHC class II molecule. Like other MHC class II molecules, HLA-DM is a heterodimer of α and β chains. However, in contrast to other class II molecules, it is not polymorphic and is not expressed on the cell surface; rather it is predominantly located in the endocytic compartment. The MHC class II/peptide complex is subsequently displayed on the cell surface, where it is recognized by $CD4^+$ T lymphocytes. The mechanism by which this complex is transported to the cell surface is thought to involve the transformation of the MHCII compartments into tubular structures that are directed toward the site of T cell interaction with the plasma membrane, thus allowing control of the formation of the immunologic synapse.[47]

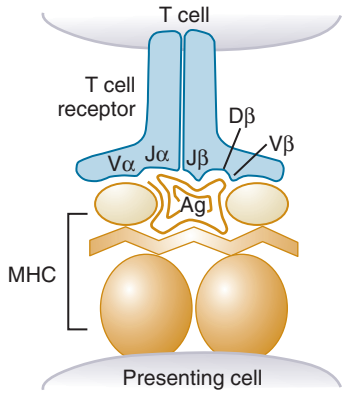

FIGURE 14-12 ■ T-cell recognition of a conventional peptide antigen. The MHC molecule on the antigen-presenting cell is *shaded* and shows the peptide-binding groove with a peptide in it. The interacting TCR is shown as a *pale* structure. Note that the junctional regions of the TCR α chain (Vα/Jα) and β chain ($V_\beta/D_\beta/J_\beta$) are depicted such that they appear to have the most important interaction with the peptide. These junctional regions form the CDR3 of the α and β chains, which is the most variable component of the TCR. The CDR1 and CDR2 loops are encoded within the Vα and Vβ regions, and these loops may have more interaction with the MHC parts of the complex compared with CDR3. A ribbon diagram of the TCR CDR loops is depicted in Figure 14-8. (Adapted from Drake CG, Kotzin BL: Superantigens: Biology, immunology, and potential role in disease. J Clin Immunol 12:140, 1992.)

Figure 14-12 shows a schematic view of antigen recognition by a $CD4^+$ T cell. A foreign peptide is contained within the antigen-binding groove of a class II MHC molecule, and the TCR simultaneously recognizes the complex of peptide and class II MHC molecule. Thus, residues of the variable region of the TCR interact with the peptide and MHC residues extending out from the

peptide-binding groove. As discussed earlier, the highly variable CDR3 region encompassing the Vβ/Dβ/Jβ and Vα/Jα junctions of the αβ TCR is frequently most important in the binding of peptide, whereas other parts of the variable regions are more involved in MHC residue interactions.[2–4]

T-cell superantigens are products of bacteria and viruses that differ in many ways from the conventional protein or peptide antigens described earlier.[50] Most striking is that their recognition by TCRs appears to depend almost entirely on the variable region of the β chain (Vβ). Thus, unlike recognition of conventional peptide antigens, the other components of the TCR (Dβ, Jβ, Vα, Jα) play little role in superantigen binding. Because the relative number of Vβ genes is limited, many T cells (~5%–30% of the entire repertoire) within an individual express responsive Vβ elements and are stimulated by a superantigen, whereas the responding frequency to a conventional antigen is usually much less than 1 in 10,000. The potential importance of superantigens in disease relates to their ability to stimulate T cells on a large scale. Although superantigens are presented by class II MHC molecules, they are not processed like conventional peptide antigens. Instead, they seem to bind directly to the outer walls of the peptide-binding cleft. Many different class II MHC molecules can usually present a particular superantigen, and thus its recognition is not MHC restricted. The best studied superantigens are the staphylococcal enterotoxins and toxic shock syndrome toxin-1. Superantigens have been noted to be produced by other bacteria, particularly group A streptococci, and occasional viruses. Studies suggest that superantigens and the massive T-cell activation induced by them play a role in diverse pathologic conditions, including toxic shock syndrome, Kawasaki disease, and possibly certain autoimmune diseases.

γδ T cells represent a separate lymphocyte subset, whose primary functional assignment is currently unknown.[27,28] Although in many ways similar to αβ T lymphocytes, they are clearly distinguished by their expression of a different set of TCR genes with different ligand specificities and by a different distribution in normal tissues. Although both αβ and γδ T cells circulate, αβ T cells tend to populate lymphoid tissues, whereas γδ T cells preferentially colonize nonlymphoid tissues, particularly epithelium-rich tissues such as skin, intestine, and reproductive tract. Bacterial antigens in general seem to be very good stimulators of γδ T cells, and it has been suggested that these cells function as a first line of defense against infectious pathogens. For example, it has been shown that the initial immune response to numerous pathogens is characterized by expansion of γδ cells. Furthermore, many γδ-cell subsets recognize mycobacterial antigens, and heat shock proteins have been shown to be the basis for the stimulation of certain clones. The ability of γδ T cells to respond to heat shock or stress proteins could provide a means of recognizing a wide variety of pathogens because these proteins are highly conserved among many species. γδ T cells have also been implicated in the regulation of various immune responses, especially in the lung.[51]

CD3 Complex and Intracellular Signaling after T-Cell Activation

An extensive description of the complex signaling events that occur in T cells[52] or B cells[53] after antigen receptor engagement and cellular activation is beyond the scope of this chapter. Briefly, in T cells, the CD3 complex of polypeptides and structurally distinct ζ chains are closely associated with the TCR heterodimer and are critical for transmitting a signal to the inside of the cell after TCR binding to antigen.[52] Triggering of the TCR/CD3 complex with effective co-stimulation is coupled to (1) protein tyrosine kinase activity associated with phosphorylation of particular tyrosine-based activation motifs within the CD3 and ζ chains and involving Lck, Fyn, and ZAP-70 protein tyrosine kinases and adapter proteins; (2) activation of phospholipase C-γ, resulting in phosphatidylinositol metabolism with generation of inositol triphosphate and diacylglycerol (DAG); (3) increase in intracellular calcium ion concentration; (4) activation of protein kinase C via DAG and calcium; and (5) activation of additional pathways involving calcineurin, Ras, and mitogen-associated protein kinase cascades, leading to the production of activated transcription factors (such as nuclear factor-κB, nuclear factor of activated T cells, and activator protein-1) to induce new gene expression and leading to cell proliferation and differentiation. In B cells, BCR aggregation by antigen initiates signal transduction by the receptor's associated CD79a and CD79b subunits.[53]

T-Cell Accessory Molecules CD4 and CD8

There are two major subpopulations of peripheral αβ-expressing T cells. The T-cell subset that expresses the CD4 molecule identifies cells that primarily recognize antigens in the context of class II MHC molecules (e.g., HLA-DR, HLA-DQ, and HLA-DP). Cells within the $CD8^+$ T-cell subset primarily recognize antigen in the context of class I MHC molecules (e.g., HLA-A and HLA-B). These accessory molecules appear to stabilize an interaction with the appropriate MHC molecule.[54–56] The CD4 molecule interacts with nonpolymorphic determinants on class II MHC molecules, whereas the CD8 molecule binds to analogous invariant residues on class I MHC molecules. The associated binding of CD8 may be especially important in stabilizing low-affinity TCR binding to the antigen/MHC complex. In addition, both CD4 and CD8 molecules participate in TCR-mediated signal transduction through associated Lck protein kinase.[52] In general, $CD4^+$ T cells have helper or inducer functions (e.g., help B cells in a T-cell–dependent antibody response), whereas $CD8^+$ T cells have cytotoxic or suppressor functions. Regulatory subsets expressing each of these coreceptors have also been described (see later discussion).

T-Cell Development and Selection of the T-Cell Repertoire

A general overview of important events in T-cell development is provided in Figure 14-13.[57] Stem cells pre-

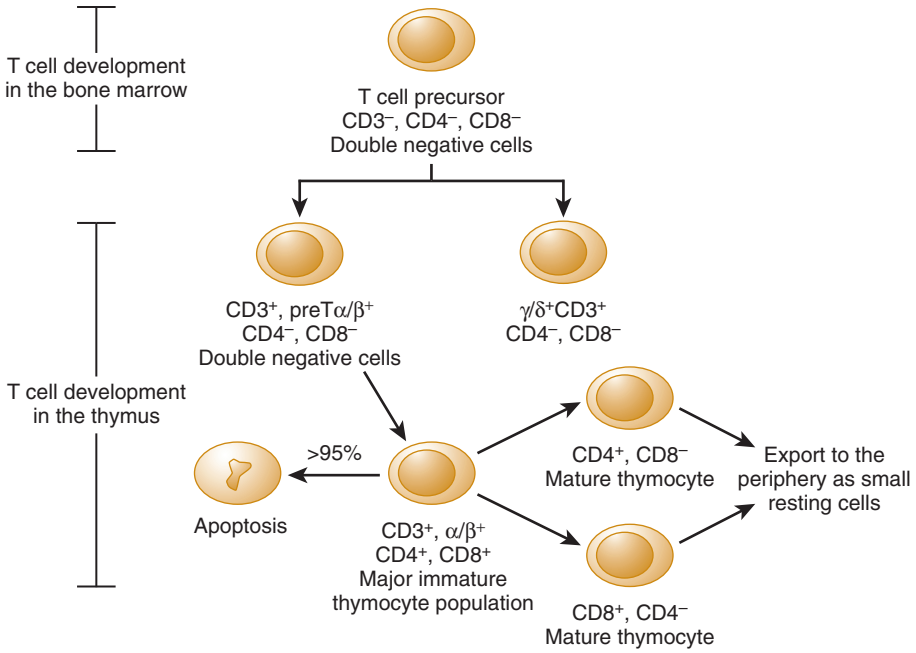

FIGURE 14-13 ■ T-cell development and maturation in the thymus. The rearrangement of the TCR β chain genes in the pre–T cell and then TCR α chain genes results in generation of a remarkably diverse TCR repertoire, expressed at the stage of the major immature thymocyte. These cells express TCR at relatively low density and are double positive for both CD4 and CD8. The repertoire is positively selected for (low) affinity to self-MHC (self-MHC restriction). Cells with TCR that do not undergo positive selection die in the thymus by apoptosis. Immature and mature thymocytes with high affinity for self-MHC peptide complexes are negatively selected and undergo apoptosis (deleted). Overall, greater than 95% of immature thymocytes fail to mature for export to the peripheral lymphoid organs. As immature thymocytes mature, they maintain CD4 expression and down-regulate CD8 (MHC class II restricted) or maintain CD8 expression and down-regulate CD4 (MHC class I restricted).

committed to the T-cell lineage arise in the bone marrow and migrate to the thymus. These cells do not express TCR molecules and do not express CD4 or CD8 molecules (i.e., they are double negative for CD4 and CD8). These cells develop by rearranging TCR β chain genes and generating a functional TCR β chain. A surrogate pre–T-cell α chain allows expression on the cell surface early in development.[58] Subsequently, the α chain genes are rearranged and TCR molecules are expressed at a relatively low density. The additional expression of both CD4 and CD8 (double-positive thymocytes) identifies the major immature thymocyte population.

The TCR repertoire of the early immature population appears to be dependent on the random rearrangement of TCR genes. Subsequently, in the thymus, two major processes modify this repertoire.[57,59,60] One process positively selects cells that have some TCR affinity for self-MHC molecules. Evidence suggests that an interaction with thymic cortical epithelial cells is involved in this positive selection step. This process allows mature cells to eventually recognize foreign antigens in the context of self-MHC antigens (a phenomenon termed *self-MHC restriction*). Cells that are not positively selected undergo programmed cell death (*apoptosis*) within the thymus. The other process deletes cells that have a high level of self-reactivity (termed *negative selection* or *self-tolerance*).[60] This deletion process primarily involves an interaction with bone marrow–derived cells (macrophages, dendritic cells, B cells) that have migrated to the thymus and specialized cells within the thymic medulla (medullary epithelial cells) that express a variety of organ-specific antigens.[61,62] The transcriptional regulator, Aire, plays an important role in T-cell tolerance induction in the thymus, mainly by promoting ectopic expression of a large repertoire of transcripts encoding proteins normally restricted to differentiated organs in the periphery.[62] Only a small percentage (~1%–3%) of thymocytes actually survive the processes of positive and negative selection and become mature thymocytes that have a relatively high level of TCR expression and express either $CD4^+$ or $CD8^+$ markers, but not both. In general, cells that are positively selected by an interaction with class II MHC molecules mature into the CD4 population, whereas cells that are positively selected on class I MHC molecules become the CD8 population.[63] Mature thymocytes subsequently migrate to peripheral lymphoid tissues, where they maintain these surface characteristics.

T-Cell Tolerance: The Prevention of Self-Reactivity

There is reason to believe that tolerance at the T-cell level is critical for the prevention of autoimmunity. Clonal deletion of self-reactive T cells in the thymus is discussed in the section on "T-Cell Development and Selection of the T-Cell Repertoire." This may be the major process for eliminating T cells that are reactive to non–organ-specific cellular proteins and to circulating

proteins, because these self-antigens are likely to be in the thymus during T-cell development. Some organ-sequestered antigens (e.g., certain uveal tract, brain, and endocrine organ antigens) are also expressed in the thymus.[61,62] However, studies have clearly shown that T cells to various self-antigens, including many organ-sequestered and posttranslationally modified antigens, are not completely deleted in the thymus. Therefore, self-tolerance must also involve the prevention of activation of these autoreactive T cells after they migrate from the thymus to the peripheral lymphoid tissues.[64,65]

Studies have shown that T cells with self-reactive TCRs are present in the peripheral lymphoid organs and the circulation of healthy individuals, but they are not sufficient for the development of autoimmune disease. Different peripheral mechanisms appear to help prevent autoimmune responses from occurring. One process appears to prevent the self-antigen from being effectively presented to a self-reactive T cell, which maintains that T cell in an ignorant state. For example, resting T cells with self-reactive potential may not be able to traffic to the tissue that expresses the antigen, or the antigen may not be presented by effective antigen-presenting cells. Some studies have suggested that inappropriate expression of class II antigens in a tissue can lead to autoimmunity, perhaps by circumventing this protective mechanism. T-cell activation triggered by a separate process (e.g., an infectious agent) may also bypass this protective mechanism by allowing cells with self-reactive potential to inappropriately traffic to tissues. T cells that do recognize antigen without effective antigen-presenting cells and co-stimulation may also be functionally deactivated (or anergized)[66] and prevented from any subsequent stimulation by that self-antigen. These cells continue to be present in the peripheral T-cell repertoire, but their prior contact with self-antigen prevents any subsequent response. Many investigators have worked on defining the intracellular mechanisms that lead to T-cell anergy, and current evidence indicates that anergic T cells activate some but not other signaling pathways after TCR engagement.[66] There is also evidence that the encounter of self-reactive T cells with antigen, but without effective presentation, sometimes leads to death of the autoreactive T cell rather than just anergy.

A final mechanism to prevent activation of self-reactive T cells involves regulatory (suppressor) T cells. In experimental animal models, there is evidence that $CD4^+$, $CD8^+$, and γδ T cells may be involved in the down-regulation of certain immune responses, and their absence may be associated with pathologic autoimmune responses. At least two subsets of regulatory $CD4^+$ T cell have been described that can inhibit cell-mediated immune responses and autoimmune pathologies: naturally occurring cells with suppressive activity and those induced by stimulation.[67,68] The naturally occurring regulatory $CD4^+$ T cells are characterized by constitutive CD25 expression and constitute 5% to 10% of the circulating $CD4^+$ population.[67–70] In murine model, depletion of these $CD4^+CD25^+$ T cells results in the spontaneous onset of multiorgan autoimmunity. These cells mediate their suppressive effects in a contact-dependent, antigen-independent manner in the absence of IL-10 or transforming growth factor-β (TGF-β). A novel member of the forkhead box/winged-helix family of transcription regulators, designated Foxp3, has been identified as a specific molecular marker for this type of regulatory T cell, and its expression is essential for programming both thymic development and function of these T cells.[67,71] In sarcoidosis, Foxp3-expressing regulatory T cells accumulate at the periphery of the granuloma in subjects with active disease.[72] However, despite suppressing mitogen-induced T cell proliferation, the regulatory T cells in lung could not completely suppress TNF-α and IFN-γ secretion, suggesting that the activity of this regulatory T-cell subset was incapable of controlling granulomatous inflammation. The other type of regulatory $CD4^+$ T cell is activation-induced, and these cells lack CD25 expression and are negative for Foxp3.[67] Much of the suppression from this group of regulatory cells can at least in part be attributable to cytokines such as TGF-β, because TGF-β is capable of suppressing both type 1 (Th1) and type 2 (Th2) T helper cell responses. It is relevant to note that mice made deficient in TGF-β by gene knockout techniques show evidence of progressive inflammation and autoimmunity involving multiple organs.[73] In some cases, regulatory $CD4^+$ T cells appear to release cytokines, such as IL-10 or even IL-4, that modulate the development and further activation of Th1-type cells involved in a cell-mediated response.[68,74,75]

GENERATION OF THE IMMUNE RESPONSE

T-Cell Activation and the Need for Co-stimulatory Molecules

Most immune responses depend on the activation of T cells, and normally, immune responses to foreign antigens are carefully orchestrated by a reciprocal communication between antigen-specific T cells and antigen-presenting cells. To be activated, naive T cells must receive several signals. One signal is antigen specific and is provided by engagement of the TCR. Additional signals are provided by co-stimulatory molecules and their interactions (Fig. 14-14). Resting antigen-presenting cells, such as resting B cells, frequently do not express significant levels of co-stimulatory molecules, and their interaction with T cells does not lead to T-cell activation. Furthermore, to be immunogenic, the antigen may need to be presented by antigen-presenting cells activated in an inflammatory context, such as during infection. Two of the most important co-stimulatory systems involve the interaction of CD28 with B7-1 (CD80) and B7-2 (CD86) and the interaction of CD40 ligand with CD40.[76] These two systems of interacting molecules also affect each other.

CD28 is constitutively expressed on $CD4^+$ T cells. Early in the immune response, B7-1 and B7-2 are up-regulated on the antigen-presenting cells. Binding of CD28 to B7 co-stimulates T-cell activation, leading to increased T-cell production of IL-2 and other cytokines,

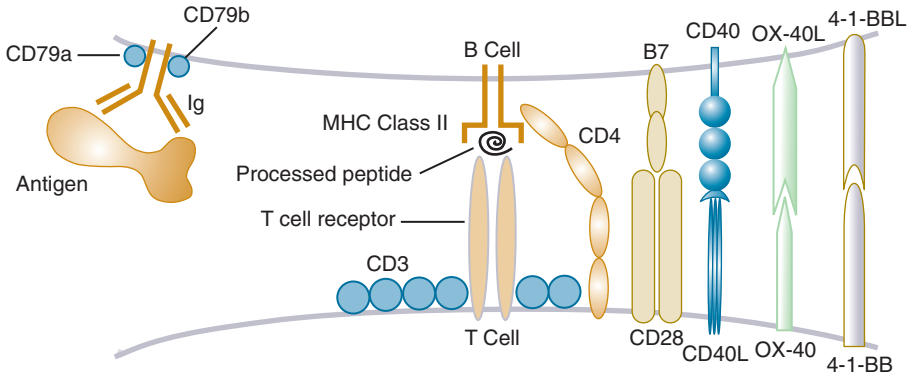

FIGURE 14-14 ■ T helper cell–B-cell interactions important for T-cell–dependent antibody production. Antigen cross-links membrane immunoglobulin (Ig) on the B cell (the BCR), which provides signal 1 for the B cell. CD79a (Ig-α) and CD79b (Ig-β) are Ig-accessory molecules necessary for transmitting the signal intracellularly. The antigen is internalized into an intracellular compartment in the B cell, processed to peptides, and combined with class II molecules for expression and presentation to the T helper cell. T-cell receptor (TCR) binding to the peptide/MHC provides signal 1 for the T cell. The CD3 complex and ζ chains allow for the TCR signal to be transmitted intracellularly. Activation of the T cell results in expression of CD40 ligand (CD40L), OX-40, and 4-1-BB. Interaction with CD40 provides the most important second signal to the B cell and is involved in T-cell activation. In addition, B7-1 (CD80) and B7-2 (CD86) are up-regulated on the B cell. Interaction with CD28 provides an important co-stimulatory signal to the T cell. This figure does not show the release of cytokines from the T helper cell that are necessary for full activation and differentiation of the B cell. In addition, this figure does not show other cellular interactions mediated by adhesion molecules. For example, the leukocyte function antigen (LFA)-1 integrin (CD11a, CD18) on the T cell interacts with intercellular adhesion molecule-1 (CD54) on the B cell. This interaction appears to be enhanced once the TCR and BCR have been engaged. CD2 on the T cell also interacts with LFA-3 on the B cell, which provides additional cell-cell adhesion.

increased cytokine receptor expression, increased cell survival, and increased T-cell proliferation.[77–79] Occupation of the CD28 receptor alone, without TCR engagement, appears to have little effect on T cells, and therefore, the signaling through CD28 is clearly a co-stimulatory event. The intracellular signaling events that occur after CD28 co-stimulation may overcome certain negative signals generated when the TCR is activated alone.[76,80,81]

Presentation in an inflammatory setting also leads to up-regulation of CD40 ligand (CD154) on the $CD4^+$ T cell.[82] CD40 ligand interacts with its counter-receptor, CD40, on B cells and other antigen-presenting cells, also inducing up-regulation of B7-1 and B7-2 as well as certain adhesion molecules and cytokine production by the presenting cell.[83] The interaction of CD40 ligand with CD40 is clearly bidirectional in that it provides signals important for T-cell and B-cell activation. CD40L is a member of the TNF receptor family, and a variety of other TNF receptor family members, such as CD134 (OX-40), CD137 (4-1BB), and CD27, have also been shown to possess co-stimulatory function following T-cell activation.[76,84] In chronic beryllium disease, CD137 has recently been shown to be the critical costimulatory molecule for the induction of T-cell proliferation and prevention of activation-induced cell death in effector $CD4^+$ T cells in lung.[85]

Other molecular interactions, especially involving adhesion molecules, have also been implicated in T-cell co-stimulation. For example, CD2 is expressed on T cells and binds to the lymphocyte function antigen (LFA)-3 molecule on antigen-presenting cells. CD2 also appears to be associated with the TCR complex and may be involved in signaling. CD2 is up-regulated on effector memory T cells, which has been used to allow selective targeting of this population by soluble LFA-3–Ig immunotherapy.[86] Other accessory molecules involved in adhesion of T cells to antigen-presenting cells, such as CD11a (LFA-1) and intercellular adhesion molecule (ICAM)-1, ICAM-2, and ICAM-3, are not specific for T-cell interactions but still may aid in achieving a threshold necessary for effective T-cell co-stimulation.

Following activation, T cells express cytotoxic T lymphocyte antigen-4 (CTLA-4) on their surface, which also binds B7-1 and B7-2 on the antigen-presenting cell and with stronger affinity than CD28.[87] This interaction appears to send a negative signal to down-regulate the T-cell response after its initial activation. CTLA-4 appears to be involved in the development of anergy and the generation of peripheral tolerance. CTLA-4–deficient mice develop a lymphoproliferative disorder and die early, and alterations in the gene encoding CTLA-4 have been associated with autoimmune endocrine diseases, further emphasizing the role of CTLA-4 in the control of lymphocyte homeostasis.[88,89] Programmed cell death 1 (PD-1) is another activation-induced inhibitory receptor that is expressed by T cells and binds B7 family members.[90] Similar to CTLA-4, PD-1 receptor engagement results in down-regulation of the immune response. Deficiencies of this gene have been associated with autoimmune diseases in animals and may be a possible gene contribution to human lupus.[91,92] In addition to these negative signals, down-regulation of the T-cell response may be further ensured by decreases in surface expression of CD40 ligand, OX-40, and 4-1BB after T-cell activation.[79,84]

As discussed earlier in the context of self-tolerance, engagement of the TCR on a naive T cell in the absence of co-stimulation can result in different outcomes.[76] In some situations, the outcome is a failure to stimulate,

and the T cell is oblivious to this encounter. At other times, recognition can induce death (apoptosis) of the responding T cells or anergy, in which case the T cells are unable to respond to a subsequent encounter with the same antigen (tolerance). Memory T cells appear to be less dependent on co-stimulatory molecules. However, antagonists that interrupt co-stimulatory interactions have been shown to have profound effects even later in the course of an established immune response. Blockers of the CD28-B7 interaction (with CTLA4-Ig, anti-B7, or anti-CD28 monoclonal antibodies) or of the CD40 ligand–CD40 interaction (with anti-CD40 ligand monoclonal antibodies), separately and together, are being investigated as therapies to treat autoimmune diseases and alloreactive responses after transplantation.[93–96] However, the recent development of cytokine storm in six healthy volunteers receiving the anti-CD28 monoclonal antibody TGN1412 as part of a phase 1 study demonstrates the potential risk of immunotherapy.[97]

Subsets of T Helper Cells

Although more sharply defined in mice than in humans, it is clear that T cells after activation may evolve into three major subsets of T helper cells, distinguished by the cytokines that they produce (Fig. 14-15).[57,74,75] Th1 cells mainly synthesize IL-2, IFN-γ and TNF-α, as well as other inflammatory cytokines, such as lymphotoxin and TNF. Th2 cells primarily are distinguished by their secretion of IL-4, IL-5, and IL-13. Th17 cells represent a distinct lineage of T cells from either Th1 or Th2 cells and express IL-17A, IL-17F, and IL-22.[98,99,99a,99b] These major types of T helper cells appear to serve very different functions. Th1 cells primarily enhance cell-mediated immune responses, such as delayed-type hypersensitivity reactions, which frequently involve activation of macrophages and effector T cells. Th2 cells mainly provide help for B cells by promoting class switching and enhancing the production of certain IgG isotypes and production of IgE. The ability to mediate an effective immune response against certain intracellular pathogens and the pathogenesis of certain diseases appears to be strongly influenced by the type of T helper cells involved. For example, in leishmaniasis and leprosy, the development of a response polarized toward the Th1 pathway is important for successful immune defense. The development of an early Th2 response may result in the inability to clear the offending organism. Inappropriately developed and activated Th1 cells have been implicated in the pathogenesis of certain autoimmune diseases, such as type 1 diabetes, multiple sclerosis, and rheumatoid arthritis. Th2 cells appear to be important for certain

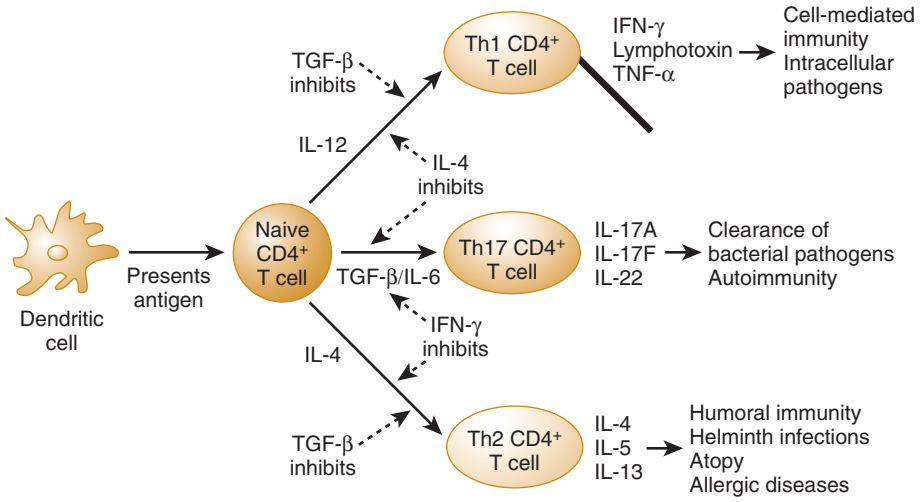

FIGURE 14-15 ■ Regulation of T helper cell activation and responses. Naive CD4⁺ T cells can develop into type 1T helper (Th1) cells if they are activated in the presence of interleukin (IL)-12, produced mostly by macrophages and other non–T cells. Interferon-γ (IFN-γ), increased by IFN-γ inducing factor (IL-18), also enhances the development toward a Th1 response. IFN-γ appears to increase the production of IL-12 and also the expression of receptors for IL-12. The generation of a Th1 response leads to the production of IL-2, IFN-γ, lymphotoxin (TNF-β), and TNF-α. These inflammatory cytokines are important for a successful immune response to intracellular pathogens. Inappropriate Th1 responses have also been implicated in organ-specific autoimmunity such as occurs in type 1 diabetes, multiple sclerosis, and rheumatoid arthritis. The early presence of IL-4 in the activation of a helper cell prevents Th1 responses and enhances the development of a type 2T helper cell (Th2) response. The source of the early IL-4 is not clear, but it may come from Th2 cells already present, NK1⁺ T cells, or non–T cells, such as mast cells and eosinophils. The Th2 response results in production of IL-4, IL-5, IL-10, and IL-13 and enhances humoral immunity. Although the Th2 cells are critical for the immune response to helminths, in the developed world, Th2 cells are probably most singled out for their important role in allergic disease and asthma. IL-4 and IFN-γ inhibit the development of a type 17 T helper cell (Th17) response that promotes bacterial clearance and may play a role in the development of autoimmunity. IL-6 and TGF-β promote the development of Th17 cells while IL-23 expressed by macrophages augments expression of Th17 cytokines by memory but not naive CD4⁺ T cells. Various regulatory CD4⁺ T cells have also been described. Regulatory CD4⁺ T cells secreting IL-10 have been shown to suppress Th1 responses. Regulatory T cells secreting transforming growth factor-β (TGF-β) have the capability to suppress both Th1 and Th2 responses. Evidence suggests that, in addition to the cytokines present at the time naive CD4⁺ T cells are stimulated, the type of dendritic cell may regulate the differentiation of CD4⁺ T cells into Th1, Th2, or Th17 subsets.

immune responses.[19] Eradication of helminths is Th2 dependent. However, Th2 cells also appear to be involved in disease by driving allergic responses, such as IgE production and eosinophil activation in asthma (see Chapter 38).[19] Th17 cells function at the interface between the innate and adaptive immune response, secreting cytokines that are important in bacterial clearance and in the pathogenesis of autoimmunity. Evidence suggests that in collagen-induced arthritis, T-cell–mediated colitis and experimental autoimmune encephalitis, Th17, as opposed to Th1, cytokines are critical for the induction and maintenance of inflammation.[100-102]

It has become clear that the Th1, Th2, and Th17 subsets develop from the same T-cell precursor, which is a naive $CD4^+$ T lymphocyte producing mainly IL-2 after stimulation with antigen. Considerable evidence indicates that the cytokine microenvironment is the primary determining factor for Th1, Th2, or Th17 differentiation (see Fig. 14-15).[57,74,75,98,99] IL-12 and IFN-γ have been shown to be most important in directing the development of Th1 cells that then go on to produce IFN-γ and TNF-α. IL-12 is produced by antigen-presenting cells (e.g., macrophages and dendritic cells) in response to Toll-like receptor stimulation by pathogens. IL-12 drives Th1 differentiation through signal transducer and activator of transcription 4 (STAT-4) and the activation of a unique Th1 transcription factor known as T-box expressed in T cells (T-bet).[103,104] Microbial products frequently induce macrophages and NK cells to release IFN-γ, which is involved in driving development of Th1 cells from their naive precursors. IFN-γ up-regulates a component of the IL-12 receptor on naive and differentiating T cells.[105] However, some organisms, such as the measles virus, have the ability to down-regulate IL-12 production by macrophages and therefore possibly evade destruction by cell-mediated immune responses. Early production of IFN-γ by Th1 cells and NK cells has been related to the production of IFN-γ–inducing factor (IL-18), and this cytokine may synergize with IL-12 for maximal early production of IFN-γ and Th1 development.

In a similar but opposite manner, the presence of IL-4 early in the immune response induces Th2 cell development from naive precursors through STAT-6, which leads to activation of the transcription factor GATA-3 and up-regulation of IL-4 and IL-5.[104,106] The effects of IL-4 in inducing Th2 development appear to be dominant over Th1- and Th17-polarizing cytokines.[74,75,107] Thus, if IL-4 levels exceed a threshold, Th2 development ensues, which leads to additional IL-4 production. Th2 cells do not respond to IL-12, which may be related to the ability of IL-4 to down-regulate expression of a component of the IL-12 receptor. The source of early IL-4 may include naive or differentiated $CD4^+$ T cells or both; the $NK1^+$ T-cell subset, which may be $CD4^+$ or double-negative; and various non–T-cell sources, such as mast cells, basophils, and eosinophils.[74,75,104]

TGF-β and IL-6 are necessary for the differentiation of naive $CD4^+$ T cells into Th17 cells.[107-109a] The orphan nuclear receptor, RORγt, is the master transcription factor in the differentiation of Th17 cells.[110] Expression of RORγt is TGF-β– and IL-6–dependent and is both necessary and sufficient to induce Th17 development in most $CD4^+$ T cells.[98] Unlike t-bet and GATA-3, the ligand of RORγt remains unknown. In the absence of IL-6, IL-21, in combination with TGF-β, can induce Th17 cells using an IL-6–independent pathway. IL-21 is also highly expressed by Th17 cells, and IL-21 production creates a positive feedback loop to further amplify Th17 responses in vivo.[107] Despite the finding that IL-23 signaling is not required for Th17 commitment and early IL-17 secretion, IL-23 is also important in amplifying and/or stabilizing the Th17 phenotype.[98]

The cytokines produced by Th1, Th2, and Th17 subsets cross-regulate one another's development and function. For example, IFN-γ produced by Th1 cells inhibits the development of Th2 and Th17 cells as well as certain humoral responses.[74,75,104] In a similar manner, IL-4 produced by Th2 cells inhibits Th1 and Th17 development and activation as well as macrophage activation by Th1 cytokines. IL-4 and IL-10 have the ability to inhibit both dendritic cell and macrophage IL-12 production. In addition, it is possible that the transcription factors GATA-3 and T-bet antagonize the development of the opposite T-cell subset by directly opposing each other's expression.[104,106] TGF-β also inhibits the development of Th1 and Th2 phenotypes.[104]

Following antigen exposure, naive T cells become activated, proliferate, and migrate to sites of inflammation. While the majority of antigen-primed cells die, a population of memory T cells develops, which allows for a more rapid and effective secondary immune response upon reexposure to antigen.[111,112] There appear to be at least two subsets of memory T cells, possessing different functional and migratory capabilities compared with naive lymphocytes. The effector memory T cell represents a terminally differentiated cell that immediately produces cytokine following antigen exposure and lacks the lymph node homing receptors L-selectin and CCR7. Conversely, central memory T cells express both L-selectin and CCR7, and these cells have the ability to differentiate into effector memory cells after restimulation. Thus, it is not surprising that the majority of $CD4^+$ T cells that localize to the lung express an effector memory phenotype.[113]

Signaling between cells of the immune system takes place both by direct cell-cell interactions involving surface molecules on interacting cells and by cytokines. In general, cytokines are designed to work at short distances and are frequently delivered in a directed fashion from the producing cell toward the cell receiving the communication. Cytokines are critically involved in both the generation and regulation of specific immune responses and the activation of nonspecific cells at sites of inflammation. The identification and detailed function of various inflammatory cytokines are described in Chapter 16.

$CD4^+$ T-Cell–B-Cell Collaboration and Regulation of Antibody Production

A central event in the immune response is the antigen-specific interaction between a T helper lymphocyte

and a B lymphocyte, which leads to their mutual activation. Although some antigens (usually nonproteins derived from bacteria) can activate B cells in a T-cell–independent fashion, the antibody response to most protein antigens requires that the relevant B cell must recognize antigen with its surface Ig receptor, and that it must also receive certain activation signals from a $CD4^+$ T helper cell. These signals include both secreted T-cell–derived lymphokines and those resulting from cell-cell contact. T-cell recognition of antigenic peptides bound to class II MHC molecules on the B-cell surface and co-stimulatory signals lead to T-cell activation and secretion of T helper lymphokines. Secretion is directed toward the site of contact with the B cell. Thus far, no combination of known T-cell–derived factors can fully replace contact with the T helper cell, indicating that the interaction of surface molecules provides additional signals to the B cell that promote its activation. Numerous interacting molecules have been identified that could transmit signals in the T-cell–B-cell interaction (see Fig. 14-14). This figure does not show the exchange of T-cell–derived helper cytokines and the binding to their corresponding receptors on the B cell.

Similar to the process of effective T-cell stimulation, which requires interaction of TCR with antigen/MHC and co-stimulatory signals, B cells also need more than one signal for activation to take place. The first signal is provided by antigen binding to surface Ig (BCR), and cross-linking of multiple receptors is usually required. The B cell then processes and presents the antigen via its class II MHC molecule to a cognate T helper cell that is specific for that peptide/MHC complex. A major second signal to the B cells occurs via CD40 on its surface through interaction with up-regulated CD40 ligand on the T helper cell. After receiving additional co-stimulatory signals from up-regulated B7-1 and B7-2 on the B cells, the activated T helper cell delivers cytokines in a focused manner to the antigen-specific B cell it is helping. Although many reciprocal receptor-ligand pairs are expressed on T cells and B cells, the signaling between CD40 ligand and CD40 has emerged as an obligatory and nonredundant interaction for functional T-cell–dependent B-cell activation to occur.[94] The signals transduced by CD40 are essential for the prevention of apoptosis of antigen-specific B cells in the germinal center and essential for B-cell proliferation and differentiation, isotype switching, and formation of memory B cells. Mutations in the CD40 ligand gene cause X-linked hyper-IgM syndrome, characterized by absent or low levels of IgG, IgA, and IgE (Ig isotypes that require T-cell help) but normal or elevated levels of IgM. Because T-cell activation also requires co-stimulatory signals through CD40 ligand, these individuals also demonstrate defects in T-cell–mediated immunity and defective T-cell activation.[114]

Interactions between LFA-1 and ICAM-1, as well as CD2 and LFA-3, are involved in T-cell–B-cell adhesion. Antigen receptor stimulation also increases the interaction between LFA-1 and ICAM-1 as well as the interaction between CD2 and LFA-3.

T-cell help is required for effective antibody responses, especially those involving specific high-affinity antibodies of the IgG, IgA, and IgE isotypes. However, as emphasized earlier, T-cell–B-cell signaling is clearly bidirectional. After resting T cells are activated, which frequently requires specialized antigen-presenting cells such as dendritic cells, antigen-specific B cells may be the most efficient presenters of determinants of a specific antigen.[115] The helper $CD4^+$ T cell recognizes a processed antigen presented on the B cell in the context of class II MHC antigens. The B cell focuses antigen for antigen-specific help by binding antigen through its Ig receptor, internalizing and processing the antigen, and presenting the derived peptides with class II MHC molecules (see Fig. 14-14). It is important to emphasize that the epitope on the native antigen recognized by the B cell is almost always different from the peptide epitope recognized by the helper T cell.

Subsequent to T-cell recognition, the T cell is activated, and help for B-cell proliferation and differentiation can be provided. T-cell help is critically dependent on the T-cell release of various cytokines, as described earlier. These cytokines have marked effects on B-cell maturation, especially in determining which isotypes will be produced by the B cell. The reciprocal surface molecular interactions, the directed nature of T cell cytokine release, and the controlled local action of these molecules result in "focused T-cell help" without generalized bystander activation of surrounding B cells.

Generation and Regulation of Cell-Mediated Immune Responses

Cell-mediated cytotoxicity is an essential defense against intracellular pathogens, including viruses and certain bacteria and parasites. Cytotoxic T cells are stimulated by presented endogenous antigens, most of them derived from intracellular pathogens and associated with class I MHC molecules. In contrast to most helper cells that express CD4, cytotoxic T cells are usually $CD4^-CD8^+$. The recognition of the antigen presented by class I MHC molecules triggers the T cell to express receptors for IL-2. Although some cytotoxic lymphocytes are able to produce their own IL-2, most depend on IL-2 produced by helper $CD4^+$ T cells of the Th1 type. The binding of IL-2 and possibly other cytokines leads to some proliferation and to the development of cytotoxic function. $CD4^+$ T helper cells (Th1 type) provide additional signals and cytokines for the generation of a maximal cytotoxic response.

Activated effector cells are capable of delivering a lethal message to a target cell, separating from their dying target, and going on to strike a new target. This creates a very efficient system of killing unwanted cells. Several mechanisms are involved in the actual killing process.[116–119] For example, cytotoxic T cells can directly signal their targets to undergo apoptosis through the interaction of Fas ligand, expressed on the surface of activated T cells, with Fas on the target cell. Stimulation of the Fas receptor results in recruitment of the caspase-8

through interaction with the adapter molecule, Fas-associated death domain protein (FADD).[116] Caspase-8 activation results in either direct caspase-3 activation or cleavage of BH3 interacting domain (BID) and translocation of BID and BCL-2 associated X protein (BAX) to the mitochondria. Once inserted into the mitochondrial membrane, BID and BAX induce the release of mitochondrial cytochrome c, which results in caspase-9 activation and ultimately activation of caspase-3. The cytotoxic T cell also produces substances such as lymphotoxin (TNF-β), trimers of which bind to receptors on the cellular targets and signal for apoptosis. During binding to the target cell, the cytotoxic $CD8^+$ T cells also release the contents of their granules, which include perforins and granule-associated serine esterases (granzymes), toward the adjacent membrane of the target cell. Released perforins assemble on the surface of the target cell and perforate the target cell plasma membrane, resulting in lysis and the entry of enzymes. The transmembrane channel created by the perforins resembles the membrane attack complex of the complement cascade. After entry into the target cell, activated granzymes released from the cytotoxic T cell activate proteins that mediate apoptosis as well as cause other types of cell damage.

SPECIFIC IMMUNE RESPONSES IN THE LUNG

Lymphocyte Populations and Trafficking in the Lung

The lung in healthy individuals usually harbors only a small number of lymphocytes.[120,121] The location of $CD4^+$ and $CD8^+$ αβ T cells can be arbitrarily separated into four compartments: bronchoalveolar space, bronchus-associated lymphoid tissue (BALT), lung interstitial tissues, and intravascular space. Although lymphocytes from these different positions may be involved in lung immune responses, there is no clear indication that these cells represent a resident lymphocyte population in the lung in humans. More likely, these lymphocytes belong to the recirculating lymphocyte pool. In contrast, γδ T cells have been localized to intraepithelial positions in the lung, and these cells may selectively reside in the lung.[28]

In a normal nonsmoking individual, lymphocytes account for approximately 10% to 15% of the bronchoalveolar cells obtained during bronchoalveolar lavage.[121] The number of bronchoalveolar lymphocytes can increase markedly in inflammatory diseases involving the alveoli and the interstitium, such as in sarcoidosis and hypersensitivity pneumonitis (see Chapters 59 and 66). Most bronchoalveolar lymphocytes are T cells, and essentially all of these cells express memory cell markers (e.g., CD45RO and low CD62L), indicating previous activation.[113] In disease, a significantly increased percentage of these T cells, compared with those in peripheral blood, also express markers of recent activation, such as HLA-DR, IL-2 receptor (CD25), and CD69.

BALT is a localized collection of lymphocytes in the subepithelial area of bronchi, analogous to gut-associated lymphoid tissue (e.g., Peyer's patches).[122] These lymphoid aggregates are separated from the airway lumen by a lymphoepithelium composed of flattened epithelial cells, which lack cilia. BALT also contains HEVs facilitating the recirculation of lymphocytes between blood and lymph. However, unlike gut-associated lymphoid tissues in the form of Peyer's patches, which are present in all mammals, BALT is only regularly present in some mammalian species. Indeed, it is usually absent in humans as long as there is no respiratory tract infection. Evidence suggests that BALT may appear in patients after chronic airway inflammation and chronic obstructive pulmonary disease.[123,124]

The interstitium of the normal lung contains few lymphoid cells, and most of these are not T cells. The majority of interstitial lymphocytes are NK cells, which constitute 10% to 15% of circulating lymphocytes. These cells do not express TCR or Ig but express markers characteristic of both T-cell and myelomonocytic lineages.[6] NK cells recognize and kill tumor cells and virus-infected cells in a nonspecific manner.[6] These cells also kill targets coated with antibodies via surface receptors for IgG (FcγRIII or CD16) in a process known as antibody-dependent cellular cytotoxicity. Furthermore, NK cells can also be an important source of cytokines (e.g., IFN-γ, TNF-α, and granulocyte-macrophage colony-stimulating factor [GM-CSF]) early in the immune response.

γδ T cells constitute only 0.5% to 10% of the peripheral blood lymphocyte population in humans.[28] However, they represent an enriched T-cell population in the pulmonary epithelium, intestinal epithelium, and skin. Unlike αβ T cells, epithelial γδ T cells do not recirculate and appear to represent resident pulmonary lymphocytes. The population of γδ T cells in the lung of normal adult C57BL/6 mice is approximately 2 to 5×10^4 cells, with the majority being either $V\gamma4^+$ or $V\gamma1^+$.[125] Importantly, the different γδ T cell subsets are thought to have different functional capabilities. For example, $V\gamma1^+$ γδ T cells enhance airway hyperresponsiveness while Vγ4 γδ T cells suppress this response in a murine model of asthma.[126] The pulmonary γδ T cells preferentially interact with $F4/80^+$ macrophages and MHC class II–expressing dendritic cells, suggesting that γδ T cells represent a primitive line of defense evolved to protect epithelial integrity and provide a possible bridge between innate immunity and acquired immune responses.

The distribution and trafficking of lymphocytes is governed by interactions between molecules on the lymphocyte surface and ligands present on vascular endothelial cells. The migration of lymphocytes from the bloodstream is not a random event, and this migration appears to be restricted to lymphoid tissue and areas of inflammation.[7] Naive T cells lack the ability to initiate an antigenic response until they are activated within a secondary lymphoid organ. Evidence indicates that their initial interaction with an antigen entering through the lung takes place in the surrounding lymphoid tissues and not in the lung directly. Naive and resting lymphocytes represent the major population that recirculates from blood to lymph via HEVs, with the initial attachment mediated by the homing receptor L-selectin (CD62L)

to peripheral lymph node addressin (PNAd) and glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1) on the surface of endothelial cells.[7] This interaction results in lymphocyte tethering and rolling along the endothelial surface. Subsequent binding of chemokines (e.g., stromal cell–derived factor-1α, 6-C-kine, and macrophage inflammatory protein-3b) to G protein–coupled receptors on the lymphocyte surface leads to activation of integrin molecules (LFA-1).[7] After activation, LFA-1 binds to ICAM-1 on the vascular endothelium, resulting in firm adhesion.[7] This is followed by transendothelial migration of the lymphocyte into the lymphoid tissue. A second family of G protein–coupled receptors, known as sphingosine-1-phosphate receptor-1, is required for lymphocyte egress from the lymph node.[127] As stated earlier, BALT consists of diffuse lymphoid aggregates found in the bronchial mucosa of most mammals.[122] In contrast to HEVs in other secondary lymphoid organs, BALT HEVs express high levels of vascular cell adhesion molecule-1 (VCAM-1), which binds $\alpha_4\beta_1$ integrin on T cells. Thus, an adhesion cascade exists involving L-selectin/PNAd, $\alpha_4\beta_1$ integrin/VCAM-1, and LFA-1/ICAM-1, which targets specific lymphocyte populations to BALT and other bronchopulmonary tissues.[7,122]

Effector and memory T lymphocytes appear to have distinct pathways of lymphocyte recirculation compared with naive lymphocytes.[7] Effector T cells, especially after activation in the lymphoid tissues, travel to regions of inflammation where chemokines and other chemotactic molecules are generated by the underlying inflammatory process.[7] Expression of various adhesion molecules on the lymphocyte and binding to their appropriate molecular targets expressed on inflamed vascular endothelium allow cells to enter sites of inflammation.[7] The expression of ICAM-1, P-selectin, and VCAM-1 on the surface of inflamed vascular endothelium is involved in lymphocyte entry into areas of inflammation.[7] Tissue tropism is established by the expression of different combinations of adhesion molecules that allow a different subset of effector cells to home to different sites. For example, circulating memory lymphocytes specific for skin-associated antigens express the cutaneous lymphocyte antigen.[7] Conversely, memory for intestinal antigens has been localized to circulating lymphocytes expressing high levels of $\alpha_4\beta_7$ integrin.[7] Thus, memory T cells display selective homing to the tissue type where antigen encounter first occurred.

Antibody-Mediated Immune Responses in the Lung

Immune Response to Extracellular Pathogens

The humoral immune response is adapted for elimination of extracellular pathogens. An example of an antibody-mediated immune response is the response that occurs after exposure to *Streptococcus pneumoniae*. This bacterium frequently colonizes the nasopharynx and is the most common cause of community-acquired pneumonia.[128] Pneumococci gain access to the lower respiratory tract via aspiration. The upper airways are equipped with clearance mechanisms (e.g., mucociliary clearance and cough) that effectively eliminate most inhaled or aspirated bacteria from the airways (see Chapter 12). If the aspirated pneumococcus evades the upper airway defenses, the pathogen first encounters the mucosal humoral immune system. IgA provides the first line of defense against infectious agents, with IgG and IgM being less important in the bronchial secretions. The major functions of secretory IgA include the prevention of microbial adherence to the epithelial surface and the promotion of the agglutination of microorganisms. The combination of inhibition of adhesion and microbial agglutination favors the clearance of pneumococci via mechanical forces. Unlike IgG, IgA is unable to activate complement, and it is not an effective opsonin.

The first exposure of the host to the pneumococcus generates a primary humoral response. Bacteria in the lung are bound by antigen-presenting cells, which migrate to secondary lymphoid organs, where antigens are processed and presented with class II MHC molecules to $CD4^+$ T cells (Fig. 14-16). After TCR binding and effective co-stimulation enhanced by an inflammatory environment, activation of specific T cells occurs, and multiple T helper cytokines are elaborated. During this process, naive B cells in the lymph node bind unprocessed antigen via surface IgM and present peptide fragments to specific T helper cells via class II MHC molecules. T-cell–B-cell interactions in the germinal

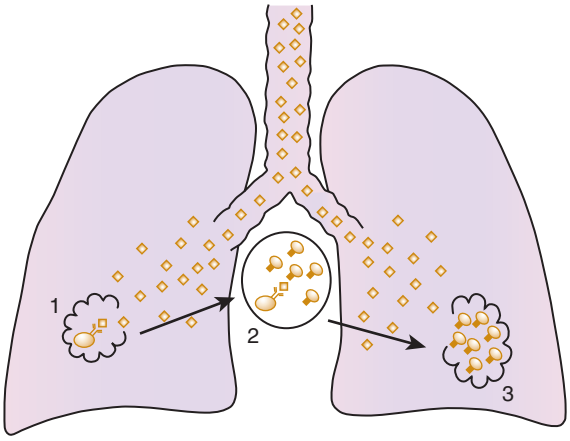

FIGURE 14-16 ■ Immune responses in the lung. Antigen (e.g., bacterial pathogen) enters the lung. Microbial products create an inflammatory environment. **1,** Antigen is taken up by nonspecific phagocytic cells and transported to regional lymph nodes. **2,** In the lymph nodes, a primary immune response is generated. Antigen-specific T cells are stimulated, and initial T helper cell–B-cell interactions and antibody production take place in the germinal centers. **3,** Antibodies, T helper cells, and effector cells circulate back to the lung for the immune response to target the pathogen. Trafficking of inflammatory cells is enhanced by the production of chemokines and other chemotactic factors and involves interactions of leukocytes with endothelial cells in the area of inflammation. In the process of the initial immune response, memory T cells and B cells are generated. This allows for a more effective secondary immune response to occur if the same pathogen is encountered at a later time.

centers lead to additional T-cell and full B-cell activation, characterized by clonal proliferation, isotype switching, and differentiation of B cells into secreting cells and memory cells. Subsequently, specific antibody, activated T cells, and perhaps some activated B cells circulate back to the lung to combat the pneumococcal infection.

In the area of infection, IgG1, IgG3, and IgM specific for intact pneumococcal antigens activate the complement system, resulting in some bacterial cell lysis. More important, antibody and complement act as opsonins, enhancing phagocytosis of encapsulated microorganisms. The release of mediators from activated T cells also enhances the antibacterial capacity of recruited nonspecific inflammatory cells in the lung. These events occur over a 4- to 7-day period and characterize the initial phase of a primary response. The time needed for peak response is approximately 7 to 10 days. The presence of memory B and T cells ensures that repeat exposure to *S. pneumoniae* results in a secondary immune response, which is characterized by a shorter lag phase and thus a more rapid response, a greater magnitude of antibody response, and a longer duration of response. Clinically, pneumococcal vaccination, which induces a primary humoral response, has decreased the rates of invasive pneumococcal disease in both children and adults.[129]

Immune Response to Autoantigens

Autoimmune disorders result when the normal mechanisms of immune self-tolerance fail. Essentially all autoimmune diseases, including antibody-mediated autoimmune diseases, appear to be dependent on the inappropriate activation of autoreactive $CD4^+$ T cells as well as on the autoreactive B cells responsible for the pathogenic autoantibodies. One example of an autoimmune disease involving the lung is Goodpasture's syndrome. This syndrome is characterized by pulmonary hemorrhage and glomerulonephritis, which are associated with elevated levels of IgG antibodies directed against basement membrane antigens. In various studies, pathologic damage has been shown to be directly dependent on the binding of these autoantibodies, which are primarily directed against the noncollagenous domain ($\alpha 3$ chain) of type IV collagen in basement membrane.[130-132] Immunofluorescent staining with anti–human IgG antibodies usually reveals a linear deposition of IgG in the glomerular and alveolar basement membranes. Despite the widespread distribution of type IV collagen in the body, disease expression is mostly limited to the lungs and kidneys. This limited disease expression suggests the possibility that other factors allow exposure of this autoantigen selectively in alveolar or glomerular basement membranes. In this regard, influenza A2 infection, hydrocarbon inhalation, and cigarette smoking have been associated with the initial episode of diffuse alveolar hemorrhage and exacerbation of disease in the setting of elevated levels of anti–basement membrane antibodies.[133] Much is now known regarding how autoantibodies cause damage in an autoimmune disease such as Goodpasture's syndrome. More recently, HLA associations and the B and T cell epitope have been identified.[134] HLA DRB1*1501 is strongly associated with the development of Goodpasture's disease whereas HLA DRB1*0701 and DRB1*0101 confer protection against development of this disease. In addition, the T-cell epitope has been mapped to the amino-terminal region of the $\alpha 3$ chain of type IV collagen.[135] As noted earlier, activation of both autoreactive $CD4^+$ T cells and autoreactive B cells appears to be necessary for a pathologic autoimmune response. These autoreactive $CD4^+$ T cells require CD28 co-stimulation, because blockade of this co-stimulatory molecule reduces anti–basement membrane antibody production and prevents the development of experimental autoimmune glomerulonephritis.[136]

Studies have identified an autoimmune etiology underlying the development of acquired pulmonary alveolar proteinosis.[137] This disorder is characterized by the accumulation of a periodic acid–Schiff staining, granular, eosinophilic material within the alveolar space (see Chapter 63). Based on the development of pulmonary alveolar proteinosis in mice rendered deficient in GM-CSF, a fundamental role of this factor in surfactant homeostasis has been discovered.[138] In addition, the presence of neutralizing IgG autoantibodies directed against GM-CSF have been identified in the bronchoalveolar lavage fluid and serum of all patients with acquired pulmonary alveolar proteinosis, but not in individuals with the congenital or secondary form of the disorder or in normal control subjects.[139] The detection of this IgG autoantibody is highly sensitive and specific and thus useful in the diagnosis of the acquired form of this disease. More recently, mutations in the ligand-binding α-chain of the GM-CSF receptor have been identified in patients with pulmonary alveolar proteinosis.[140]

Immune Response in Allergic Disease

Atopic asthma results when an immune response and IgE antibodies are directed against normally harmless proteins present in the environment (see Chapter 38). Numerous cell types, including mast cells, eosinophils, macrophages, and $CD4^+$ T lymphocytes, as well as the specific IgE-secreting B cells, are important in the development of allergy and asthma. The $CD4^+$ T cells, which accumulate in the lungs of asthmatics, display a Th2 phenotype,[141] and studies using murine asthma models have shown that allergic airway inflammation is dependent on Th2-type $CD4^+$ T cells. As discussed earlier, the development of a Th2 response is prompted by exposure of naive $CD4^+$ T cells to IL-4 at the beginning of an immune response.[74,75,104,106] In the presence of high expression of IL-4 and low IFN-γ, these Th2 $CD4^+$ T cells induce isotype switching in antigen-specific B cells to IgE.[142] The elevated levels of IgE in the asthmatic are essential for the immediate hypersensitivity response. The presence of IL-4 and IL-5 and the production of various chemokines during T-cell activation also enhance accumulation of eosinophils and basophils in the airways. Studies in murine models of allergic asthma have suggested an important role for another Th2 cytokine, IL-13, which was capable of inducing the pathologic features of asthma independent of IgE and eosinophils.[143] Related

to the Th2 dependence of asthma in humans, susceptibility to disease has been linked to loci on chromosome 5q, which contains the genes for IL-4 and IL-13.[144] Studies also suggest that genetically determined abnormalities in antigen-presenting cells may also play a role in the development of allergic reactions. In atopic individuals, antigen-presenting cells were shown to underproduce IL-12 or overproduce prostaglandin E_2, which favors a Th2 response.[145]

Cell-Mediated Inflammatory Responses in the Lung

Cell-mediated immune responses can be divided into two major categories: (1) $CD4^+$ T cells that mediate delayed-type hypersensitivity reactions and (2) $CD4^+$ T cells that help effector T cells with cytotoxic function.

Granulomatous Lung Disease

Granulomas are characteristic of infections that live at least partly intracellularly, such as *Mycobacterium tuberculosis*, *Mycobacterium leprae*, and organisms that are large and persistent. There is considerable evidence to suggest that $CD4^+$ T cells and the elaboration of Th1 cytokines are required for maximal granulomatous inflammation in the response to these infections. The triggering event in the development of noninfectious granulomatous lung disease is the deposition of antigen in the lung parenchyma. In the case of chronic beryllium disease[85,146] and hypersensitivity pneumonitis (see Chapter 66), the antigenic stimulus is known. In sarcoidosis, the inciting agent is unknown, although the immunopathogenic events are believed to be the same (see Chapter 59).[147] Thus, the unknown antigen is likely to be engulfed by antigen-presenting cells (i.e., dendritic cells and macrophages) in the lung parenchyma and presented to naive $CD4^+$ T cells in the peripheral lymphoid organs. Exposure of these activated naive $CD4^+$ T cells to IL-12 released by macrophages, and in the absence of IL-4, directs the T cell toward a Th1 response.[74,75,104,106] The development of a Th1 response is also influenced by early release of IFN-γ through the up-regulation of IL-12 production by macrophages and through the up-regulation of receptors for this cytokine on Th1 cells.

Production of chemokines and other chemotactic factors at the site of inflammation in the lung directs migration of activated effector $CD4^+$ T cells to the lung. The Th1 cytokines and other mediators produced by these T cells are responsible for the recruitment and activation of macrophages and other nonspecific inflammatory cells. The accumulation of inflammatory cells within the alveolus (alveolitis) appears to be the initial lesion characterizing sarcoidosis and other granulomatous lung diseases. In sarcoidosis, the accumulated $CD4^+$ T cells (obtained at bronchoalveolar lavage) include expanded subsets, identified by expression of particular TCR Vβ and Vα regions. Within these subsets are expansions of T-cell clones, each with a unique TCR β chain and α chain sequence. The presence of these oligoclonal expansions indicates a T-cell response to conventional peptide antigens, and the presence of different T-cell clones with related TCRs indicates a response to the same antigen. Both the HLA haplotype (the presenting class II MHC molecule) in an individual and stimulating antigen(s) will determine the TCRs utilized in these T-cell responses. In chronic beryllium disease, particular HLA-DP alleles (e.g., *HLA-DPB1* alleles expressing a glutamic acid residue at the 69th position of the β-chain) appear to be most important in the presentation of antigen to beryllium-specific T cells,[148] and this likely explains the increased disease susceptibility in individuals with the same HLA-DP alleles.[149] $CD4^+$ T-cell clones expressing similar TCRs (with the same V regions and highly similar CDR3 regions) have been noted to be expanded in the lungs of different individuals with chronic beryllium disease, reflecting similarities in presenting MHC class II molecules and the same stimulating antigen (beryllium).[146] In sarcoidosis, an association between the TCR usage of Vα2.3 and HLA-DR17 (DR3) expression has been reported.[150] It is important to emphasize that the pathologic T-cell responses in these diseases are compartmentalized to the lung, because the same T-cell clones are either absent or rare in the peripheral blood.[113]

The major effector cells of inflammation in chronic beryllium disease, sarcoidosis, and other granulomatous diseases appear to be macrophages primarily derived from circulating monocytes during the process of inflammation. Activated alveolar macrophages express MHC class II molecules and may contribute to antigen presentation. The formation of noncaseating granulomas occurs by coalescence of activated macrophages, which can also fuse to form multinucleated giant cells. $CD4^+$ T cells predominate in the center of the noncaseating granuloma, with $CD8^+$ T cells located at the periphery of the granulomatous response.

Cytotoxic T-Cell Reactions in the Lung

Cytotoxic T lymphocytes (CTLs) are critical in the recognition and elimination of virus-infected cells and tumor cells as well as in allograft rejection. These cells predominantly express CD8, although $CD4^+$ CTLs and NK cells may also be involved in cytotoxic T-cell responses. $CD4^+$ T helper cells are almost always required for full expression of a cytotoxic T-cell reaction. CTL responses have been detected in humans after infection with numerous viruses, including respiratory syncytial virus, parainfluenza, and influenzas A and B. Once a $CD8^+$ CTL recognizes a respiratory syncytial virus–infected cell, there are at least three distinct mechanisms by which the CTL can induce cell death.[116–119] Thus, as discussed earlier, the cytotoxic T cell can secrete cytotoxic cytokines such as TNF-α and IFN-γ in the vicinity of the target cell. In addition, direct contact between the activated CTL can be followed by the release of granule enzymes, including perforins and granzymes, which cause pore formation in the membrane of the target cell and enzyme-mediated apoptosis. The third mechanism

of CTL-induced cell death involves the interaction of Fas ligand on the surface of the CTL with Fas on the target cell. $CD4^+$ CTLs do not have cytotoxic granules and primarily utilize Fas-mediated apoptosis as their mechanism of cytotoxicity.

NK cells have a role complementary to that of CTLs in combating virus-infected cells or tumor cells.[6] NK cells constitute 5% to 10% of peripheral blood lymphocytes and appear to form the first line of defense against viral infection, providing nonspecific cytotoxic activity. These cells differ from CTLs in their lack of TCRs, and they recognize their targets in a non–MHC-restricted fashion. However, the mechanism of NK cell killing appears to be similar to that employed by $CD8^+$ CTLs. In addition, NK cells have receptors for IgG (FcγRIII; CD16) and can bind to the Fc region of antibody attached to the surface of a target cell and mediate antibody-dependent cellular cytotoxicity.

KEY POINTS

- The health of the lung and the individual depends on a functional immune system to protect against microbial invasion.
- Pathogens are targeted by both specific humoral immune responses and a variety of cell-mediated responses that result in the accumulation and activation of leukocytes.
- Although effector leukocytes may be both antigen specific and antigen nonspecific, essentially all of these immune responses are dependent on specific T (helper) cells for full expression and maximal effect.
- The vast array of pathogens and their large number of strategies to subvert the immune system is combated by a system of defense with remarkable specificity and yet enormous diversity. These capabilities are achieved through unique molecular mechanisms of BCR and TCR repertoire formation, which are fundamental for understanding the immune response.
- The generation and regulation of specific immune responses are also dependent on a complex series of molecular and cellular interactions.
- In occasional individuals, the defense system may break down, and in others, aberrant immune responses appear to contribute to various pathologies relevant to the lung and respiratory tract. With additional knowledge regarding the structure and function of the immune system, it is likely that new insight into these diseases will occur and that new therapeutic approaches will be conceived.

CHAPTER 15

GENERAL FEATURES OF NON-NEOPLASTIC RESPIRATORY PATHOLOGY

Rubin M. Tuder, MD • Stephen Groshong, MD • Carlyne D. Cool, MD

INTRODUCTION

LUNG PROCESSING

ACUTE LUNG PROCESSES
Diffuse Alveolar Damage
Acute Bronchopneumonia
Diffuse Alveolar Hemorrhage
Acute Eosinophilic Lung Processes
Acute/Subacute Lymphocytic Lung Processes
Organizing Pneumonia

INTERSTITIAL LUNG FIBROTIC PATTERNS
Acute Interstitial Pneumonitis
Usual Interstitial Pneumonitis
Desquamative Interstitial Pneumonitis
Lymphocytic Interstitial Pneumonitis
Nonspecific Interstitial Pneumonitis
Other Forms of Idiopathic Interstitial Lung Pattern

GRANULOMATOUS LUNG PATTERNS

BRONCHIOLAR DISEASE PATTERNS
Chronic Bronchiolitis
Granulomatous Bronchiolitis
Obliterative Bronchiolitis

PULMONARY VASCULAR DISEASE PATTERNS

TRANSBRONCHIAL BIOPSY

INTRODUCTION

Pulmonary pathology plays a central role in the management and diagnosis of patients with lung diseases. Furthermore, the autopsy assessment of lungs provides important data regarding underlying acute or chronic disease in a high number of cases. Proper histopathologic interpretation of the lung requires a solid grasp of fundamental cellular processes, including inflammation and repair, neoplasia, and vascular alterations. Furthermore, the complexity of the normal gross and microscopic anatomy of the lung imposes significant challenges for the proper histopathologic alterations of lung diseases. The lung contains at least 30 different cells in the normal physiologic state, any of which can be increased or decreased in disease. The histopathologic identification of these cellular components and processes, their location, and overall interaction is often limited by the fact that the lung or biopsy fragments representative of lung tissue are subject to its state of inflation. In face of variable degrees of alveolar collapse present in histologic sections, the ensuing significant challenges can be overcome only with experience and a significant insight into clinical data regarding a given patient.

The widespread use of transbronchial and computed tomography–guided transthoracic needle biopsies has provided a formidable advance in the everyday clinical management of patients with lung diseases. However, the potential pitfalls outlined previously are exaggerated because of the potential for crush artifact and limited tissue sampling. The potential for misleading diagnosis has to be carefully considered throughout the histopathologic reading. As already stated, these limitations and the potential for errors can be significantly minimized with a solid knowledge of the fundamental cellular and pathologic processes in the lung allied to an open line of communication with the clinical team. This communication has to be established prior to the act of sampling the lung, because sampling accuracy can be significantly increased, and proper handling of lung fragments can be accomplished by the clinical team during the process of obtaining lung tissue. A summary of recommendations

are outlined in the sections that follow. This chapter also outlines a summary of relevant information regarding tissue processing and sections performed. Special histopathologic stains are described, with an emphasis on their utility in the histopathologic evaluation of the lung.

The pathologic interpretation can be broadly framed as aimed at either defining a "histopathologic pattern," reflecting the histopathologic alterations present in lung sections, or a conclusive final diagnosis. In the former, significant pathologic alterations are used to determine whether the lung is involved by an acute, granulomatous, or chronic and interstitial lung disease. Each histopathologic pattern carries a specific clinical differential diagnosis that warrants a detailed investigation. As an example, the diagnosis of alveolar hemorrhage with or without capillaritis entails the investigation of a set of diseases known to present with this particular pattern, including collagen vascular diseases and systemic vasculitides. The converse also applies in that specific diseases present with more than one pattern. For instance, scleroderma may present with acute lung injury (ALI), alveolar hemorrhage, bronchiolitis obliterans organizing pneumonia (BOOP), fibrosing pneumonias, and/or pulmonary vascular disease.[1] Patterns may occur in isolation or in combination; ALI and BOOP, for instance, may coexist. Therefore, proper interpretation of the predominant pattern is critical for proper patient management. Incorrect pathologic interpretation can result in delays or improper treatment. Conversely, what appears to represent a histopathologic process (e.g., ALI) may also carry a specific and final diagnosis. This is indeed the case with cytopathic lung viruses, including cytomegalovirus or herpesvirus infections, mycobacterial granulomatous inflammation, and *Pneumocystic jirovecii* infection. The converse also applies to infectious agents, that is, an infectious agent may be associated with several histopathologic patterns. This is also the case with *P. jirovecii* infection, which can produce the classic foamy or granular alveolar infiltrate or ALI pathology. The pathologic diagnosis of a neoplastic process is also a specific and final diagnosis; however, one should consider that inflammatory/repair-related histopathologic processes may accompany neoplastic processes, such as BOOP.

LUNG PROCESSING

Lung tissue requires some degree of inflation, which can be accomplished with instillation of formalin or any solution that can maintain the alveolar tissue open, preferably recapitulating alveolar structure at total lung capacity. Whole lungs should be inflated with a 10% buffered formalin solution under 25 cm H_2O pressure. Each lung will require approximately 2 to 4 L to achieve inflation, a volume that approximates total lung capacity. The advantages offered by formalin inflation are the immediate fixation (e.g., preservation of molecular and morphologic details) due to cross-linking of macromolecules and relative accessibility to immunohistochemical stains. Alternative approaches have been developed to also allow ease to perform frozen sections. These approaches rely on a 50% solution of OCT (optimal cutting temperature) or a buffered solution containing 0.5–2.0% agarose instilled at approximately 40°C to 60°C.[2] Lung biopsies are also amenable to inflation using 10% formalin injected with a syringe and a 15-gauge needle. Alternatively, gently tapping the fragment with a wooden stick in formalin can lead to air being expelled and improved infiltration by formalin. The staples can be removed on wedge biopsies and the tissue gently tapped in order to provide adequate infiltrate of formalin. Finally, the histopathologic interpretation of transbronchial biopsies can be enhanced by immediate placement in formalin and gently tapping each fragment against the vial wall, allowing the expansion of the periphery of the fragment. The general rules for proper fixation require that the relative volume relationship between tissue and the fixative should be 1:10; that is, the volume of formalin should be 10 times that of the target tissue. Furthermore, formalin penetrates and fixes tissues at a rate of 1 mm/hr. A maximum thickness of 4 mm is required for proper fixation, because thicker sections lose integrity and are not suitable for histopathologic analyses. The fragments are processed through gradients of alcohol (leading to loss of glycogen) and then sequential immersions in three containers with xylene, leading to dehydration of the tissue and clearing with removal of hydrophobic molecules, including lipids and fatty acids. The fragments are then embedded into molds of molten paraffin (at 60°C). This stage allows for proper orientation of the relevant samples. The bottom of the mold is then sectioned on a microtome and made into histologic slides. Most histopathologic interpretations are carried out using histologic slides stained by hematoxylin (an acidic nuclear stain that reacts with basic DNA histones) and eosin (for cytoplasmic details). Additional special stains used in the histopathologic evaluation of the lung are mentioned later under the specific topics.

ACUTE LUNG PROCESSES

Acute lung processes may appear within hours before a biopsy is obtained. Most of these involve early inflammation, which is usually characterized by varying degrees of edema, protein exudates, hemorrhages, inflammatory cell infiltrate including neutrophils, eosinophils, lymphocytes, occasionally multinucleated giant cells, and cellular damage to alveolar epithelial and endothelial cells. The relative contribution of each of these events and their preferential anatomic location in the alveolar unit allow one to diagnose a specific acute lung process. Predominance of red cells points toward alveolar hemorrhage, whereas predominance of intra-alveolar neutrophils strongly suggests bronchopneumonia. We included under the "acute" category the entities that present for several days that we opted to describe as "subacute." The correlation between the acute lung processes and specific clinical diagnoses is highlighted in Table 15-1.

TABLE 15-1. Acute Lung Processes and Underlying Clinical Entities

Acute lung injury (ALI): viral and bacterial infection, sepsis, hemorrhage and blood transfusions, drug toxicity, trauma, environmental exposures including hot or toxic fumes, aspiration, collagen vascular diseases, idiopathic (acute interstitial pneumonia [AIP]).

Diffuse alveolar hemorrhage (DAH) with or without capillaritis: idiopathic and restricted to the lung; collagen vascular diseases (rheumatoid arthritis, polymyositis, scleroderma, lupus erythematosus), transplant rejection, influenza virus infection, *Nocardia* infection, retinoid acid in acute myelogenous leukemia (M3), Wegener's granulomatosis, systemic vasculitis (perinuclear antineurophil cytoplasmic antibody [p-ANCA] vasculitis), Goodpasture's syndrome.

Acute eosinophilic lung processes: acute eosinophilic pneumonia, Löffler's syndrome, drug toxicity.

Acute/subacute lymphocytic lung processes: hypersensitivity pneumonitis, viral infections.

Organizing pneumonias: viral and bacterial pneumonias, drug toxicity, inhalational toxicity, collagen vascular disease, reaction to expansile tumors including granulomas and neoplastic processes, idiopathic.

Diffuse Alveolar Damage

Diffuse alveolar damage (DAD) is the pathologic presentation of ALI or acute respiratory distress syndrome (ARDS). An identical pathologic presentation is seen in acute interstitial pneumonia (AIP).[3] DAD always has an underlying causes, such as infections, drug reactions, transfusions, trauma, collagen vascular disease, or viral infections. AIP in its early stages describes the idiopathic form of DAD and, therefore, is a diagnosis of exclusion. The early events are characterized by alveolar edema, with leakage of plasma products, particularly of fibronectin, into the alveolar space (Figs. 15-1A and B and 15-2).[4] This results in the formation of hyaline membranes. Variable hemorrhage is present, but acute inflammation is not prominent. Type II cell hyperplasia and reactive atypia is a frequent finding, particularly when DAD is caused by drug toxicity. These acute events transition rapidly (i.e., 36–48 hr) to a macrophage and fibroproliferative process, which organizes the intra-alveolar exudate. The early organization is best appreciated with the Movat (or pentachrome) stain, which highlights the presence of mucopolysaccharides deposited by the proliferating fibroblasts. Fibrin is a common finding in thrombi in pulmonary arteries with ALI. The chronic stage entails alveolar collapse, fibrosis, and potential honeycombing, which are described in the next section. Most of the cases of DAD associated with ARDS or ALI will resolve, leaving some structural alterations that may underlie potential alterations in pulmonary performance. Infectious agents may lead to a DAD pattern, including *P. jirovecii*, and viral infections, including herpes and adenovirus infection (see Fig. 15-1B). Figure 15-1 outlines the histopathologic findings according to the evolution of ALI/DAD.

Acute Bronchopneumonia

Acute bronchopneumonia is the most frequent presentation of an acute lung process. It is a common finding at autopsy; however, it may be present in transbronchial or video-assisted thoracic surgery (VATS) biopsies, particularly in atypical clinical presentations. Bronchopneumonia is characterized by alveolar hemorrhage early in its course (i.e., ≤6 hr). This stage is followed by neutrophil accumulation in alveolar septa with prominent spilling into the alveolar spaces (see Fig. 15-1C). Most bacterial infections show predominance of neutrophil accumulation versus hemorrhage, yet we have observed cases with predominance of fresh alveolar hemorrhage, particularly in the setting of anaerobic or *Nocardia* infection. With the introduction of antibiotic therapy, the exudative component is rapidly (i.e., after 24 hr) organized with formation of fibroproliferative plugs, that is, the process becomes organizing pneumonia (OP).

Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) is characterized by the presence of intra-alveolar hemorrhage. Red cells may be seen admixed with polymerized fibrin, often abutting the alveolar septum (see Fig. 15-1D). Red cells can permeate the alveolar septa and accumulate in the alveolar spaces or can be engulfed by alveolar macrophages. The differential diagnosis of artifactual bleeding due to surgical manipulation is sometimes difficult. In the latter case, red cells are usually less tightly packed within the alveolar space, hemosiderin in either the septa or within macrophages is absent, and red blood cells are not detected leaving the alveolar capillaries. Evidence of capillaritis can accompany alveolar hemorrhage (see Fig. 15-1E). Capillaritis is defined by the septal infiltration of neutrophils, with evidence of nuclear fragmentation. In the more advanced stages of capillaritis, microabscesses with septal necrosis may be identified. In comparison with bronchopneumonia, capillaritis shows less prominent intra-alveolar accumulation of neutrophils, whereas the converse applies to bronchopneumonia. Evidence of chronic hemorrhagic events is identified by hemosiderin accumulation in macrophages or in alveolar septa and variable degrees of septal fibrosis. This morphologic pattern is similar to that seen in chronic passive congestion due to left ventricular failure. An often difficult differential diagnosis is the distinction between DAH and desquamative interstitial pneumonitis (DIP) pattern. However, DIP lacks the features outlined earlier for DAH. The recognition of DAH carries important clinical implications as the differential diagnosis includes systemic vasculitis with high morbidity/mortality, such as Wegener's granulomatosis and Churg-Strauss vasculitis. In case the distinction of DAH/capillaritis versus bronchopneumonia is difficult, it is important to convey that a given case may represent the former, warranting a careful clinical screening of clinical conditions associated with this histologic pattern.[5] Frozen tissue may be suitable for immunofluorescence, particularly when

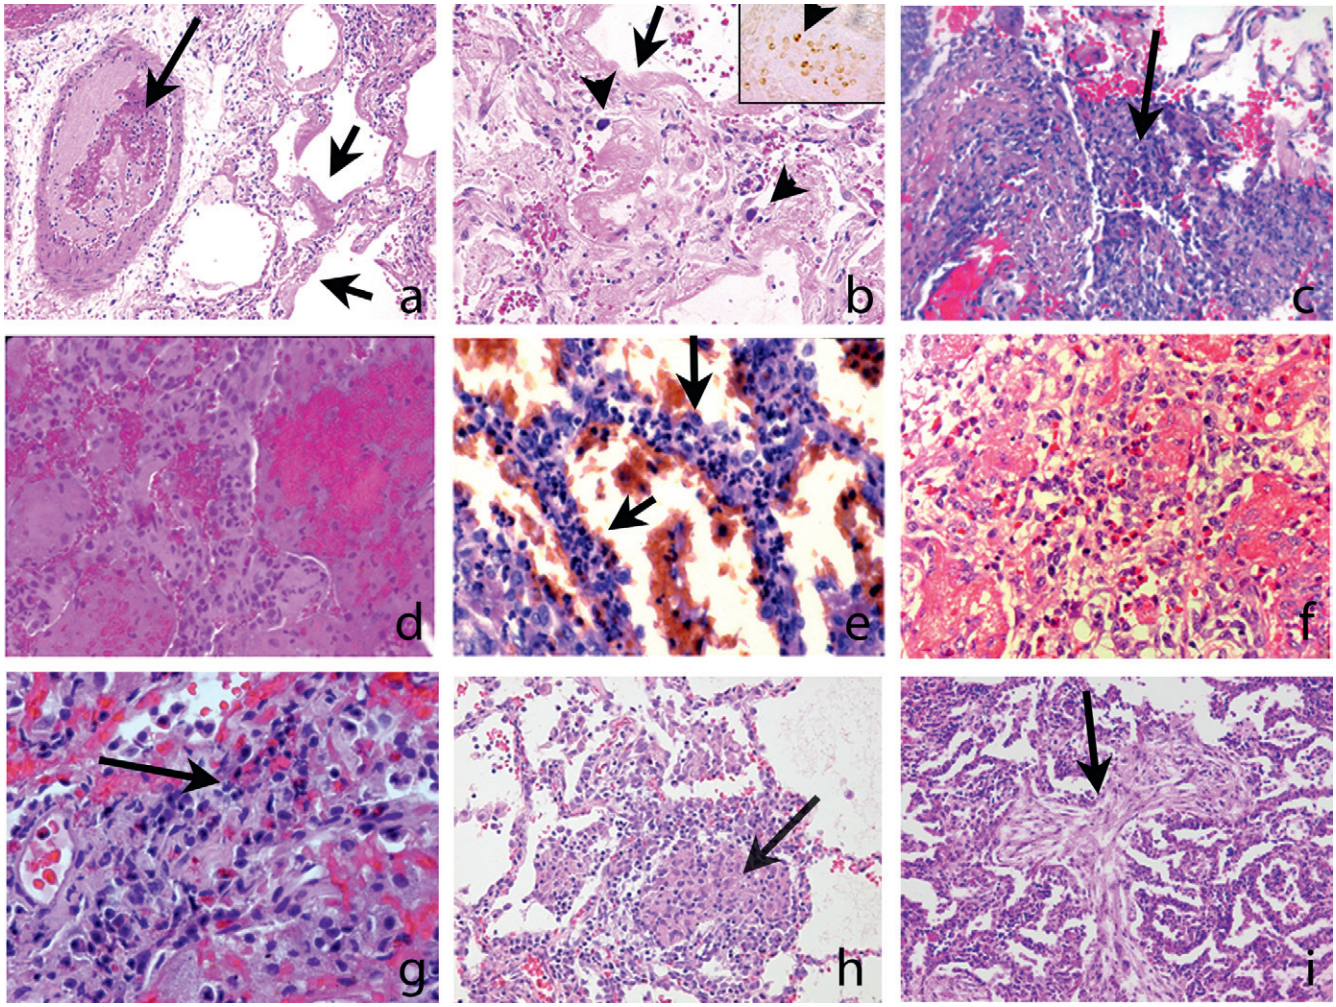

FIGURE 15-1 ■ Acute lung processes. **A,** Acute lung injury (ALI) with prominent hyaline membranes (*arrows*) lining alveolar septa. A medium-size pulmonary artery shows a recent thrombus (*long arrow*). **B,** ALI pattern with hyaline membranes (*arrow*) in a case of adenovirus infection, with the cytopathic effect (*arrowheads*). Viral identity is confirmed by immunohistochemistry (*inset, arrowhead*). **C,** Acute bronchopneumonia with accumulation of neutrophils in the intra-alveolar space (*arrow*). **D,** Diffuse alveolar hemorrhage (DAH). **E,** Capillaritis with septa infiltrated by neutrophils (*arrows*). **F,** Acute eosinophilic lung pattern with intra-alveolar accumulation of fibrinous exudates and eosinphils. **G,** Degranulated eosinophilic granules in eosinophilic lung disease (as reported by Gerhardt SG et al[29]) (*arrow*). **H,** A case of recent acute hypersensitivity pneumonitis with the presence of granulomas in the alveolar septa (*arrow*). **I,** Bronchiolitis obliterans with organizing pneumonia with a cast of granulation tissue in the alveolar duct (*arrow*).

associated with lupus erythematosus or Goodpasture's syndrome, and provide a final diagnosis.

Acute Eosinophilic Lung Processes

Acute eosinophilic processes are seen in idiopathic acute eosinophilic pneumonia, or in association with parasitic diseases (also known as Löffler's syndrome), bronchopulmonary aspergillosis, asthma, eosinophilic granuloma, cancer, and others. The typical finding is a dense infiltration of eosinophils in alveolar septa and intra-alveolar spaces (see Fig. 15-1F and G). The authors have often found large areas with cell-free eosinophilic granules, which likely represents the degranulation of infiltrating eosinophils (see Fig. 15-1G). Variable interstitial or perivascular infiltration of eosinophils can be seen with chronic diseases, including chronic eosinophilic pneumonia and Churg-Strauss vasculitis. The clinical history, radiologic presentation, and specific areas of histologic involvement aid in the proper differential diagnosis of the conditions associated with acute eosinophilic lung diseases.

Acute/Subacute Lymphocytic Lung Processes

Although most acute lung diseases show neutrophilic or eosinophilic infiltration, there are some clinical conditions in which a lymphocytic infiltration may

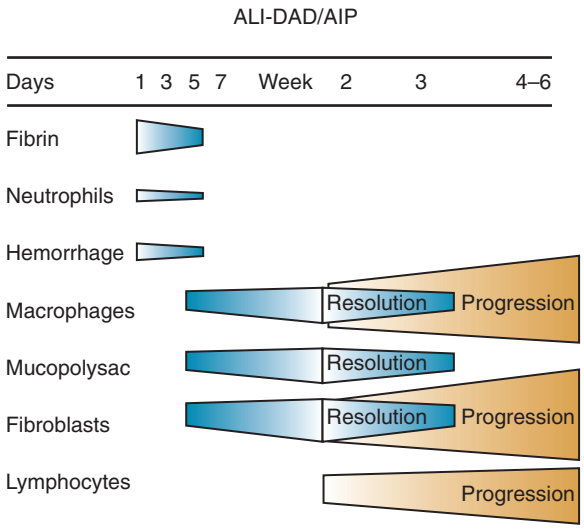

FIGURE 15-2 ■ Summary of histopathologic alterations present in ALI/diffuse alveolar damage through the course of the disease. These alterations can be followed either by resolution or with progression to a fibrotic lung with honeycombing. Color and thickness of the *horizontal bars* are proportional to the intensity of a particular histopathologic finding (based on Katzenstein's data[3]). Resolution of ALI between week 1 and 2 leads to progressive disappearance of the features present during the early stages of the disease. However, progression to chronicity leads to persistence or increase of features associated with interstitial inflammation and fibrosis.

predominate, including drug toxicity, viral infections, or immunologic reactions. In the latter condition, mycotoxins can cause an acute form of hypersensitivity pneumonitis (HP) in which granulomas may coexist with the lymphocytic infiltrate (see Fig. 15-1H). It is noteworthy that most of the lung lymphocytic processes are chronic, often accompanied by varying degrees of interstitial thickening by cells and fibrosis, as in lymphocytic interstitial pneumonitis (LIP) (see later), nonspecific interstitial pneumonitis (NSIP), and others.

Organizing Pneumonia

Organizing pneumonia (OP) is one of the most common acute/subacute patterns seen in lung biopsies, often being an accessory and therefore nonspecific pattern in several lung diseases. OP (also known as BOOP) is characterized by the presence of a loose, mucopolysaccharide-rich matrix, with young fibroblasts extending from an attachment site in the alveolar duct and filling the lumen (see Fig. 15-1I).[6] A central vessel and accumulation of centrally placed macrophages may also be seen. The alveolar septa may show varying numbers of lymphocytic or plasmacytic cell infiltrates. As mentioned, an interpretation of OP or BOOP should be considered with care prior to reaching a final clinical diagnosis. BOOP may occur in association with several clinical conditions (see Table 15-1). Once several of the more frequent conditions have been excluded by clinical workup, the final diagnosis of idiopathic BOOP should be considered.

TABLE 15-2. Interstitial Lung Diseases and Underlying Clinical Entities

Usual interstitial pneumonia (UIP)–like pattern: idiopathic (UIP), collagen vascular disease (scleroderma), asbestos interstitial lung disease.

Desquamative interstitial pneumonitis (DIP): idiopathic.

Lymphoid interstitial pneumonitis (LIP): idiopathic, collagen vascular disease (Sjögren's disease), AIDS, immunosuppression (acquired or hereditary), viral (Epstein-Barr virus [EBV] infection).

Nonspecific interstitial pneumonitis (NSIP): idiopathic; NSIP-like due to hypersensitivity pneumonitis, NSIP-like due to collagen vascular disease (i.e., scleroderma).

Giant cell interstitial pneumonitis (GIP): heavy metal exposure.

INTERSTITIAL LUNG FIBROTIC PATTERNS

This overall pattern, which encompasses most of the interstitial lung diseases (ILD), results from insults to the alveolar septa leading to a variable recruitment of lymphocytes, plasma cells, macrophages, and eosinophils. The key finding is the destruction of alveolar structures and/or thickening of alveolar septa by fibrosis. One study outlined the value of lung biopsy in the diagnosis of the clinical conditions associated with interstitial pneumonitis.[7] The patterns under this category are listed in Table 15-2 and illustrated in Figure 15-3.

Acute Interstitial Pneumonitis

AIP is the only entity that allies a component of acute lung disease with a rapidly evolving course with extensive alveolar collapse and replacement by collagenous tissue. The pathology of early disease is identical to that seen in DAD with hyaline membranes (see Figs. 15-1 and 15-2). The hallmark of this process is the uniformity of lung destruction, with little areas that are spared, which is not seen in usual interstitial pneumonia (UIP; see later). Furthermore, the process of fibrosis in AIP is distinctly irregular, because there are areas that show features of honeycombing, whereas other regions may show predominance of fibrosis admixed with chronic inflammatory infiltrate, with relative preservation of the overall septal outline.

Usual Interstitial Pneumonitis

UIP is a paradigmatic pattern of chronic and fibrotic lung disease that, in its idiopathic form, correlates with the clinical entity of idiopathic pulmonary fibrosis (IPF) (see Fig. 15-3A–C). The lung bases are predominantly involved with extensive alveolar replacement by fibrosis, chronic inflammatory infiltrates, and honeycombing. The extensive areas of fibrosis alternate with focally spared lung tissue (see Fig. 15-3A–C). Within the areas of fibrosis, focal organizing exudates protrude into the adjacent alveolar space to form the so-called fibroblastic foci, a

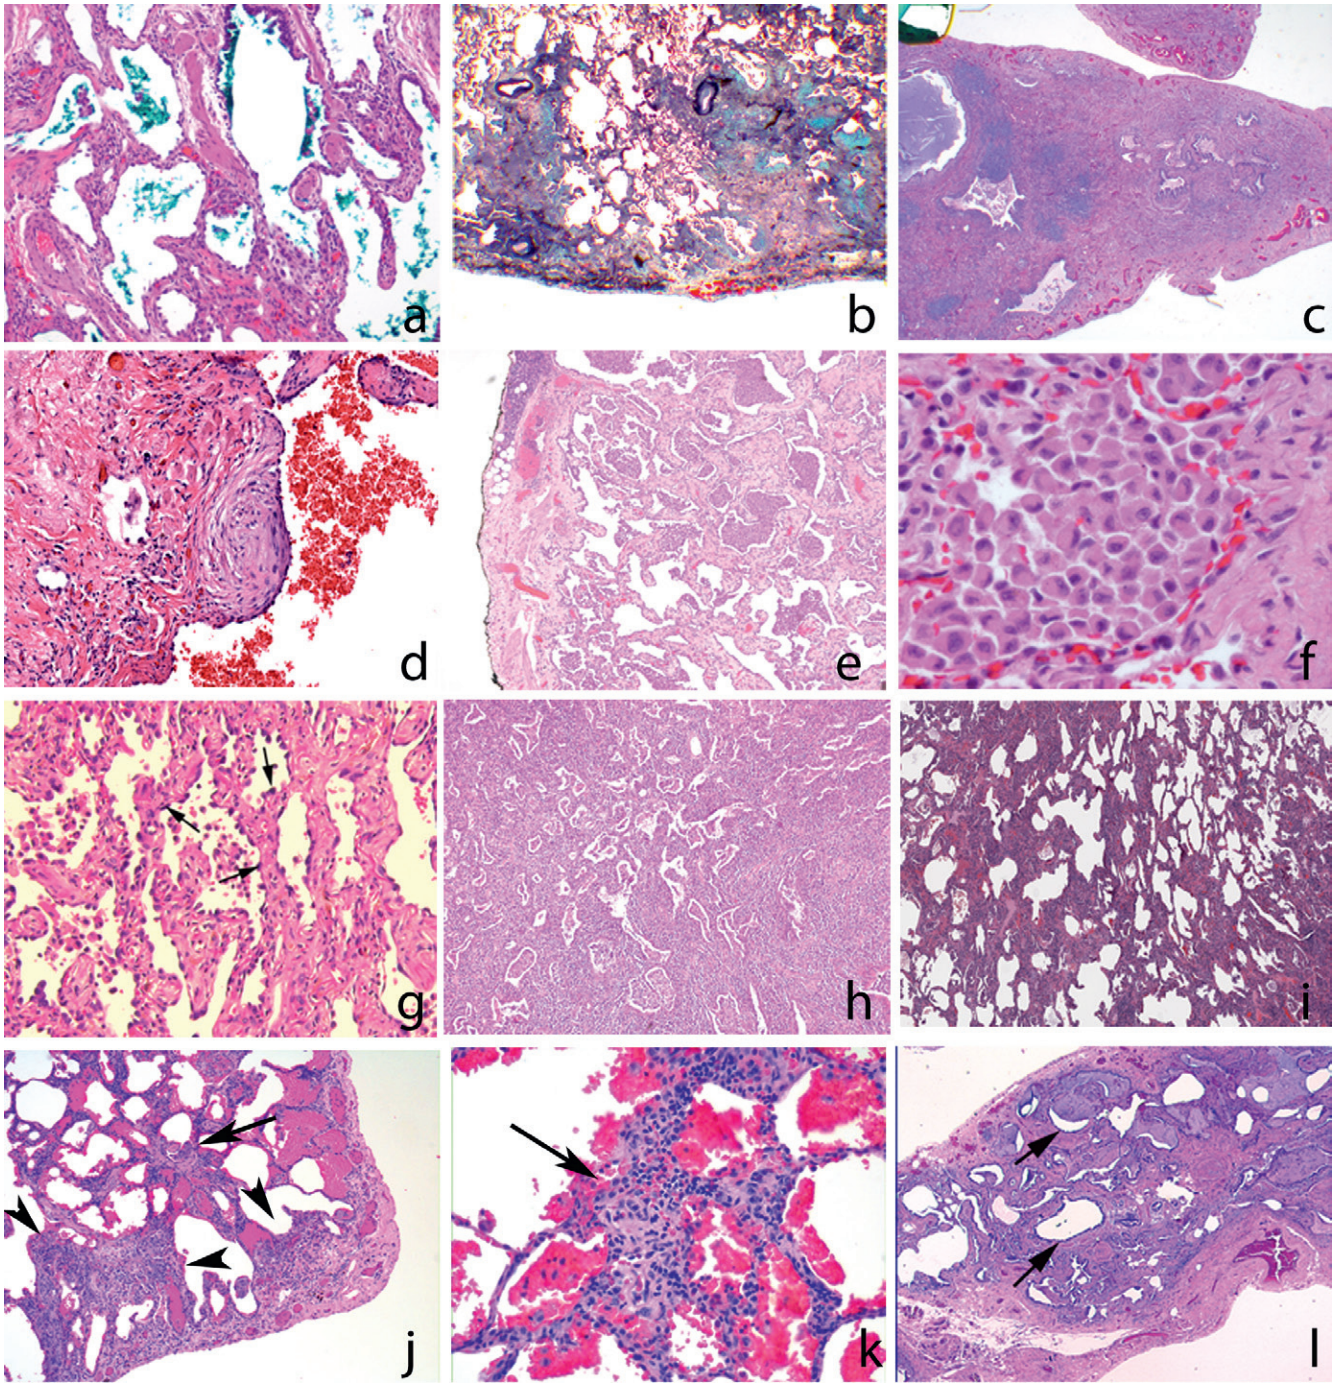

FIGURE 15-3 ■ Chronic interstitial lung patterns. **A,** Acute interstitial pneumonia (AIP) evolving into fibrotic stage with extensive and relatively diffuse septal thickening by fibrosis. **B–D,** Usual interstitial pneumonia (UIP), showing its heterogeneous presentation, with areas of alveolar collapse and replacement by active fibrogenic and inflammatory process (**B**), with areas of honeycombing (**C**), and presence of fibroblastic foci (**D**). **E–G,** Desquamative interstitial pneumonitis (DIP) with the characteristic uniform filling of alveolar spaces (**E**) with macrophages (**F**); once treated, DIP presents with a nonspecific type of regular interstitial thickening (*arrows*) (**G**). **H,** Lymphocytic interstitial pneumonitis (LIP) with dense and uniform infiltration by lymphocytes and plasma cells. **I** and **J,** Nonspecific interstitial pneumonitis (NSIP) type III with temporally homogeneous extensive fibrosis (**I** and **J**), alternating with areas with irregular interstitial inflammation (**I** and **K;** *arrows* in **J** and **K** highlight septal inflammation extending into intralobular septa—compare with **L;** *arrowheads* highlight similar inflammatory process but with alveolar collapse in the subpleural region). **L,** Honeycombing with lung parenchyma replaced by cystic areas surrounded by dense fibrosis and containing mucinous material (*arrows*).

key pathogenetic process involved in UIP (see Fig. 15-3D). These pathologic structures resemble the organization seen in BOOP, but in BOOP (or OP), the granulation tissue projects symmetrically from within an alveolar duct or respiratory bronchiole and fills the air space in a serpiginous manner (see Fig. 15-1I). UIP relatively spares the upper lobes; however, patients with advanced disease may show upper lobe involvement. If there is a predominance of upper lobe involvement, other etiologies such as fibrosing stage of HP or collagen vascular diseases should be considered in the differential diagnosis. UIP may be complicated by acute exacerbations with either an ALI pattern or areas of bronchopneumonia. There is a wide differential clinical diagnosis of entities that share the UIP pattern (see Table 15-2). Perhaps the most frequently encountered is the distinction between the idiopathic form of UIP, known as IPF, and that caused by collagen vascular disease, particularly scleroderma. Given the heterogeneity of the pathologic presentation in UIP, open-lung biopsies (two or three lobe biopsies) are necessary to provide accurate diagnosis. Transbronchial biopsies are generally not indicated for diagnosis. It is well recognized that the UIP pattern may have some common histopathologic features with those encountered in NSIP; thus, the final diagnosis may rely on the integration with the clinical presentation and radiologic features.

Desquamative Interstitial Pneumonitis

DIP is a well-recognized pathologic presentation of ILD, with several features in common with those encountered in respiratory bronchiolitis (RB) (see Fig. 15-3E–G). There is a spectrum of lesions that typify DIP. All include variable numbers of loosely clustered intra-alveolar macrophages (see Fig. 15-3E and F) and a range of fibrosis from mild airway fibrosis and interstitial thickening (similar to RB) to more diffuse, fibrotic interstitial thickening (see Fig. 15-3G). The alveolar macrophages, especially in those cases associated with cigarette smoking (>90% of cases), contain yellow-brown finely pigmented inclusions within their cytoplasm. Variable numbers of eosinophils may be admixed with the macrophages. The characteristic morphology may not be present in treated cases, in which case there is a reduction of the cellular interstitial inflammation and number of intra-alveolar macrophages. However, there may be residual interstitial thickening (see Fig. 15-3G).

Lymphocytic Interstitial Pneumonitis

LIP can present with a wide range of associated conditions, including collagen vascular disorders, immunosuppression (in cases of human immunodeficiency virus [HIV] infection), or inherited causes of immunosuppression (see Fig. 15-3H). LIP is characterized by extensive infiltration by a mixture of lymphocytes and plasma cells, often effacing the normal microscopic architecture of the alveolar septa. Secondary germinal centers may be observed, both in the parenchyma and in the peribronchiolar regions. Granulomas may be present in variable numbers and structural composition, sometimes leading one to consider the differential diagnosis of HP. Although some of these cases may represent a clonal (i.e., neoplastic) proliferation, the clinical progression is more often that of a chronic inflammatory condition. Transbronchial biopsies can be informative when evaluated in the context of the clinical and radiologic presentations. The immediate differential diagnosis involves conditions associated with lymphoplasmacytic infiltrates, including NSIP and HP, or conditions associated with granulomatous patterns, including HP, sarcoidosis, and mycobacterial infections.

Nonspecific Interstitial Pneumonitis

NSIP, a somewhat controversial pathologic and clinical presentation of interstitial lung diseases,[8] has been recently reviewed in a consensus conference[9] (see Figs. 15-3I–K). NSIP involves a spectrum of pathologic presentations that suggests there may be stages that progress from inflammation to fibrosis in patients. However, it is also conceivable that the different types of interstitial involvement represent static stages. The so-called type I,[8] or cellular variant, is characterized by prominent but irregular interstitial infiltrate by lymphocytes and plasma cells, with mild fibrosis, and focal areas of BOOP (see Fig. 15-3I). The differential diagnosis includes acute lymphocytic lung processes, which are of shorter duration and not associated with an increase in interstitial fibrosis. Granulomas are not in the spectrum of type I NSIP, but rather raise the suspicion of HP (Fig. 15-4G). Types II and III have variable degrees of fibrosis (see Fig. 15-3I–K). Type II has a uniform type of interstitial fibrosis accompanied by chronic inflammatory infiltrate (see Fig. 15-3K); although this overall pattern may again suggest HP, granulomas are not a feature of NSIP. Type III NSIP has marked areas of alveolar collapse, with replacement by extensive fibrosis (see Fig. 15-3L). There may be early microscopic honeycombing and low numbers of fibroblastic foci, but dense honeycombing or abundant fibroblastic foci are not observed in type III NSIP. All subtypes of NSIP are characterized by a uniform pattern of involvement within the secondary lobular unit, whereas UIP has a distinct heterogeneity, in which lobular areas vary between foci of honeycombing with areas of active inflammation or preserved alveolar structures. In our experience, lung involvement by a pathologic process akin to NSIP can be clearly seen in collagen vascular diseases, drug toxicity, and HP; thus, it is best to include these diseases in the differential diagnosis of NSIP.

Other Forms of Idiopathic Interstitial Lung Pattern

Other, rarer forms of ILD patterns include giant cell interstitial pneumonitis, reported in association with heavy metal exposures, end-stage sarcoidosis, and end-stage fibrotic lung (honeycombing pattern only). These patterns require a detailed clinical history and clinical correlation. In the case of end-stage sarcoidosis, it is

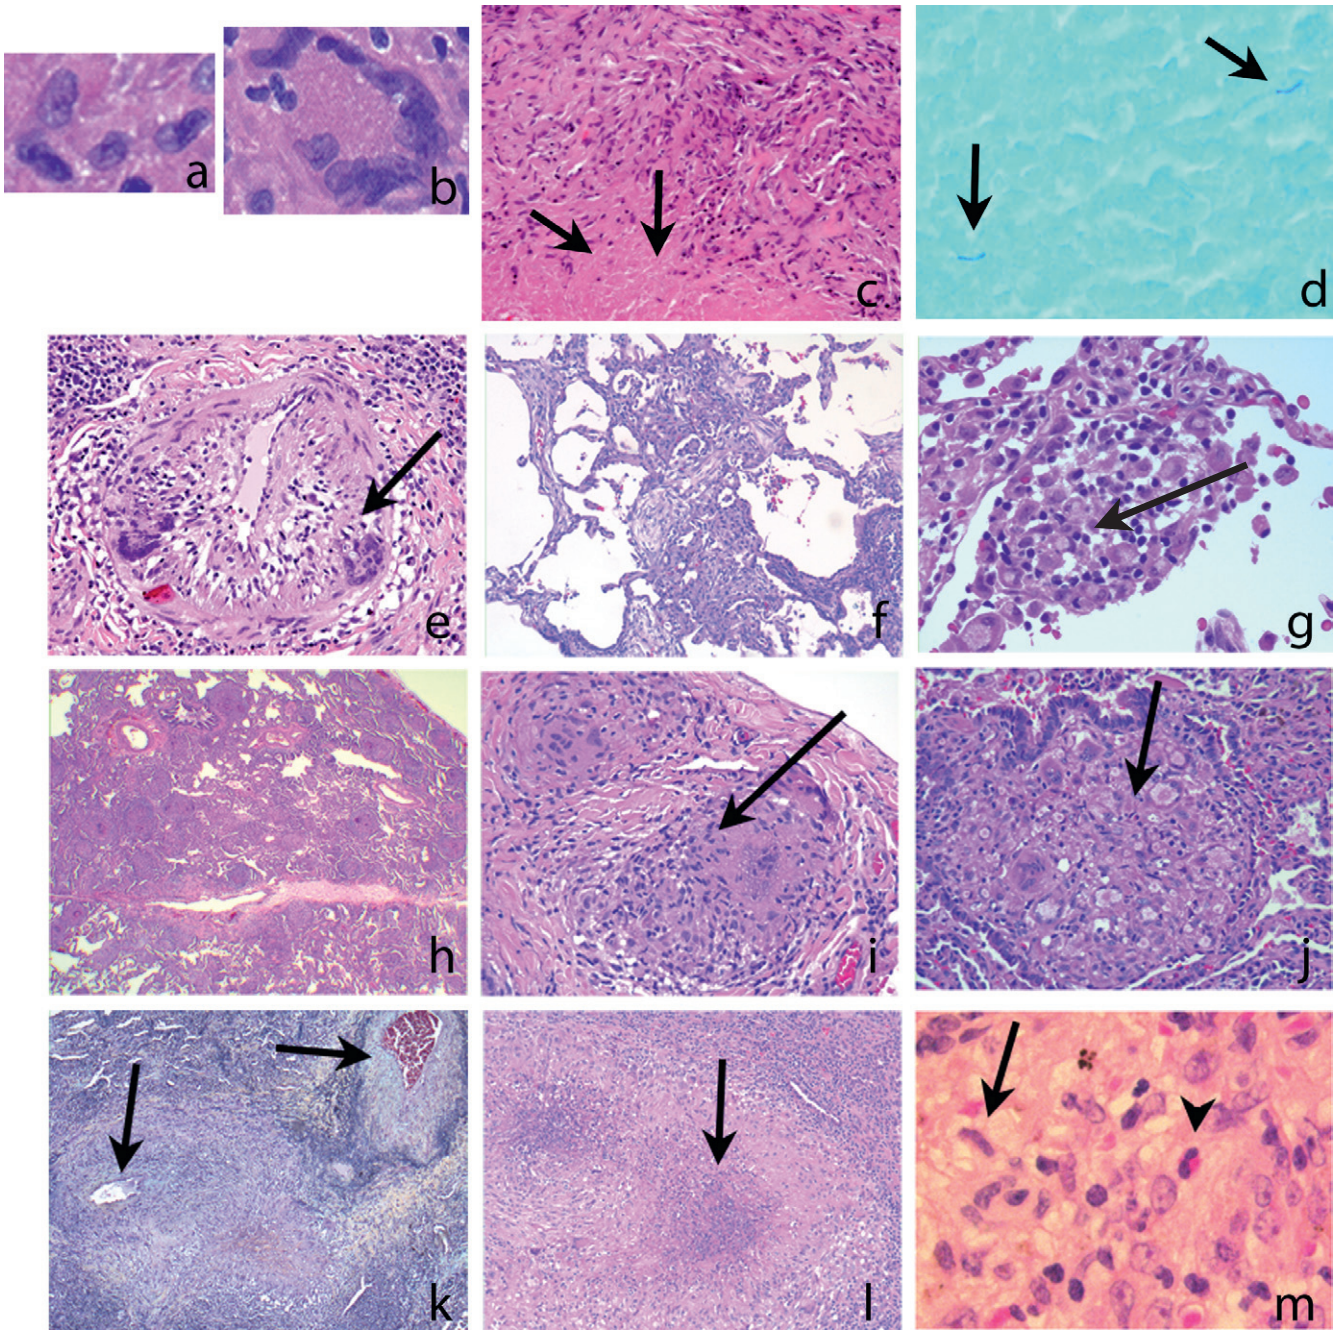

FIGURE 15-4 ■ Granulomatous lung patterns. **A,** High power of an epithelioid histiocyte. **B,** High power of multinucleated histiocyte. **C** and **D,** Tuberculous granulomas (**C**) with presence of caseous necrosis (*arrows* in **C**) and mycobacteria present in the acid-fast stain with methyl green counterstain (*arrows* in **D**). **E,** Atypical mycobacterial granulomas within the pulmonary artery (causing granulomatous vasculitis, *arrow*). **F** and **G,** Hypersensitivity pneumonitis showing an NSIP pattern of interstitial inflammation and fibrosis (**F**) and poorly formed granulomas in the septal-alveolar interface (*arrow* in **G**). **H–J,** Sarcoidosis, with extensive interstitial and alveolar involvement (**H**), with well-formed granulomas in subpleural (*arrow* in **I**) and intrabronchial locations (*arrow* in **J**). **K** and **L,** Wegener's granulomatosis, with necrotizing granulomas (*arrows* in **K**), seen invading the vessel wall in the Movat-stained section (*arrow* in **L**). **M,** High magnification of an eosinophilic granuloma lesion, with Langerhans histiocyte (*arrow*) and eosinophils (*arrowhead*).

possible to identify scattered active or hyalinized granulomas in the midst of the fibrous tissue as the remaining evidence of underlying sarcoidosis. Honeycombing is a terminal stage of ILDs in which the underlying cause may not be identified. It is characteristically seen in UIP and UIP-like conditions (see Fig. 15-3C).

GRANULOMATOUS LUNG PATTERNS

Granulomas are defined as organized conglomerates of histiocytes (macrophages). Most of the granulomatous lung diseases involve the formation of epithelioid granulomas, in which the characteristic cell is the epithelioid

TABLE 15-3. Conditions Associated with Granulomas

Typical and atypical mycobacterial infections:
Pattern: well-formed granulomas with variable caseous necrosis.
Fungal infections:
Pattern: well-formed granulomas with variable caseous necrosis
Hypersensitivity pneumonitis:
Pattern: nonspecific interstitial pneumonitis (NSIP)-like changes with poorly organized granulomas in alveolar-interstitial junction.
Sarcoidosis and berylium disease:
Pattern: well-formed granulomas along lymphatics; rarely with fibrinoid necrosis (in necrotizing sarcoidosis)
Immunodeficiencies:
Pattern: NSIP-like changes accompanied with poorly formed granulomas.
Lymphocytic interstitial pneumonitis (LIP):
Pattern: dense lymphoplasmacytic infiltrate with scattered well or poorly formed granulomas
Wegener's granulomatosis:
Pattern: necrotizing process with scattered giant cells and histiocytes in alveolar, vascular, and/or bronchiolar compartments.

histiocyte (see Fig. 15-4A and B). This cell is clustered within the granulomas and is characterized by an elongated profile with indistinct cytoplasmic membranes. Multinucleated giant cells may or may not be present. An outside rim of chronic inflammatory cells, predominantly lymphocytes, may be present in variable numbers. The differential diagnosis encompasses several potential entities, including infectious (mycobacterial or fungal), sarcoidosis, HP, interstitial pneumonitis not otherwise specified, NSIP-like due to immunosuppression, LIP, and granulomatous vasculitits (Table 15-3; see also Fig. 15-4). Some of the latter discussed entities present with a diffuse infiltration of macrophages, such as with areas of DIP-like lung pathology or a pseudo-DIP due to associated alveolar hemorrhage (which may occur in interstitial pneumonitis associated with collagen vascular diseases).

Central caseous necrosis (see Fig. 15-4B) points toward mycobacterial or fungal infection, which can be ascertained by acid-fast stain (see Fig. 15-4D) or Gomori silver methanamine stains, respectively, or tissue cultures. Caseating granulomas are usually well-formed with epithelioid macrophages, giant cells, and lymphocytes surrounding a centrally placed necrotic, eosinophilic core (see Fig. 15-4C). Calcifications may be present in chronic lesions. Miliary nodules may have less-well-formed organization, with areas of organizing exudate. Infectious granulomas, particularly atypical mycobacterial infection, can affect pulmonary arteries with a true granulomatous vasculitis, similar to Wegener's granulomatosis (see Fig. 15-4E).

Hypersensitivity pneumonitis (HP), which has a characteristic interstitial involvement (see Fig. 15-4F), also presents with granulomas, which are characteristically poorly organized, that is, the cells are loosely arranged without a clear rim of lymphocytes or connective tissue on the outside border. These granulomas are located in the alveolar septal–air space interface, often leading to a blurred outline of the alveolar structure (see Fig. 15-4G). As described previously, HP shows variable infiltration by lymphocytes and plasma cells, often in a centrilobular (bronchiolocentric) location.

Sarcoid granulomas are generally solid, well-formed granulomas, with no evidence of central necrosis (see Fig. 15-4H–J). Sarcoid granulomas are preferentially distributed along lymphatics, which are located in the pleura and along the bronchovascular tree (see Fig. 15-4H). Sarcoid granulomas may present as single structures, be located in the subpleural region or airway (see Fig. 15-4J) and vascular walls, but can coalesce when in abundant numbers. Focal fibrinoid necrosis may also occur and is characterized by a deep eosinophilic hue that resembles that of polymerized fibrin. Extensive central necrosis, however, is much more typical of infectious etiologies.

In conditions associated with alterations of immune responses, such as HIV infection, genetic causes, or immunodeficiency, a cellular interstitial pneumonitis can be identified in association with granulomas. These cases usually warrant in situ hybridization for Epstein-Barr viruses.

Systemic vasculitides can also present with granulomas. Wegener's granulomatosis shows poorly formed granulomas located in the interstitium (see Fig. 15-4K and L), surrounding areas of "dirty" necrosis containing necrotic neutrophils and cellular debris, interspersed with pockets of neutrophils and scattered multinucleated giant cells (see Fig. 15-4K). The edges of this process are effaced, giving it an appearance of a confluent pneumonic process, and the classic "geographic necrosis" outlines (see Fig. 15-4J). Alveolar hemorrhage with or without capillaritis may follow the granulomatous response in Wegener's granulomatosis. Clusters of Langerhans histiocytes (resembling granulomas) are characteristic of eosinophilic granulomas (Fig. 15-5I–L; see also Fig. 15-4M).

BRONCHIOLAR DISEASE PATTERNS

Terminal bronchioles account for the largest sectional area of airways. They branch dichotomously between cartilaginous bronchi and respiratory bronchioles for 20 to 24 generations. The terminal bronchioles are lined by a pseudostratified epithelium, lined predominantly by ciliated cells. The epithelium lies over a thin basement membrane (subbasal lamina). A submucosa brings blood supply within a mesh of loose connective tissue. The muscular layer accounts for approximately 20% of the thickness of the bronchiolar wall. The adventitial tissue surrounds the terminal bronchiole and connects it to the adjoining pulmonary artery.

Chronic Bronchiolitis

Chronic inflammatory processes involving the terminal bronchiole are frequent and relatively nonspecific because they are often associated with infectious

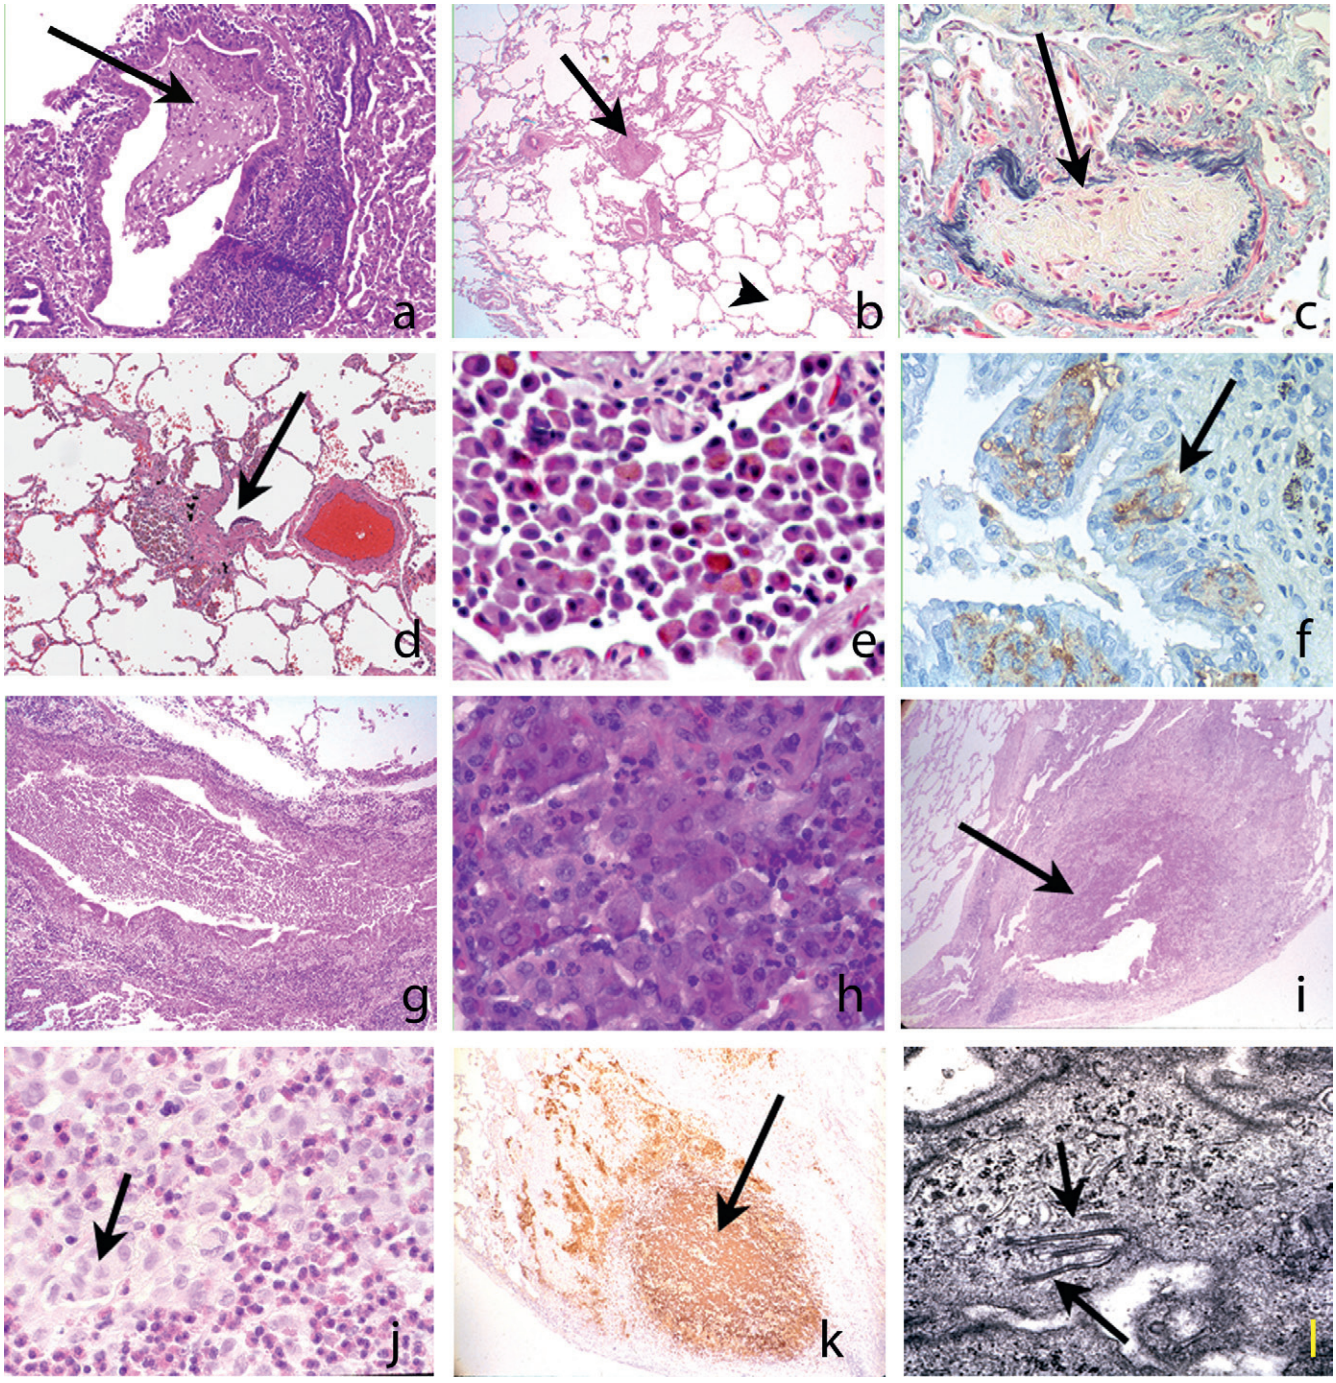

FIGURE 15-5 ■ Bronchiolar diseases. **A,** Chronic bronchiolitis with heavy lymphoplasmacytic infiltrate in bronchiolar wall, dilation of the lumen, and accumulation of mucus in bronchiolar lumen. This pattern can be seen in collagen vascular diseases, atypical presentation of cystic fibrosis, or chronic bronchitis in chronic obstructive pulmonary disease. **B** and **C,** Obliterative bronchiolitis showing areas of scarring in centrilobular regions, with a paucity of bronchioles (*arrow*). There is associated air space enlargement as seen in emphysema (*arrowhead*). **C,** Movat stain highlights disruption of the basement membrane and obliteration of the bronchiolar lumen (*arrow*). **D** and **E,** Respiratory bronchiolitis with distortion of terminal and respiratory bronchioles (**D**) and accumulation of pigmented macrophages in the affected airways (**E**). **F,** Neuroendocrine hyperplasia with increased numbers of chromogranin-positive cells (*arrow*). **G** and **H,** Diffuse panbronchiolitis with accumulation of neutrophils and mucus in the dilated bronchiolar lumen. Adjacent to the compromised airway, there is accumulation of foamy macrophages (**H**). **I–L,** Eosinophilic granulomas, with a cavitary lesion (*arrow* in **I**), surrounded by Langerhans histiocyte (*arrow* in **J**), which stain strongly with S100 antibody (*arrow* in **K**). These cells contain the characteristic tennis racket–shaped structures at electron microscopy (*arrows* in **L**).

processes (i.e., mycoplasma or viral infections), collagen vascular diseases, cigarette smoking, or asthma (see Fig. 15-5). In fact, this can the early and sole presentation of rheumatoid arthritis, even before serologic confirmation of the disease (see Fig. 15-5A[10]). This lymphocytic infiltrate can sometimes lead to the formation of lymphoid follicles that are characteristic of follicular bronchiolitis, which can be seen as the result of viral infections or collagen vascular diseases (such as Sjögren's disease) (see Fig. 15-5A). The Movat stain aids in the recognition of obliterative changes in which the airway is completely or partly obliterated by connective tissue (see Fig. 15-5B and C) (see later).

Bronchiolitis is frequently seen in association with cigarette smoking, which can cause RB and pulmonary Langerhans cell histiocytosis (or eosinophilic granuloma). RB is a nearly universal finding in chronic smokers, leading to the distortion of bronchiolar walls, increased wall fibrosis, and intraluminal accumulation of iron- and aluminum-containing pigmented macrophages (see Fig. 15-5D and E). RB is now interpreted as part of a spectrum that includes DIP.[11] Infrequently, pure respiratory bronchiolitis may be associated with a restrictive disease, known as respiratory bronchiolitis interstitial lung disease (RB-ILD). Although increased interstitial fibrosis is believed to underlie the clinical presentation of RB-ILD, it is unclear as to the extent of architectural changes of the bronchiolar wall and peribronchiolar tissue that can cause the alteration in lung function of this condition.

Distorted airways, like that seen in RB, can result from the accumulation of neuroendocrine cells staining positively for chromogranin (see Fig. 15-5F), characteristic of neuroendocrine hyperplasia. The pathologic changes can be subtle, although patients may show severe airway limitation.

Idiopathic small airway diseases include the entity of diffuse panbronchiolitis[12] (see Fig. 15-5G and H). Allied to a distinct tree-in-bud radiologic pattern, the morphology is characterized by intraluminal accumulation of large numbers of preserved and fragmented neutrophils amid abundant mucus and basophilic strands suggestive of degraded DNA. The bronchiolar wall is infiltrated by chronic lymphoplasmacytic infiltrates that extend into the adjacent alveolar tissue. A prominent and distinctive feature is the finding of interstitial foamy macrophages (see Fig. 15-5H). In our experience, a pattern quite similar to diffuse panbronchiolitis can be also seen in association with airway infections, including unusual cases of atypical mycobacteria. Therefore, clinical and radiologic correlation is warranted for a final diagnosis.

Pulmonary Langerhans cell histiocytosis (or eosinophilic granuloma) is seen almost exclusively in smokers and is characterized by bronchiolar fibrosis that radiates from the bronchiolar wall into the adjacent alveolar tissue, with accumulation of the distinctive histiocytes (Langerhans) that show indented kidney-shaped nuclei (see Figs. 15-4M and 15-5J). These cells form large clusters that stain positively for S100 protein, CD1a, and CD7 immunohistochemical markers and contain diagnostic Bierback structures at electron microscopy (see Fig. 15-5L). This infiltrative process is associated with increased numbers of eosinophils amid the Langherhans cells (see Fig. 15-5J). The lesions will evolve with progressive fibrosis and a marked decrease in the cellular infiltrate, imparting some difficulty in the diagnostic workup. However, the pattern of bronchiolar stellate fibrosis suggests the diagnosis of eosinophilic granuloma. Sometimes, a central cavitation can be seen (see Fig. 15-5I). A very similar fibrotic pattern is also seen in patients with chronic lesions due to tuberous sclerosis. Pulmonary arteries may be involved in association with severe pulmonary hypertension,[13] which carries a worse outcome.[14]

Granulomatous Bronchiolitis

Granulomatous lung diseases, such as mycobacterial, fungal, sarcoidosis (see Fig. 15-4J), and others, can also compromise the terminal bronchioles. The pattern of granulomatous involvement is similar to that described in the section on "Granulomatous Lung Patterns." A distinct form of granulomatous bronchiolitis is the bronchocentric granulomatosis, usually caused by infectious agents or by Wegener's granulomatosis.[15]

Obliterative Bronchiolitis

Inflammatory bronchiolitis can be associated with fibrous obliterative changes, which are centered in the submucosa and lead to progressive encroachment of the lumen. Obliterative bronchiolitis pattern can be seen in collagen vascular diseases, including rheumatoid arthritis, post lung transplant, and chronic graft-versus-host disease, or as an idiopathic disease. The characteristic feature is the evidence of active fibrogenesis with collagen and increased number of fibroblasts in a subepithelial location. The bronchiolar epithelium shows features of injury/regeneration, with flattened cytoplasm or areas of detachment from the underlying basement membrane. Inflammatory cell infiltrate is variable, but often seen migrating along penetrating blood vessels that insinuate from the outside bronchiolar wall through the bronchiolar smooth muscle cell layer. The smooth muscle layer is progressively disrupted, with residual clusters of fibers surrounded by collagenous tissue. The diagnosis is greatly aided by the identification that the bronchiole is of smaller diameter than the accompanying pulmonary artery, because these structures are of similar diameter throughout the lung, and by the pentachrome or Movat stain. This stain colors the elastic tissue black, the basement membrane and collagen yellow, the smooth muscle cell cytoplasm red, and any mucopolysaccharides blue. The pentachrome or Movat stain therefore highlights the disruption of the basement membrane and the collagenous infiltration of the lumen and bronchiolar wall. Chronic injury eventually leads to complete disappearance of the bronchiolar structure, replaced by a longitudinal scar that accompanies the adjacent pulmonary artery. Pentachrome stain reveals fragments of basement membrane, which are the reflection of a prior bronchiolar structure. Obliterative bronchiolitis can be diagnosed by transbronchial biopsy if the aforementioned criteria are applied stringently to the diagnostic workup.

Clinically, these cases present with airflow limitation and persistent hyperinflation in radiologic tests. In our experience, the correlation between clinical airflow limitation and degree of pathologic airway obstruction is poor.

PULMONARY VASCULAR DISEASE PATTERNS

The pulmonary arterial system is characterized histologically by a progressive loss of medial elastic layers in vessels smaller than 500 μm in diameter and diminution of a muscular layer that is present in vessels down to 70 μm in diameter.[16,17] As the arteries lose their muscular layer, they branch into precapillary segments, followed by capillaries. This unique anatomic organization allows for low alveolar perfusion pressures, which are represented by a low right ventricular afterload.

There is increased realization of the importance of pulmonary vascular disease and pulmonary hypertension in the outcome of several lung diseases.[17a] The pathology of pulmonary vascular disease was extensively documented in descriptive chapters[18] or independent reports of a series of cases.[19,20] Based on these descriptions, a pathologic classification emerged that was applied to all cases of pulmonary hypertension, although initially, the classification was intended to apply to cases of pulmonary hypertension associated with congenital heart malformations.[19] The "pulmonary vascular pathologic era" culminated with the 1973 World Symposium with a pathologically driven overall classification of the disease. The present clinical definition and classification of pulmonary hypertension has been outlined in the Venice International Symposium in 2004[21,22] and recently revised in the 2008 International Symposium in Dana Point, California.[22a] The role of pathology in the clinical workup of patients with potential pulmonary hypertension is quite limited, because the disease is defined hemodynamically as an elevation of pulmonary artery pressures in excess of 25 mm Hg. This reduced role of pulmonary vascular pathology has largely resulted from the difficulty of sampling of lung tissue of patients with the disease and the realization that the pulmonary vascular pathologist was not able to discriminate among the various clinical conditions associated with pulmonary hypertension (illustrated by the First International Pulmonary Hypertension Symposium in 1973[23]). The Second International Symposium of Pulmonary Hypertension in Evian, in 1998,[24] proposed a more descriptive role for pulmonary vascular pathology, aimed at a supportive role in the clinical workup, when biopsies were taken or autopsy material was available (with modification in Table 15-4[17]). The Third symposium in Venice proposed some changes in the pathologic consideration of pulmonary vascular disease,[25] particularly with emphasis in some changes in terminology, that is, complex vascular lesions for plexiform/dilation lesions and emphasis on the presence of venous pathology in conditions felt to compromise predominantly pulmonary arteries.

TABLE 15-4. Histopathological Classification of Pulmonary Hypertension Based on the Evian World Symposium

PRECAPILLARY CHANGES
Endothelial cell proliferation (based on endothelial cell immunostaining):
Small clusters
Plexiform lesions
Dilation lesions
Smooth muscle cell changes (based on smooth muscle cell immunostaining):
Intima
Media
Adventitia—fibroblasts
Thrombi
POSTCAPILLARY CHANGES
Vein wall thickening
CAPILLARY CHANGES
Capillary hemangioma
ASSOCIATED FINDINGS
Perivascular inflammation
Recent/old hemorrhage
Septal fibrosis

Given the limitations imposed by the assessment of pulmonary vascular pathology, the interaction with the clinical team is critical. The descriptive diagnosis should emphasize endothelial, smooth muscle and adventitial fibroblast-based remodeling[26] (Fig. 15-6). Each of these vascular types of remodeling should be correlated clinically and hemodynamically with the severity of the pulmonary vascular disease. Large pulmonary arteries show changes similar to those of atherosclerosis (see Fig. 15-6A). Intima lesions consist of smooth muscle–based lesions, which consist of eccentric and concentric intimal thickening. Endothelial cell–based lesions consist of plexiform (see Fig. 15-6C and D), dilation, and concentric lesions. Endothelial cell–based lesions and concentric thickening, with smooth muscle cell or endothelial cells, are associated with severe pulmonary hypertension, that is, in excess of 40 to 45 mm Hg and poor outcome. Intima thickening compromising most of the inner circumference of the pulmonary arteries is a relatively frequent finding when present in a few vessels of normal lung; however, cigarette smoking causes this pattern of vascular remodeling in a large number of pulmonary arteries.[27] These alterations are associated with pulmonary vascular dysfunction, including reduced nitric oxide–mediated vasodilation.[28] Medial lesions consist of smooth muscle cell hypertrophy/hyperplasia (see Fig. 15-6B). Medial thickening can be seen in conditions not related to pulmonary hypertension, including bystander remodeling in ILD or cigarette smoke–related lung disease (including RB and DIP). In our experience, the degree of intimal or medial thickening is a poor predictor of levels of pulmonary artery pressures, often

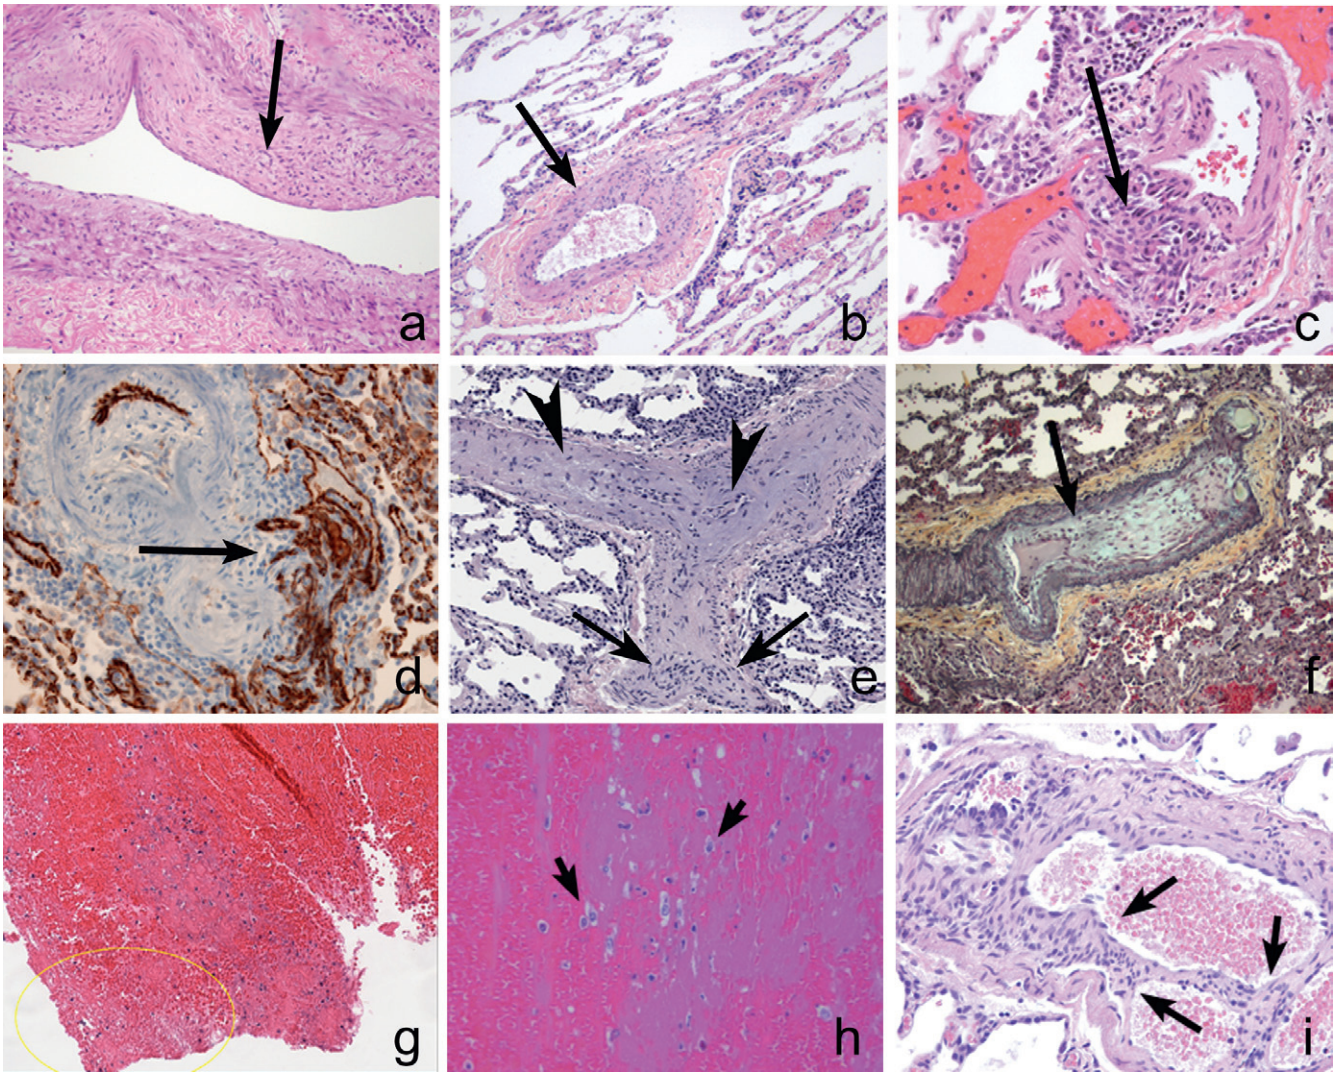

FIGURE 15-6 ■ Pulmonary vascular disease. **A,** Atherosclerotic-like changes with intima thickening in a large (elastic) pulmonary artery (*arrow*). **B,** Medial thickening (*arrow*) in a muscular pulmonary artery in idiopathic pulmonary hypertension. **C** and **D,** Plexiform lesion (*arrows*) consisting of intraluminal growth of endothelial cells highlighted by CD31 immunohistochemistry (*arrow* in **D**). **E,** Muscular artery with marked intima thickening (*arrowheads*), extending to branches (*arrows*) in a case of idiopathic pulmonary arterial hypertension. **F,** Pulmonary vein occluded by an organized thrombus, which is highlighted by the Movat stain (*arrow*) and diagnostic of veno-occlusive disease. **G–I,** Evolution of pulmonary thromboembolus with lines of Zhan in the circled area (**G**), and clearing around inflammatory cells trapped in the fibrin mesh (*arrows* in **H**). Organization of the thromboembolus leads to fibrotic bridges traversing the lumen of pulmonary artery (*arrows* in **I**).

needing a close correlation with clinical data. Occlusive lesions can also be found in pulmonary veins, characteristic of veno-occlusive disease[27a] (see Fig. 15-6F).

Adventitia thickening by fibroblasts and collagen is a relatively common occurrence, particularly in cases of pulmonary hypertension in neonates and in adults with scleroderma-associated pulmonary hypertension.

A common finding is pulmonary vascular remodeling due to localized or diffuse thromboembolic disease. Recent emboli are commonly encountered, because there are approximately 500,000 annual cases of pulmonary embolization, with an overall 20% mortality. Common risk factors are obesity, postoperative inactivity, and genetic alterations in anti- or procoagulant mediators. In lethal events, the histopathologic timing of clot formation in pulmonary arteries may be required for correlation with clinical events or for medicolegal reasons. Based on extensive experimental and histopathologic studies performed in the 1950s and 1960s, the morphologic events underlying the evolution of thrombi have been well delineated. Within minutes of formation of the platelet plug at the site of endothelial cell injury, fibrin is polymerized forming a mesh, which traps platelets, inflammatory cells, and red cells (see Fig. 15-6G and H). Thrombolysis starts immediately with activation of plasmin and therefore opposes the forces driving the formation and expansion of the thrombus. Up to 12 to 24 hours after formation of a thrombus, inflammatory

cells are still seen with preservation of the cellular structure. After this initial period, inflammatory cells undergo cell death and lysis, leading to the formation of a clear halo. In the first 48 hours, flattened cells (probably endothelial cells) expand from the intima into partially lysed fibrin strands (see Fig. 15-6G and H). After the first 48 hours, progressive organization occurs with fibrin lysis, incorporation of endothelial cells along fibrin stands, and early blood vessel formation. These processes, over the ensuing 2 to 3 weeks, progress with the incorporation of recanalized thrombi, in which the fibrin has been replaced by a collagenous background containing proliferated capillaries. Some thrombi may be extensively lysed, becoming a residual acellular, often eccentric, fibrotic intima thickening. Over months to years, luminal occlusions give rise to intraluminal bands of fibrous tissue (see Fig. 15-6I), with spaces in which blood flows. It is important to note that, in cases of emboli, the detached fragment will represent a potential extension rather than the early region of the thrombus. Therefore, precise timing of the pulmonary thromboembolus has to be interpreted with caution, with the caveat that its timing represents the events ongoing in the primary site and organizational events in the pulmonary arteries.

Pulmonary infarcts may complicate approximately 20% of pulmonary thromboemboli, particularly in patients with left heart failure. This low level of infarction is due to the dual lung circulation, including the bronchial circulation, which supplies an alternative to the pulmonary artery flow for lung structures.

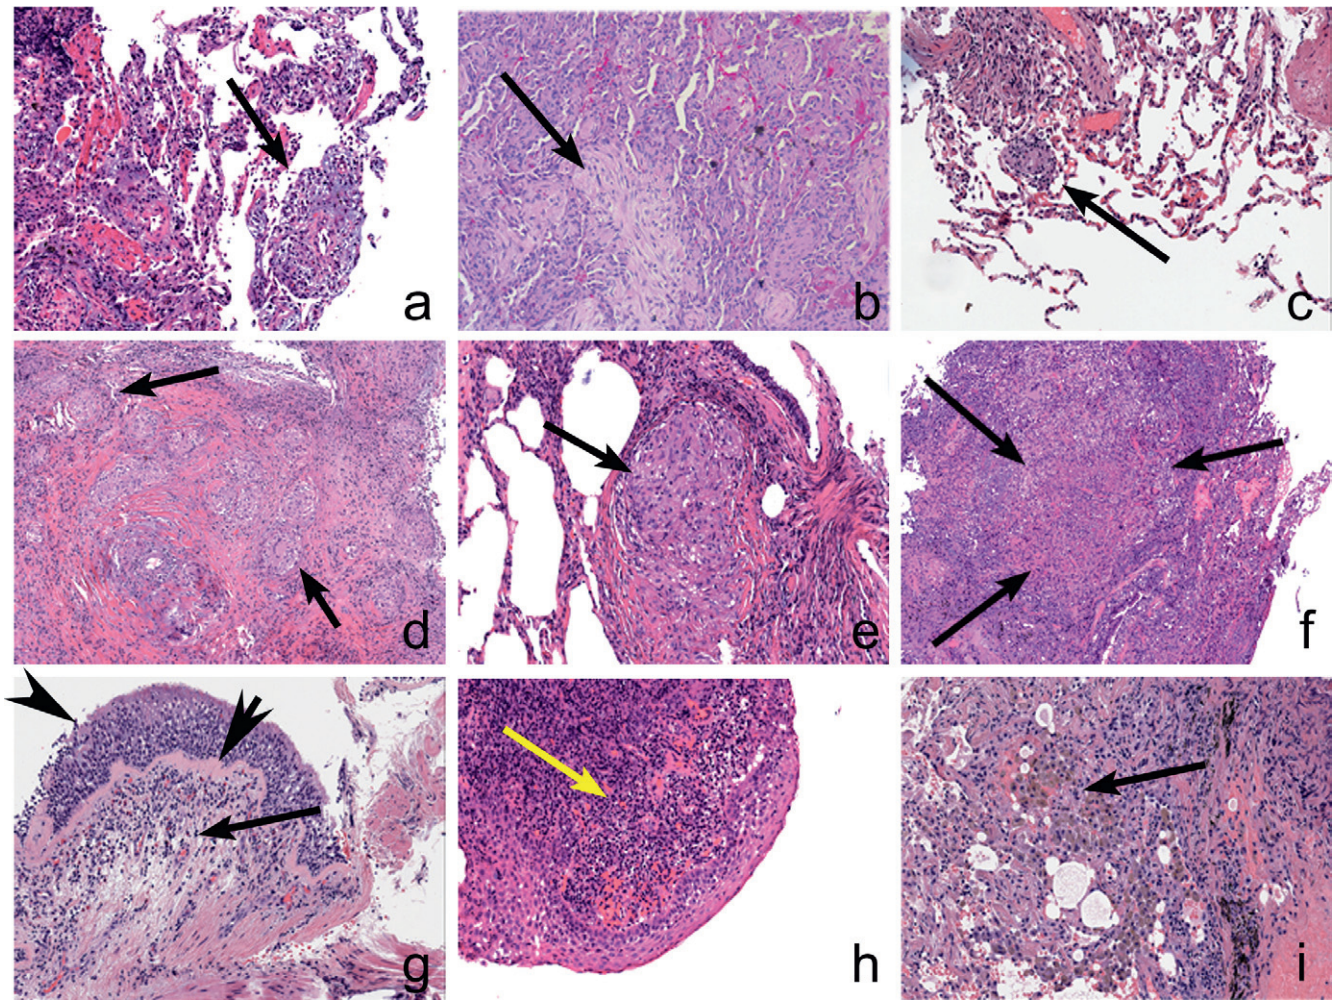

FIGURE 15-7 ■ Examples of pathologic processes identified in transbronchial biopsies. **A,** Acute bronchopneumonia with accumulation of neutrophils in the alveolar space (*arrow*). **B,** Organizing pneumonia organizing exudate (*arrow*) with granulation tissue in the alveolar space. **C,** Presence of poorly formed granulomas in biopsy of hypersensitivity pneumonitis (*arrow*). **D,** Example of confluent granulomas with extensive perigranulomatous fibrosis (*arrows*). **E,** Case of localized well-formed granuloma (*arrow*). **F,** Necrotizing granulomas with geographic necrosis (demarcated by *arrows*), consistent with Wegener's granulomatosis. **G,** Example of asthmatic large airway with thickened basement membrane (*short arrow*), detached superficial lining cells (*arrowhead*), and submucosal inflammation (*long arrow*). **H,** Intense chronic bronchiolitis (*arrow*). This process would be consistent with collagen vascular disease or graft-versus-host disease. **I,** Respiratory bronchiolitis with pigmented macrophages (*arrow*).

TRANSBRONCHIAL BIOPSY

Transbronchial biopsies have a central role in the management of patients with lung diseases. As mentioned previously, the accuracy of interpretation requires a deep knowledge of fundamental processes concerning inflammation, repair, scarring, proper tissue handling and processing, and an open line of communication with the clinical team. A poor indication for a transbronchial biopsy and inaccurate interpretation of the findings present in histologic slides can be avoided with these requirements. Figure 15-7 shows several examples of histopathologic patterns present in representative small fragments obtained from transbronchial biopsies.

KEY POINTS

- The interaction between the clinical team and the pathologist is critical for the proper pathologic interpretation of a lung biopsy.
- Most of the non-neoplastic lung diseases manifest histologically as particular pathologic patterns. The final diagnosis requires that the clinical team rules out/in clinical conditions associated with a particular pattern.
- Some non-neoplastic lung diseases, such as viral disease, may be associated with characteristic cytopathic alterations, which support a final pathologic diagnosis rather than the interpretation of a pattern of pulmonary disease.
- Histopathologic lung patterns are associated with multiple clinical diagnoses; conversely, specific diseases cause multiple lung patterns.
- Proper histopathologic recognition of patterns requires examination in low power to define which lung structures are predominantly compromised, followed by high-magnification examination of cellular features involved in specific lung patterns.

Does Lung Repair Recapitulate Lung Development?

INTRODUCTION

Much of pulmonary medicine is grounded in the concepts of injury and repair. However, neither of these terms is rigorously defined in the literature. Injury can be viewed at different levels—in the context of whole-organ function or at the level of individual cells or molecules. Similarly, repair can be considered at several levels—as a sequence of pathologic processes as in classical repair of a skin wound, at the level of single cell replacement, at the level of patching of holes physically torn in plasma membranes during injurious mechanical ventilation, and at the level of single molecules destroyed in the proteosome and replaced by new synthesis. Given this complexity and lack of consensus, we have provided our definition of the terms *injury* and *repair* with the aim of limiting what would otherwise be a very large subject. With this approach, we focus the discussion at a more conceptual level rather than on a detailed review of the primary literature. This chapter outlines challenges and questions that are inherent in the study of lung pathophysiology, and provides an overview of the essential concepts in lung injury and repair.

CONCEPTS OF LUNG INJURY AND REPAIR

The major physiologic function of the lungs is the uptake of oxygen and elimination of carbon dioxide from pulmonary capillaries. Respiratory failure reflects the inability of the breathing apparatus to provide adequate oxygenation of the arterial blood with or without adequate elimination of carbon dioxide. Dysfunction of various components of the respiratory system, alone or in combination, can result in respiratory failure, including in the airways (status asthmaticus), lung parenchyma (acute respiratory distress syndrome and acute interstitial pneumonitis), chest wall (trauma), and neuromuscular processes involved in respiration (Guillain-Barré syndrome).

Lung Injury

A broad definition of lung injury can be stated as: *the loss of normal lung function, structure, or architecture that results in respiratory failure or the inability of the lung to provide adequate oxygenation of the arterial blood and elimination of carbon dioxide.* Though deformities of the neuromuscular system and chest wall can result in alterations in oxygenation and carbon dioxide elimination, these disorders would not usually be considered to directly cause injury to the lung. We believe it is most appropriate to focus on lung structure and, in particular, to consider the issues of injury at the cellular and molecular level. Our concept of lung injury focuses primarily on cellular injury and destruction, with underlying diminution or loss of lung structure and function. Destruction here implies death of the cell, either by a variety of processes collectively termed *programmed cell death* and exemplified by apoptosis, or direct, externally mediated cell death, usually termed *necrosis.* Clearly, each of the more that 40 different types of cells known to reside in the lung performs individual functions, and injury should also be extended to abnormalities or loss of function to each type of cell, even if the cell is not overtly destroyed. In this chapter, we use as examples vascular endothelial cells, epithelial cells of the airways and alveoli, "interstitial" cells, nerves, and cells of the innate immune system. Loss or dysfunction of any of these cell types may also induce secondary effects on the tissue matrices, with further implications for overall lung function.

Whenever the term *injury* is used, we believe that the discussion should include specifics of what target is being injured, how the injury is mediated, how it is being assessed, and the overall effects on lung physiologic function. Thus we note as an example the attempt to define the concept of "acute lung injury" in animal models, which emphasize a multifaceted definition of lung injury that includes physiologic, histopathologic, and biochemical components.[1]

Lung Repair

The broad concept of lung repair includes *processes by which the function of the injured lung is restored to normal.* In regard to reparative processes, we focus on cellular aspects including replacement of both cells and supporting structures of the lung.

Repair and Homeostasis

The presumed function of reparative processes is to restore and maintain normal function (i.e., functional homeostasis). The healthy lung has an ample capacity to maintain its architecture and homeostatic activity through replacement of effete (expired) cells. In the absence of overt injury, the life span of lung cells (e.g., epithelial or endothelial cells) is thought to be long and their reparative potential high (see later). Under these conditions, *regeneration,* defined as complete restoration of any decline or abnormality of cell activity or numbers, would result in constant lung function over time[2] (Fig. 16-1, black line). However, the lung is a major portal to the environment and is exposed to diverse chemical and biologic agents that cause acute alterations in lung cellularity (i.e., loss of cell function or numbers). Normal aging can be viewed as a process in which steady and progressive declines in cell number and/or function reflect parallel decrements in the capacity of the epithelium or endothelium to heal itself (Fig. 16-1, blue line). Acute episodes of injury to the lung and its cellular and structural components, such as viral infection or chemical exposures, result in temporary fluctuations in lung function that reflect in part the ensuing response to exposure. *Repair,* therefore, can be defined as restitution of the cells and thus, the lung, to the preinjury level of structure and function. In aggregate, these processes would return the organ to a healthy state that is capable of responding to subsequent injuries (Fig. 16-1, green line).

Chronic lung disease is associated with a progressive loss of lung function that is exacerbated by environmental exposures. Individuals affected by chronic lung disease may be predisposed to repeated episodes of lung injury and may undergo cycles of injury that result in an accelerated decline in lung function (Fig. 16-1, yellow line). Chronic lung disease is often characterized by pathophysiologic alterations that can be considered *remodeling* processes, that is, fundamental alterations in cellular structure/function that modify interactions between the various types of cells. Classically, in the skin wound situation, this can involve the development of granulation tissue (inflammatory cells, fibroblasts, matrix deposition, neovascularization, etc.) that may or may not resolve to return the tissue to its original state. Similar processes occur in all tissues, including the lung.

Once a hypothetical functional threshold is reached (Fig. 16-1, red line), the lung may no longer have the

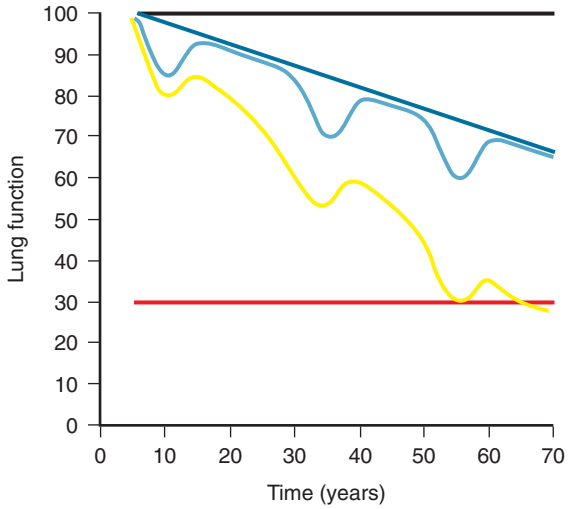

FIGURE 16-1 ■ Conceptual relationship between lung function and time. See text for discussion. (Adapted from Lazaar AL, Panettieri RA Jr: Is airway remodeling clinically relevant in asthma? Am J Med 115:652–659, 2003.)

capacity to repair itself and functionality is irreversibly lost. Under these conditions, an imbalance in the reparative capacity of adjacent tissues may result in *replacement,* that is, substitution of one tissue with another. A classic example of this is the development of fibrosis (sclerosis).

More Subtle Concepts of Injury and Repair

A more general concept of cellular injury might also include altered function such as secretion of surfactant, changes in the integrity of intercellular junctions, and effects of excessive biomechanical forces (stretch) on epithelial cells that may also lead to pathophysiologic effects but that may not be permanent (i.e., can be repaired without having to replace the cells). The effects of physical forces are of considerable importance in the lung, an organ that is constantly expanding and contracting, although these mechanisms are still poorly understood at the cellular and molecular levels.

Tissue Homeostasis and Cell Turnover

The underlying concept is that "injury" is occurring constantly but is normally mostly invisible due to protective and compensatory processes of avoidance or "repair." These processes range from blockade of the injurious stimulus to ongoing replacement of damaged and dead cells or structural components such as the basement membrane. As one of the key surfaces of the body that is exposed to the external environment, the respiratory tract is especially susceptible to environmental influences and injurious stimuli. Evolutionary forces have led to adaptation to this situation in other organs by creating rapidly replaceable and highly "plastic" structures such as the epithelium of the gut and skin. It is intriguing that the prevailing wisdom is that epithelial cells of the lung are long lived—a notion that may not be correct. The issue of rapidity of cell turnover has been addressed recently in cardiomyocytes (also considered to be long lived) utilizing an analysis based on the spike in radioactivity generated by atomic bomb testing in the 1950s. This analysis revealed a higher degree of turnover of these cells than had been formerly thought.[3] In fact, Shapiro and colleagues used this same approach to show that the lung matrix protein elastin turned over remarkably slowly.[4] However, lung cells were not examined.

Snapshot analyses of lung tissue from "normal" adult humans or experimental animals usually indicate only small scattered examples of replicating cells or of cells undergoing apoptosis (programmed cell death). Given the problems of sampling an organ such as the lung from tissue sections (one section usually represents only a minute percentage of the whole lung volume and only a single time point), the fact that evidence of cell turnover is detectable at all indicates a much higher degree of cellular turnover than used to be thought. Clearly this is an important area that needs more investigation with quantitative techniques and with attention to rates of turnover of the individual cell types. Thus we know that the resident alveolar macrophage (which is in fact located outside the body, i.e., on the surface of an exterior epithelium) is comparatively long lived (in comparison, for example, with macrophages at other sites in the body). In mice and dogs, the life span of these cells has been estimated in months, representing a significant proportion of the animal's life span. This raises questions about what maintains their persistence and the implications for the surveillance and protective functions of macrophages in the respiratory system.

Animal Models

It is important to recognize that much of our information about injury and repair comes from experimental animals, nearly all of which exhibit substantial differences from humans. This is especially important when we think about the plethora of human lung diseases that develop over years and in later life (e.g., after the lung has been in continuous operation for over 50 years). Most of our experimental animals are four footed, with consequently different lung orientation. The human upper respiratory tract is unique, as is the degree of mouth breathing by humans (most of our experimental animals are exclusive nose breathers, with significant implications for filtering and conditioning of the air that reaches the lower airways). Many studies are now carried out in mice, which, despite the high degree of common functional and evolutionary heritage with humans, differ from humans in many aspects. These differences should be carefully considered so that experimental observations in animals are not automatically applied to the human condition. Examples include the size, number of branches, composition, and vasculature of the airways. Mice have short airways, with a much higher proportion of bronchiolar structure and, allegedly, no bronchial circulation. However, there are many similarities between the anatomy (and presumable function) of small airways and subtended alveolar units between mice and humans, allowing cautious extrapolation of the results of experimental murine models to human disease.

THE CLINICAL CONTEXT: HETEROGENEITY IN THE INJURY AND REPAIR PROCESS

Many common pulmonary disorders, such as chronic obstructive pulmonary disease (COPD), interstitial lung diseases (ILDs), asthma, cystic fibrosis, acute lung injury (ALI), and the acute respiratory distress syndrome (ARDS), are characterized by injury to various cell types of the lung resulting in clinically significant physiologic abnormalities. The length of time from the onset of injury until the development of impairment depends on the intensity and duration of the insult. In ALI and ARDS, the degree of the initial injury is severe enough to result in respiratory failure over a period of hours or days. By contrast, patients with COPD usually require years of exposure to the offending agent (usually cigarette smoke in the developed world) prior to the development of

alterations in respiratory function. Finally, the clinical course of some lung diseases may reflect a complex mixture of both injury and repair. For example, patients with ILD often have a stuttering course with periods of rapidly declining lung function (thought to reflect injury to lung epithelium) interspersed with periods of relative quiescence (thought to reflect aberrant attempts at repair).

Representative Example: ALI/ARDS

ALI and its most severe form, ARDS, are frequent complications in critically ill patients and affect more than 200,000 individuals in the United States annually. Importantly, these conditions are responsible for significant morbidity and mortality, and the expenditure of more than $10 billion annually in direct health care costs.[5] Treatment of the underlying condition and excellent supportive care using "lung-protective" mechanical ventilation and conservative fluid management strategies contribute to successful clinical outcomes.[6] However, aside from the use of activated protein C[7] in the subset of ALI/ARDS patients with sepsis, and possibly treatment with glucocorticoids,[8] specific therapies are lacking and the cascade of events leading to ALI/ARDS, once in progression, is much less amenable to specific treatment.

Not all patients who are exposed to stimuli that can cause injury to the lung actually develop physiologic abnormalities. For example, smoking is the dominant risk factor for the development and progression of COPD; however, less than 25% of smokers develop COPD. Fortunately, not all critically ill patients develop ALI. Based on the results of several epidemiologic studies published over the last 2 decades, a variety of factors have been identified that can alter the susceptibility of an individual patient to the development of ALI. These factors can be separated into three general categories: the acute medical condition, preexisting acquired disorders, and genetic determinants (Fig. 16-2). The identification of such patient-specific characteristics could significantly improve both our understanding of the pathogenesis of ALI and our ability to care for these critically ill patients.

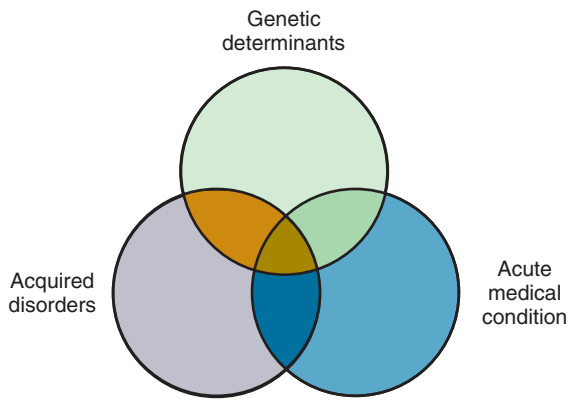

FIGURE 16-2 ■ Acute lung injury: clinical risk factors.

Characteristics of the Injurious Insult

The acute intensity of the injurious insult is a determining factor in the subsequent development of physiologic dysfunction in the lung. For example, acute damage to the lung caused by the inhalation of toxic agents can be caused by the accidental release of chemicals into an enclosed environment. The concentration of the toxic agent is a major determinant of the severity of the damage to the lung. Nitrogen dioxide is produced in silos and, when dissolved in water, creates nitrous acid and nitric acid, which are irritants to mucous membranes. Lower concentrations of nitrogen dioxide (50 to 100 ppm) can cause injury and the immediate onset of respiratory symptoms that may eventually be associated with the development of bronchiolitis obliterans. However, nitrogen dioxide concentrations of greater than 200 ppm can cause ALI and death within minutes. Another example showing the effect of the intensity of the insult is the increased likelihood of developing lung injury or pneumonitis from radiation exposure. The chance of developing radiation pneumonitis and the degree of impairment depend in part on the dose of radiation that is delivered, the dose per daily fraction, and the amount of lung volume that is treated.

For many types of injurious stimuli, the intensity and/or quantity of exposure correlates with the development of clinically significant pulmonary abnormalities. For example, longitudinal studies have shown accelerated decline in forced expiratory volume at 1 second (FEV_1) in a dose-response relationship to cigarette smoking, related to both the duration of smoking and the amount smoked. This dose-response relationship of pulmonary function with cigarette smoking accounts for the association of higher prevalence rates for COPD with increasing age. Similarly, in patients with cystic fibrosis, the number of acute exacerbations per year is strongly related to the decline in pulmonary function as measured by FEV_1. In ALI/ARDS, the number of transfusions or the severity of sepsis correlates with the risk for development of lung injury.

Characteristics of ALI/ARDS

Fowler and colleagues identified and monitored all patients who required mechanical ventilation for one of eight different conditions: cardiopulmonary bypass, burns, bacteremia, hypertransfusion, multiple long bone or pelvic fractures, disseminated intravascular coagulation, severe pneumonia, and aspiration of gastric contents.[9] In total, 88 of these patients developed ARDS, with an incidence ranging from 1.7% after cardiopulmonary bypass to 35.6% with pulmonary aspiration. Using a similar study design, Pepe and colleagues followed patients with a variety of diagnoses, including sepsis syndrome, aspiration of gastric contents, pulmonary contusion, hypertransfusion, and multiple fractures.[10] The incidence of ARDS among these at-risk diagnoses ranged from 8% for major fractures to 38% with sepsis syndrome.

These landmark studies identified several specific diagnoses that were common in critically ill patients and

were associated with an increased risk of developing ARDS (see Fig. 16-2). The majority of these patients can be classified into three common diagnoses: pneumonia, nonpulmonary sepsis, and aspiration of gastric contents. In one large population cohort study, pneumonia, severe sepsis, and witnessed aspiration accounted for 93% of the patients who developed ALI (46%, 36%, and 11%, respectively).[11] Major trauma was the fourth most common diagnosis associated with ALI. Additional studies have identified secondary factors that were associated with an increased risk for ARDS in trauma patients, including long bone fractures, chest trauma, and the requirement of blood transfusion during resuscitation. More recently, patients following pulmonary resection surgery were reported to be at increased risk for ARDS. In a study of 1139 patients who underwent lung surgery, 3.9% of the patients developed ALI or ARDS on average 4 days postoperatively.[12] Since lung surgery is a relatively common procedure, this relatively low percentage still represented nearly one new ARDS patient every 2 months following pulmonary resection at a single institution.

Preexisting Acquired Disorders

The presence of several preexisting medical disorders can modify the susceptibility to develop ALI in those patients who have developed one of the risk factors for ALI/ARDS described previously. Importantly, none of these conditions by itself is associated with the onset of ARDS. A history of alcohol abuse or dependence was the first reported comorbid condition that altered susceptibility to ARDS. In a study of 351 critically ill patients, 43% of the patients with a prior history of alcohol abuse developed ARDS, as compared with 22% in those patients without a history of alcohol abuse.[13] This initial association between alcohol abuse and an increased susceptibility for ALI/ARDS has been validated in several other populations, including patients with septic shock, critically ill patients requiring blood transfusions, surgical patients after lung resection, and intensive care unit patients in one epidemiologic survey in the Netherlands.[14–17]

Diabetes mellitus is another chronic medical condition that theoretically alters susceptibility for ARDS. Several different studies support the theory that proinflammatory cytokines, and more specifically the activation and recruitment of circulating neutrophils into the lung parenchyma, are an integral component of the pathogenesis of ARDS. The same alterations in the inflammatory cascade that predisposed diabetic patients to develop serious infections were hypothesized to be protective against the onset of ALI/ARDS. One study identified 113 patients with septic shock, of whom 28% had a history of diabetes.[18] In both univariate and multivariable analyses, the incidence of ARDS was significantly greater in the nondiabetic patients as compared with those who had a history of diabetes. These results also have been validated in a subsequent study of 688 patients at risk for ARDS, with a significantly reduced odds ratio for ARDS in patients with a history of diabetes (0.58).[19]

Older age has also been reported to be associated with an increased risk of developing ARDS, as it is for many different examples of lung injury and repair processes. Trauma patients over 70 were twice as likely to develop ARDS when compared to patients between 18 and 29 years of age.[20] Similarly, in patients with skin burns, increasing age has a positive association with ARDS.[21]

Several recent studies have reported that a delay in the initiation of specific therapies during the initial resuscitation period can also alter susceptibility for development of ALI/ARDS. In a study of 160 patients with septic shock, delayed initiation of early goal-directed therapy and antibiotic treatment during the first 6 hours were both independently associated with an increased risk for ALI/ARDS.[22] The delayed implementation of low tidal volume ventilation has also been reported to be a risk factor for ALI/ARDS. Several single-center studies and one secondary analysis of a large international survey have reported that the early use of high tidal volume is associated with the subsequent development of ALI/ARDS.[23] Finally, an association between the transfusion of blood products and the development of ALI/ARDS has been recognized for many years.[24]

Genetic Determinants

Discoveries about the genetic control of innate immunity and the inflammatory response have raised the question of whether polymorphic alleles of genes that encode cytokines and other mediators of inflammation can result in phenotypic differences in the host inflammatory response. These differences might account for some of the heterogeneity in individual susceptibility to develop ALI.[25] The possibility that genetic factors might be involved in the pathogenesis of ALI/ARDS was first raised when Marshall and colleagues reported an association between a specific polymorphism in the angiotensin-converting enzyme (ACE) gene and an increased mortality in patients with ARDS.[26] Experimental evidence suggests that activation of the pulmonary renin-angiotensin system might influence the pathogenesis of ARDS via mechanisms that include altered vascular permeability, vascular tone, and fibroblast activity, and by reducing alveolar epithelial cell survival and fibroblast activation. The human ACE gene (*DCP1*) is located on chromosome 17q23 and contains a restriction fragment length polymorphism consisting of the presence (insertion, I) or absence (deletion, D) of a 287-bp Alu repeat sequence in intron 16. Among 80 healthy white individuals, the I/D polymorphism accounted for 47% of the variance in plasma ACE, being highest in those with the DD genotype. When compared with a variety of controls, including patients with non-ARDS respiratory failure, those undergoing coronary artery bypass surgery, and the general population, the DD genotype frequency was highest in those patients with ALI/ARDS and was also associated with an increased ALI/ARDS-related mortality.

More recently, several other specific genetic polymorphisms have been associated with ARDS. Using the can-

didate gene approach, several studies have focused on the role of pre–B-cell colony-enhancing factor (PBEF), a cytokine involved in B-cell maturation, in the pathogenesis of ARDS. Of the 11 single nucleotide polymorphisms (SNPs) that were identified in the PBEF gene, the G allele of the 21001 T/G SNP both was associated with increased promoter activity and had a higher frequency in patients with sepsis-mediated ALI. In contrast, the T variant of the 21543 C/T SNP resulted in a twofold decrease in promoter activity and conferred protection from ALI. These two studies show that some of the differences in the degree of injury and the ability to repair the injured lung is related to genetic determinants. Ultimately, a clearer understanding of these genetic determinants will facilitate the development of more directed therapies that decrease the degree of injury and improve the reparative process in patients with ALI/ARDS.

Remarkably, the lung is capable of repairing the extensive amount of injury that occurs in most patients with ALI/ARDS. The majority of improvement in pulmonary physiologic measures and symptomatology occurs in the first 3 months after extubation. However, persistent respiratory symptoms and pulmonary function abnormalities are more common than initially appreciated in survivors of ALI/ARDS. Certain patients with ALI/ARDS are unable to normally repair their injured lungs and can develop persistent fibrotic changes in the lungs. Factors related to the severity of the ALI are the most accurate predictors of persistent respiratory compromise in survivors of ARDS, including increased fraction of inspired oxygen ($F_{I_{O_2}}$), higher levels of positive end-expiratory pressure, and decreased static pulmonary compliance during the acute clinical course of ARDS.

Physiology, Cell Biology, and Immunology of ALI

Common Pathway to ALI/ARDS

Regardless of the inciting event (acute medical condition), the clinical and pathologic manifestations of ALI/ARDS are similar, indicating the existence of common pathways that represent potential therapeutic targets.[27] ALI/ARDS reflects severe inflammatory injury to the endothelium and epithelium resulting in compromise of pulmonary barrier and transport functions leading to high-permeability pulmonary edema.[28]

Clinical and Pathologic Manifestations

Clinically, an initiating event (sepsis, shock, multiple transfusions, etc.) triggers a systemic inflammatory response with activation of macrophages, in turn leading to sequestration of large numbers of neutrophils in the lung. Histologically, ALI is characterized by large numbers of neutrophils in the vascular, interstitial, and alveolar spaces in association with endothelial and epithelial injury.[29] This, combined with the potential of neutrophils to induce tissue injury in diverse experimental systems, has led to the widely held concept that these potent phagocytes are central to the pathogenesis of ALI, a notion supported by numerous human and animal studies.[30] Further evidence points to specific pathogenic roles for neutrophil-derived microbicidal products, including reactive oxygen (O_2^-, H_2O_2) and nitrogen (NO, $ONOO^\bullet$) species and proteinases such as neutrophil elastase and matrix metalloproteinases. It is noteworthy that inflammation is inherently beneficial and may even actively participate in normal repair processes (see later); only when it becomes excessive or unregulated does host damage ensue.[31] Given the occurrence of ALI/ARDS in neutropenic patients, however, it is clear that other mechanisms also contribute to lung injury.[32]

Distinct Phases of Injury

Acute lung injury is a progressive and dynamic process that is characterized by distinct stages, each with different clinical, histopathologic, and radiographic features. The acute, or exudative, phase is characterized by the rapid onset of hypoxemic respiratory failure after an initiating event. Physiologically, at this stage the lungs have decreased compliance and there is significant ventilation-perfusion mismatch and shunting of venous blood, leading to profound arterial hypoxemia that is refractory to supplemental oxygen. The chest radiograph shows bilateral pulmonary infiltrates, which can be patchy or asymmetrical, and pleural effusions are often present. Importantly, studies involving computed tomographic scanning have revealed that the alveolar filling and atelectasis are not diffuse but rather tend to predominate in dependent lung zones with relative sparing of other areas. At this early stage, the histopathologic appearance is characterized by diffuse alveolar damage; the alveolar spaces are filled with protein-rich edema fluid, erythrocytes, neutrophils, and macrophages. Fibrin-rich hyaline membranes are prominent at this stage. This appearance reflects profound disruption of the integrity of the alveolar-capillary membrane, with loss of the barrier and transport functions of both the microvascular endothelium and epithelium.

Extent of Epithelial Injury Predicts Outcome

Injury to the distal lung epithelium is pivotal to the development of as well as the recovery from ALI. In fact, the extent of injury to the alveolar epithelium is an important predictor of the outcome of ALI/ARDS. In health, two types of alveolar epithelial cells exist in the lungs. Flattened type I cells form approximately 90% of the alveolar surface area and are most susceptible to injury. Cuboidal type II cells that are situated in the alveolar "corners" make up the remaining 10% of the alveolar surface area. Type II cells have several critical functions, including production of surfactant, ion and fluid transport, and—especially relevant to repair of the injured lung—proliferation and differentiation to type I cells after injury.

The loss of epithelial integrity and function in ALI is critically important not only to the genesis of pulmonary dysfunction, but also to repair of the injured lung. Under physiologic conditions, the alveolar epithelium is much

less permeable than the microvascular endothelium and, consequently, injury to the epithelium with loss of its barrier function contributes significantly to the formation of alveolar edema. Since alveolar epithelial cells contribute to fluid transport, injury to these cells also impairs the clearance of edema fluid from the alveolar space. Furthermore, dysfunction of alveolar type II cells compromises the production and turnover of surfactant, a factor that contributes to widespread atelectasis and further compromises the innate immune system of the lung. Lastly, the extent of injury to the alveolar epithelium has a major impact on repair of the injured lung.

In some patients, the acute phase of lung injury resolves completely, leaving these individuals with relatively normal lung function. However, in other patients, the process can be progressive, leading to diffuse pulmonary fibrosis with markedly diminished pulmonary compliance, persistent hypoxemia, and increased alveolar dead space. In the most severely affected individuals, pulmonary hypertension may develop, reflecting obliteration of the pulmonary capillary bed. The histolopathologic appearance of the lung in these patients includes the presence of excess collagen and other extracellular matrix proteins involving the alveolar and interstitial spaces, along with chronic inflammatory cells. In this phase, radiographic studies reveal diffuse interstitial linear opacities that are reflective of the fibrotic process. In addition, bullae and pneumothoraces sometimes occur.

Clinically, the recovery phase is characterized by gradual resolution of hypoxemia and radiographic infiltrates and improved pulmonary compliance. Interestingly, despite the presence of pulmonary fibrosis, the chronic phase resolves in many patients, and pulmonary function returns to normal.

CAUSES AND MECHANISMS OF LUNG INJURY

Causes of Injury

As would be expected for an organ that is open to the external environment, the lung is exposed to a wide variety of potentially injurious factors ranging from physical insults to infections to inhaled toxins or gases. In addition, the lung is also susceptible to injury from the vascular surface (e.g., blood-borne toxins or cell-derived products) as well as from mechanical effects generated during expansion and contraction. External insults will affect the epithelium with graded effects from the upper airways down to the alveolus, depending in particular on the physical size of the stimulus. Inhaled particles of less than 2 to 5 μm gain direct access to the alveolar surface, whereas larger particles are deposited in the airways, predominantly at bifurcations of the bronchial tree. However, materials inspired from the oropharynx reach all areas of the lung and can induce substantial epithelial injury. Hematogenous injury, initially to the endothelium, also occurs in many circumstances but particularly in sepsis, thrombotic conditions, and—perhaps more often than currently recognized—systemic autoimmune conditions. In most of these varied circumstances, the primary effects occur on the epithelial or endothelial cells.

A key contributor to lung injury, from either the vascular or epithelial surface, is the inflammatory process, including the effects of inflammatory mediators and the accumulation and activation of inflammatory cells. For example, Figure 16-3 depicts damage to endothelial and alveolar epithelial cells accompanying sequestration and activation of neutrophils in an acute inflammatory response. The process is usually associated with increased vascular and alveolar permeability (as illustrated in the figure), sometimes with sufficient damage to the alveolar wall to result in coagulation (fibrin) and erythrocyte accumulation in the air space. Importantly, in a "normal" and presumably protective local and self-limited inflammatory response, the fluid, debris, and other elements of the inflammation are rapidly removed and the epithelium and endothelium are quickly replaced and/or repaired. Inflammatory cells (e.g., neutrophils) can migrate into the alveolus in response to local chemoattractants without causing significant injury to the alveolar wall, unless they receive additional stimuli to release their toxic constituents.

Mechanisms and Pathways of Lung Cell Injury

Here again at the cellular level we encounter the issue of a reasonable definition of "injury." Externally or

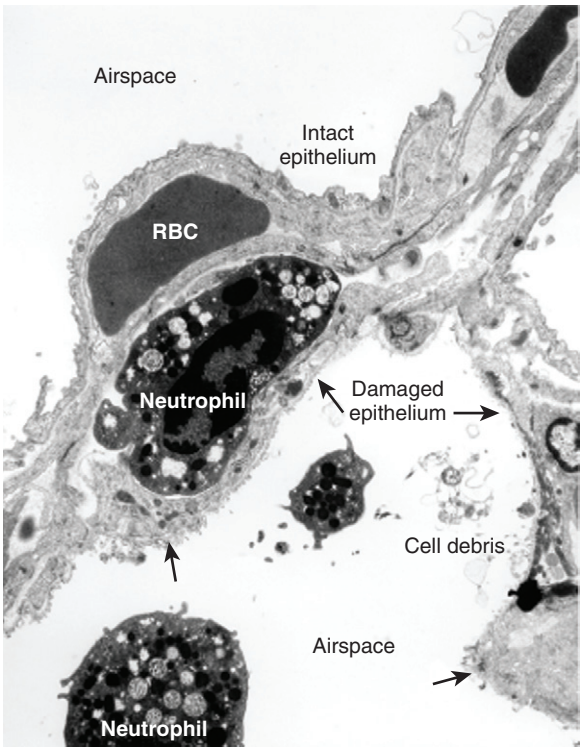

FIGURE 16-3 ■ Electron micrograph of inflammatory injury to the murine lung.

endogenously induced alterations of cell function could be considered injurious if they negatively affected the primary functions of that cell. For example, in broad terms, one key endothelial and epithelial function is maintenance of a barrier. Dysfunction would be manifest as increased permeability with egress of plasma constituents from the blood or access of environmental materials to the interstitium from the air spaces. Tight junctions between both epithelium and endothelium can "open" in response to stimuli or intracellular conditions without permanent destruction/death of the cells. In fact, such a transient permeability change is an important element of the host defense function of the inflammatory reaction and thus could be considered a physiologic response. This points out the fine line between what is often called injury, versus normal tissue responses—with a possible emphasis on how widely distributed the effect and how long the response persists. Local, transient barrier disruption and alveolar edema may thus occur to deal with a local inflammatory insult without substantial effect on whole-lung function, whereas the same mechanism applied across the entire tissue may lead to a condition (as in ALI/ARDS) that is clearly considered lung injury. However, in ALI/ARDS and such generalized inflammatory conditions, there is also overt epithelial cell death, so the concept of system-wide transient nonlethal cell "dysfunction" may be primarily hypothetical. Perhaps the most remarkable consideration is that, despite the myriad opportunities for damage, there is not more cellular injury or death in the lung, and/or that injury that does occur, perhaps all the time, is so readily and rapidly repaired that it is essentially invisible except in extreme situations.

Cell Death: Programmed Cell Death versus Toxic and Necrotic Cell Death

There has been a surge in interest in recent years about the mechanisms and importance of cell death, particularly the various forms of *programmed cell death* (PCD) in which processes intrinsic to the cell itself lead or contribute to death. Formerly, describing the mechanisms by which cells die fell largely to the pathologists and led to the recognition that cell death could be programmed (one form of which was termed *apoptosis*[33]). It is important to note that there are many forms of PCD,[34] so the term *apoptosis* is often used indiscriminately and thus erroneously in this regard. Originally a morphologic definition, apoptosis might best be defined currently not only on the basis of nuclear condensation and characteristic DNA fragmentation as well as other morphologic characters, but also based on its induction mechanisms and requirement for the action of a series of intracellular caspase proteases.

Many recent reviews address the various mechanisms and pathways leading to apoptosis and other forms of PCD.[34–37] However it is important to note two major pathways (as well as minor pathways) leading to apoptosis: the intrinsic pathway, involving signaling from the mitochondria; and the extrinsic pathway, deriving from signals generated from external stimulation of "death" receptors, usually members of the tumor necrosis factor receptor family such as Fas. The critical role played in apoptosis by the mitochondria cannot be overstated and has intriguing evolutionary implications, including pathways leading to cell death even in single-celled eukaryotes. In mammalian neutrophils, the mitochondria have essentially lost their energy-supplying function and could be considered primarily as an engine for the initiation of apoptosis in a cell that has an intrinsic life span of only a few hours. In other words, there are many ways by which cells may die, some arising from functional defects that cannot be repaired (e.g., DNA damage, the unfolded protein response, or an excessive autophagic response), and some from external stimuli.

Likewise, many different processes induce necrosis, that is, forms of cell death that do not normally require active participation of cellular processes and generally lead to disruption of the cell membrane with subsequent release of cellular contents. These would include physical effects of acid from inspiration of stomach contents, inhalation of toxic materials or fumes, infection with lytic viruses or bacterial products, mechanical disruption of cell membranes, and other effects.

Most forms of PCD, including apoptosis, are considered processes whose primary effect is silent (noninflammatory and nonimmunogenic) removal of cells from tissues. Normally the removal process is highly efficient, but if defective or overloaded, then apoptosis itself leads to loss of plasma membrane integrity and disruption of the cell—so-called secondary necrosis or post-apoptotic cytolysis. Because of the proinflammatory, and sometimes proimmunogenic, properties of intracellular constituents, this can lead to prolonged inflammation, as suggested in cystic fibrosis[38] or autoimmunity (as in systemic lupus erythematosus).

Protection of Cells from Damage

The lung has many mechanisms to protect cells from damage. The surfactant layer in the alveolus and the mucus barrier in the airways provide one such protection against external insults. A key issue for cells in the lung is the constant exposure to high oxygen tensions and oxidants, and lung cells contain abundant antioxidant defenses. The alveolar macrophages perform key scavenging functions for particles that do gain access to the alveolar compartment. An intriguing but understudied issue for the lung is the potential for mechanical injury to lung cells induced by the process of breathing. Studies in skeletal and cardiac muscle have shown that tears in the plasma membrane do occur in such mechanically stressed cells, and that there are substantial inbuilt repair processes involving the protein dysferlin that "plug" the holes with new membrane.[39] The effects of stretching can also be extended to other lung cell functions, and this is now receiving attention, for example, in the context of the potential damaging effects of mechanical ventilation with high tidal volumes as well as in normal breathing. PCD is also highly regulated and in many cases only occurs after the internal insult overcomes a threshold of the relative reparative or protective

activities. An example here is the autophagic response of cells to nutritional stress that can serve in the short term to keep the cell alive until the stress is relieved but that *in extremis* actually initiates PCD.

Assessing Programmed Cell Death

The inherent importance of cell injury and death in normal cell turnover and particularly in lung diseases implies a need to assess its presence. However, since these processes are part of normal tissue homeostasis, there are also potent mechanisms to either repair the cell or, if this is not possible, to remove it. Thus cells undergoing PCD are normally cleared so rapidly that it is hard to detect significant numbers of such cells in tissues, even if death and removal is actively ongoing.[40] For example, alveoli full of neutrophils in bacterial pneumonia can resolve the inflammation (i.e., clear these inflammatory cells) despite the fact that, at any given time, no more than 1% of the cells can be detected as apoptotic. This may lead to confusion, because the absence of detectable apoptosis does not necessarily mean cells are not dying and, in contrast, detectable apoptotic cells may reflect defective clearance mechanisms rather than increased cell death. These processes must be considered as well controlled and dynamic. A specific example may be in emphysema, where a number of investigators have shown increased numbers of detectable apoptotic cells in the pulmonary parenchyma that are likely to be both endothelial and epithelial cells. Whether this represents increased cell death or defective clearance, or both, is not clear. In emphysema, experimental evidence suggests that clearance processes are defective. Cigarette smoke can damage lung cells; however, the increase in numbers of apoptotic cells can be detected even years after a patient has stopped smoking. Therefore, if increased apoptosis is occurring, it must be attributed to other causes, or perhaps to persistence of toxins from earlier smoke exposure, or to an effect that only acts when the "long-lived" cells start to divide.

Manifestations of Lung Injury: Loss of Structure Leads to Loss of Function

There is increasing evidence for significant structural and functional interconnectivity between the various cellular layers of the alveolus.[41] This suggests that damage to the epithelium can be transmitted to interrelated injury to the endothelium as well as interstitial cells such as fibroblasts. Rapid repair of the cells might avoid significant damage to the alveolar matrix and thus preserve overall structure and function. However, injury to cells that is not readily reparable in an appropriate timeframe might also result in altered matrix, and derangement of the alveolar scaffold upon which cellular repair and maintenance of alveolar structure depend. These concepts tie together the proteolytic and cellular hypotheses of emphysema (destruction of the matrix versus epithelial or endothelial damage). Alterations in cell function, integrity, or presence can lead to overt manifestations of lung injury:

1. Alterations in alveolar-capillary barrier function with accumulation of alveolar exudate, as in ARDS
2. Accelerated cell death and/or loss of alveolar structure leading to loss of normal lung architecture, as in emphysema
3. Abnormalities of surfactant amount, composition, or function leading to altered structure through alveolar collapse
4. Dysfunction of the airways epithelium leading to abnormal mucus composition or amounts, ciliary function, etc.
5. Abnormal repair processes after injury, as in fibrosis of the airways or parenchyma

Each of these examples can lead to primary disruption of the gas exchange functions of the lung.

Modeling Acute Lung Injury in Animals

In humans, the diagnosis of ALI and ARDS is based on a well-defined set of clinical parameters that include: (1) acute onset of respiratory distress; (2) radiographic evidence of diffuse bilateral pulmonary infiltrates; (3) evidence of profound alterations in the gas-exchange function of the lung as assessed by the ratio of the arterial P_{O_2} to $F_{I_{O_2}}$ (ratio <300 mm Hg for ALI and <200 mm Hg for ARDS); and (4) absence of left ventricular dysfunction or other causes of elevated left atrial pressure (to exclude primary cardiogenic causes of pulmonary edema).[42] However, it is difficult to translate some of these criteria to experimental animal models. For example, although arterial blood gas analysis, radiographic assessment of pulmonary infiltrates, echocardiography, and even cardiac catheterization can all be performed in small animals, including mice, the equipment required to make all of these measurements is rarely available in all but the most highly specialized laboratories. Furthermore, the measurements are often incompatible with the design of experimental systems. Thus, it is not practical to use the human criteria in many experimental situations, particularly in studies involving small animals. An alternative approach is to define ALI in animals based on histopathologic criteria similar to those seen in humans with ALI and ARDS. In humans, the pathologic correlate of ALI/ARDS is diffuse alveolar damage (DAD), which is characterized by inflammatory infiltrates, thickened alveolar septae, and deposition of hyaline membranes. However, none of the available models of ALI in animals reproduces all the pathologic features of DAD. Therefore, the criteria used to define ALI and ARDS in humans should be translated to most animal models of ALI with appropriate caution.[1]

Feasible Assessment of Acute Lung Injury in Animal Models

The following represent the primary manifestations of pulmonary dysfunction that can be assessed in animal models of ALI.

Abnormalities of Gas Exchange. In humans, an elevated alveolar-to-arterial gradient, reflecting compromise of the gas-exchange function of the lungs, is one of the major parameters used to diagnose, stratify, and monitor patients with ALI/ARDS. While it is feasible to conduct arterial blood gas analysis in larger animals, it is more difficult in rodents and especially mice because of the difficulty obtaining a sufficient sample of arterialized blood. Noninvasive continuous monitoring of capillary or tissue oxygen saturation using conventional oximetry is a useful parameter to monitor if the appropriate instrumentation is available.

Decreased Lung Compliance. Decreased lung compliance due to pulmonary edema and atelectasis is a primary feature of human ALI/ARDS. It is important and easy to assess in animal models by determining the pressure-volume curve after a lung recruitment maneuver.

Assessment of Increased Permeability of the Alveolar-Capillary Membrane. This is a critical parameter and one that defines the pathophysiology of ALI in humans and in animal models. However, its measurement is subject to many potential technical difficulties that depend on the method used. The principal of this measurement is that, in ALI, the selective barrier function of the alveolar-capillary membrane (contributed to by the barrier functions of the pulmonary endothelium and epithelium) is compromised in response to injury. This is manifest by leakage of protein-rich fluid from the vascular to the interstitial and/or alveolar space and the accumulation of high-molecular-weight proteins that are normally excluded from the alveolar space. Many methods have been developed to assess lung permeability, but measurement of the concentration of albumin and higher molecular weight proteins in bronchoalveolar lavage fluid compared to their concentrations in plasma, and wet-todry weight of the excised lungs, are the most widely used.

Histologic Assessment of Lung Injury. One of the most challenging aspects of animal models of ALI is the histologic assessment of lung injury. In humans, the characteristic pathologic feature of ALI/ARDS is DAD. Key features of DAD include neutrophil accumulation in the vascular, interstitial, and alveolar spaces (evidence of an inflammatory response); deposition of hyaline membranes composed of fibrin and other proteinaceous debris (evidence of disruption of the alveolar/capillary membrane); interstitial thickening; and the formation of microthrombi (evidence of endothelial injury and intraluminal activation of the coagulation cascade). Animal models of ALI/ARDS should reflect some but not necessarily all of these features. It is important to bear in mind that some of the histologic features of human ALI/ARDS are not present or are present to a lesser degree in animal models of ALI, such as typical hyaline membranes and microvascular thrombi.

REPAIR OF THE LUNG

Repair of the damaged lung implies return to normal structure and function. In most cases of injury this would mean clearance of excess lung fluid; resorption of inflammatory exudate; removal of soluble and insoluble proteins, abnormal lipids, particles, and cell debris; apoptosis; removal of any inflammatory cells that have accumulated in response to the injury; and repopulation of the damaged structure with the appropriate cells and matrix. More persistent injury is often associated with fibroproliferative and neovasular responses (as in granulation tissue and wound healing in most sites in the body), which also has to be resolved if true repair is to be achieved, but which often may lead to more permanent scarring.

Mechanisms and Pathways of Lung Cell Replacement

Where do the replacement epithelial and endothelial cells come from? Studies completed in the 1970s clearly demonstrated that epithelial cells of the airways and alveolar space were replaced through proliferation and differentiation of endogenous lung progenitor cells.[43] These cells exhibit a secretory phenotype in the steady state, are most commonly referred to as airway Clara cells and alveolar type II cells, and function as the preferred precursor for replacement of injured cells. Some effort has been spent determining whether extrapulmonary cells can populate or replace injured epithelial cells. Although relevant for cell-based therapy for acute or chronic lung disease, the majority of studies failed to demonstrate functional restitution of the epithelium and/or significant epithelial reparative potential within the hematopoietic cell population.[44]

In contrast with the epithelium, repair of the endothelium can occur through two mechanisms. First, cells within existing vessels can act as progenitors for generation of new vessels. This process is termed *angiogenesis.* Alternatively, new vessels can form spontaneously through a process called *vasculogenesis.* This latter mechanism likely involves endothelial progenitor cells that are part of the hematopoietic cell lineage and are recruited to the injured lung.

Similar to the endothelium, the lung mesenchyme, which includes fibroblasts and smooth muscle, can be replaced by endogenous progenitors or recruited cells. Either cell type can contribute to productive repair of lung injury but may also participate in tissue remodeling under disease conditions. Several studies indicate that bone marrow–derived mesenchymal stem cells can modulate lung injury through regulation of inflammation. However, specific subtypes of bone marrow–derived cells may contribute to further lung injury. Consequently, more studies are needed to evaluate the pros and cons of lung cell replacement therapy focused on readily accessible cell sources such as the bone marrow.

Stem Cells, Constitutive Cell Turnover, and Reparative Cell Types

Hierarchies of Reparative Cells

The concept of injury and repair is fundamentally linked to the stem cell attributes of *mitotic potential* and

differentiation capacity. Mitotic potential has two components, the number of times a cell can undergo cell division and how these cell divisions are distributed over time. Differentiation potential is defined in terms of the number of differentiated cell types that can be generated by a mitotic cell.

Classical Stem Cell Hierarchy

Within a classical stem cell hierarchy (Fig. 16-4), the *stem cell* is defined as the reparative cell with the greatest mitotic and differentiation potential. A stem cell proliferates incrementally and thus distributes its mitotic potential over the life span of the organism. These attributes of "stemness" are controlled by interaction with the *stem cell microenvironment or niche.* The niche serves a protective function directed primarily toward sequestration of the stem cell from differentiation-promoting factors. Stem cell division produces two daughter cells whose fate is determined by interactions with the stem cell niche. *Symmetrical cell division* results in both daughter cells retaining contact with the niche and retention of these nascent cells as stem cells. This mechanism, which results in amplification of stem cell number, has been demonstrated in tissues with rapid cell turnover, such as the bone marrow and gut. In contrast, *asymmetric cell division* results in generation of one daughter cell that maintains contact with the niche and is retained as the stem cell. The second daughter cell loses contact with the niche and undergoes repeated cell division over a short period of time. This daughter cell is the founding cell for the *transit-amplifying* cell population. Transit-amplifying cells are transient constituents of the niche. They proliferate repeatedly over a short time period and withdraw from the cell cycle as they commit to a differentiation pathway. Thus, transit-amplifying cells serve to increase cell number and are destined to produce *terminally differentiated* cells. Terminally differentiated cells can have one or more phenotypes, constitute the majority of cells within a tissue, and provide functions characteristic of a specific tissue. Terminally differentiated cells are postmitotic and short lived. Thus, constant turnover of the terminally differentiated cell population acts as a stimulus for differentiation of transit-amplifying cells and resupply of this population via stem cell proliferation.

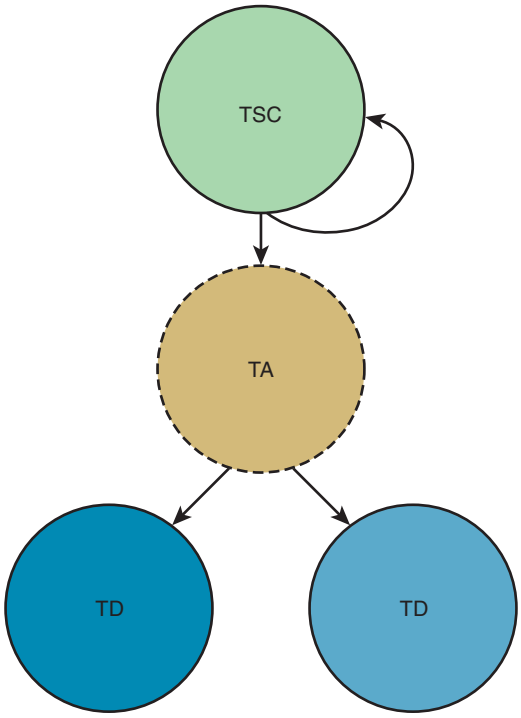

FIGURE 16-4 ■ Classical stem cell hierarchy: stem cell (TSC), transit-amplifying cell (TA), and terminally differentiated cell (TD).

Cells Involved in Lung Repair

Progenitor Cell. The term *progenitor cell* is a collective term used to describe any cell that has the capacity to proliferate. It is commonly used to indicate a cell that is in the process of cell division or has the potential to enter the cell cycle. The functional distinctions among lung progenitor cells are defined here.

Tissue-Specific Stem Cells. A tissue-specific stem cell is a rare cell type that is undifferentiated relative to its progeny. This cell has the capacity for unlimited self-renewal as a consequence of stable interactions with a stem cell niche. In the context of a hierarchy, the stem cell is defined as the reparative cell with the greatest mitotic and differentiation potential. Adult tissue stem cells have a differentiation potential equivalent to the cellular diversity of the tissue in which they reside.[45] Due to the relatively quiescent state of the pulmonary epithelium, lung stem cells are identified as cells that are activated in response to severe cell depletion. As a consequence of this experimental approach, the properties of lung stem cells must be viewed in the context of severe injury.

Tracheobronchial tissue-specific stem cells have been evaluated in humans and mice. These cells exhibit a low cuboidal to pyramidal morphology and are termed *basal cells.* Additional studies have suggested that the tracheobronchial tissue-specific stem cell resides within specialized microenvironments located at the submucosal gland duct junction and in intercartilagenous regions of the trachea and bronchial epithelium.[46] Within the bronchiole, tissue-specific stem cells have been identified within the neuroepithelial body and bronchiolar duct junction microenvironments. These cells are resistant to Clara cell–specific toxicants and express the molecular marker Clara cell secretory protein (CCSP).[43] Alveolar stem cells have not been identified. This deficiency is due in part to the lack of cell-selective injury methods that retain viability of the host. Several studies have used stem cell markers/activities such as telomerase, Hoechst efflux, label-retention, and CD43/Sca1 expression[47] to identify cells that fit one of the criteria used to define tissue-specific stem cells. These studies suggest that alveolar stem cells maintain individual alveolar saccules rather than broad regions of the parenchyma.

Facultative Progenitor Cell Pools. A facultative progenitor cell is one that exhibits differentiated features in the quiescent state yet has the capacity to proliferate for maintenance of normal tissue and in response to injury. In contrast with the bone marrow and gut, the lung epithelium is maintained and repaired under most conditions by an abundant, broadly distributed facultative progenitor cell pool. Facultative progenitor cells exist in two states: quiescent and reparative. In the steady state, facultative progenitor cells are nonmitotic and carry out differentiated functions necessary for tissue homeostasis. In response to injury, facultative progenitor cells dedifferentiate, enter the cell cycle, self-renew, and have a context-dependent probability of differentiating into regionally specific terminally differentiated cell types (ciliated epithelial cells and alveolar type II cells).[48–51] Pulmonary facultative progenitor cells are commonly known as the Clara cell and the alveolar type II cell (alveolus).[43]

Loss of Regenerative Potential: Depletion of the Facultative Progenitor Cell Pool

Multifunctional properties of pulmonary facultative progenitor cells also limit their ability to repair the injured epithelium. First, the metabolic pathways that allow the Clara cell to eliminate lipophilic agents also sensitize it to the toxic effects of these compounds.[52–54] Second, the phenotypic plasticity that is essential to the Clara cell's ability to detect and eliminate pathogens may compromise the reparative functions of this cell type.[55–57] Finally, repeated participation in epithelial repair may deplete the mitotic potential of the facultative progenitor cell pool. Depletion of this cell type would leave the epithelium deficient in both regenerative and differentiated functions and could result in a cascade of changes that contribute to epithelial fragility through loss of cellular autocrine/paracrine protective mechanisms, epithelial hypoplasia, and dysregulation of interactions between the epithelial, mesenchymal, and vascular compartments.

Histologic measures of the abundance of Clara cells and CCSP support the concept that the facultative progenitor cell type(s) are depleted in ALI and chronic lung diseases. These studies suggest that four processes lead to depletion of this critical cell type.

First, transition to a mucus-producing cell type may alter both progenitor function and cellular interactions. Within small airways of COPD patients and asthmatics, Clara cells undergo a metaplastic transition to a mucosecretory phenotype.[58] In severe disease, both Clara cells and mucosecretory cell types are depleted and the epithelium becomes hypoplastic.[59–61] Analysis of colony-forming cells within the human bronchial epithelium demonstrated that human mucus cells are postmitotic cells.[62] These data suggested that hyperplasia of mucus cells in the context of acute or chronic lung disease is a consequence of a phenotypic transition by non–mucus-producing cells.

Second, transition of progenitor cells from a facultative to an obligate progenitor state may also lead to depletion of reparative cells. Increased epithelial proliferation in lungs of smokers suggests an ongoing injury process and the potential for replicative senescence within the facultative progenitor cell pool.[63] Senescent cells persist and consequently inhibit activation of the remaining reparative cells. Thus, senescent cells would compromise differentiated functions while also acting to block cell replacement mechanisms.

Third, entry of the facultative progenitor cell into the cell cycle is accompanied by loss of differentiated functions such as secretion of CCSP or production of surfactant. Extensive analysis of CCSP levels in acute and chronic lung disease, including COPD, suggests that differentiated functions of the facultative progenitor cells are compromised[64,65] and that these cells are a direct target of toxic environmental agents. Thus, injuries that activate facultative progenitor cells may adversely affect protective mechanisms and render the epithelium susceptible to further injury.

Finally, defects in cellular maturation may also contribute to a failure to establish the facultative progenitor cell pool or to deplete it after injury. The lung undergoes extensive maturation during the postnatal period. The maturation process is interrupted by preterm birth and associated oxygen treatment, and is attenuated by postnatal exposure to environmental agents, including ozone and side-stream tobacco smoke in term infants.[66–68] These exposures are associated with depressed protective and reparative functions and morphologic and functional alterations to airway and alveolar facultative progenitor cells. These observations suggest an interaction between lung maturation and irritant exposure that leads to dysregulation of airway reparative processes.

These data support the concept that failure to establish or maintain an appropriately sized pool of facultative progenitor cells fosters environmentally induced chronic injury and repair cycles characteristic of lung disease. Hypoplasia of bronchial Clara cells is associated with tissue remodeling characterized by hyperplasia of an alternative progenitor, the basal cell, and consequent squamous metaplasia.[69–71] In contrast, Clara and alveolar type II cells are the sole progenitors of the bronchiolar and alveolar epithelium, respectively.[49,51] Depletion of either of these cell types leads to epithelial hypoplasia and remodeling of adjacent tissue compartments. Thus, changes in function and/or abundance of the facultative progenitor may be the nexus for the complex pathophysiologic alterations that occur in chronic lung diseases.

Gene-Environment Interactions in Lung Injury and Repair

The four Rs (regeneration, repair, remodeling, and replacement) are presented as distinct processes;

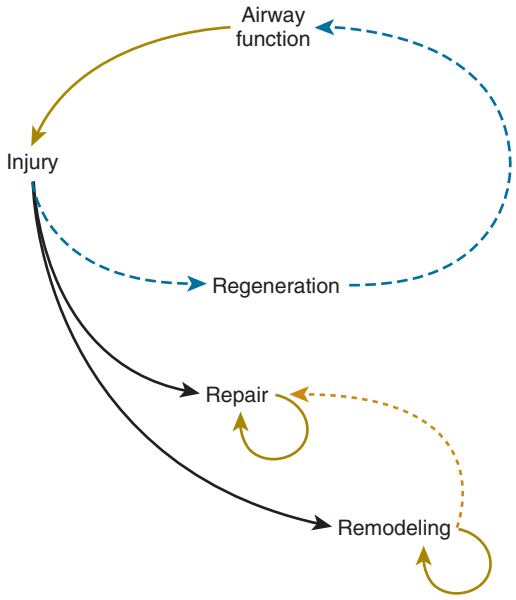

FIGURE 16-5 ■ Gene-environment interactions in lung injury, regeneration, repair, and remodeling. (Adapted from Lazaar AL, Panettieri RA Jr: Is airway remodeling clinically relevant in asthma? Am J Med 115:652–659, 2003.)

however, they are actually intertwined responses to acute or chronic lung injury[1] (Fig. 16-5). These relationships are modified by gene-environment interactions, the concept that genetic constitution determines the response to deleterious agents within the environment. Genetic predisposition has been associated with allelic variants that modify cellular susceptibility to environmental agents, including chemical (ozone, naphthalene) and bacterial (lipopolysaccharides, viral pathogens) agents. Such alleles can sensitize an individual to an initial or repeated injury but can also render him or her resistant to subsequent exposures through induction of tolerance.

Genotype is also a determinant of the cellular response to an agent. Specific genetic backgrounds are susceptible to metaplastic transitions such as conversion of airway secretory cells into a mucus-producing goblet cell phenotype (e.g., C57BL/6 vs. Balb/c strains of mice). Such transitions are associated with protection of the epithelium from further injury. Alterations in cellular phenotype may also extend to interactions between endogenous lung elements (epithelium, mesenchyme, nerves) and recruited elements such as inflammatory cells. Specific inbred strains of mice (e.g., C57Bl/6) are susceptible to bleomycin-induced inflammation and develop transient replacement of alveolar structures with mesenchymal cells (fibrosis). Thus, susceptibility to injury and the response to such an insult are determined by multiple factors, including the nature of the agent, dose and route of exposure, exposure history, and host genotype.

Abnormal Cellular Repair

The transition (transformation) of epithelial cells to a mesenchymal (myofibroblast) phenotype, termed *epithelial-mesenchymal transition* (EMT), is a key process in development as well as in pathologic processes such as neoplasia and fibrotic responses in the lung and other organs.[72] EMT involves the loss of epithelial phenotype, manifest by loss of intercellular junctions, cell spreading, and enhanced motility. This is accompanied by a loss of epithelial-specific proteins such as E-cadherin and cytokeratin and enhanced expression of mesenchymal proteins, including smooth muscle α-actin and vimentin. In the lung, EMT is believed to contribute to the peribronchial fibrosis that characterizes airway remodeling in chronic asthma and to fibrotic responses in the lung parenchyma, such as interstitial pulmonary fibrosis.[72,73]

Does Lung Repair Recapitulate Lung Development?

Numerous signaling processes are known to be involved in lung development (Wnt/β-catenin, notch-delta, sonic hedgehog-patched, FGF-FGFR, BMP/TGFβ).[74] These pathways are interactive and integrate formation and appropriate differentiation of tissues (epithelium, mesenchyme, vasculature) during lung development. During lung injury and repair, reactivation of many of these pathways has been reported. However, it is unclear whether integration of various signaling pathways occurs and whether this signaling results in productive cell replacement. An impediment to resolution of this question is the fact that analysis of damaged human lung tissue is descriptive at best, and cause and consequence usually cannot be separated. In contrast, analysis of signaling in animal models, which is the state of the art, relies on elimination of a specific pathway or profound mis-regulation of the targeted process. Consequently, feedback mechanisms are likely to be disrupted and may result in altered activation/inactivation of parallel or sequential signaling networks. Development of methods to simultaneously monitor alterations in multiple signaling cascades is needed to address this fundamental obstacle to understanding the molecular regulation of reparative processes.

KEY POINTS

- A typical definition of lung injury cites clinical endpoints that reflect decrements in gas exchange. But the mechanisms of injury are rooted in the cellular and molecular changes that *initiate* structural alterations and lead to compromised lung function.
  - Acute lung injury can be linked to specific inciting events, including infection, aspiration, and trauma, and results in decreased arterial P_{O_2}. At the tissue and cellular level, these stimuli result in increased vascular permeability and loss of alveolar epithelial barrier function consequent to cell alteration or death. These cellular changes result in edema which in turn compromises gas exchange.
  - Susceptibility to lung injury is determined by general health, previous exposures, and the individual's genetic constitution. This "gene-environment interaction" is the cornerstone of research initiatives directed at identification of susceptibility genes as well as those that modify the response to treatment.
- Repair of lung damage goes hand-in-glove with lung injury. The type of reparative process, be it cellular (migration, proliferation, metaplasia, or death) or molecular (metabolism, catabolism, macromolecule synthesis) is determined by the agent, dose, route, duration, and preexisting conditions within the lung. Consequently the reparative process reflects the current exposure in the context of past exposures.
  - The interface between the lung and the environment is reflected in a vast reparative capacity. Cells and macromolecules that are damaged are removed and replaced without disruption of lung function. This process occurs *silently* in normal individuals and is usually accompanied by processes that suppress both inflammation and incipient autoimmunity.
  - Tissue cell replacement is mediated primarily by facultative progenitor cells: those that perform critical homeostatic functions but retain the capacity to proliferate in response to injury. These cells are abundant and broadly distributed thereby forming a defensive shield against cellular injury.
  - Tissue-specific stem cells maintain themselves and have the capacity to regenerate all cell types within a specific tissue type. Such cells have been identified in the lung epithelium, endothelium, and mesenchyme of animals following extensive injury.
- When injury exceeds the ability of the lung to repair, a cascade of events results in remodeling of the target tissue as well as disruption of the interactions between adjacent tissues including the immune system. These *imbalances* may result in an exaggerated response that perpetuates the initial injury. One result of such lung remodeling is fibrotic lung disease which exhibits elements of epithelial, mesenchymal, and immune system disruption.

CHAPTER 17

HISTORY AND PHYSICAL EXAMINATION

Dean E. Schraufnagel, MD • John F. Murray, MD

INTRODUCTION
Electronic Medical Record
Communication Skills
MEDICAL INTERVIEW
Chief Compliant and Present Illness
Major Pulmonary Symptoms
Family and Social Histories
Past History
Questionnaires, Computer-Assisted and Nursing History
PHYSICAL EXAMINATION
Examination of the Chest
Extrapulmonary Manifestations

INTRODUCTION

Taking a careful and complete history and performing a thorough physical examination are hallmarks of the good internist and one of the distinguishing characteristics of a master clinician. The initial visit sets the tone of the immediate and future relationship with the patient and begins the process of diagnosing and managing the illness: a dynamic encounter with each of the patient's responses stimulating further probing and diagnostic hypotheses formation. The physician must be attentive to the patient's story, piecing together each bit of evidence to form a tentative preliminary diagnosis and differential diagnoses. Nothing should escape the eyes and ears of a watchful diagnostician. History taking is more than information gathering: it affords the opportunity to observe the patient's reactions as the inquiry proceeds. At this stage, no symptom or circumstance should be disregarded. With an understanding of biology and medicine coupled with past experience, the physician tries to connect the salient parts of the patient's story to develop a plausible explanation of the physiologic or pathologic events that lead to illness.

Although striving for a single diagnosis, the physician should realize that more than one disease may be present and that rare diseases are diagnosed only by those who consider them. Nevertheless, the maxim "uncommon presentations of common diseases are more frequent than common presentations of uncommon diseases" is likely to be true. It is important to continue both to gather information and to be open to reforming the diagnostic hypothesis as more information becomes available. Premature judgment or the failure to continue considering reasonable alternatives after an initial diagnosis is made is the single most common diagnostic error.[1,2]

Bayes' theorem implies that diagnostic tests will have a higher yield if their prior probability is high. Specific details from the history raise the probability of different diagnoses and direct further tests in a productive manner. Further diagnostic investigations—imaging, blood tests, pulmonary function studies, and even parts of the physical examination—depend on the history. Historic clues raise or lower probabilities, thereby improving the value of subsequent questions and evaluations. Test results plus findings from the history and physical examination may confirm or refute the main and differential diagnoses, setting up either management or need for an alternative hypothesis.

The assessment and plan, at the end of the initial write-up, should identify problems and a course of action that takes into account the patient's concerns and questions. The patient should feel satisfaction that the physician has done a thorough job of exploring his or her complaints, has provided a plausible explanation for them, and has planned a reasonable course of action.

Electronic Medical Record

The electronic medical record now allows documents of higher quality than written records, owing to improved organization, increased readability, use of supplementary

material, and better comparisons. It eliminates poor handwriting and lost or misplaced information. Additional benefits include cost saving for storage, easy accessibility, and quick transfer to another health care provider.[3] The electronic medical record facilitates a coordinated team approach and reduces duplication of tests. Patients with complicated illnesses often have several different physicians and electronic records can make it easier for one team to follow what another team is doing. Easy accessibility to a complete record is especially important in emergency situations for physicians who are unfamiliar with the presenting patient. Common electronic medications lists and reminders can save time and reduce errors. Electronic prescriptions provide greater patient safety.

Writing directly into the medical record, or initially through a word-processing program, makes a cogent summary and chronological story easier to produce. The ability to insert information where it belongs helps maintain a congruous timeline. Spelling and grammar checks and autocorrection of abbreviations should make the finished report an easily readable document.

The disadvantages of electronic medical records include "information overload" and potential loss of privacy. Software downtime can be crippling. Learning how to use the software and developing typing skills may require training. Most electronic medical record word processing software is less efficient than commonly used commercial word processing software.

The "cut-and-paste" technique, beginning where the last visit left off, both saves time and ensures that ongoing problems are not overlooked. The problem with the cut-and-paste approach is that too much and irrelevant information may get deposited and duplicated in the medical record. Such excess text can at times replace essential information and impair easy understanding and critical reasoning. Cutting-and-pasting of information from consultants and other involved persons should never substitute for one's own primary history gathering or clinical thought. Cutting-and-pasting information gathered by someone else implies agreement with the statements. Proofreading is essential, especially of electronic prescriptions, because of the different doses and means of delivery of certain drugs.

Transfer of electronic medical information is not foolproof. Patients and physicians find it easy and convenient to communicate and transfer information by email, but there is a risk that the record of these interchanges may not get placed in the patient's permanent medical record or may be the cause of misunderstanding. Physicians may send patients electronic copies of their record, but if these are in a word processing format, patients could alter the record for secondary gain. Many of these concerns could have medicolegal consequences.[3]

Communication Skills

The ability to listen skillfully, and to communicate clearly and empathetically with the patient, is the foundation for the physician-patient relationship. Communicating effectively with patients and peers underlies the success of a physician. The physician's communication should be objective, nonjudgmental, and empathic. Physicians are often better at obtaining medical information than they are at understanding how the illness affects the patients.[4]

Communication contains both verbal and nonverbal interactions.[5] A calm atmosphere, relaxed setting, and ample time are essential, particularly when disclosing bad news,[6] but even then, a physician with good communication skills should be able to make the patient pleased that she or he saw the physician. This can be accomplished by always stating the truth but by cushioning bald facts with hope. When realistic, the physician might say that the cancer was caught early, provide reassurance about a probable good outcome, or suggest a specific therapy.

MEDICAL INTERVIEW

There is much more to the medical history than a recitation of questions and recording of answers. Instead, the medical interview has been defined as the entire medium of patient-physician interaction.[7] From this interactive experience, both physicians and patients learn about each other: the knowledge shared and feelings imparted influence subsequent trust, understanding, concern, and adherence to the health plan. Experience is valuable in the acquisition of clinical pattern recognition and in cumulative clinical knowledge. Although interviewing skills can be systematically learned,[8] acquiring the art of adept history taking and physical examination is a lifelong process that is incrementally improved by careful practice.

The main purposes of the medical interview are to (1) gather useful information, (2) develop rapport, (3) respond to concerns, and (4) educate the patient. The ease with which patients can access information may lead to a more active role on their part. Patients may be well informed or misinformed about their actual or perceived diagnoses. Whatever their knowledge, most patients want to be accurately informed about their condition and to be involved in the deliberations and decision making.[9] At the same time, they generally want their physician to direct their health care in a reasoned manner. This entails taking into account the patients' background knowledge, prejudices, and culture in a sensitive manner. The physician's plan should take into account the individuality of the patient.

Encouraging the patient to take the lead in expressing his or her symptoms and relationships to these symptoms forms the basis for the patient-centered interview[10] and develops appropriate rapport. Even in this era of reliance on laboratory studies, Platt's[11] original claim that a diagnosis can be obtained by history taking alone in most patients has been reaffirmed by several subsequent investigations.[12–14]

Chief Complaint and Present Illness

The medical history has traditionally been subdivided into the chief complaint; present, past, family, and social histories; and systems review. Because of its relevance

and importance in the evaluation of patients with known or suspected pulmonary diseases, the occupational history is included as a separate component of the social history. Travel history, also included in the social history, is helpful in diagnosing certain lung diseases.

Only the chief complaint stands alone as a discrete response to a single question. It is generally recommended that the chief complaint be written in the patient's own words, lest the doctor's interpretation be substituted prematurely for the patient's unique concern. Each chief complaint must be explored in detail, and the resulting aggregate of information constitutes the history of the present illness. The various elements of the remainder of the history are sorted into their proper categories after the interview has been completed. The resulting history of present illness is a cogent chronological story that incorporates all the facts and their relationships that support the preliminary diagnosis and differential diagnoses. Although an open-ended and free-flowing encounter, the interview still should be focused and organized. Each new question is often linked to the answer to the previous one. At the end, the review of systems is a series of questions designed to cover previously unexamined territory.

Major Pulmonary Symptoms

Because dyspnea, cough, and chest pain are among the most common reasons for patients to visit physicians, and because these symptoms may result from serious underlying chest disease, careful questioning is needed to establish their etiology and significance. The anatomic and pathophysiologic basis of these cardinal symptoms is provided in Chapters 28 through 30. To aid the interviewer in obtaining a medical history, a brief overview of dyspnea, cough, and chest pain, as well as of hemoptysis, a corollary complaint is provided in this section.

Dyspnea

When healthy persons increase their physical activity, they eventually become aware of their breathing; if they increase the level of activity even further, this awareness increases and the sensation becomes progressively more unpleasant, until it finally causes them to slow down or stop.[15] Although dyspnea, shortness of breath and breathlessness are often used interchangeably, as in Chapter 28, some purists use the term dyspnea only when the symptom is abnormal, which implies that the awareness is disproportionate to the stimulus and that the sensation is pathologic. Many patients describe their breathing discomfort as "breathlessness," but many others will complain only of "tightness," "choking," "inability to take a deep breath," "suffocating," "can't get enough air," and occasionally even "tiredness."

The mechanisms that underlie the sensation of dyspnea remain poorly understood, and are reviewed in Chapter 28. In contrast to pain and cough, for which specific receptors and neural pathways have been identified, similar detailed knowledge is lacking for dyspnea, although evidence is mounting that links the symptom with pain.[15,15a] Studies of the neurophysiology of dyspnea are further complicated by the lack of objective tools to quantify a subjective sensation that has considerable interindividual variation. Rating instruments—such as the Borg scale,[16] and questionnaires, such as the British Medical Research Council questionnaire,[17] and Pulmonary Functional Status and Dyspnea Questionnaire[18]—have been validated as useful in measuring dyspnea. Self-administered, computerized versions of the Transitional Dyspnea Index (TDI) and Multidimensional Baseline Dyspnea Index (BDI) appear to be at least as good as interview questioning for this assessment.[19] Progress, though, is being made: recent studies have clearly shown that dyspnea during exercise in patients with chronic obstructive pulmonary disease (COPD) is closely linked to dynamic lung hyperinflation.[20]

Clinical Features. Patients with respiratory, cardiac, hematologic, metabolic, and neuromuscular disorders may all complain of dyspnea. A careful and detailed history is necessary to uncover the cause of the sensation. In addition, it is important to document the impact of the symptom on the patient's daily activities and to be alert to the "decreased activity phenomenon." The latter describes patients who say their dyspnea has not worsened, but only because they now walk more slowly or no longer climb stairs or engage in athletic activities. Sometimes, this slowing down occurs so gradually, patients may not be aware of it or attribute to aging. Assessing the activity required to bring about the dyspnea is important. How many stairs can be climbed before stopping? How far can someone walk on level ground at her or his own pace without stopping? Does talking on the phone, getting dressed, or eating cause dyspnea? Is the patient short of breath at rest?

The course over time should be noted. Sudden dyspnea without an obvious provocation suggests pulmonary embolism or pneumothorax, although myocardial ischemia and asthma also may have a rapid onset. Dyspnea caused by cigarette smoke, dusts, molds, perfumes, newly cut grass, cats, and strong odors is characteristic of the increased bronchial reactivity seen in asthma. Associated features, such as wheezing and the presence and type of chest tightness or pain, are important clues. Worsening dyspnea with cough productive of increased quantities of purulent sputum, occurring over 1 to 3 days, characterizes an exacerbation of COPD.

Special types of dyspnea are sufficiently distinctive to warrant separate designations. Episodes of breathlessness that wake persons from a sound sleep, *paroxysmal nocturnal dyspnea*, usually denote left ventricular failure, but may also occur in patients with chronic pulmonary diseases because of pooling of secretions, gravity-induced decreases in lung volumes, sleep-induced increases in airflow resistance, or nocturnal aspiration. *Orthopnea*, the onset or worsening of dyspnea on assuming the supine position, like paroxysmal nocturnal dyspnea, is found in patients with heart disease and chronic lung disease. Measurement of amino-terminal pro-B-type natriuretic peptide has proved useful in differentiating between a cardiac or a respiratory origin in patients with dyspnea.[21]

The inability to assume the supine position (*instant orthopnea*) is characteristic of paralysis of both leaves of the diaphragm. Dyspnea soon after assuming the supine position also may be associated with other conditions, such as arteriovenous malformation, bronchiectasis, and lung abscess. *Platypnea* denotes dyspnea that occurs in the upright position and *trepopnea*, an even rarer form of dyspnea that develops in either the right or the left lateral decubitus position, suggest lung vascular shunting. Both the terms *hyperpnea*, an increase in minute ventilation, and *hyperventilation*, an increase in alveolar ventilation in excess of carbon dioxide production, indicate that ventilation is abnormally increased. Neither term, however, carries any implication about the presence or absence of dyspnea.

Cough

The quantity of bronchial secretions produced each day by a nonsmoking healthy adult is not precisely known, but it is sufficiently small to be removed by mucociliary action alone: healthy persons seldom cough.[22] As described in Chapter 29, coughing is an essential mechanism that protects the airways from the adverse effects of inhaled noxious substances and defends the lungs by clearing excess secretions.[23] Coughing can be occasional, transient, and unimportant. By contrast, it may indicate the presence of severe intrathoracic disease.

Clinical Features. Most episodes of coughing are associated with short-lived upper respiratory tract infections or allergies, and patients, recognizing this, seldom visit their doctors. Nevertheless, cough is the most common complaint for which patients seek medical attention and the second most common reason for having a general medical examination.[24] Physicians should realize that when patients seek their help for cough, it is often out of concern for something new, different, and alarming about the symptom. The essential first step in evaluating a patient with cough is to obtain a thorough history, paying particular attention to the following aspects: acute or chronic, productive or nonproductive, character, time relationships, type and quantity of sputum, and associated features. It is noteworthy that, of the various components of the workup used by the authors of a systematic anatomic investigation to determine the causes of chronic cough, the medical history alone led to the correct diagnosis in 70% of 102 patients.[24]

Acute coughing is frequently associated with nasopharyngitis, laryngotracheobronchitis, or other, usually virus-induced, upper respiratory tract infections. Less commonly, it may be the chief manifestation heralding the onset of viral or bacterial bronchopulmonary infection or the inhalation of allergenic or irritating substances. The causes of cough that persisted for 3 weeks or longer in 102 patients were postnasal drip (41%), asthma (24%), gastroesophageal reflux (21%), chronic bronchitis (5%), and bronchiectasis (4%).[24] Other important but less common conditions were eosinophilic bronchitis[25] and the use of angiotensin-converting enzyme inhibitors.[26] The importance of the "big three"—postnasal drip, asthma, and gastroesophageal reflux—was verified by the results of another survey of the causes of chronic cough.[27] Not everyone agrees, however, and some experts claim that emphasis on the top three conditions is unwarranted and, moreover, that it stifles interest and research into other important causes and mechanisms of chronic cough.[28]

A careful history of patients with cough lasting at least 3 months revealed that nearly all the patients misdiagnosed as "psychogenic" had one of the conditions listed previously for chronic cough.[29] Even cough that is made worse with psychological stress is often caused by lung disease. Patients with exaggerated cough responses or habit cough may have a "psychogenic" component; nevertheless, even when chronic cough has a pulmonary etiology, it may respond to behavioral modification.[30]

Most physicians have heard that cough may be the initial signal of lung cancer; the diagnostic axiom that any change in the character or pattern of a chronic cough in a smoker demands a prompt chest radiographic evaluation for lung cancer bears remembering. Less well known is that cough may be the sole presenting manifestation of asthma[31] or gastroesophageal reflux disease.[32]

In low-income countries of the world, where the great majority of the global population lives, cough, usually productive but not always, of 3 weeks or longer has been the traditional (and reliable) clinical marker of possible pulmonary tuberculosis that should trigger examination of sputum specimens for *Mycobacterium tuberculosis*. Recent recommendations by partners of the Tuberculosis Coalition now include cough of "2 or 3 weeks," or longer, as an indication for sputum examination.[33]

Among the many complications of persistent or recurrent cough are tussive syncope; retinal vessel rupture; persistent headache; chest wall and abdominal muscle strains, including the development of abdominal wall hernia[34]; and even rib fractures. Severe chronic cough may cause devastating personal distress, causing patients to restrict their social and professional activities because of it.

Hemoptysis

The expectoration of any amount of blood denotes hemoptysis. Every patient with new-onset or appreciable hemoptysis deserves a thorough diagnostic workup, which generally includes computed tomography (CT) of the thorax and bronchoscopy. For centuries, hemoptysis was considered pathognomonic of pulmonary tuberculosis, a view that is summarized in the Hippocratic aphorism "the spitting of pus follows the spitting of blood, consumption follows the spitting of this and death follows consumption."[35] The frequency of the different conditions that cause hemoptysis depend to a large extent on the population studied, but bronchitis, lung cancer, tuberculosis, and bronchiectasis are usually the most common causes.[36–38] These are also the causes massive hemoptysis (defined in various series as >200 to >600 mL of blood in 24 hr). Lung cancer and bronchitis usually cause mild to moderate bleeding, whereas patients with bronchiectasis, lung abscess, fungal disease, and bleeding diathesis are more likely to have severe

bleeding.[36] Less common conditions associated with hemoptysis include arteriovenous malformations, broncholithiasis, foreign bodies, aspergilloma, mitral stenosis, trauma, anticoagulation excess, pulmonary hemorrhage syndromes, heart failure, pneumonia, and Wegener's granulomatosis.

Clinical Features. Prompt workup, beginning with a thorough history, is required in all patients. It is important to determine where the blood is coming from. Surprisingly, patients may not always be able to distinguish hemoptysis from hematemesis and nasopharyngeal bleeding. Vomiting blood may follow a prolonged coughing episode. Patients may swallow or aspirate blood from the upper airway. Some patients report only that the blood "welled up" in their throats. Others will say that it is mixed with sputum. Hematemesis can usually be differentiated from hemoptysis by the presence of symptoms of gastrointestinal involvement, such as nausea and vomiting, a history of peptic ulcer disease, alcoholism, or signs of cirrhosis; when in doubt, esophagoscopy is indicated.

Following physical examination, a chest radiograph and (often) a thoracic CT are required. Depending on the magnitude of the blood loss and the clinical circumstances, bronchoscopy is indicated to determine the location of the bleeding. Although these studies generally reveal which region of the lungs is the source, the cause of hemoptysis cannot be determined in 20% to 30% of cases.[39] Recent radiologic advances, particularly multidetector computed tomographic (MDCT) angiography, which enhance identification of the actual bleeding vessel, whether systemic or pulmonary, have greatly helped the interventionist when embolization is required to stop the bleeding.[40]

Chest Pain

Various types of chest pain are extremely common; their mechanisms and clinical patterns are described in Chapter 30. Chest pain is one of the most common symptoms that cause the sufferer to seek medical attention. Because there is no clear relationship between the intensity of the discomfort and the importance of its underlying cause, all complaints of chest pain must be carefully considered. The recent development of dedicated chest pain centers within emergency departments has improved the diagnosis, treatment, and survival of patients with this always troublesome symptom.[41]

Clinical Features. Pleurisy, or acute inflammation of the pleural surfaces, usually causes chest pain that has several distinctive features. Pleuritic pain is usually localized—nearly always on one side or the other—and tends to be distributed along the intercostal nerve zones. Pain from diaphragmatic pleurisy is often referred to the ipsilateral shoulder and side of the neck. The most striking and important characteristic of pleuritic pain is its clear relationship to respiratory movements. The pain may be variously described as "sharp," "burning," or simply "a catch," but it is typically worsened by taking a deep breath, and coughing or sneezing causes intense distress. Patients with pleurisy frequently also experience dyspnea because the aggravation of their pain during inspiration makes them conscious of every breath.

Acute pleuritic pain is found in patients with spontaneous pneumothorax, pulmonary embolism, and pneumonia, especially pneumococcal pneumonia, whereas a gradual onset over several days is observed in patients with tuberculosis; an even slower development is characteristic of primary or secondary malignancies. Chronic pleuritic pain is characteristic of mesothelioma. It may be difficult to distinguish pleuritic pain from the pain of a rib fracture, although point localization favors the latter. Pericardial pain is typically sharp, retrosternal in location, and relieved by sitting up and leaning forward.

The distribution and the superficial, knifelike quality of the pain of intercostal neuritis or radiculitis may resemble pleural pain because it is worsened by vigorous respiratory movements but, unlike pleurisy, not by ordinary breathing. A neuritic origin may be suggested by the presence of lancinating or electric shock–like sensations unrelated to movements, and hyperalgesia or anesthesia over the distribution of the affected intercostal nerve provides confirmatory evidence. In many instances of new-onset, neuritic chest wall pain, the diagnosis becomes clear a day or two later when the typical vesicular rash of herpes zoster breaks out.[42]

Among the most important types of chest pain is that of myocardial ischemia, which is usually caused by coronary artery atherosclerosis. These attacks, which are provoked by an inadequate oxygen supply to the myocardium, span a continuum of severity from chronic stable angina to classic acute myocardial infarction. Typical anginal pain is induced by exercise, heavy meals, and emotional upsets; the pain is usually described as a substernal "pressure," "constriction," or "squeezing" that, when intense, may radiate to the neck or down the ulnar aspect of one or both arms.[43] Pain from variant or Prinzmetal's angina is similar in location and quality to typical anginal pain but occurs in cycles at rest rather than during stressful episodes.[44] Both typical and variant types of angina are relieved by coronary vasodilator drugs, such as nitroglycerin. Typical angina also decreases with rest or removal of the inciting stress.

By contrast, the pain of acute myocardial infarction, although similar in location and character to anginal pain, is usually of greater intensity and duration, is not alleviated by rest or by nitroglycerin, may require large doses of opiates, and is often accompanied by profuse sweating, nausea, hypotension, and arrhythmias. During attacks of myocardial ischemia and myocardial infarction, patients are often short of breath from associated pulmonary edema, which may be severe, but the pain itself is not related to breathing. Pain similar to that of myocardial ischemia also occurs in patients with aortic valve disease, especially aortic stenosis, and other noncoronary heart disease and noncardiac disorders.

Inflammation of or trauma to the joints, muscles, cartilages, bones, and fasciae of the thoracic cage is a common cause of chest pain.[45] Redness, swelling, and soreness of the costochondral junctions is called Tietze's syndrome. All of these disorders are characterized by point tenderness over the affected area.

Most pulmonary thromboembolism is not associated with chest pain. The hallmark of pulmonary infarction, however, is typical pleuritic pain. Both acute and chronic causes of pulmonary hypertension may be associated with episodes of chest pain that resemble the pain of myocardial ischemia in their substernal location and pattern of radiation and in their being described as "crushing" or "constricting."[46] This type of chest pain is believed to result from right ventricular ischemia owing to impaired coronary blood flow secondary to increased right ventricular mass and elevated systolic and diastolic pressures or to compression of the left main coronary artery by the dilated pulmonary artery trunk.

Family and Social Histories

The family history provides important clues to the presence of heritable pulmonary diseases, such as cystic fibrosis, alpha$_1$-antitrypsin deficiency, hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease), immotile cilia syndrome, and immunodeficiency syndromes. Careful history taking also can uncover even more common familial disease associations, which are polygenic or in which the exact mode of genetic transmission has not yet been established. As the genetic profiles of more diseases are being uncovered, the family history assumes an even more important function. The family history should encompass at least three generations to account for sex-linked traits. Family history also can identify exposures such as to tuberculosis or other contagious diseases.

Of course, no evaluation of pulmonary symptoms is complete without a detailed history of smoking habits. The physician should ask, "Have you ever smoked?" A negative answer should prompt a confirmatory response such as, "So you are a lifelong nonsmoker?" and a complement if the second answer is yes. If the patient has smoked, the next questions should be, "When did you start?" "When did you quit?" and "How much did you smoke while you were at it?" Ask also about different forms of tobacco and exposure at home or workplace to other peoples' tobacco smoke. A history of exposure to environmental smoke is also important.[47] In many developing countries, smoke from indoor cooking and heating fires is a major cause of lung disease, especially in women. Risk factors for infection by the human immunodeficiency virus, such as homosexual activity, multiple sexual partners, transfusions, and injection drug abuse, should be specifically queried.

Medications and Allergies

A complete list of all medications is essential to a thorough history. Ideally, the patient should bring in all his or her medications and the physician should carefully go through each one, checking that the prescription has been properly written and filled and that the patient understands the benefit and possible side effects of each medicine. It is vital to note whether the patient has ever had an allergic or toxic reaction and what these reactions were. A complete listing of supplements and herbals should also be recorded and checked for potential interaction with medications. No drug history is complete without assessing whether the patient drinks alcoholic beverages or uses illicit drugs. The amount and frequency of their use should be recorded.

Occupational History

The occupational history, which is often included as part of the social history, is an integral part of a thorough medical interview. Unless a relationship is established between an occupationally related lung disease and the patient is removed from the exposure, the disease is likely to progress and may cause irreversible damage. Moreover, accurately diagnosed work-related illness can allow justifiable compensation for the patient and correction of the exposure by the industry.

The workup of suspected occupational lung disease is discussed in Chapters 64 through 66. Although only a few questions are asked in most initial medical interviews, if occupational illness is seriously considered, a detailed inquiry about each industry, profession, and job the patient has held needs to be carried out.[48,49] Because there are so many environmental agents and different illness, the diagnostician should consult online agencies such as the National Institute for Occupational Safety and Health (NIOSH), the Environmental Protection Agency (EPA), Hazardous Substances Data Bank, Occupational Safety and Health Administration (OSHA), or other online resources to learn more about the putative environmental toxicant.[50,51]

Travel History

The sites of residence help with the diagnosis of endemic fungal diseases, especially histoplasmosis and coccidioidomycosis. A history of recent travel may help establish the possibility of exposure to other infectious diseases, because several are restricted to specific geographic regions.[52] The physician should inquire into the duration of travel. Knowing about air travel is important because symptomless deep venous thrombosis, which can lead to pulmonary embolism, is reported to occur in up to 10% of passengers on long-haul flights.[53] It is important to consider events after travel: symptoms of pulmonary thromboembolism and infarction occur a variable time after the inciting event. The recent onset of severe acute respiratory syndrome (SARS) in Southeast China and its rapid spread throughout the world by airline passengers emphasizes the importance of obtaining a careful travel history.

Past History

Many pulmonary diseases tend to recur (e.g., tuberculosis), and new diseases may complicate old ones (e.g., bronchiectasis as a sequela of necrotizing pneumonia). Information about previous illnesses, operations, and trauma involving the respiratory system may be essential to understanding the current problem. Although these data may be gathered as part of past medical history,

much of the pertinent information will be absorbed into the chronological sequence of the history of present illness. An important aid in the evaluation of a patient with an abnormal chest radiograph is a previous radiograph for comparison. Patients should be asked to bring in past films, but if unavailable, physicians should make every effort to obtain them, because old radiographs may save needless costly and dangerous interventions.

Questionnaires, Computer-Assisted and Nursing History

Printed or computer-based questionnaires and histories taken by nurses or allied health professionals are often used to expedite history taking. They can identify problems that can be explored further in the medical interview. They are often used in certain clinical settings, such as preoperative anesthetic evaluation. Occupational questionnaires have been shown to enhance recognition of occupational illness and correlate well with the findings of an industrial hygienist.[54] Computer-based interviews can gather more information, allow more time to complete the interview, uncover sensitive information, and may be adaptable to persons speaking a language different from that of the physician and those with hearing impediments.[55]

These forms of information gathering should be considered adjuncts and not a substitute for the thorough history taken by the physician. The limitations of the programmed questions are that the patient may not understand or be able to express her or his concerns when confined by a form that does not allow the free exploration of symptoms that the open interview does. It, of course, lacks the benefits gained from the patient-physician interaction, such as the establishment of rapport and the ability to observe nonverbal behavior. The interview time is also important for the physician to fully comprehend the patient's illness and to contemplate the primary and differential diagnoses.

For monitoring the course of certain disorders such as asthma, daily recording of symptoms, such as wheezing and breathlessness, and objective assessments of severity of disease, such as peak expiratory flow, in a diary are preferable to a single questionnaire because recall of symptoms may be faulty and one measurement may not be representative. The electronic monitoring that now comes as standard equipment with most home noninvasive ventilation devices gives the date and time of the respiratory events and the use of these devices.

PHYSICAL EXAMINATION

Sadly, the declining emphasis on proficiency in physical examination during medical school and residency training and the ever-increasing reliance on technology-based diagnosis have led to a decreased interest in, some say even the "demise" of, the physical examination.[56] However, the old observation that 88% of all diagnoses in primary care were established by taking a thorough medical history and performing a complete physical examination[57] probably still holds today. At the very least, a carefully executed history and physical lead to more intelligent and cost-effective use of diagnostic technology. Plus, a physical examination can be performed virtually anywhere, may provide important information, lends itself to serial observations, and increases patients' confidence in their physicians.

Examination of the Chest

Physical examination of the chest employs the four classic techniques of inspection, palpation, percussion, and auscultation. Each is described subsequently, as are the constellations of abnormalities that allow the examiner to infer the presence and type of various pulmonary disorders. Apart from inspection, which is not only a visual, but also sometimes an olfactory and always a structured cognitive skill, the other three modalities depend on the generation and the perception of sound or tactile sensations and vibrations. As was true of the history, the environment in which the physical examination occurs must be appropriate to the needs of both the examiner and the examined. Privacy, warmth, good light, and quiet are all essential. The best light source is natural sunlight, which should be used if possible. An ill-lit, noisy, or distracting environment will likely result in a physical examination that is flawed or incomplete.

Inspection

The physical examination begins the moment the clinician first sees the patient, even before the introductions and beginning the medical interview. Keen observations, and the ability to pursue and interpret these observations, are the keys to skilled clinical diagnosis.

Inspection of the chest is carried out after sufficient clothing has been removed and the patient has been suitably draped to permit observation of the entire thorax. Ordinarily, inspection is performed with the patient sitting, but if the patient is too weak or cannot sit unaided, he or she should be supported in this position. Observing the shape and symmetry of the chest allows such abnormalities as kyphoscoliosis, pectus excavatum, pectus carinatum, ankylosing spondylitis, gynecomastia, and surgical scars or defects to become obvious.

Several classic patterns of ventilation can be readily recognized (Fig. 17-1). For example, *tachypnea*, which is almost uniform rapid shallow breathing; *Kussmaul's breathing*, which is relentless, rapid, and deep breathing (air-hunger); *Cheyne-Stokes respirations*, a cyclical waxing and waning of the depth of breathing with regularly recurring periods of apnea; and *Biot's breathing*, which is totally irregular breathing, both the size of breaths and the periods of apnea, which are sometimes prolonged. Impending respiratory failure from muscle fatigue can be detected by observing rapid shallow breathing, abdominal paradoxical motion, and alternation between rib cage and abdominal breathing, so-called *respiratory alternans*.[58] Hoover's sign is the paradoxical

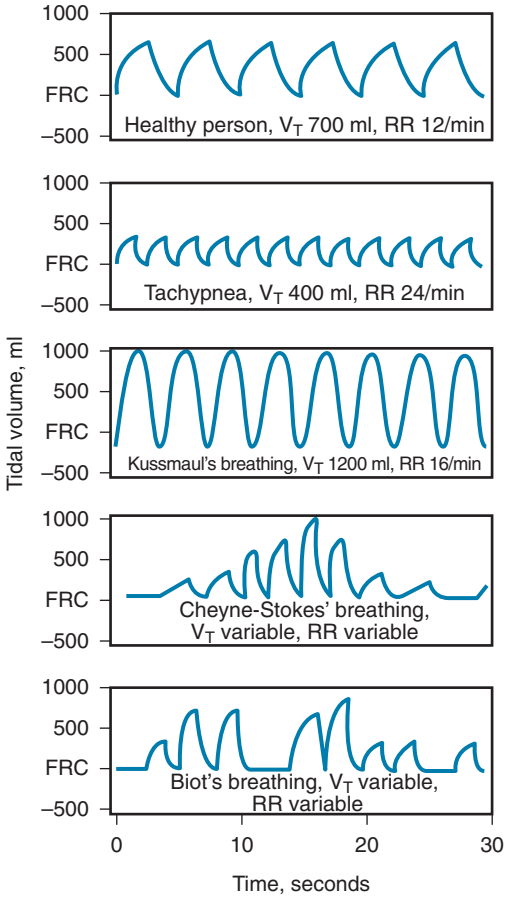

FIGURE 17-1 ■ Schematic drawing of different patterns of breathing. FRC, functional residual capacity, the normal lung volume at the end of expiration; RR, respiratory rate; VT, tidal volume.

inward displacement of the costal margin at the end of inspiration or throughout inspiration. Decreased regional ventilation can often be detected be seeing a lag in the motion of the affected part of the chest wall during breathing.

Palpation

Palpation of the thorax is a necessary part of the cardiac, breast, and lymph node examinations and often can detect bony abnormalities, such as a cervical rib, and subcutaneous calcinosis seen with systemic sclerosis. It is essential in examining causes of pain to determine point tenderness and thoracic spinal tenderness. It can detect fluctuant areas associated with empyema necessitans and crepitant areas associated with subcutaneous emphysema. Location by palpation of the trachea in the suprasternal notch is a useful way to detect shifts of the mediastinum. A spastic back muscle can be palpated as firm to identify a cause of pain. A lag in movement of the chest wall, suspected from inspection, can be confirmed by placing the two hands over opposite portions of each hemithorax and both feeling and observing whether or not the thorax moves symmetrically.[59] Symmetry is as important in palpation as it is in inspection.

A palpable vibration felt on the body, usually over the chest, is called *fremitus*. Vocal fremitus is elicited by having the patient speak "one, two, three," while the examiner's two palms or sides of the hands are moved horizontally from top to bottom of the two hemithoraces. Vocal fremitus is increased over regions of lungs through which there is increased transmission of sound, for example, consolidation from pneumonia. Conversely, fremitus is decreased in conditions in which sound transmission is impaired, for example, pleural effusion. Occasionally, fremitus over part of the chest wall can detect the presence of airway secretions (rhonchal fremitus) or an underlying pleural friction rub (friction fremitus).

In examining the heart, the examining physician should always search for an apical impulse, heaves and lifts, thrills, and palpable valve closure. In patients with severe COPD, abnormal cardiac movements are often better felt in the subxiphoid region than over the precordium.

Percussion

Skillful percussion depends on a uniform free and easy stroke of the striking finger (plexor) on the finger being struck (pleximeter), the ability to sense minor changes in pitch, and a keen sense of vibration—although the percussion note is heard, it is predominantly felt. Percussion of the thorax over normal air-containing lung produces a resonant note.

Sounds and tactile perception from percussion vary depending on the thickness of the skin, subcutaneous layer, breast tissue, and chest wall, as well as on the quality, distribution, and tension of the air under the area percussed. Pathologic processes may impair or enhance the resonating quality of the thorax. For example, the percussion note over a large pneumothorax is hyperresonant and becomes tympanitic when tension is present; in contrast, percussion over a pleural effusion or pneumonia produces dullness, which has been defined as a low-intensity sound of short duration, feeble carrying power, and rather high pitch.[60] Flatness is the unresonating sound obtained by percussing over the liver. Three different tonal zones can be detected when percussing large pleural effusions: normal resonance above the fluid, dullness in the middle, and flatness when completely below the fluid; these variations in sound may result from the presence of an internal meniscus or fluid wedge, which points upward into the lung above it. Carrying out a thoracentesis in the dull area offers the best chance of obtaining pleural fluid and avoids puncturing either an abdominal viscus or air-containing lung.

Auscultation

A stethoscope draped around the neck has long been the badge of the medical professional, and it is worn with pride by doctors, nurses, and respiratory therapists, despite predictions such as "it, too, will someday be relegated to a museum shelf."[61] Not for a long time, however, according to Murphy,[62] who mounts a spirited

TABLE 17-1. Classification of Common Lung Sounds

	Acoustic Characteristics	American Thoracic Society Nomenclature	Common Synonyms
Normal	200–600 Hz	Normal	Vesicular
	Decreasing power with increasing Hz		
	75–1600 Hz	Bronchial	Bronchial
	Flat until sharp decrease in power (900 Hz)		Tracheal
Adventitious		Adventitous	Abnormal
	Discontinuous, interrupted explosive sounds (loud, low in pitch), early inspiratory or expiratory	Coarse crackle	Coarse crackle
	Discontinuous, interrupted explosive sounds (less loud than above and of shorter duration; higher in pitch than coarse crackles or crackles), mid- to late inspiratory	Fine crackle	Fine crackle, crepitation
	Continuous sounds (>250 msec, high-pitched; dominant frequency of 400 Hz or more, a hissing sound)	Wheeze	Sibilant rhonchus
	Continuous sounds (>250 msec, low-pitched; dominant frequency about ≤200 Hz, a snoring sound)	Rhonchus	Sonorous rhonchus

defense in favor of stethoscopes, which he backs up with analyses of breath sounds obtained by respiratory acoustic recording. Indeed, mapping by computer-assisted imaging systems of breath sounds has provided new insights into their origin and clinical significance.[63] In addition, computerized multisensor breath sound imaging proved to be a sensitive and specific tool for differentiating pneumonia or pleural effusion from normal lungs.[64] Similarly, signal analysis of heart sounds recorded by digital electronic means has promising clinical applications and is useful for teaching cardiac auscultation.[65]

Stethoscopes are also helpful in picking up wheezes in asthmatics and crackles in patients with interstitial lung disease whose chest radiographs are normal. Moreover, patients expect their doctors to listen to their heart and lungs if they have cardiorespiratory complaints.

The terminology of breath sounds has been standardized and simplified to enhance understanding and communication (Table 17-1). Although a standardized nomenclature has been proposed by the American Thoracic Society[66] and the Tenth International Conference on Lung Sounds,[67] communication at the bedside often strays from recommended terminology.

The basic technique of auscultation with an ordinary stethoscope is well known to most physicians: the diaphragm detects higher-pitched sounds, and the bell lower-pitched, although if the bell is tightly pressed against the body, the taut underlying skin itself may serve as a "diaphragm" and improve perception of higher pitches. Conversely, the bell should be applied very lightly to hear, for example, the low-pitched rumble of mitral stenosis. Full contact with the skin is necessary for best listening, which may pose a problem in a patient whose intercostal spaces are sunken from weight loss. In addition, the skin or hairs may brush against the diaphragm and produce a sound that resembles a pleural friction rub. As with examiners' hands, a warm stethoscope head is appreciated by patients. The importance of a quiet room and of applying the stethoscope directly to the skin rather than through clothing has recently been reemphasized.[68] At times, especially in the intensive care unit, it is not always possible to sit patients up to listen carefully to their backs, which compromises the completeness of auscultation.

The recommended term for the ordinary breathing-associated sounds heard with a stethoscope placed on the chest of a healthy person is the *normal lung sound*, but, as shown in Table 17-1, many physicians prefer the older term "vesicular sound." The usually predominating inspiratory component arises from sounds generated by turbulent airflow within the lobar and segmental bronchi, whereas the weaker expiratory component arises within the larger, more central airways.[66] Sounds are attenuated as they move peripherally along the air passages, and are further damped by the large volume of the lungs' air spaces. The intensity of normal breath sounds varies with the magnitude of regional ventilation and, like percussion notes, diminishes with increasing thickness of the tissue overlying the chest wall. There is considerable variation among persons in the quality of breath sounds, which makes it essential to compare breath sounds from one side with those heard over the same location on the opposite hemithorax.

The transmission of normal lung sounds to the chest wall in pathologic conditions may be either attenuated or exaggerated. When the lung parenchyma is consolidated and the airway leading to the involved region is patent, breath sounds are overly well transmitted to the chest wall, and are termed *bronchial breath sounds*. Bronchial breath sounds are loud, high-pitched, tubular, or whistling sounds with expiration as loud as or louder than inspiration. Bronchial breath sounds are similar to tracheal breath sounds and their presence is the classic auscultatory sign of pneumonia. Similar sounds occur in patients with other types of consolidation, such as pulmonary edema and hemorrhage. The presence of this sign assumes that the sounds originate centrally and reach the chest wall. If the bronchus supplying the region of consolidation is not patent, the

central breath sounds tend to be attenuated, but voice-generated sounds, which are clearly of central origin, are increased.[69]

Interposition of a sound barrier between the central airways where sounds originate and the chest wall where they are heard also attenuates or interrupts transmission of normal lung sounds. Accordingly, normal breath sounds are diminished or absent over a pleural effusion, pneumothorax, and peripheral bullae, or distal to an obstructing mass lesion. Conversely, they may be increased if chest wall deformity or bronchial or tracheal derangement allows movement of air to be closer than usual to the stethoscope.

Adventitious Sounds

The major types of adventitious sounds are classified in Table 17-1. Two generic categories of adventitious sounds have been documented by high-speed recording techniques, and each of these has two subdivisions: discontinuous sounds, including fine crackles and coarse crackles, and continuous sounds, including wheezes and rhonchi.[70]

Discontinuous Sounds (Crackles)

Crackles, still often referred to as "rales" in the United States and "crepitations" in Great Britain, consist of a series of short explosive nonmusical sounds that punctuate the underlying breath sound; fine crackles are softer, shorter in duration, and higher in pitch than coarse crackles. There is general agreement that the brief recurrent detonations that characterize fine crackles are caused by the explosive openings of small airways that had closed owing to the surface forces within them.[66,71] This explains why fine crackles are much more common during inspiration than during expiration, and why they are best heard over dependent lung regions—where airways are more likely to close—than over uppermost regions. This is also compatible with the presence of crackles in healthy elderly persons in whom dependent airway closure occurs at resting lung volumes. Crackles, therefore, are best heard during the first deep breaths at the lung bases posteriorly; after several such breaths, the small airways may remain open for the time the patient is being examined.[71]

The timing of crackles is also important. Nath and Capel[72] have shown that late-inspiratory crackles are more often found in restrictive than obstructive lung disease. In a study by Pürilä and colleagues,[73] the crackles of fibrosing alveolitis began at 45% of inspiration, whereas those of COPD (25%), bronchiectasis (33%), and heart failure (37%) occurred earlier. The crackles of fibrosing alveolitis also lasted longer—88% of the inspiratory time.[73] This suggests that more tension is required to open individual airways in fibrosis than in lungs with secretions or edema, in which either obstruction with secretions or surfactant dilution may allow closure of the small airways. As inspiration progresses, radial traction on the airway wall increases until it suddenly pops open.[72] Expiratory crackles are much less frequent than inspiratory crackles and are often seen in obstructive lung disease.[71]

Continuous Sounds (Wheezes)

The American Thoracic Society Committee on Pulmonary Nomenclature defined wheezing as high-pitched (dominant frequency of ≥400 Hz) continuous adventitial lung sounds.[70] Continuous sounds are longer than 250 msec in duration. Wheezes are usually louder than the underlying breath sounds and frequently noted by patients. A leading theory is that wheezes are produced by fluttering of the airway walls and fluid together induced by a critical flow velocity.[74] The pitch of the wheeze is dependent on the mass and elasticity of the airway walls and the flow velocity. The degree of bronchial obstruction is proportional to the amount of the respiratory cycle that it occupies. There is no relationship to the intensity or pitch of the wheeze and pulmonary function. Wheezes are well heard over the trachea and listening over the trachea may be superior to listening over the lung in most asthmatic patients.[74] Wheezing with forced expiration can often be provoked in healthy subjects,[66] and does not establish a diagnosis of asthma. In fact, several disease states are associated with wheezing and additional information should be obtained to make the correct diagnosis.

Rhonchi are low-pitched continuous sounds with a dominant frequency about 200 Hz or less. These sounds are likely to originate from rupture of fluid films and airway wall vibrations.[66] Rhonchi may clear with cough and suctioning in intubated patients.

Voice-Generated Sounds

Another way of generating sounds for auscultation is to have patients speak while the examiner listens to their chests. Ordinarily, the patient is asked to say in a quiet voice "one, two, one, two," "ninety-nine, ninety-nine," or "E, E." If enhanced responses are heard, the patient repeats the words while whispering. Because sounds of central origin are attenuated as they are transmitted peripherally through normal air-filled lung, voice-generated sounds have a muffled quality and the words are indistinct. In contrast, in the presence of consolidation, the characteristics of the sounds are remarkably different. The term *egophony* indicates sounds that have a high-pitched, bleating quality; a change in sound-filtering properties of consolidated lungs accounts for the presence of egophony, which does not require, as often stated, the presence of an overlying pleural effusion. *Bronchophony* and *pectoriloquy* both mean that spoken sounds are transmitted with increased intensity and pitch; when each syllable of every word, especially when whispered, is distinct and easily recognized, pectoriloquy is the preferred description. An E to A sign occurs when the spoken letter "E" sounds like "A" while listened to over the lungs. Each of these auscultatory findings is a manifestation of the same acoustic property of consolidated lungs and thus has similar diagnostic significance.

Pleural Friction Rub

The small amount of liquid normally present in the pleural space separates the visceral and the parietal pleural layers and allows the lungs to expand and contract freely during breathing. In contrast, when the pleural surfaces are thickened and roughened by an inflammatory or neoplastic process, easy motion is prevented and a pleural friction rub may be produced. These sounds vary in intensity but often have a leathery or creaking quality that may be exaggerated by pressure with the stethoscope. Typically, rubs are heard during both inspiration and expiration, but they are evanescent and variable and may occur as a single component during any part of the respiratory cycle. Surprisingly, rubs may still be heard in the presence of a large pleural effusion, which prevents the coarsened pleural surfaces from actually rubbing against each other.

Nonpulmonary Sounds

The presence of air or other gas in the mediastinum may be associated with crunching, crackling sounds that are synchronous with cardiac contraction and are audible when breathing is momentarily stopped. The finding of a mediastinal crunch by auscultation usually signifies mediastinal emphysema, even when the chest radiograph shows no abnormalities. A pericardial friction rub is multiphasic and has a higher pitch, which usually makes it distinguishable.

Stridor is a high-pitched continuous sound produced by turbulent flow in the extrathoracic airway, which—in contrast to wheezing—is louder and longer during inspiration than expiration. Stridor has many causes,[74a] some of which are life-threatening and need immediate attention (see also Chapter 43).

As previously mentioned, various sounds may originate from the chest wall itself. Some of these have pathologic significance; others do not. Rubbing hairs trapped between the skin and the stethoscope produce intermittent crackling sounds that may be confused with crackles. Variable crackles are also produced when the stethoscope is placed over an area of subcutaneous emphysema and is rocked back and forth. Contracting chest wall muscles may generate sounds that have a muffled, distant, low-pitched, and rumbling quality. Occasionally, it is possible to hear a snapping sound during breathing from motion of a newly fractured rib.

Interpretation

When abnormalities are discovered on physical examination of the chest, it is useful to identify them by their anatomic location in the involved lung. This requires knowledge of the surface projections of the underlying bronchopulmonary lobes, which are shown in Figure 17-2. The upper and lower lobes of both lungs are separated by the two oblique fissures, which course from the spinous process of the third thoracic vertebra posteriorly to the level of the 6th rib in the midclavicular line anteriorly. On the right side anteriorly, the upper and middle lobes are separated by the horizontal fissure, which lies at about the level of the fourth costal cartilage. In the presence of either distortions of pulmonary anatomy or the shape of the rib cage, the surface projections of the underlying lung also change.

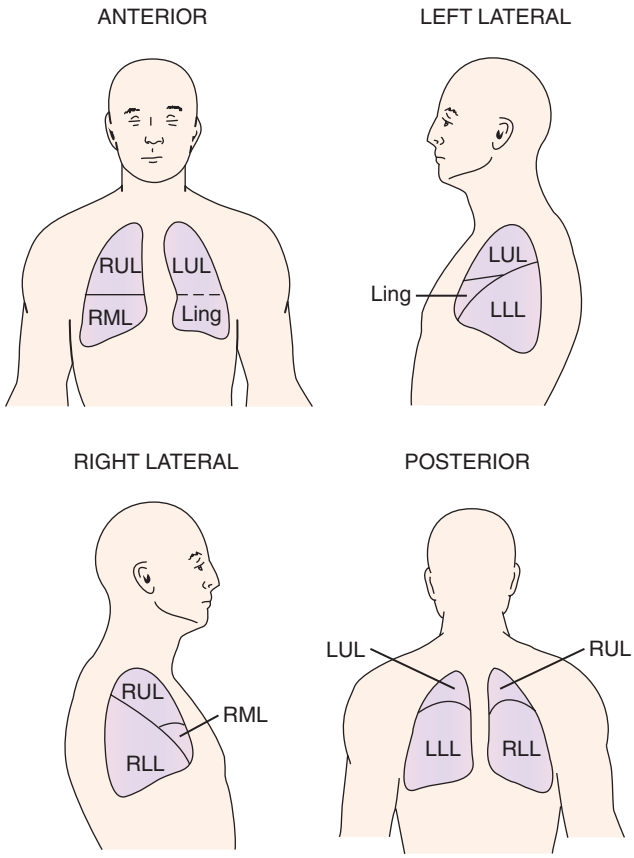

FIGURE 17-2 ■ Schematic drawing shows surface projections of underlying lobar anatomy of a healthy man. ling, lingular division of left upper lobe; LLL, left lower lobe; LUL, left upper lobe; RLL, right lower lobe; RML, right middle lobe; RUL, right upper lobe.

The classic findings on physical examination of the chest in some common pulmonary disorders are shown in Table 17-2. Ordinarily, consolidation must be within 1 or 2 cm of the costal surface to be reliably detected. Even then, physical examination alone cannot be relied upon to diagnose or exclude pneumonia.[75] Some pneumonias, such as mycoplasma pneumonia, typically cause surprisingly few physical abnormalities despite extensive radiographic involvement, but even in patients with classic lobar pneumonia, the findings may be nonspecific. Although unable to distinguish reliably between new-onset pneumonia and other pulmonary diseases, the findings from physical examination—vital signs, mental confusion, cyanosis, use of accessory muscles, and paradoxical breathing—are extremely important in assessing severity and in deciding whether or not to hospitalize patients with pneumonia.[76]

The distinction between pleural effusion and atelectasis, which depends on which side the heart and mediastinal contents have shifted toward, can usually be made only if the effusion is large or the atelectasis involves at

TABLE 17-2. Classic Physical Findings in Some Common Pulmonary Disorders

Disorder	Inspection	Palpation	Percussion	Auscultation
Bronchial asthma (acute attack)	Hyperinflation; use of accessory muscles	Impaired expansion; decreased fremitus	Hyperresonance; low diaphragm	Prolonged expiration: inspiratory and expiratory wheezes
Pneumothorax (complete)	Lag on affected side	Absent fremitus	Hyperresonant or tympanitic	Absent breath sounds
Pleural effusion (large)	Lag on affected side	Decreased fremitus; trachea and heart shifted away from affected side	Dullness or flatness	Absent breath sounds
Atelectasis (lobar obstruction)	Lag on affected side	Decreased fremitus; trachea and heart shifted toward affected side	Dullness or flatness	Absent breath sounds
Consolidation (pneumonia)	Possible lag or splinting	Increased fremitus on affected side	Dullness	Bronchial breath sounds; bronchophony; pectoriloquy; crackles

Modified from Hinshaw HC, Murray JF (eds): Diseases of the Chest (4th ed). Philadelphia: WB Saunders, 1980, p 23.

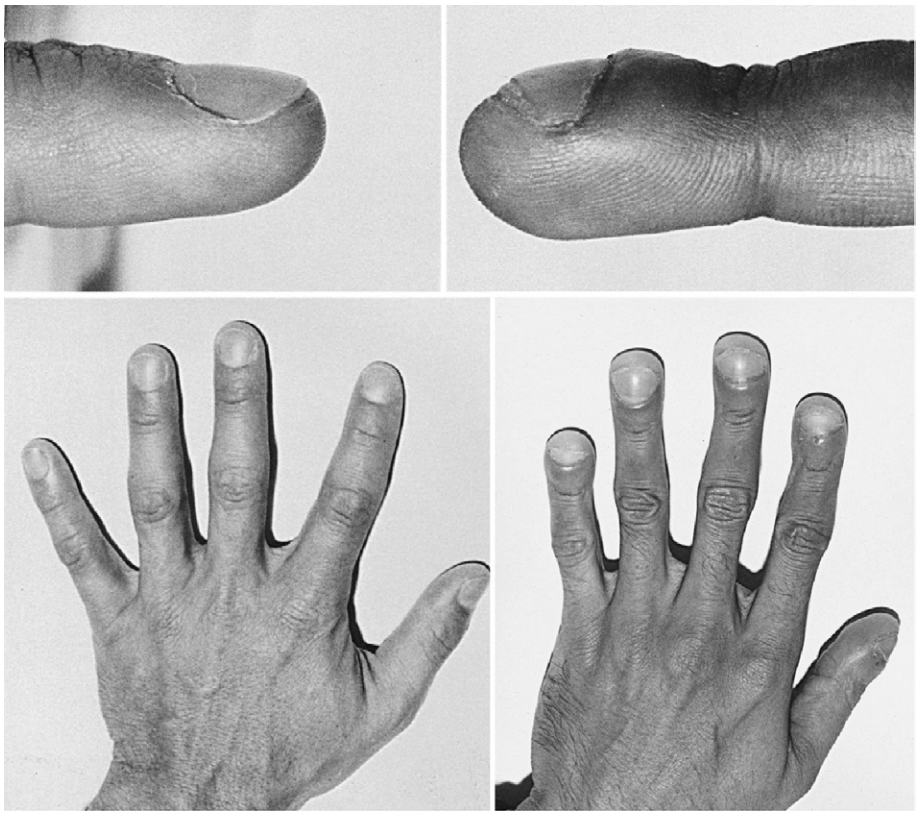

FIGURE 17-3 ■ Photographs show the hands and index fingers of a normal person (*left panels*) and a person with clubbing of the digits (*right panels*) secondary to severe diffuse pulmonary interstitial fibrosis.

least one lobe. When these full-blown manifestations are present, the presence of the causative disorder can be inferred with reasonable certainty. However, the absence of these findings does not exclude an abnormality, and a chest radiograph must always be taken as part of the complete pulmonary workup.

Extrapulmonary Manifestations

The examination of the lungs and pleura unlock only some of the clues to the presence of lung disease. Looking for extrapulmonary signs can often point toward a specific pulmonary disease, show that the lungs are involved in systemic diseases such lupus erythematosus, or demonstrate that the pulmonary abnormalities are secondary to diseases arising elsewhere in the body. Certain extrapulmonary manifestations are particularly useful.

Clubbing

The association of clubbing of the fingers or toes with disease has caught the attention of physicians since the time of Hippocrates. Clubbing is easy to recognize when

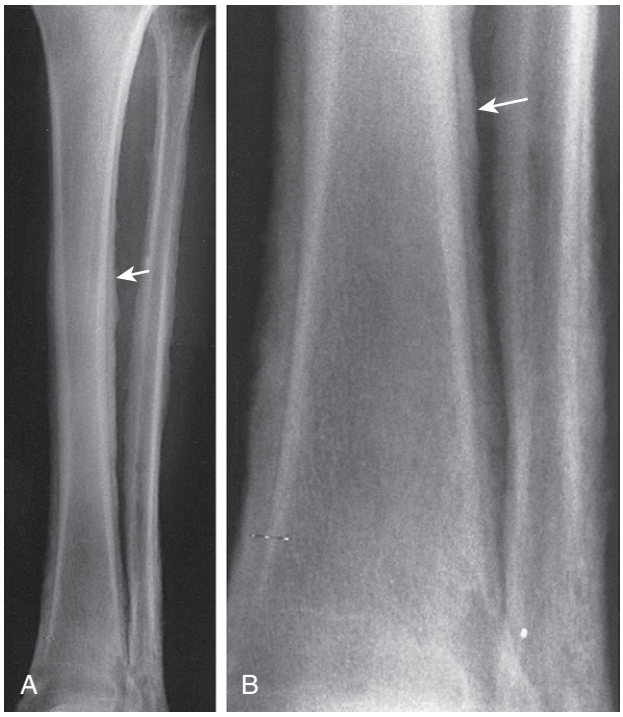

FIGURE 17-4 ■ Radiographs of the leg show marked subperiosteal new bone formation (*arrows*) that is diagnostic of hypertrophic osteoarthropathy. **A,** Most of tibia and fibula. **B,** Detailed view near the ankle.

it is severe (Fig. 17-3), but subtle changes are more common and less reliable. The hallmarks of clubbing are (1) a softening and periungual erythema of the nail beds, which causes the nails to seem to float rather than to be firmly attached, (2) an increase of the normal 165-degree angle that the nail makes with its cuticle, (3) an enlargement or bulging of the distal phalanx, which may be warm and erythematous, and (4) a curvature of the nails themselves. Of these features, the straightening of the nail cuticle angle appears to be the most sensitive measurement.[77]

Patients with clubbing may also have *hypertrophic osteoarthropathy*, a condition characterized by subperiosteal formation of new cancellous bone at the distal ends of long bones, especially the radius and ulna and the tibia and fibula. Hypertrophic osteoarthropathy (Fig. 17-4) is almost always associated with clubbing, particularly in patients with bronchogenic carcinoma, other intrathoracic malignancies, and cystic fibrosis. It occasionally occurs in patients with bronchiectasis, empyema, and lung abscess, but is rare in patients with most of the other conditions in which clubbing has been observed.[78] One of the striking features of clubbing is the speed with which it can develop, about 2 weeks in patients with new-onset empyema, and with which it can reverse, also about 2 weeks in patients after corrective cardiac surgery. The presence of clubbing, which was found in 1% of all admissions to an internal medicine department, was associated with "serious disease" in 40% of afflicted patients[79]; therefore, new-onset clubbing always warrants a chest radiograph, and if no abnormality is found, a CT to look for a pulmonary neoplasm or other lesion, which may still be localized and curable.

Clubbing has been found in many diverse conditions, such as children with human immunodeficiency virus,[80] hepatopulmonary syndrome,[81] and benign asbestos pleural disease[82] (Table 17-3). Both clubbing and hypertrophic osteoarthropathy can be idiopathic or familial; the familial form is often transmitted as a dominant trait. The hereditary form of hypertrophic osteoarthropathy is also called *pachydermoperiostosis*, a condition in which bone and joint involvement is often mild but furrowing of the skin of the face and scalp is usually marked.

The main pathologic finding in clubbing is increased capillary density. The most potent stimulus to new capillary growth is hypoxia, which causes an intense production of vascular growth factors, such as vascular endothelial growth factor (VEGF). With histochemical staining, Atkinson and Fox[83] showed increases in VEGF, platelet-derived growth factor, hypoxia-inducible factor (HIF)-1α, and HIF-2α along with increased microvessel density in the stroma of clubbed digits. The second common characteristic of patients with digital clubbing is shunting of blood past the capillary bed of either the lung or the liver, which suggests that lack of metabolism of angiogenic factors that bypass a critical organ may be involved. Several of the conditions associated with clubbing have inflammation and shunting, such as bronchiectasis and liver cirrhosis.

Other Extrapulmonary Associations

Besides clubbing, thoracic neoplasms may cause other extrathoracic abnormalities that may become evident on physical examination, including anemia, Cushing's syndrome, gynecomastia, and other paraneoplastic syndromes (Table 17-4). Other common extrathoracic manifestations that provide clues to the presence or state of an underlying malignancy are wasting, hoarseness, adenopathy (especially supraclavicular), and hepatomegaly. When evaluating patients with dyspnea, a thorough examination of the neck veins for evidence of increased central venous pressure and careful cardiac auscultation for the presence of a third heart sound or distinctive murmurs, are important findings in patients with heart failure.[84] The extremities should also be examined for evidence of peripheral edema, venous thrombosis, chronic venous stasis, and intravenous drug abuse.

The association of abnormalities in other organ systems with underlying lung disease can be very helpful in making a diagnosis. A wide variety of cutaneous or subcutaneous lesions (Table 17-5)[85] and ocular lesions (Table 17-6)[86] has been associated with various primary lung disorders. Likewise, persons presenting with a combination of lung and kidney disease (Table 17-7); lung and bone; joint, muscle, or nerve lesions (Table 17-8); and lung and gastrointestinal disease (Table 17-9) may denote a unifying disease process that can be detected by physical examination.

TABLE 17-3. Causes of Clubbing (partial listing)

NOT ASSOCIATED WITH OVERT DISEASE
Hereditary clubbing
Sporadic clubbing
Pachydermoperiostosis

THORACIC NEOPLASMS
Lung cancer especially fibrous tumors (accounts for most clubbing)
Benign and malignant pleural tumors
Other thoracic neoplasms, including esophageal cancer, and lymphoma

HEART AND VASCULAR DISEASE
Cyanotic congenital heart disease
Subacute bacterial endocarditis
Infected aortic graft
Aortic surgery
Takayasu's arteritis
Behçet's disease

PULMONARY AV SHUNTING
Cyanotic congenital heart disease
Acquired heart disease
Pulmonary AV fistula
Hereditary hemorrhagic telangiectasias

INTERSTITIAL LUNG DISEASE
Asbestosis
Idiopathic pulmonary fibrosis
Collagen vascular disease
Langerhans histiocytosis
Lipoid pneumonia

CHRONIC INFECTIONS
Bronchiectasis
Bronchiectasis from sarcoidosis or tuberculosis
Lung abscess
Empyema
Cystic fibrosis

GASTROINTESTINAL AND LIVER DISEASE
Inflammatory bowel disease
  Crohn's disease
  Ulcerative colitis
  Polyposis coli
Amebic colitis
  Bacillary dysentery
Liver disease
  Hepatoma
  Hepatopulmonary syndrome
  Biliary cirrhosis
Esophageal stricture

HEMOGLOBINOPATHY
Hemoglobinopathies
Congenital methemoglobinemia

OTHER
Thyroid acropathy
Secondary hyperparathyroidism
HIV related
  Lymphoid interstitial pneumonia
  Other infections
Prostaglandin infusion
Fabry's disease
Toxic exposure to arsenic, mercury or beryllium

UNILATERAL CLUBBING
Vascular disorders
  Subclavian artery aneurysm
  Brachial AV fistula
Subluxation of the shoulder
Median nerve injury
Local trauma
Hemiplegia

AV, arteriovenous; HIV, human immunodeficiency virus.

TABLE 17-4. Paraneoplastic Syndromes (partial listing)

PARANEOPLASTIC SYNDROMES
Acanthosis nigricans
Clubbing
Dermatomyositis-polymyositis
Hypertrophic osteoarthropathy
Intravascular thrombosis
Muscle weakness
Neuropathy
Phemphigoid
Raynaud's phenomenon

ENDOCRINE SYNDROMES ASSOCIATED WITH LUNG NEOPLASMS
Hypercalcemia (parathyroid-like substance)
Hyponatremia (inappropriate antidiuretic hormone)
Carcinoid syndrome (serotonin)
Cushing's syndrome (ACTH)
Hyper- and hypoglycemia (insulin)
Gynecomastia (gonodotropins) (prolactin)
Skin pigmentation (melanocyte-stimulating hormone, ACTH)
Acromegaly (growth hormone)
Diarrhea (vasoactive intestinal peptide)

ACTH, adrenocorticotropic hormone.

TABLE 17-5. Skin and Subcutaneous Lesions Associated with Lung Disease

SKIN LESIONS

Diffuse pigment change
- Acanthosis nigricans—lung neoplasm
- Albinism—Hermansky-Pudlak syndrome
- Bronze pigmentation—hemosiderosis
- Gray-brown—Whipple's disease

Cutaneous draining sinus
- Fungal infections (especially histoplasmosis)
- Mycobacterial infections (especially tuberculosis)
- Neoplasms (especially mesothelial tumors)
- Necrotizing vasculitis
- Other bacterial infections (especially actinomycosis)

Cutaneous ulcers
- Beryllium disease
- Chronic venous insufficiency
- Fungal infections (especially histoplasmosis)
- Mycobacterial disease
- Necrotizing vasculitis
- Parasitic disease
- Polycythemia
- Sickle cell disease
- Tularemia

Cutaneous vasculitis
- Behçet's syndrome
- Churg-Strauss syndrome
- Collagen vascular disease
- Sarcoidosis
- Wegener's granulomatosis

Erythema multiforme
- Drug reactions
- Fungi (especially coccidiomycosis)
- Mycoplasma and other infectious agents
- Neoplasms

Exfoliative dermatitis
- Adverse drug reactions
- Chemotherapy
- Disseminated malignancy
- Graft-versus-host disease
- Radiation therapy

Flushing
- Bronchial carcinoid, pheochromocytoma, other neoplasms
- Carbon dioxide, cyanide, and other toxins
- Drugs
- Foods and vasodilatory substances
- Hormones
- Mastocytosis
- Metabolic states (e.g., hyperthyroidism, fever)

Macular rash
- Anti-basement membrane disease
- Café-au-lait spots (neurofibromatosis)
- Coal miner's scars
- Collagen vascular disease
- Idiopathic pulmonary fibrosis
- Rose spots (psittacosis)
- Sarcoidosis
- Syphilis
- Viral pneumonia

Maculopapular rash
- Amyloidosis
- Drug-induced lung disease
- Collagen vascular disease
- Gaucher's disease
- Kaposi's sarcoma
- Lung neoplasm
- Lymphomatoid granulomatosis
- Lymphoma
- Parasites
- Sarcoidosis
- Syphilis
- Vasculitis
- Viral pneumonia

Sicca syndrome (dry mouth and eyes)
- Gaucher's disease
- Lymphocytic interstitial pneumonia
- Sjögren's syndrome

Telangiectasia
- Arteriovenous malformation
- Ataxia-telangiectasia
- Carcinoid syndrome
- Cushing's disease
- Hepatopulmonary syndrome and other chronic liver diseases
- Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu)
- Mastocytosis
- Systemic sclerosis and other collagen vascular diseases

Urticaria
- Asthma
- Drug reactions
- Cystic fibrosis
- Exercise-induced urticaria
- Food allergy
- Hereditary angioneurotic edema
- Inhaled antigens
- Insect bites and stings
- Infectious agents, such as mycoplasma and helicobacter
- Mastocytosis
- Occupational sensitization
- Parasites
- Vasculitis

NAIL CHANGES WITH LUNG DISEASE

Color changes
- Cigarette smoking discoloration
- Splinter hemorrhages
- Yellow nail syndrome

Beau's lines (any severe illness)
- Dermatomyositis
- Sarcoidosis
- Seronegative arthropathies
- Systemic sclerosis

LUNG DISEASE WITH SUBCUTANEOUS INVOLVEMENT

Adenopathy
- Environmental mycobacteria
- Fungal infections
- HIV infections
- Metastatic neoplasm
- Leukemia
- Lymphoma
- Sarcoidosis
- Tuberculosis

Calcinosis
- Dermatomyositis
- Metastatic osteosarcoma
- Mixed connective tissue disease
- Scleroderma
- Tuberculosis
- Uremic metastatic calcification

Erythema induratum (Bazin's disease)
- Aortic stenosis
- Cryoglobulinemia
- Nodular vasculitis
- Panniculitis
- Peripheral neuropathy
- Takayasu's disease
- Streptococcus infection
- Tuberculosis and other mycobacterial disease
- Weber-Christian disease

Erythema nodosa
- Neoplasm
- Other infectious and inflammatory diseases
- Primary coccidiomycosis, histoplasmosis
- Primary tuberculosis
- Psittacosis
- Sarcoidosis

Subcutaneous nodules
- Amyloidosis
- Neoplasm
- Neurofibromatosis
- Rheumatoid arthritis
- Tuberous sclerosis (angiofibromas)
- von Recklinghausen's
- Weber-Christian disease

LUNG DISEASE WITH SALIVARY GLAND ENLARGEMENT

Bulimia and aspiration
Gaucher's disease
Lymphoid interstitial pneumonitis
Lymphatic carcinoma
Lymphoma
Other causes of lymphadenopathy
Sarcoidosis
Sjögren's disease

HIV, human immunodeficiency virus.

Pulmonary fibrosis
Mycobacterial disease

KEY POINTS

- Taking a careful history and performing a thorough physical examination are essential first steps in formulating a preliminary differential diagnosis of the patient's complaints.
- After arriving at a tentative diagnosis, selected radiographic, laboratory, and other tests are ordered for further and confirmatory evaluation.
- The electronic medical record provides documents of higher quality than written records, owing to improved organization, increased readability, use of supplementary material, and better comparisons.
- Because dyspnea, cough with or without hemoptysis, and chest pain are among the most common reasons for patients to visit physicians, and because these symptoms may result from serious underlying chest disease, careful questioning and workup, as described, is mandatory.
- Physical examination can be performed virtually anywhere, provides important information, lends itself to serial observations, and increases patients' confidence in their physicians.
- New-onset clubbing of the digits warrants detection and investigation owing to its frequent association with serious underlying disease.
