Interestingly, two more recent studies have demonstrated that ANCA antibody status may characterize two distinct clinical phenotypes in CSS[87,88] (Table 61-3).

TABLE 61-3. Distinct Phenotypes of Churg-Strauss Syndrome

	Vasculitic Phenotype	Tissular Disease Phenotype
Respective frequency	~40%	~60%
ANCA	Present (mostly p-ANCA with anti-MPO specificity)	Absent
Predominant clinical and histopathologic features	Glomerular renal disease Peripheral neuropathy Purpura	Cardiac involvement (eosinophilic myocarditis) Fever
Predominant histopathologic features	Biopsy-proven vasculitis	Eosinophilic pneumonia

ANCA, antineutrophil cytoplasmic antibody; MPO, myeloperoxidase; p-ANCA, perinuclear antineutrophil cytoplasmic antibody.
Adapted from Sable-Fourtassou R, Cohen P, Mahr A, et al: Antineutrophil cytoplasmic antibodies and the Churg-Strauss syndrome. Ann Intern Med 143:632–638, 2005; and Sinico RA, Di Toma L, Maggiore U, et al: Prevalence and clinical significance of antineutrophil cytoplasmic antibodies in Churg-Strauss syndrome. Arthritis Rheum 52:2926–2935, 2005.

Hence, patients with ANCA, representing 38% of patients in both studies, have a *vasculitic phenotype* of disease with an increased frequency of extracapillary glomerular lesions, peripheral neuropathy, purpura, and biopsy-proven vasculitis. Conversely, CSS patients without ANCA have more frequent cardiac and pulmonary involvement (and fever), thus corresponding to an eosinophilic tissue disease phenotype of CSS. The latter might conceivably represent a variant of the HES with systemic manifestations.[88,116] The vasculitic phenotype of CSS is more frequent in patients carrying the major histopathology complex DRB4 allele[98] and, in those with the IL-10-3575/1082/592 TAC haplotype (part of the ancient haplotype IL10.2 correlated with increased IL-10 expression), is significantly associated with ANCA-negative CSS,[117] thus indicating that genetic predisposition may affect the phenotype of CSS.

Treatment and Prognosis

Corticosteroids are the mainstay of treatment of CSS and suffice in a large number of cases.[73,118,119] Initial methylprednisolone pulses, for 1 to 3 days, are useful in the most severe cases, then oral treatment is started, usually with 1 mg/kg/day of prednisone. Treatment is prolonged for several months with progressive reduction of doses. Relapses are common, and asthma often persists (or reappears if it had disappeared during high-dose corticosteroid treatment). Distinguishing relapse or persistence of so-called difficult asthma from relapse or persistence of CSS requires very precise evaluation taking into account the levels of blood eosinophils (generally $<1 \times 10^9$ in asthma without CSS relapse).

Cyclophosphamide therapy should be added to corticosteroids in patients with manifestations that could result in mortality or severe morbidity.[120] A retrospective study of patients with either polyarteritis nodosa or CSS[118] identified five factors with significant pronostic value and responsible for higher mortality (five factor score): proteinuria greater than 1 g/day; renal insufficiency with serum creatinine greater than 15.8 mg/L (140 μmol/L); gastrointestinal tract involvement; cardiomyopathy; and central nervous system involvement. Cardiomyopathy and central nervous system involvement were associated with a relative risk of mortality of 2.2 and 1.8, respectively (not statistically significant). The combination of immunosuppressors with corticosteroids improved disease control, despite associated infections (which could be decreased by using bolus instead of oral cyclophosphamide administration).[121,122] Mortality was associated with disease severity, and treatment with cytotoxic agents did not prevent relapses.[123] Although the optimal duration of therapy remains to be determined, 12 cyclophosphamide pulses were better able to control the disease than a 6-pulses regimen in patients with CSS and at least one poor prognosis factor at onset.[124] Corticosteroid treatment alone for CSS patients without poor prognostic factors at onset is efficient, with about half of the patients achieving complete remission without relapse.[125] Therefore, immunosuppressive therapy (most commonly with intravenous pulses of cyclophosphamide) in addition to corticosteroids is warranted in patients with poor prognostic factors at onset (e.g., five factor score ≥ 1). Oral azathioprine in addition to corticosteroids may be useful in patients who relapse under 20 mg/day or more of prednisone.

Subcutaneous interferon-alfa was successfully used mainly in CSS patients with severe disease.[126] High-dose intravenous immunoglobulins, cyclosporin A, and more recently, rituximab[127–130] have been occasionally used successfully. The anti-IgE omalizumab has been used successfully in patients with CSS to treat persistent asthma[131,132]; however, it does not control the systemic disease, and careful clinical monitoring is warranted.

The prognosis of CSS has improved considerably over time with almost 80% of patients alive at 5 years,[118] and 97% alive at 5 years in one recent series of CSS without poor-prognosis factors.[133] Most deaths during the first year of treatment are due to cardiac involvement.[134] In one series, CSS did not appear to confer increased mortality, a rather surprising finding.[76] As most patients continue to take oral corticosteroids over the long term, treatment-related side effects cause significant morbidity.[133] In addition, airflow obstruction due to uncontrolled asthma is present despite corticosteroids in many patients during follow-up, and persistent airflow obstruction may develop (38% of patients with at least 3 years follow-up in our series).[135] Airflow obstruction may not respond to inhaled bronchodilators, but may be still partly reversible with increased oral corticosteroid treatment.[135]

Hypereosinophilic Syndrome

The definition of the "idiopathic" HES proposed by Chusid and coworkers[136] in 1975 included (1) a persistent eosinophilia greater than 1.5×10^9/L for longer than 6 months, or death before 6 months associated with the signs and symptoms of hypereosinophilic disease, (2) a lack of evidence for parasitic, allergic, or other known causes of eosinophilia, and (3) presumptive signs and symptoms of organ involvement, including hepatosplenomegaly, organic heart murmur, congestive heart failure, diffuse or focal central nervous system abnormalities, pulmonary fibrosis, fever, weight loss, or anemia. The 14 cases they reported[136] included 2 patients with "prolonged benign hypereosinophilia," 3 with eosinophilic leukemia, and 1 with possible CSS. The later published cases of the idiopathic HES also proved heterogeneous, although patients with typical chronic disease shared some common complications, especially cardiac involvement.

Pathogenensis

In contrast with common hypereosinophilia, which is usually a reactive nonclonal process (as in parasitic disorders), several studies demonstrated that HES may result from a clonal proliferation of lymphocytes producing eosinophilopoetic chemokines ("lymphocytic variant" of HES), or from the clonal proliferation of the eosinophil cell lineage itself ("myeloproliferative variant" of HES, sometimes referred to as chronic eosinophilic

leukemia).[137-142] The term *idiopathic* should probably be abandoned in the classification of HES,[143] and may be appropriate only for the proportion of cases that cannot at present be classified in either category. In such genuinely idiopathic cases, innovative diagnostic tools such as the quantitative assessment of the *WT1* transcript in peripheral blood may help to differentiate HES from other causes of eosinophilia of determined cause.[144]

The **"lymphocytic variant"** of HES, which may account for about 30% of patients with HES, results from the production of chemokines (especially IL-5) which promote the accumulation of eosinophils by clonal Th2 lymphocytes (as demonstrated by clonal rearrangement of the TCR) bearing an aberrant immunologic phenotype (such as $CD3^-$ $CD4^+$). Lymphocyte phenotyping to detect a phenotypically aberrant T-cell subset, and analysis of the rearrangement of the TCR genes in search of T-cell clonality, should be performed on the peripheral blood (and bone marrow). Serum levels of IgE are elevated as a consequence of IL-4 and IL-13 production by Th2 lymphocytes.[143,145,146] Serum levels of IL-5 and TARC are increased.[147] The majority of reported patients was recruited from dermatology clinics and had papules or urticarial plaques infiltrated by lymphocytes and eosinophils (and in some of them, a cutaneous T-cell lymphoma or the Sezary syndrome was ultimately present). In such cases, the HES may be considered as a premalignant T-cell disorder.[145,146,148]

The **"myeloproliferative variant"** of HES (or chronic eosinophilic leukaemia), accounting for 20% to 30% of cases, is caused by a constitutively activated tyrosine kinase fusion protein created by fusion of *Fip1L1 – PDGFR-α* as a consequence of an interstitial chromosomal deletion of a region in the long arm of chromosome 4 (q12) not detectable by karyotype analysis.[149,150] Hepatomegaly, splenomegaly, mucosal ulcerations, severe cardiac manifestations resistant to corticosteroid treatment, anemia, thrombocytemia, increased serum vitamin B_{12}, leukocyte alkaline phosphatase and serum tryptase, and circulating leukocyte precursors are common and suggestive of the diagnosis, whereas cutaneous manifestations are infrequent. Diagnosis is confirmed by chromosomal rearrangement analysis and transcript study of the *Fip1L1 – PDGFR-α* fusion gene, which should be systematically performed in patients with HES. The fusion protein transforms hematopoietic cells and is inhibited by imatinib, a 2-phenylaminopyrimidine–based tyrosine kinase inhibitor originally used to treat chronic myelogenous leukemia. Imatinib proved efficient in the treatment of chronic myeloproliferative diseases and gastrointestinal stromal tumors (also characterized by aberrant constitutively activated tyrosine kinases). Imatinib proved efficient for several months in treating HES in patients refractory to corticosteroids, hydroxyurea, and/or interferon-α. Relapse occurred in one patient due to a mutation in *PDGFR-α* conferring resistance to imatinib (thus demonstrating that the FIP1L1-PDGFR-α fusion protein is the target of imatinib). Interestingly, IL-5 overexpression is necessary in mice to induce a condition similar to HES, suggesting that additional mechanisms may cooperate with the *Fip1L1 – PDGFR-α* fusion gene in disease etiology.[151]

Clinical Features

The pulmonary involvement in patients with eosinophilia of clonal origin has not been hitherto studied extensively, and especially has not been examined in cases classified according to the previously discussed two variants. However, lung or pleural involvement, although uncommon, has been mentioned in some cases[145,146,152] in patients with clonal lymphoid proliferations. The following data derived from older studies including cases with the two previously mentioned variants of HES may therefore need reevaluation in the future, and the prevalence of pulmonary involvement might be much lower than previously considered.

The HES is more common in men than in women (9:1), and occurs at ages between 20 and 50 years.[153] The onset is generally insidious, with eosinophilia discovered incidentally in 12% of the patients.[154] The mean eosinophil count at presentation was 20.1×10^9/L, with an average highest value of 44.4×10^9/L in one series.[155] Extremely high values of eosinophilia, in excess of 100×10^9/L, are found in some patients.[136]

The main presenting symptoms are weakness and fatigue (26%), cough (24%), and dyspnea (16%).[154] Cardiovascular involvement, present in 58% of the patients,[153] is a major cause of morbidity and mortality. Fibrotic thickening of the endocardium by collagen-rich connective tissue (endomyocardial fibrosis) is characteristic of cardiac disease in HES,[154,156] which differs from the cardiac involvement seen in CSS.[90] Endomyocardial fibrosis is preceded by an initial acute necrotic stage followed by a thrombotic process.[153] Cardiac manifestations include dyspnea, congestive heart failure, mitral regurgitation, and cardiomegaly.[154,157] Echocardiography demonstrates the classic features of HES consisting of mural thrombus, ventricular apical obliteration, and involvement of the posterior mitral leaflet.[158] The other manifestations of HES[153] include neurologic manifestations (thromboemboli, central nervous system dysfunction, and peripheral neuropathies), cutaneous manifestations (erythematous pruritic papules and nodules, urticaria, and angioedema).[153,159]

Imaging

Pulmonary involvement present in about 40% of patients[136,154] includes pleural effusion, pulmonary emboli, cough, and interstitial opacities. Severe coughing attacks were present in 40% of the cases in one series[155] with no other mention of bronchopulmonary disease. In another series,[157] cough was also the predominant feature, with bronchospasm and pulmonary opacities in 11/40 patients each.

CT findings in 5 patients consisted of small nodules with or without a halo of ground-glass attenuation and focal areas of ground-glass attenuation mainly in the lung periphery.[160] CT findings are poorly specific, and

a correct diagnosis was obtained in only one third of patients with the HES in a series of 111 patients with eosinophilic diseases.[27] Furthermore, some of the observed pulmonary imaging changes may correspond to pulmonary edema resulting from cardiac involvement, rather than genuine eosinophilic lung involvement.

Laboratory Studies

Only mild eosinophilia at BAL contrasting with high levels of eosinophilia in the blood has been reported in patients with the HES,[161,162] suggesting that eosinophilia may be compartmentalized in some patients with HES. Serum levels of mast cell tryptase may be elevated, and dysplastic mast cells may be found in the bone marrow, with some patients meeting minor criteria for systemic mastocytosis.[163]

Treatment and Prognosis

Imatinib has become the first-line therapy in patients with the myeloproliferative variant of HES, especially (but not exclusively) when the Fip1L1 – PDGFR-α fusion protein is present.[149,150] Corticosteroids may be used especially in the "lymphocytic variant" of HES (with response in only about half of the patients).[157,164] The anti-IL5 antibody mepolizumab has recently been shown to be beneficial as a corticosteroid-sparing agent in HES patients negative for the *Fip1L1 – PDGFR-α* fusion gene and requiring 20 to 60 mg/day of prednisone to maintain a stable clinical status and a blood eosinophil count of less than 1×10^9/L.[165] Other treatments include chemotherapeutic agents (hydroxyurea, vincristine, etoposide), cyclosporin A,[153,155,164] and interferon-alfa either as monotherapy[166–169] or in association with hydroxyurea, particularly in the myeloproliferative variant.[170,171]

Whereas the 3-year survival was only 12% in the first published series,[136] the prognosis has improved markedly in later series with about 70% survival at 10 years,[154] and 80% survival at 5 years and 42% at 10 and 15 years, respectively.[157] It is fascinating that advances in gene molecular biology may result in direct clinical benefit with a better prognosis for patients with an up-to-now almost untreatable disease.

EOSINOPHILIC LUNG DISEASE OF DETERMINED CAUSE

Eosinophilic Pneumonias of Parasitic Origin

The eosinophilic pneumonias related to parasite infestation probably represent the most common cause of eosinophilic pneumonia in the world. Parasitic eosinophilic pneumonia arises mainly in humans following infection by helminths (large multicellular worms) and especially nematodes (roundworms). The parasites may or may not be found at pathologic examination of the lung.

Tropical Eosinophilia

Clinical Features. Tropical eosinophilia[172] is a syndrome characterized by severe spasmodic bronchitis, leukocytosis, and high blood eosinophilia. The clinical manifestations of tropical pulmonary eosinophilia occur mainly in the second and third decades of life, with male predominance. It has been reported mostly in Indians, and occasionally in patients originating from India or Asia and living in North America or in Europe.[175,176] Tropical pulmonary eosinophilia is one of the most common causes of cough in tropical areas with endemic filariasis.[173] Patients develop a dry, hacking cough exacerbated at night (especially between 1 and 5 AM) and often associated with expiratory dyspnea and wheezing. Associated fever, loss of weight, and anorexia are common. Eosinophils, and sometimes Charcot-Leyden crystals, are present in the sputum. At chest x-ray, disseminated bilateral opacities are present.

Pathogenesis. Tropical eosinophilia is caused by the filarial nematodes *Wuchereria bancrofti* and *Brugia malayi* that infect more than 150 million persons in the world. The disease is endemic in the tropical and subtropical areas of coastal regions of Asia, southern and western Pacific, and Africa (less commonly in South and Central America). The adult worms reside in the lymphatic vessels, leading to lymphatic obstruction with subsequent elephantiasis. Humans are infected by infective larvae deposited in the skin by mosquitoes, which develop into mature worms within 6 to 12 months. First-stage larvae or microfilariae released from the fecund female's uterus circulate in the bloodstream from where they are ingested by the mosquitoes.

Patients with tropical pulmonary eosinophilia do not usually have clinical features of lymphatic filariasis. Microfilariae are usually not found in the blood or the lung. The circulating microfilariae are trapped in the lung vasculature where they release their antigenic contents, further triggering the inflammatory pulmonary reaction. The clinical features of tropical pulmonary eosinophilia largely result from an immune response of the host to the parasites.[174]

Although blood eosinophilia is high at the early stage (<2 wk) of pulmonary disease, no prominent eosinophilic infiltration is found in the lung. At this early stage, there is dense infiltration with histiocytes. Eosinophilic pneumonia is seen later (1–3 mo), with the formation of eosinophilic abscesses and granulomatous lesions characterized by the presence of foreign body giant cells, fibroblasts, and epithelioid cells; prominent eosinophilic infiltration is present at the periphery of the granuloma. Cases left untreated for 5 years or more eventually show pulmonary fibrosis with histiocytic infiltration.

Laboratory Studies. Blood eosinophilia is prominent, with more than 2×10^9 eosinophils/L in all cases, and up to 60×10^9/L in some cases.[177] IgE levels are increased. Antifilarial IgG antibodies are increased, as in all patients with filariasis. BAL shows intense alveolitis with a mean percentage of 54% of eosinophils with marked degranulation.[178] EDN may play an important role in the pathogenesis of pulmonary tropical eosi-

nophilia, as suggested by selective high levels of this eosinophilic granular protein in BAL.[179] In patients treated with diethylcarbamazine, BAL eosinophils drop within 2 weeks; blood eosinophils also decrease rapidly upon treatment.[178]

Persisting irregular basilar opacities are present in about two thirds of patients after 1 year. A "reticulonodular pattern" on chest CT is present in a majority of patients, with other features consisting of bronchiectasis, air trapping, and mediastinal lymphadenopathy.

Lung function tests show a restrictive ventilatory defect, with a reversible obstructive ventilatory defect and hypoxemia in about a quarter of the patients.[180,181]

Because microfilariae are not detectable in the blood, diagnosis is made in patients with residence for several months in an endemic area by the combination of the clinical, epidemiologic, and laboratory features including blood eosinophilia persisting for weeks with an absolute eosinophil count in the blood greater than 3×10^9/L, IgE levels exceeding 10,000 ng/mL, and markedly increased antifilarial IgG. Diagnosis is further supported by clinical improvement in the weeks following treatment. The current diagnostic criteria of tropical pulmonary eosinophilia include cough worse at night; residence in a filarial endemic area; eosinophil count greater than 3300 cells/mm^3; and clinical and hematologic response to diethylcarbamazine.[182]

Treatment. Diethylcarbamazine, which kills microfilariae and adult-stage worms, is the only effective drug for tropical pulmonary eosinophilia; corticosteroids in addition to diethylcarbamazine may be beneficial.

Ascaris Pneumonia

Pulmonary infiltrates with eosinophilia (Löffler's syndrome) may develop during the migration of the larvae of the parasite through the lung.

Ascaris lumbricoides, a nematode or roundworm, is the most common helminth infecting humans, especially children, in the tropical and subtropical areas. Mature females in the human intestine release large numbers of eggs. The eggs expelled with stools may survive for several months or years. The disease is transmitted through food or water contaminated by human feces. The infective larvae formed within eggs develop in the small intestine, penetrate through the intestinal wall, and migrate via the venous circulation to the lungs where they break out into the alveoli. They then migrate through the bronchi and trachea, are swallowed, and mature into adult worms in the small intestine.

Pulmonary manifestations occur during larval migration to the lungs. Usually, pulmonary symptoms are mild, with cough and wheezing, transient pulmonary opacities, and blood eosinophilia. Transient fever is present in the majority of patients, with possible pruritic eruption at the time of respiratory symptoms. Blood eosinophilia may be as high as 22×10^9/L.[183] Symptoms spontaneously resolve in a few days, whereas blood eosinophilia may remain elevated for several weeks. The diagnosis may be made by finding larvae in the sputum or gastric aspirates, but is more usually made by the delayed finding of the worm or ovae in the stool within 3 months of the pulmonary manifestations.

Intestinal ascariasis is treated with mebendazole for 3 days, or pyrantel palmoate and albendazole.[184]

Eosinophilic Pneumonia in Larva Migrans Syndrome

Visceral larva migrans[185] is a zoonotic infection caused in humans by *Toxocara canis*, a parasite infecting many dogs and other canines. Toxocariasis is found in all temperate and tropical areas of the world. Eggs released by female worms pass in feces of infected dogs, and the soil of public playgrounds in urban areas is therefore often contaminated with eggs of *Toxocara*. Children playing in contaminated areas may become infected, especially when they practice geophagia. Ingested eggs hatch in the intestine, migrate through the portal circulation, and invade the liver, lung, and other organs. However, in humans, the development of the parasite is blocked at the larval stage.

Visceral larva migrans occurs predominantly in children, the majority of whom remain asymptomatic and undiagnosed. When symptomatic, patients present with fever, pulmonary manifestations, seizures, and fatigue. Pulmonary manifestations in about 80% of cases consist of cough, wheezes, and dyspnea; pulmonary opacities at chest x-ray are present in approximately half the patients with pulmonary symptoms.[185] Severe pulmonary involvement, which is seen in about 17% of cases, may benefit from corticosteroids.[186]

Although uncommon in adults, toxocariasis is nevertheless a possible cause of pulmonary disease with eosinophilia that may be severe[187,188] and necessitate mechanical ventilation. Patients present with fever, dyspnea, and pulmonary opacities at chest x-ray. Wheezes or crackles are present at pulmonary auscultation. Blood eosinophilia may be present initially, or may develop only in the following days. Eosinophils are increased upon BAL differential cell count.

The diagnosis of toxocariasis is obtained by serologic methods, and especially by enzyme-linked immunosorbent assay (ELISA).

Visceral larva migrans usually requires only symptomatic treatment, the use of antihelmintics being controversial. Corticosteroids seem beneficial in cases with severe pulmonary involvement.

Strongyloides stercoralis Infection

Strongyloides stercoralis is an intestinal nematode that may cause severe autoinfection in immunocompromised patients. Strongyloidiasis is widely distributed in the tropics and subtropics. Human infection is acquired through the skin by contact with the soil of beaches or mud. Then larvae pass through the circulation to the lungs where they break into alveoli, ascend the trachea, are swallowed, and reside in the small intestine where they mature. Females deposit eggs that hatch into larvae that pass with feces. Eosinophilia is usually present in recently infected patients, but it is often absent in

disseminated disease.[189] *S. stercoralis* infection may persist for years and give rise thereafter to severe disseminated strongyloidiasis, which may affect all organs (hyperinfection syndrome), especially with immunosuppression from any cause.

Löffler's syndrome occurs when larvae migrate through the lungs after acute infection. Peripheral blood eosinophilia, in association with pneumonia, bronchospasm, or bronchitis, and abdominal pain or diarrhea, suggests strongyloidiasis in patients living, or having traveled, in endemic areas.

About 20% of hospitalized patients with strongyloidiasis have coexisting chronic lung disease.[190] Patients with chronic obstructive pulmonary disease or asthma receiving corticosteroids and immunocompromised patients are at risk of massive larval infection (hyperinfection syndrome) manifesting with fever, abdominal pain, ileus or small bowel obstruction, jaundice, or meningitis. Eosinophilia may or may not be present. Cough, wheezing, and dyspnea are associated with bilateral patchy opacities. Rhabditiform larvae may be recovered by BAL or bronchial washing[191,192] or in the sputum.[193]

Diagnosis of strongyloidiasis depends on the demonstration of larvae in the feces or in any secretion or tissue specimen (including sputum and BAL fluid). Immunodiagnostic assays by ELISA methods may be useful for diagnosis and screening.

Because of the risk of hyperinfection syndrome that persists for years, all infected patients are treated by thiabendazole when diagnosed.

Eosinophilic Pneumonias in Other Parasitic Infections

The dog hookworm *Ancylostoma brasiliense* causing cutaneous helminthiasis (creeping eruption) may produce, in 50% of cases, a typical Löffler syndrome with transitory migratory pulmonary infiltration and peripheral eosinophilia, with almost complete absence of clinical signs or symptoms of systemic disease. Pulmonary manifestations develop after the seventh day of cutaneous eruption. The human hookworms *Ancylostoma duodenale* and *Necator americanus* are other possible causes of Löffler's syndrome.

In early acute schistosomiasis (due to infection with either *Schistosoma haematobium* or *S. mansoni*), patients may develop transient multiple small pulmonary nodules on chest x-ray (best seen on CT scan) and eosinophilia.[194] In chronic schistosomiasis, embolization of ova in small arteries in the lungs results in granuloma formation, occlusion of pulmonary arteries, and further pulmonary hypertension.[195] The granuloma comprises lymphocytes, eosinophils, and giant cells. A posttreatment eosinophilic pneumonitis (also called lung shift, verminous pneumonia, and reactionary Löffler's-like pneumonitis) may develop.[196] It could result from parasitic antigen release following treatment.

The filarial parasite of dog *Dirofilaria immitis* (the pulmonary fluke) may occasionally develop into adult worms in the human lungs after inoculation of infective larvae by mosquitoes. It manifests mainly as solitary pulmonary nodules or masses with or without eosinophilia, but eosinophilic pulmonary infiltrates have been reported.

Other parasites causing rare pulmonary manifestations with eosinophilia include *Paragonimus westermani*, *Trichomonas tenax*, *Capillaria aerophila*, and *Clonorchis sinensis*.

Eosinophilic Pneumonias of Other Infectious Causes

Pulmonary infection with eosinophilia has been reported with the fungi *Coccidioides immitis*, *Bipolaris australiensis*, and *Bipolaris spicifera*. BAL eosinophilia has been reported in *Pneumocystis jirovecii* pneumonitis in patients with acquired immunodeficiency syndrome. Bacterial or viral pulmonary infection (e.g., tuberculosis, brucellosis, respiratory syncytial virus infection) may occasionally be a cause of eosinophilic pneumonia.

Allergic Bronchopulmonary Aspergillosis and Related Syndromes

Allergic Bronchopulmonary Aspergillosis

ABPA is distinct from the other pulmonary manifestations due to the fungus *Aspergillus* such as invasive pulmonary aspergillosis developing in immunocompromised patients or aspergilloma developing in preexistent pulmonary cavities. ABPA is characterized by asthma, eosinophilia, and bronchopulmonary manifestations with bronchiectasis secondary to a complex allergic and immune reaction to the presence of *Aspergillus* colonizing the airways. ABPA occurs in 1% to 2% of adults with previous asthma present for several years (with a prevalence of 1%–2%), and also in up to 7% to 10%[197,198] of patients in large series of cystic fibrosis. ABPA may be associated with allergic *Aspergillus* sinusitis,[199,200] which has been considered as a sinus equivalent of ABPA[200–205] and resulting in a syndrome called *sinobronchial allergic aspergillosis*.

Pathogenesis. ABPA may have an environmental (and especially occupational) dimension, as suggested by a study of workers in the bagasse-containing sites in sugar cane mills, where ABPA was diagnosed in 7% of workers who had chronic respiratory problems.[206]

Interestingly, an increased prevalence of heterozygotic cystic fibrosis transmembrane conductance regulator (CFTR) gene mutations has been reported in non–cystic fibrosis patients with ABPA or sinobronchial allergic mycosis,[207] suggesting that CFTR gene mutations could be involved in the development of these conditions without overt cystic fibrosis. Genetic susceptibility to develop ABPA has also been suggested by association with a polymorphism within the IL-4 receptor α-chain gene[208] and association with HLA DR subtypes.[209] Infection with nontuberculous mycobacteria may be seen with increased frequency in patients with ABPA.[210]

ABPA results from an immune and inflammatory reaction in the bronchi and the surrounding parenchyma in response to antigens from *Aspergillus* growing in mucous plugs in the airways of asthmatics. The immunologic response of the host includes—but is not restricted to—both type I hypersensitivity mediated by IgE antibodies and type III hypersensitivity with the participation of IgG and IgA antibodies and of a Th2 $CD4^+$ T-cell mediated immune response. Over time, the associated inflammatory reaction results in damage to the bronchial epithelium, submucosa, and adjacent pulmonary parenchyma.[211,212]

Clinical Features. The current primary diagnostic criteria include asthma, history of pulmonary infiltrates, proximal bronchiectasis, elevated serum IgE, and immunologic hypersensitivity to *A. fumigatus* such as immediate reaction to prick test for *Aspergillus* antigen, precipitating antibodies against *A. fumigatus*, and elevated specific IgE against *A. fumigatus*.[213,214] There are approximately 40 antigenic components that can bind with IgE antibodies, of which 22 recombinant *Aspergillus* allergens (named *Asp f1* to *Asp f22*) are identified.[215] Specific antibodies to *Asp f4* and *Asp f6* may be the most helpful for diagnostic purposes.[216]

Other common findings in patients with ABPA comprise the expectoration of mucous plugs, the presence of *Aspergillus* in sputum, and late skin reactivity to *Aspergillus* antigen.[213] In patients with ABPA, typical proximal bronchiectasis may be absent; such cases are designated ABPA-seropositive.[215] Five stages of ABPA have been distinguished: acute, remission, recurrent exacerbations, corticosteroid-dependent asthma, and fibrotic end stage. Pulmonary infiltrates or peripheral blood eosinophilia may be present only during the acute phase or recurrent exacerbations of the disease.

Imaging. Damage to the large bronchi is a major feature of ABPA, with mucous plugs containing *Aspergillus* obstructing the airways with subsequent atelectasis and bronchial wall damage. Proximal bronchiectases predominate in the upper lobes and are well visualized on CT.[217–219] In asthmatic patients, the presence of bronchiectasis affecting three or more lobes, centrilobular nodules, and mucoid impaction on CT scan are highly suggestive of ABPA (Fig. 61-7)[220]; because of its characteristic imaging presentation, the correct diagnosis of ABPA was made on CT scan in 84% of cases of ABPA in a series of patients with eosinophilic lung diseases.[27] Although surgery is seldom warranted, eosinophilic pneumonia may be found in resection specimens from patients with asthma and ABPA with chronic pulmonary consolidation.[217,221]

The acute stage of ABPA is characterized on imaging by either fleeting infiltrates due to eosinophilic pneumonia or mucus plugging with ensuing segmental, lobar, or even whole-lung atelectasis. Fever is present. Blood eosinophilia is generally greater than 1×10^9/L. Sputum and expectorated plugs contain eosinophils and Charcot-Leyden crystals. Serum levels of TARC are elevated and might be used as a marker for identification and monitoring of ABPA.[222,223] Mucoid impaction is typically characterized by a V-shaped lesion with the vertex pointing toward the hilum and atelectasis.[224]

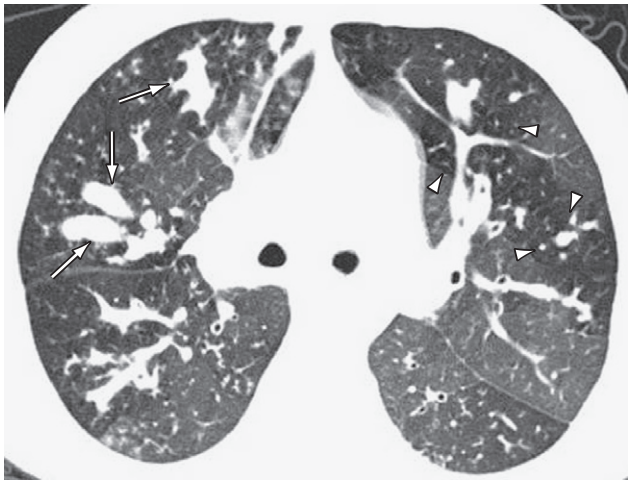

FIGURE 61-7 ■ Axial CT scan of a patient with allergic bronchopulmonary aspergillosis shows central bronchiectasis with mucoid impaction (*arrows*). Diffuse bilateral inhomogeneous lung opacity is present, with areas of low attenuation throughout the pulmonary parenchyma (*arrowheads*) representing mosaic perfusion resulting from a combination of large and small airway inflammation. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

Treatment. The treatment of ABPA mainly relies on corticosteroids during attacks, with long-term corticosteroids maintained only in patients with frequent symptomatic attacks or evidence of progressive lung damage. Treatment of episodes of pulmonary consolidation may prevent the progression of ABPA to the fibrotic end stage.[225] Inhaled corticosteroids may reduce the need for long-term oral corticosteroids. Oral itraconazole is a useful adjunct to corticosteroids, allowing reduction of the doses of corticosteroids.[226,227] A double-blind, randomized, placebo-controlled study indicated that patients with corticosteroid-dependent ABPA generally benefit from concurrent itraconazole treatment; improvements included the immunologic and physiologic criteria and the corticosteroid dose, but there was no significant effect on pulmonary infiltrates.[228] Another randomized, double-blind, placebo-controlled study with itraconazole for 16 weeks in stable subjects with ABPA demonstrated that subjects receiving itraconazole had a decrease in sputum eosinophils, sputum ECP levels, serum IgE levels, and serum IgG levels to *A. fumigatus* and had fewer exacerbations than patients receiving placebo.[229] Itraconazole interacts with many medications and may further induce adrenal insufficiency.[230,231] Measuring total serum IgE level may be helpful for monitoring therapy.

Treatment with an anti-IgE recombinant antibody omalizumab may be useful in some cases.[232–234] The newer agent voriconazole has been successfully used in ABPA only in isolated case reports.[235,236]

Other Allergic Bronchopulmonary Syndromes Associated with Fungi or Yeasts

A similar syndrome of allergic bronchopulmonary disease may be produced by other fungi or yeasts including *Pseudallescheria boydii*, *Cladosporium herbarum*, *Candida albicans Stemphylium* sp., *Torulopsis* sp., *Curvularia lunata*, *Bipolaris* sp., *Rhizopus* sp., *Trichosporon terrestre*, *Fusarium vasinfectum*, and *Helminthosporium* sp.

Bronchocentric Granulomatosis

Bronchocentric granulomatosis[237] is an inflammatory and destructive process beginning within the bronchiolar walls and further extending into the surrounding parenchyma with a peribronchiolar distribution of the lesions.[238] The granulomatous inflammatory process destroys both the mucosa and the walls of the bronchioles, and the necrotic areas resulting from the destroyed bronchioles are often surrounded by palisading histiocytes. Eosinophils represent the major component of the cellular infiltrate. Scattered fungal hyphae may be demonstrated by the Grocott silver stain in some patients. A dense inflammatory infiltrate is, in most cases, present in the peribronchial tissue but may occasionally extend more distally in the parenchyma. In asthmatic patients with bronchocentric granulomatosis, eosinophils compose the major proportion of the infiltrate. Other possible changes include vascular inflammation and mucoid impaction.[238,239]

About half the patients with bronchocentric granulomatosis at lung pathologic examination are asthmatics who further present with fever and cough. A peripheral blood eosinophilia is common, generally greater than 1×10^9 eosinophils/L.[238,239] The radiographic features consist of masses, alveolar opacities or pneumonic consolidation, or reticulonodular opacities, which predominate in the upper lobes and are unilateral in a majority of patients.[240,241] Most of these patients fulfill the criteria for ABPA, and corticosteroids are efficient with an excellent prognosis, although recurrences are common.[238]

Eosinophilia is usually not conspicuous when bronchocentric granulomatosis occurs in patients without asthma (an infectious cause is found in some cases).

Drug, Toxic Agents, and Radiation-Induced Eosinophilic Pneumonias

Drugs

More than 80 drugs have been reported to cause eosinophilic pulmonary infiltrates (Table 61-4). However, the causality has not been established in many case reports, and thus, the number of drugs that can reliably be considered as a common cause of drug-induced eosinophilic pneumonia is much smaller. Drugs causing eosinophilic pneumonia are mainly nonsteroidal anti-inflammatory drugs and antibiotics.

Drug-induced eosinophilic lung disease may present in three main clinical settings: (1) some patients taking a drug for several months (or years) for the treatment of chronic disease progressively develop increasing dyspnea with cough and mild fever; (2) in asymptomatic patients, the interstitial lung disease may be discovered by routine chest x-ray; (3) some patients present with acute eosinophilic pneumonia sometimes requiring mechanical ventilation. Associated extrapulmonary iatrogenic manifestations, especially including cutaneous rashes, fever, or nausea, may be present.

All the drugs taken in the weeks or months preceding the clinical syndrome must be carefully recorded in any patient presenting with eosinophilic pneumonia, including illicit drugs (cocaine, heroin), the intake of which is often denied by the patient.

Transient interstitial infiltrates with eosinophilia (Löffler's syndrome), chronic eosinophilic pneumonia, and acute eosinophilic pneumonia have all been reported as drug-induced syndromes. Systemic eosinophilic vasculitis involving the lung (and thus closely resembling CSS) has also been reported.[102,242]

The regression of eosinophilic lung disease after stopping the drug is the best clue for an iatrogenic reaction. However, this may take a long time, and therefore, in many reported cases, corticosteroids have been given concomitantly with drug withdrawal, so that the responsibility of the drug cannot be definitely established. The only absolute proof of the drug responsibility is obtained by its reintroduction with ensuing relapse of pneumonia, but this may be dangerous and thus unethical if done only for scientific purposes. Careful reintroduction of a drug presumed to be the cause of eosinophilic pneumonia may be considered with careful monitoring only when no alternative treatment for a serious disease is available.

Presentation of eosinophilic drug-induced pneumonia is generally nonspecific. Although, in most cases, patients present with pulmonary manifestations compatible with ICEP (with the exception of possible associated pleural effusion and extrapulmonary manifestations including cutaneous rash), other patients present with features characteristic of IAEP. Therefore, in any case of "idiopathic" eosinophilic pneumonia, an iatrogenic cause must be systematically considered.

The eosinophilia-myalgia syndrome, which developed in 1989 in the United States, was related to the intake of contaminated preparations of L-tryptophan. It manifested with frequent dyspnea and cough, myalgia, fatigue, rash, paresthesia, swelling, and muscle weakness, with interstitial lung disease or infiltrates at CT in 13% of cases,[243] and peripheral blood eosinophilia. The outcome was favorable, especially in patients receiving corticosteroids.[243–245]

Toxic Oil Syndrome

Ingestion of denatured cooking oil was the cause of the toxic oil syndrome, which affected about 20,000 people in Spain in 1981.[246] This scleroderma-like disorder was characterized by an interstitial-alveolar pattern on chest imaging and eosinophilia during the first 4 months. In the acute phase, death was mainly due to respiratory

TABLE 61-4. Drugs That May Cause Eosinophilic Pneumonia

DRUGS WITH TYPICAL PULMONARY EOSINOPHILIA
Acetylsalicylic acid
Captopril
Diclofenac
Ethambutol
Fenbufen
Granulocyte-macrophage colony-stimulating factor
Ibuprofen
Minocycline
Naproxen
Para (4)-aminosalicylic acid
Penicillins
Phenylbutazone
Piroxicam
Pyrimethamine
Sulindac
Sulfamides-sulfonamides
Tolfenamic acid
Trimethoprim-sulfamethoxazole

DRUGS WITH OCCASIONAL PULMONARY EOSINOPHILIA
Bleomycin
Carbamazepine
Chlorpromazine
Cocaine
Desipramine
Dapsone
Febarbamate
Gold salts
Heroin
Imipramine
Isoniazid
Loxoprofen
Mephenesin
Methotrexate
Methylphedinate
Nitrofurantoin
Nomifensine
Pentamidine
Perindopril
Phenytoin
Propranolol
Sulfasalazine[275]
Trimipramine

DRUGS WITH EXCEPTIONAL EOSINOPHILIA
Amiodarone
Aminoglutethimide
Ampicillin
Beclomethasone
Bicalutamide
Bucillamine
Cephalosporins
Chloroquine
Chlorpropamide
Clarithromycin[276]
Clofibrate
Cromoglycate
Diflunisal
Erythromycin
Fludarabine[277]
Furazolidone
Glafenine
Indomethacin
Iodinated contrast medium
Levofloxacin
Maloprim
Maprotiline
Mesalazine (5-aminosalicylic acid)
Metronidazole
Nalidixic acid
Nilutamide
Paracetamol
Penicillamine
Procarbazine
Propylthiouracile
Oxaliplatin[278]
Ranitidine
Scotch-Guard
Streptomycin
Tenidap
Tetracycline
Tolazamide
Tosufloxacin tosilate
Trazodone
Troleandomycin
Venlafaxine

From Cordier JF: Eosinophilic pneumonias. *In* Schwarz MI, King Jr TE (eds): Interstitial Lung Disease (4th ed). London: BC Dekker, 2003, pp 657–700.

failure, whereas the chronic stage of disease was characterized by pulmonary hypertension, scleroderma, hepatic disease, sicca syndrome, polyneuropathy, joint contractures, and chronic pulmonary sequelae.

Radiation Therapy

Chronic eosinophilic pneumonia developing after radiation therapy for breast cancer has been reported.[247,248] It was seen in women with a history of asthma or allergy, at a median time of 3.5 months and up to 10 months after completion of radiotherapy for breast cancer. Dyspnea and cough were the main presenting symptoms, with pulmonary opacities at imaging being unilateral (irradiated lung) or bilateral, and possibly migratory. All patients had blood eosinophilia of 1.0×10^9 g/L or greater and/or eosinophilia greater than 40% on the BAL differential cell count. Patients rapidly improved with oral corticosteroids without sequelae, but some patients relapsed after treatment withdrawal. This syndrome is similar to the organizing pneumonia syndrome primed by radiation therapy to the breast,[249] with eosinophilic pneumonia occurring preferentially in patients with asthma or atopy. We hypothesize that eosinophilic pneumonia may develop upon radiation therapy preferentially in patients with a preexisting Th2-oriented lymphocyte response,[247,250,251] together with yet unidentified genetic predisposition, environmental factors, and/or additional triggers.

MISCELLANEOUS LUNG DISEASES WITH ASSOCIATED EOSINOPHILIA

Eosinophilia in blood and/or in BAL has been reported in some pulmonary disorders in which eosinophilic pneumonia is not a major finding.

Organizing Pneumonia

Organizing pneumonia is defined by the presence of buds composed of inflammatory cells, fibroblasts, and connective tissue within the lumen of distal air spaces. It may be secondary to various causes (such as infection or drug-induced reactions) or be cryptogenic. The typical clinical and imaging features (patchy alveolar infiltrates) of organizing pneumonia may closely mimic ICEP.[252] Furthermore, pathologic overlap of organizing pneumonia

and ICEP may be encountered, with foci of organizing pneumonia in ICEP and eosinophils in organizing pneumonia. In some cases, organizing pneumonia may represent the evolution of an untreated CEP.[252] Eosinophilia in BAL may be present in cryptogenic organizing pneumonia, but it is usually less than 20% at differential cell count.

Asthma and Eosinophilic Bronchitis

Infiltration of the airways by eosinophils is common in eosinophilic pneumonias, but may also be an isolated phenomenon. The eosinophil is considered to play a major role in the pathogenesis of asthma.[253] Eosinophilic inflammation of the airways present in the submucosa and epithelium of patients with asthma is correlated with severity of asthma.[254] Furthermore, BAL has shown mildly increased levels of eosinophils (usually <5%) on differential cell count in asthmatics, with the increase in eosinophils in the alveolar samples less than in bronchial samples.[255] Interestingly, although eosinophilic infiltration of the bronchi is common in the eosinophilic pneumonias, asthma is not a constant feature in such disorders.

Eosinophilic bronchitis (without asthma) with a high percentage of eosinophils (about 40%) in sputum is a cause of chronic cough responsive to corticosteroid treatment,[256] with normal lung function and absence of bronchial hyperreactivity.[257,258] Eosinophilic pneumonia does not occur. The observed values of sputum eosinophils are often much higher in eosinophilic bronchitis than in asthma.[258] The *FIP1L1 – PDGFR-α* fusion gene has been reported in one patient with eosinophilic bronchitis.[259] Prolonged treatment with inhaled corticosteroids may be beneficial.[256,260] Eosinophilic bronchitis is distinct from bronchial asthma, although it may in some cases evolve over time to irreversible airflow obstruction without asthma or to genuine asthma.[261,262]

Idiopathic Interstitial Pneumonias

Mildly increased levels of eosinophils may be found at BAL differential cell count in the idiopathic interstitial pneumonias (idiopathic pulmonary fibrosis, nonspecific interstitial pneumonia, cryptogenic organizing pneumonia). Increase of BAL eosinophils is associated with a poor clinical response to corticosteroids.[263–265]

Focal eosinophilic pneumonia has been reported in cases of usual interstitial pneumonia,[266] and focal eosinophils are a minor feature of nonspecific interstitial pneumonia.[267]

Langerhans Cell Granulomatosis

Pulmonary Langerhans cell granulomatosis (also designated as eosinophilic granuloma or pulmonary histiocytosis X) results from the proliferation of Langerhans cells. The pulmonary pathologic lesions consisting of nodules often assuming a bronchiolocentric stellate shape are composed of Langerhans cells with variable numbers of eosinophils, plasma cells, and lymphocytes. Eosinophils usually present in the initial active stage of disease contribute to the "eosinophilic granuloma." Numerous in about 25% of cases, they are usually situated at the periphery of the lesions. The eosinophils are rare or absent at the chronic stage of disease.

Lung Transplantation

Eosinophilic alveolitis in lung transplant recipients may be indicative of acute rejection (tissue eosinophilia is involved in rejection after renal, cardiac, hepatic, and pancreatic transplantation). However pulmonary eosinophilia in lung transplant recipients may also result from infectious agents such as *Aspergillus*, *Pseudomonas*, or coxsackievirus.[268]

Other Lung Diseases with Occasional Eosinophilia

Blood eosinophilia and tissue eosinophilia may be present in sarcoidosis, but are usually mild.[269] Pulmonary eosinophilia developed in two patients after transplantation for sarcoidosis, with bronchiolitis obliterans syndrome developing after resolution of pulmonary eosinophilia.[270] A case of ICEP overlapping with sarcoidosis and Behçet's disease has been reported.[271] Sarcoidosis developed in a patient with blood eosinophilia and a previous history of asthma and eosinophilic pneumonia.[272]

Eosinophilic pneumonia was reported in a patient with gastric cancer producing GM-CSF and IL-5.[273]

KEY POINTS

- Although they have lung and/or airways eosinophilia as a common denominator, the eosinophilic lung diseases correspond to a wide and heterogeneous spectrum of disorders.
- Eosinophilic lung disease may manifest clinically as a pulmonary disease of varying severity, ranging from chronic or transient infiltrates with mild symptoms to the acute severe eosinophilic pneumonia resembling ALI or ARDS and necessitating mechanical ventilation.
- Blood eosinophilia greater than 1×10^9 eosinophils/L (and preferably greater than 1.5×10^9/L) is of considerable help for suggesting the diagnosis. However, blood eosinophilia

KEY POINTS—CONT'D

may be absent (as in the early phase of IAEP or when patients are already taking corticosteroids).

- On BAL, high eosinophilia (>25%, and preferably >40%) may be considered diagnostic of eosinophilic pneumonia in a compatible setting.
- There is currently little if any indication for pulmonary biopsy in the diagnosis of the eosinophilic lung diseases.
- The etiologic diagnosis of eosinophilic lung diseases is crucial, and will be directed by the clinical syndrome.
  - Inquiry as to drug intake must be meticulous and any suspected drug should be withdrawn.
  - Travel history or residence in areas where parasites are endemic must be recorded, and laboratory investigations for parasitic causes must take into account the specific epidemiology of parasites throughout the world.
  - The appropriate diagnostic laboratory tests for parasites must be selected according to the instructions of a specialist.
  - The other known causes of eosinophilic lung disease must also be searched (with the help of a checklist if possible). If no cause is found, the eosinophilic lung disease is considered idiopathic.
- When present, extrathoracic manifestations raise the suspicion of a systemic eosinophilic disease such as CSS or HES, thus necessitating specific diagnostic investigations.
- Corticosteroids remain the cornerstone of symptomatic treatment for eosinophilic disorders, and these are necessary in the idiopathic eosinophilic pneumonias, ABPA flares, and the CSS (with the addition of cyclophosphamide in patients with poor-prognostic factors). The response to corticosteroids is usually dramatic in ICEP and in most cases of CSS, but relapses are common when tapering the doses or after stopping treatment.
- Imatinib, a tyrosine kinase inhibitor, has proved very effective in the treatment of the myeloproliferative variant of HES, a disorder heretofore resistant to treatment.

PROGRESSION AND PROGNOSIS

FUTURE CLINICAL TRIALS IN LYMPHANGIOLEIOMYOMATOSIS

INTRODUCTION

Lymphangioleiomyomatosis (LAM) is a rare, neoplastic, systemic disease characterized by a genetic association with the neurocutaneous syndrome, tuberous sclerosis complex (TSC). There is a marked female gender predominance. It is characterized by cystic destruction of the lung, progressive dyspnea on exertion, recurrent pneumothorax, abdominal tumors, and chylous fluid accumulation in the chest and abdomen.[1,2]

LAM was first reported in a patient with TSC who presented with bilateral spontaneous pneumothorax in 1918[3] and in a patient without TSC in 1937.[4] In the 1950s through the late 1960s, there were solitary case reports or small case series with a varied and confusing pathologic nomenclature. Cornog and Enterline,[5] for example, described 6 cases of "lymphangiomyoma" and reviewed 14 cases in the literature with similar pathology that had been termed "lymphangioma," "lymphangiomyoma," "lymphangiopericytoma," "leiomyomatosis," "lymphangiomatosis malformation," and "intrathoracic angiomatous hyperplasia." Since the late 1970s, however, larger case studies have better defined the natural history, pathologic classification, and clinical presentation of LAM, including those of Silverstein and coworkers,[6] Corrin and colleagues,[7] Taylor and associates,[8] Kitaichi and coworkers,[9] Oh and colleagues,[10] Chu and associates,[11] Taveira-DaSilva and coworkers,[12] Hayashida and colleagues,[13] and Urban and associates.[14] Most significantly, recent synergistic interactions between pulmonary investigators, tuberous sclerosis geneticists, *Drosophila* biologists, and patient advocacy groups have resulted in truly significant progress in our understanding of the molecular and cellular basis of LAM.[15]

EPIDEMIOLOGY

LAM almost exclusively affects young women, primarily in their reproductive years. It occurs in the setting of tuberous sclerosis complex (TSC-LAM) and also in a sporadic form in women who do not have TSC (sporadic LAM [S-LAM]) (Table 62-1).[1,2]

TSC-LAM is typically accompanied by the multiple system involvement and varied clinical presentations that are associated with TSC. TSC is an autosomal dominant genetic disorder associated with development of hamartomas and dysplastic lesions in several organs,

TABLE 62-1. Comparison of TSC-LAM and S-LAM

	TSC-LAM	S-LAM
Estimated no. patients on earth	250,000	6000–15,000
Reported in males	+	+
Reported in children	+	+
Ascertainment	Screening, dyspnea, pneumothorax	Dyspnea, pneumothorax, chylothorax, incidentally on CT
Germline TSC mutations	+	–
Inheritable	+	–
TSC1/TSC2 mutations reported	33%/66%	0%/100%
Renal angiomyolipomas	93% Bilateral 81% Multiple 60%	33% Bilateral 19% Multiple 6%
Hepatic angiomyolipomas	33%	2%
Lymphangiomyomas	9%	29%
MMPH	+ (~12%)	Very rare (~1%)
CNS/skin/eye/cardiac lesions	+	–
Retroperitoneal, thoracic adenopathy	Rare	+
Dyspnea	Less common	More common
Chylothorax	Uncommon	33%
Pneumothorax	Less common	66%
Respiratory failure	Less common	More common

CNS, central nervous system; CT, computed tomography; LAM, lymphangioleiomyomatosis; MMPH, multifocal micronodular pneumocyte hyperplasia; S-LAM, sporadic lymphangioleiomyomatosis; TSC, tuberous sclerosis complex.

including cortical tubers, giant cell astrocytomas and subependymal nodules in the central nervous system; angiofibromas, Shagreen's patches, and ash leaf macules of the skin; and angiomyolipomas and cysts of the kidney.[16]

In S-LAM, by contrast, manifestations that accompany the pulmonary cystic changes include only renal and extrarenal angiomyolipomas and smooth muscle infiltration and obstruction of the lymphatic system. Clinical presentations consistent with LAM have also been described in a few males with TSC,[17] including three biopsy documented cases, two with TSC,[18,19] and one without evidence of TSC.[20]

Careful epidemiologic analyses of the ethnic and racial distribution of LAM have not been performed. Although the biases introduced by the rarity of the illness, the protean presentation, and the disproportionate reporting of LAM patients in large series from the United States, Europe, and Asia[9–12,14] might suggest a predilection of the disease for whites and Asians, as with TSC, it is likely that all races are affected and that countries and populations with the greatest access to health care resources are overrepresented in these studies.

The prevalence of LAM estimated from various international registries and surveys is approximately 2.5 cases per million in the United States (846 U.S. LAM patients are registered with the LAM Foundation [Sally Lamb, personal communication, The LAM Foundation]), 1.2 to 2.3 cases per million in Japan,[13] 0.9 cases per million in the United Kingdom,[21] and 1.3 cases per million in France.[14] LAM often presents in a protean manner, however, and it is likely that LAM is severalfold more common than these numbers suggest. Indeed, the calculated prevalence of TSC-LAM alone is significantly greater than 1 to 3 cases per million. Considering that the incidence of TSC is about 1/6000 births and that TSC occurs equally in both genders,[22] the estimated worldwide prevalence of TSC is approximately 1.2 to -1.5 million people, with 0.6 to 0.75 million of them being women. Cystic pulmonary changes are found in roughly one third of women with TSC,[23–25] suggesting a global TSC-LAM prevalence of approximately 250,000 individuals, or about 40 TSC-LAM cases per million people.

Although screening of TSC populations identifies a subset of patients who have a range of cystic change in the lung from very mild to severe, it has been estimated that pulmonary manifestations reach clinical significance in only about 5% to 10% of patients with TSC-LAM.[26] TSC-LAM is certainly underrepresented in large databases: TSC-LAM patients made up only about 10% to 15% of the 243 patients who enrolled in the National Heart, Lung, and Blood Institute (NHLBI) Registry and 9.5% of patients who are listed in the LAM Foundation database (Sally Lamb, personal communication, The LAM Foundation). Although TSC-LAM is predicted to be 10-fold more common than S-LAM, most (~90%) LAM patients who seek medical attention with pulmonary specialists have S-LAM. This observation is consistent with the notion that TSC-LAM identified through screening is often a milder disease than S-LAM, which reaches attention through progressive dyspnea or pneumothorax/chylothorax, and/or that other TSC comorbidities overshadow the pulmonary manifestations of TSC-LAM and prevent TSC-afflicted patients from seeking medical care for their lung disease.

GENETIC AND MOLECULAR BASIS OF TUBEROUS SCLEROSIS COMPLEX AND LYMPHANGIOLEIOMYOMATOSIS

Inheritance

Approximately two thirds of new TSC cases arise from de novo mutations, which occur during embryogenesis. Familial TSC, which results from inheritance of germline mutations, accounts for one third of new cases.[27] There have been several reports of familial TSC-LAM,[23,28] but mother-daughter transmission of S-LAM has never been reported.

Molecular Pathogenesis

Our understanding of the genetic and molecular basis of TSC and LAM has increased substantially since the late 1990s. The most significant findings have included that LAM is a neoplastic and metastatic process, that LAM is caused by mutations in TSC genes,[29] and that dysregulation of the Akt signaling pathway plays a central role in TSC and LAM cell growth, motility, and survival.[30,31]

Tumor Suppressor Proteins Control Cell Growth

Clinicians have long recognized that the lung disease that occurs in women with TSC is pathologically indistinguishable from that which occurs in women with S-LAM.[5,32] However, the demonstration that S-LAM and TSC-LAM are genetically linked was reported only relatively recently.[33] The lag period in our understanding was due, in part, to the failure to appreciate that a nonfamilial disease could share a common genetic basis with an inheritable disease. There are several precedents for this phenomenon among the class of diseases known as tumor suppressor syndromes (including neurofibromatosis and von Hippel–Lindau syndrome), of which TSC is a member.

Tumor suppressor proteins regulate orderly cell growth and differentiation by sensing the surrounding environment, transmitting signals to the nucleus, and directly affecting transcription, translation, survival, or cell division. In the classic "two-hit" paradigm,[34] a mutant copy of a tumor suppressor gene is inherited from one parent and a tumor or dysplastic lesion develops when the second "good" parental copy of the tumor suppressor gene is inactivated through a random, somatic mutation. This first (inherited) hit, often a point mutation or a small insertion or deletion, results in heterozygosity for the wild-type allele. The second mutational event is usually a large deletion, resulting in the loss of a chromosomal segment. A polymerase chain reaction (PCR) technique can be used to detect the "loss of heterozygosity (LOH)" for the wild-type allele caused by the deletion. When both copies of a tumor suppressor gene contain critical mutations, the protein produced by the gene becomes defective or deficient, protein function is lost, and cell growth, survival, and synthetic function become dysregulated.

The Tuberous Sclerosis Complex Proteins Regulate Signaling through the Akt Pathway

TSC is caused by inactivating mutations in either of the two known TSC loci, TSC1 on chromosome 9q34[35] and TSC2 on chromosome 16p13.[36] The proteins encoded by TSC1 and TSC2 are hamartin and tuberin, respectively. Hamartin has no informative homologies with other proteins in the National Center for Biotechnology Information (NCBI) database, whereas tuberin has a domain with GAP (GTPase-activating protein) homology.[37]

Until very recently, very little was known about the function of TSC proteins other than that they modulate cell growth. In 1999, it was reported that the enlarged eye cells phenotype of the mutant fruit fly, *Gigas*, was the result of genetic inactivation of the fly homologue for tuberin.[38] The loss of tuberin results in a defect in cell cycle control, which causes cells to repeat S phase without entering M phase. Several laboratories subsequently reported that tuberin and hamartin regulate signaling through the PI3K/PKB(Akt)/S6K pathway, which controls cellular size and proliferation.[39–41]

Our understanding of the function and positioning of the TSC proteins in the Akt/S6K pathway has been a rapidly evolving process, and the available data to date are modeled in Figure 62-1. Tuberin and hamartin associate into a complex that functions as a master regulator for the kinase, mTOR, or mammalian target of rapamycin (sirolimus), through an intermediate G protein called Rheb.[42,43] The intact tuberin/hamartin complex acts as a GAP for Rheb, and maintains Rheb in an inactivated, nonphosphorylated state (Rheb-GDP). Phosphorylation of tuberin by Akt inactivates the GAP activity of the tuberin/hamartin complex, increases the abundance of Rheb-GTP, drives association of mTOR with raptor (and mLST8 and PRAS40, not shown) to form the mTORC1 complex, and results in phosphorylation and activation of downstream kinases mTOR, S6K, and the initiation factor 4E-binding protein (4E-BP1). The association of mTOR with raptor (and mSIN1 and mLST8, not shown) to form mTORC2 results in activation of ROCK and rho kinase, cytoskeletal rearrangement, and cell movement through a separate pathway. Thus, genetic mutations that result in the absence or dysfunction of tuberin or hamartin, as occur in patients with tuberous sclerosis and LAM, ultimately cause constitutive activation of S6 and eIF4E, two proteins that are intimately involved in the regulation of protein translation, as well as Rho kinase, which regulates intracellular trafficking, cell adhesion, and cell movement. The end result is the inappropriate stimulation of protein synthesis, cell motility, and cell growth.[31] Multiple mTOR effectors and mTOR itself were found to be highly phosphorylated in tumors of rats,[44] mice,[45] and humans[46] with mutations in TSC genes. Sirolimus, a microbial product that binds the intracellular receptor FKBP12 (an FK-506–binding protein) to inhibit mTOR activity, extinguished phosphoS6 staining and caused widespread apoptosis in the rat renal tumors.[44]

Tuberous Sclerosis Complex Mutations Are Found in the Lung and Kidney Lesions of Patients with Sporadic Lymphangioleiomyomatosis

Tuberous sclerosis patients have germline mutations in TSC genes, but S-LAM patients do not.[47] Smolarek and coworkers[48] first implicated TSC genes in the pathogenesis of S-LAM by finding that LOH for TSC2 was present in the renal angiomyolipomas (AMLs) and lymph nodes from S-LAM patients. Proof that the loss of tuberin function was responsible for lung disease in LAM was provided by Carsillo and colleagues, who demonstrated the

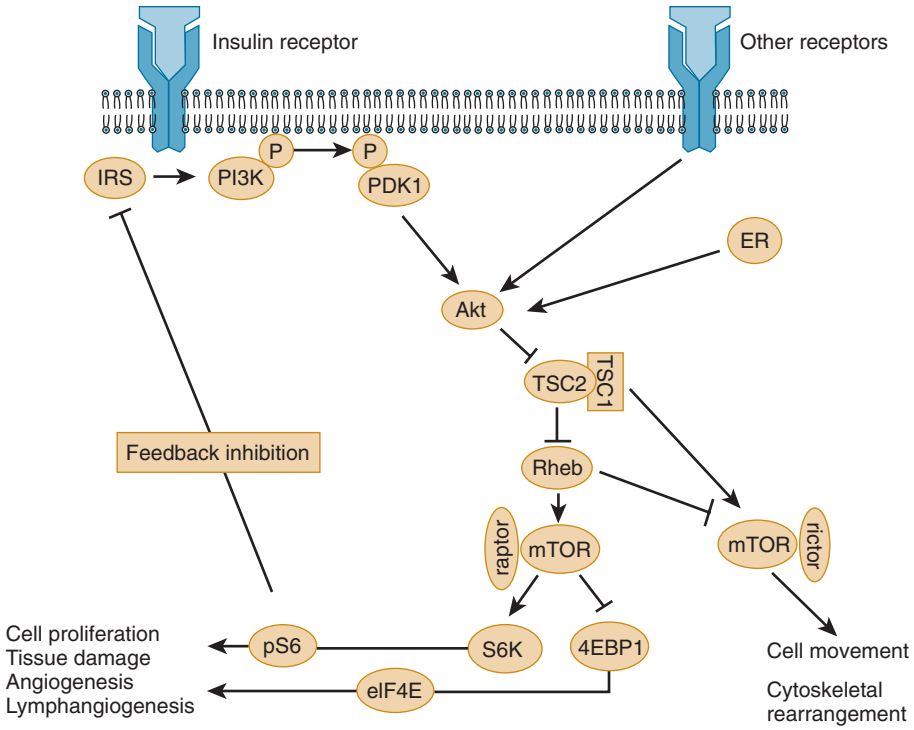

FIGURE 62-1 ■ Tuberous sclerosis proteins regulate signaling through the Akt growth and protein translation pathway. The binding of a ligand to a growth factor receptor (such as the insulin receptor) activates phosphatidylinositol-3-kinase (PI3K) followed by Akt. Activated pAkt phosphorylates tuberous sclerosis complex-2 (TSC2), which blocks its GTPase-activating protein (GAP) activity. When not phosphorylated, TSC2 complexed with TSC1 functions as a GAP for Rheb, maintaining Rheb in an inactivated Rheb-GDP state. Activated Rheb (Rheb-guanosine triphosphate [GTP]) is therefore abundant when TSC1 or TSC2 is missing or when TSC2 is phosphorylated. Rheb GTP activates mTOR, in a manner that is potentiated by the availability of amino acids, phosphatidic acid, and adenosine triphosphate, and blocked by the absence of these substrates or the presence of sirolimus. Activated mTOR complexed with raptor phosphorylates downstream targets S6K and 4E-BP1. pS6K phosphorylates S6 and 4E-BP1 releases eIF4E, which together activate the cellular translational machinery and promote cell growth. S6 also feeds back to inhibit upstream signaling, which restrains cell growth and "malignant" cellular behavior. Activated mTOR complexed with rictor signals through a divergent pathway to control cytoskeletal dynamics and cell movement through Rho kinases. (Adapted from Kwiatkowski DJ: Rhebbing up mTOR: New insights on TSC1 and TSC2, and the pathogenesis of tuberous sclerosis. Cancer Biol Ther 2:471–476, 2003.)

presence of missense and protein truncating TSC2 mutations associated with LOH in the abnormal lung and kidney tissue of patients with S-LAM.[33] Samples taken from the normal regions of lung and the kidney in those patients did not exhibit TSC mutations.[47] These findings were subsequently confirmed in 21 patients by Hino and associates,[49] and all S-LAM mutations described to date have been in the TSC2 locus.[33,49,50] These data indicate that S-LAM is caused by somatic mutations in both TSC2 alleles that occur after conception and result in defects or deficiency in tuberin. TSC1 and TSC2 mutations have been described in TSC-LAM,[23,51] and future studies may reveal TSC1 mutations to be causative in S-LAM as well.

Genetic Evidence Suggests That Lymphangioleiomyomatosis is a Metastatic Neoplasm

Cornog and Enterline[5] were the first to suggest that despite their benign appearance, cells that make up the LAM lesion are a clonal, neoplastic proliferation of smooth muscle cells. The demonstration of LOH in the lung, kidney, and lymph node lesions in LAM patients was the first indication that Cornog and Enterline's suspicions regarding neoplasia and clonality were correct.[48] Carsillo and colleagues[33] further demonstrated that the mutations present in the cells of the kidney tumor and lung lesion of a given individual with S-LAM were identical, suggesting that they arise from a common precursor.

A model for LAM was proposed in which the lung infiltration occurs as a consequence of benign metastasis of LAM cells from a remote and as yet unidentified source, such as the bone marrow, the lymphatic system,[52] the uterus,[53] or AMLs.[54] Reports of recurrence of LAM in the donor lung of LAM patients who had undergone lung transplant are also consistent with this metastatic theory[55-58]; in two cases, the recipient origin of lung metastases were proved by genetic and molecular techniques.[58,59] These data contradicted earlier reports that the recurrent lesions were derived from donor cells,[55,56] but in retrospect, the initial studies were limited by the spatial resolution that can be achieved with the immunohistochemical techniques used to colocalize cellular markers. Cells containing LOH for TSC genes have been isolated from the blood of LAM patients,[60] consistent with dissemination through the systemic circulation.

Other rare diseases that result from metastases of benign smooth muscle cells in women include leiomyomatosis peritonealis disseminate,[61] intravenous leiomyomatosis,[62] and benign metastasizing leiomyomatosis.[63] The metastatic theory of LAM suggests possible novel approaches for treatment based on preemptive removal of the source, once its identity is known.[29]

Role of Lymphangiogenesis and Lymphatic Spread in Dissemination of Lymphangioleiomatosis

Approximately 30% of LAM patients have axial abdominal or thoracic lymphadenopathy.[64] In some cases, LAM is restricted to the retroperitoneum, abdomen, or pelvis and is associated with normal lung parenchyma or only a very few lung cysts, consistent with regional spread from a subdiaphragmatic source.[65] Clusters of cells in the chylous pleural fluid of patients with LAM were first described by Valensi[66] in 1973. Later, Itami and coworkers[67] demonstrated that the clusters originated in the dilated lymphatic system and were composed of alpha smooth muscle actin–positive spindle cells enveloped by a single layer of endothelial cells. They suggested that LAM cell clusters could be used diagnostically to obviate the need for biopsy in patients with chylous manifestations of LAM. Data from Japan provide additional evidence that a likely source and mechanism of spread of LAM may be through the lymphatic circulation.[52,68,69] In a small autopsy series, Kumasaka and colleagues[52,70] described the presence of LAM cell clusters enveloped by lymphatic endothelial cells budding from the walls of lymphatic vessels.

Induction of lymphangiogenesis appears to play an important role in this process, based on abundant expression of lymphatic endothelial markers such as podoplanin (D2-40), LYVE-1, vascular endothelial growth factor receptor (VEGFR)-3, VEGF-C, and VEGF-D.[70] Two laboratories have recently reported that VEGF-D is elevated over three- to eightfold in the serum of patients with LAM, a finding that may prove to be useful for distinguishing LAM from other cystic lung diseases and for following response to therapy.[71,72] LAM cell clusters were also found in the lymphatic lumen, in regions between axial lymph nodes (retroperitoneal, mediastinal, and left venous angle) that were infiltrated with LAM cells, and in chylous fluids examined from patients with chylous ascites and chylothorax. They speculated that LAM cell clusters enter the venous circulation at the insertion of the thoracic duct into the junction of the left internal jugular and subclavian veins and disseminate throughout the pulmonary capillary bed. LAM cell emboli impacted in the lung vasculature may then proliferate intravascularly through a novel mechanism called "invasion-independent metastasis."[73,74]

Mechanisms of Matrix Remodeling in Lymphangioleiomyomatosis

Cystic destruction of the lung parenchyma causes progressive decline in lung function in patients with LAM, and proteases are believed to play a major role in the process. The spectrum of metalloproteinases that are aberrantly expressed in LAM has not been fully characterized, but matrix metalloproteinase (MMP)-2 is the most abundant of those studied to date. Overexpression of MMP-1, MMP-9, MT1-MMP, and MMP-14 has also been reported,[75] and serum levels of MMP-9 are elevated in patients with LAM.[76] MMP-1, MMP-2, and MMP-9 are able to degrade elastin, consistent with the loss and degradation of elastic fibers that is known to occur in LAM.[75] Zhe and associates have proposed that increased expression of serum response factor (SRF) may lead to MMP activation[77–80] and down-regulation of tissue inhibitor of metalloproteinase (TIMP)-3 in LAM cells,[77] leading to an imbalance of proteases and protease inhibitors. Recently, abundant expression of cathepsin K was reported in LAM, suggesting a possible pathogenic role.[81]

LAM lesions have also been reported to contain abundant tryptase-positive mast cells, which express basic fibroblast growth factor (bFGF) and receptors Bek (FGF-R-2) and Flg (FGF-R-1), as well as chymases, renin, angiotensin-converting enzyme, and angiotensin receptors type I and type II.[82,83] Insulin-like growth factors (IGFs) are involved in normal pulmonary development and in the pathogenesis of smooth muscle cell proliferation. IGF-I, IGF-II, IGF-I receptor, IGF-binding protein (IGFBP)-1, IGFBP-2, IGFBP-4, IGFBP-5, and IGFBP-6 are expressed in lung tissue from patients with LAM.[84] Carelli and coworkers[85] recently showed that $TSC2^{-/-}$ human smooth muscle cells derived from AMLs express the apoptosis inhibitor protein survivin when exposed to IGF-1. Transforming growth factor-β1 (TGF-β1), a profibrotic cytokine, is enriched in highly cellular areas of the LAM lesion.[85a] Targeting autocrine systems that promote fibroproliferative responses induced by bFGF, the renin-angiotensin system, IGFs, and TGF-β1 are possible therapeutic strategies for the future.

Preclinical Evidence and Human Trials

Estrogen

Estrogen-containing drugs have been implicated in the worsening of LAM. Estrogen regulates the transcription of many genes, and there is some evidence that estrogen can modulate signaling through the Akt pathway.[86,87] Estrogen may play a role in LAM cell migration, infiltration, proliferation, or secretion of destructive proteases.[31,87] Recently, estrogen was shown to promote pulmonary metastases and enhanced survival of TSC2 deficient cells in mice.[87a]

Sirolimus

Sirolimus, a natural macrolide immunosuppressant, has been shown to silence S6 phosphorylation, and induce apoptosis, necrosis, and tumor reduction of renal cystadenomas in TSC mutant (Eker) rats and the hepatic tumors of TSC heterozygous null mice.[88,89]

The demonstration that TSC mutations are present in patients with S-LAM has focused the attention of LAM scientists and trialists on the Akt pathway that has proved

to be central to TSC pathogenesis.[15] Goncharova and colleagues[90] reported abundant S6 phosphorylation and unregulated cell proliferation in LAM cells isolated from explanted LAM lungs harvested at lung transplant. They further demonstrated that sirolimus blocked the hyperphosphorylation of S6 and restored orderly cell growth.

These and other studies formed the basis for phase I/II trials of sirolimus in patients with tuberous sclerosis and LAM, the Cincinnati Angiomyolipoma Sirolimus Trial (CAST; NCT00457964).[91] In this open-label study, 25 patients with AMLs, including 6 patients with S-LAM and 12 with TSC-LAM and (7 with TSC alone), were treated for 1 year with sirolimus and followed with serial magnetic resonance imaging (MRI) studies of the kidneys, computed tomography (CT) scans of the lungs, and pulmonary function tests. AML volume of the 20 patients that reached the 1-year mark shrunk by an average of 47%, and forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) in 11 LAM patients still enrolled at a year increased by 118 mL and 390 mL, respectively. The residual volume fell by 440 mL, and cyst volume percent, a measurement of the fraction of the pulmonary parenchyma that is occupied by cysts, tended to decline on therapy but did not reach statistical significance.[92] Parameters that did not change included total lung capacity (TLC), 6-minute walk distance, and diffusing capacity for carbon monoxide (D_{LCO}). There were a number of adverse events while patients were taking the study article, including mouth ulcers and cholesterol elevations in most subjects and hospitalizations for pneumonia, diarrhea, cellulitis, pyelonephritis, palpitations, and mucositis.

In the second year of the trial, patients were observed off the study article at 6-month intervals. The average AML volume increased again and reached 77% of the original volume at 18 months and 86% at 24 months. In 25% of patients, however, AML size remained below 70% of baseline through the 2-year point. The FEV_1 and FVC declined off therapy at rates that are generally consistent with untreated LAM patients,[93] but remained 62 mL and 364 mL above baseline at 24 months, respectively. The effect of sirolimus on residual volume was durable in most patients, and residual volume remained 333 mL below baseline at 24 months, indicative of relief of gas trapping. Controlled trials will be required to determine if sirolimus has beneficial effects on lung function that outweigh the risks (NCT00414648).

CLINICAL FEATURES

The clinical onset of LAM usually occurs during the reproductive years, with a mean age at the onset of symptoms in the early to mid-30s.[8,9,14,94] Although new diagnoses of LAM have been reported in patients ranging in age from 12 to 75 years,[95,96] documented cases of the disease prior to menarche are rare. A number of reports in the literature describe women in whom the diagnosis was made after menopause.[8,9,14,94,97–100] LAM does not appear to be smoking-related, because the majority of patients in the largest case series were nonsmokers.[9,12,14]

Because LAM is rare and the symptoms are often nonspecific, the diagnosis is often delayed with a mean interval between the onset of symptoms and diagnosis of 5 to 6 years.[8,11,14,101] Initial incorrect diagnoses in these series typically included bronchial asthma, emphysema, chronic bronchitis, chronic obstructive pulmonary disease, sarcoidosis, diffuse panbronchiolitis (in Asia), and even idiopathic interstitial pneumonias including idiopathic pulmonary fibrosis.

In the patients reported by Urban and associates,[14] exertional dyspnea and spontaneous pneumothorax were the initial symptoms in 49% and 46% of patients, respectively. During the course of the illness, dyspnea developed in 87% of patients, and pneumothorax developed in 68% of patients. The first pneumothorax precedes the diagnosis of LAM in 82% of patients; in fact, most patients have two pneumothoraces before the diagnosis is made.[21,102] Pneumothorax is often recurrent.[7,11,14] In LAM patients who have a pneumothorax, the likelihood of an ipsilateral or contralateral recurrence is greater than 70%.[102] Pneumothorax most likely results from the rupture of subpleural blebs, but whether the event is triggered by progressive degradation of connective tissue matrix or airflow obstruction and overdistention of distal air spaces, or both, is unclear.

Other signs and symptoms of LAM, which may be present at the onset or may develop during the course of the disease, include fatigue, cough, hemoptysis (rarely massive), chest pain, and symptoms related to reflux of chylous fluid into pleural (33% of patients) and extrapleural locations, such as the peritoneum (chylous ascites) or pericardium (chylopericardium), airway (chyloptysis), and genitourinary tract (chyluria and chylous metrorrhea). It is likely that the chylous complications of LAM result from obstruction of lymphatic channels due to infiltration by smooth muscle cells.

AMLs, unusual hamartomas composed of fat, smooth muscle, and abnormal blood vessels, may occur in virtually any location in the chest and abdomen but are most common in the kidney. About 29–33% of S-LAM patients have renal AMLs, compared with about 88–93% of TSC or TSC-LAM patients.[23,103] AMLs are more commonly unilateral and solitary in S-LAM patients, and more commonly bilateral and multiple in TSC-LAM patients.[64] Blood vessels in AMLs are often tortuous and aneurysmal and are composed of cells with normal genotype and cells with TSC mutations,[104] which may partially explain their propensity to bleed. Spontaneous hemorrhage into AMLs may produce severe flank or abdominal pain, acute hypotension, and/or anemia, occasionally in association with circulatory collapse. Renal cysts are frequently present in patients with LAM; in TSC-LAM, polycystic kidney disease may occur due to a contiguous gene deletion of PKD1 which is adjacent to TSC2 on chromosome 16.[105] Rarely, LAM presents as retroperitoneal masses, including cystic lymphangioleiomyomas or adenopathy, which mimic lymphoma, ovarian or renal cancer, or other malignancy.[106,107]

There have been case reports of exacerbation of LAM associated with birth control pill use[108] or during pregnancy.[109–113] In a group of 69 patients with sporadic LAM,

the onset of pulmonary symptoms occurred during pregnancy in 9 of the 46 patients (20%) with a history of pregnancy before or at the time of diagnosis.[14] In this same group, a marked exacerbation of previously diagnosed pulmonary LAM was observed in 2 (14%) patients during pregnancy. The effect of pregnancy or exogenous estrogen use on LAM has not been systematically studied, however.

PHYSICAL EXAMINATION

The physical examination in LAM is often nonspecific. Lung auscultation is usually uninformative but may reveal crackles in 15% to 20% of patients and rhonchi or wheezing in less than 15%.[9,11,14] Clubbing is uncommon, being reported in 3% and 5% of patients in two larger case series.[9,11] Physical examination may also reveal evidence of pleural effusion, ascites, or pneumothorax, if present. Careful dermatologic, ocular, and dental surveys should be performed for evidence of TSC, including facial angiofibromas, subungual fibromas, palpable dysplastic cutaneous lesions called Shagreen's patches, hypomelanotic macules including those with ash leaf or confetti configurations, and dental pitting.[16]

IMAGING STUDIES

Early in the disease, the chest radiograph may appear normal or may suggest hyperinflation only. As the disease progresses, the chest radiograph demonstrates diffuse, bilateral, and symmetrical reticulondular infiltrates, which can progress to cysts, bullae, or a "honeycomb" appearance in the later stages.[9,14] Pleural effusion and pneumothorax may also be apparent (Fig. 62-2).

One characteristic chest radiographic feature of LAM is the preservation of lung volumes despite the presence of increased interstitial markings. This finding distinguishes LAM from most other interstitial lung diseases, in which alveolar septal and interstitial expansion tends to increase the lung's elastic recoil properties and decrease lung volumes. The chest radiograph may also reveal one of the common thoracic complications of LAM, either pneumothorax or chylous pleural effusion. The presence of a pneumothorax may allow visualization of cystic changes in the deflated lung, which are not visible in the fully inflated lung.

The high-resolution computed tomography (HRCT) chest scan is much more sensitive than the chest radiograph in detecting cystic parenchymal disease and is usually abnormal at the time of diagnosis, even when the chest radiograph and pulmonary function assessments are normal.[9,11,14,114] The CT shows diffuse, round, bilateral, thin-walled cysts of varying sizes ranging from 1 to 45 mm in diameter (see Fig. 62-2).[11,14] The numbers of cysts varies in LAM from a few to complete replacement of the normal lung tissue. The morphology of the cysts is useful in differentiating LAM from other cystic lung diseases. The presence of internal septa or a "centrilobular dot" consistent with a vessel is frequently seen in emphysema, but virtually never in LAM. In emphysema, the borders of the cystic spaces are difficult to discern, whereas in Langerhans cell histiocytosis, another LAM mimic, the cyst walls are thicker and more bizarre in shape. Other CT findings in LAM patients may include dilation of the thoracic duct or enlargement of mediastinal lymph nodes. Blinded expert radiologists can correctly identify LAM among a pool of CTs consisting of a variety of other cystic lung diseases about 72% of the time.[115] Other CT features include linear densities, (29%), ground-glass opacities (12%),[9] nodular densities (11%), hilar or mediastinal lymphadenopathy (9%), pleural effusion, pneumothorax, lymphangiomyomata, and dilated thoracic duct.[11,14]

In patients with TSC, nodular densities on HRCT may represent multifocal micronodular pneumocyte hyperplasia (MMPH), clusters of hyperplastic type II pneumocytes[23,116,117] (Fig. 62-3). MMPH may be present in males or females with TSC alone, but is very rare in

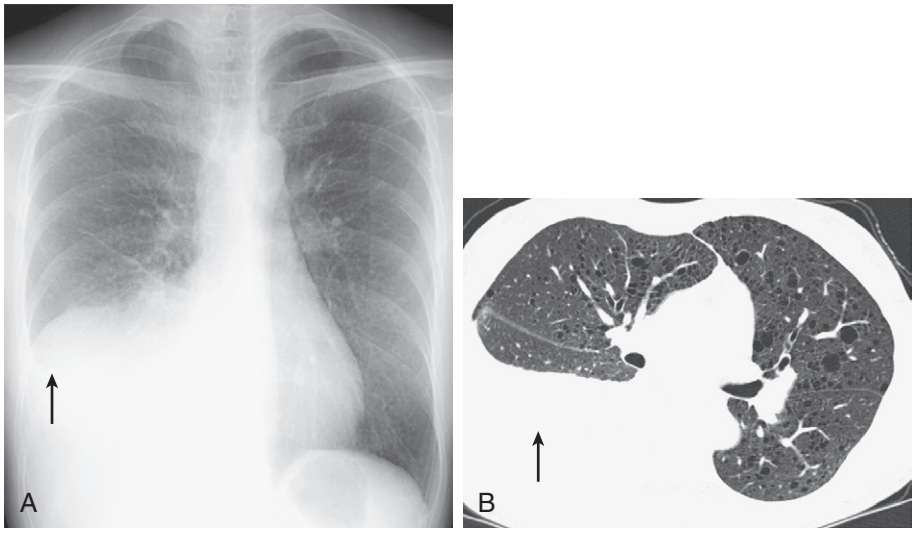

FIGURE 62-2 ■ Chest roentgenogram (**A**) and high-resolution computed tomography (HRCT; **B**) of a 40-year-old woman with sporadic lymphangioleiomyomatosis (LAM). Diffuse cystic changes and a right-sided chylothorax (*arrows*) are present.

patients with S-LAM.[118] MMPH has no known physiologic or prognostic consequences.

Chu and associates[11] reported that ventilation/perfusion scans were abnormal in 34/35 women with LAM. The most common abnormality was nonspecific, diffuse heterogeneity, usually grossly matched. These authors also described an "unusual," "speckling pattern" on the ventilation images in 74% of patients, consisting of "small, often peripheral collections of radioisotope."

LAM and AML lesions do not typically exhibit increased uptake of [(18)F]2-fluoro-2-deoxyglucose (FDG) on PET scanning. So other neoplasms (or sources of inflammation) should be considered in patients who are found to have positive studies.[118a]

Abnormalities on abdominal imaging, such as renal AML and enlarged lymphatic structures, are also common in LAM (Figs. 62-4 and 62-5). Fat density within a renal mass is pathognomonic of AMLs. AMLs are more frequently bilateral, larger, and more common in patients with TSC-LAM than in S-LAM patients, and AML size correlates with the prevalence of pulmonary cysts in patients with TSC.[23] Chu and associates[11] reported the results of abdominal CT and ultrasound imaging in 35 patients with LAM. Twenty-two (63%) of these patients were found to have solid renal masses. In 9 patients, the solid masses were multiple, and in 6, they were bilateral. Renal abnormalities with features suggesting AML were seen in 18 (51%) patients, consistent with prior studies.[119] These lesions were multiple in 6 patients, and bilateral in 4. Axial lymphadenopathy was also commonly seen in this series, including the presence of retroperitoneal nodes in 66% of patients. Less common findings were

ascites and renal cysts. Avila and coworkers[120] reported that abdominal lymphangioleiomyomas, often containing both cystic and solid components, were seen in 27 of 128 LAM patients.

Central nervous system abnormalities, such as cortical or subependymal tubers and astrocytomas, are common in patients with TSC, including those with TSC-LAM, but are not found in women with S-LAM. Moss and associates[121] reported that women with S-LAM and TSC-LAM may have an increased incidence of meningioma, but the significance of that finding has been questioned.[122]

PULMONARY FUNCTION TESTING

Pulmonary function testing in patients with LAM may be normal or may reveal obstructive, restrictive, or mixed patterns, with obstructive physiology being the most common abnormality. Quality controlled lung function data were collected prospectively by the NHLBI Registry,[103] a 5-year study of LAM patients in centers around the United States. Spirometry revealed obstructive changes in about 57% of patients and normal results in 34%.[103] Restriction, defined as a TLC value that is less than the lower limit of normal, was seen in 11%. Hyperinflation was unusual, present in about 6%. The average residual volume was 125% of predicted when measured by plethysmography, but was 103% of predicted determined with gas dilution methods. These data suggest that a significant proportion of gas trapped in the chest is not in communication with the airway. Approximately 25% of patients with obstructive physiology may demonstrate bronchodilator responsiveness.[12] The obstructive physiologic defect in LAM is primarily attributable to airflow obstruction and, to a lesser degree, to a modest increase in lung compliance.[123]

The most common finding on initial pulmonary function testing in various case series was abnormal gas transfer, as assessed by the D_{LCO}, described in 82% to 97% of patients.[8,9,11,14] Reduction in D_{LCO} and increase in residual volume are generally considered to be the earliest physiologic manifestations of LAM, and it is not unusual for D_{LCO} to be reduced out of proportion to FEV_1.[12]

Cardiopulmonary exercise testing in patients with LAM reveals that exercise-induced desaturation is often present, even in patients with normal or near normal D_{LCO} and FEV_1.[124,125] Crausman and colleagues[126] studied the mechanism of exercise limitation in 16 patients with LAM. They concluded that poor exercise performance was primarily due to airflow obstruction and increased dead-space ventilation, caused by pulmonary vascular disease or extensive cystic change. Cardiopulmonary exercise testing in a much larger cohort of patients with LAM revealed a reduced maximal oxygen consumption ($\dot{V}O_2max$) and anaerobic threshold in 217 patients.[124] Exercise-induced hypoxemia occurred even in patients who did not have resting abnormalities in FEV_1 and D_{LCO}. In most patients, exercise was felt to be ventilation limited, owing to airflow obstruction and increased dead-space ventilation.

Disease progression is usually accompanied by a progressive obstructive ventilatory defect, and decline in FEV_1 is the most commonly used parameter to monitor disease progression. Although resting pulmonary hypertension appears to be unusual in LAM, pulmonary arterial pressure often rises with low levels of exercise, related in part to hypoxemia.[125]

Taveira-DaSilva and coworkers[12] correlated lung function testing with lung histology in 74 patients and reported that a positive bronchodilator response was associated with a predominantly solid pattern of lung lesions (as opposed to cystic pattern), but not with airway inflammation (bronchiolitis), which was identified in 61% of lung biopsies. They also found that the D_{LCO} correlated with the lung $\dot{V}O_2max$ and the lung histology score (LHS), a quantification of the extent of involvement with cystic lesions and LAM cells. FEV_1 and D_{LCO} were the best predictors of $\dot{V}O_2max$, however.

PATHOLOGY

Grossly, LAM lungs are enlarged and diffusely cystic, with dilated air spaces as large as several centimeters in diameter[7,127] (Fig. 62-6). Microscopic examination of the lung reveals foci of smooth muscle cell infiltration of the lung parenchyma, airways, lymphatics, and blood vessels, associated with areas of thin-walled cystic change. LAM lesions contain a striking abundance of lymphatic channels, forming an anastomosing meshwork of slitlike spaces lined by endothelial cells. LAM cells have been observed to invade the airways, the pulmonary artery, the diaphragm, aorta, and retroperitoneal fat, to destroy bronchial cartilage and arteriolar walls, and to occlude the lumen of pulmonary arterioles.[7]

There are two major cell morphologies in the LAM lesion, small spindle-shaped cells and cuboidal epithelioid cells.[128] All LAM cells stain positively for smooth muscle actin, vimentin, and desmin (Fig. 62-7). The cuboidal cells within LAM lesions also react with a monoclonal antibody called HMB-45, developed against the premelanosomal protein gp-100, an enzyme in the mela-

nogenesis pathway.[128] This immunohistochemical study is very useful diagnostically, because other smooth muscle–predominant lesions in the lung do not react with the antibody.[129] The spindle-shaped cells of the LAM lesion are more frequently proliferating cell nuclear antigen (PCNA)-positive than the cuboidal cells, consistent with a proliferative phenotype.[128] Compared with cigar-shaped normal smooth muscle, spindle-shaped LAM cells contain less abundant cytoplasm and are less eosinophilic. Estrogen and progesterone receptors may also be present in LAM lesions,[130,131] but not in normal lung tissue.[132] The smooth muscle–like cells of AMLs are morphologically and immunohistochemically similar to LAM cells, including reactivity with antibodies directed against actin, desmin, vimentin, and HMB-45 as well as estrogen and progesterone receptors.[133,134] Unlike the dilated air spaces in emphysema, the cystic spaces may be lined with hyperplastic type II cells.[135] Diffuse nodular

proliferation of type II cells indicative of MMPH may also occur in patients with TSC, in the presence or absence of the cystic pulmonary changes of LAM (see Fig. 62-3).[118]

DIAGNOSIS

The diagnosis of LAM is often delayed, and many patients are treated for several years for alternative diagnoses. Sadly, it is unusual for young dyspneic women with LAM to receive the correct diagnosis until a pneumothorax or chylothorax develops or interstitial lung disease or an AML is discovered. This unfortunate circumstance arises because the disease is rare, the symptoms are often nonspecific, and the radiographic manifestations can be protean. Many young women presenting with mild dyspnea are treated for asthma without extensive evaluation. Indeed, the findings of airflow limitation on spirometery discovered in LAM patients are consistent with asthma. Unless full pulmonary function testing is ordered, "red flags" such as reduced D_{LCO} will not be appreciated.

Clinical Diagnosis

In the proper clinical context, a diagnosis of LAM may be reasonably established based on radiographic findings alone. For instance, classic LAM cystic changes on HRCT of the lung along with a chylothorax documented by thoracentesis or CT evidence of fat-containing renal masses consistent with AMLs establishes the diagnosis with a high degree of certainty. There are rare exceptions, however, because lymphoma can present with pulmonary cystic change and chylothorax, and Birt-Hogg-Dube (BHD) can present pulmonary cystic change, fat-containing renal masses (angiolipomas), and angiofibromas. Pulmonary cystic change in a nonsmoking woman with TSC is consistent with LAM and does not usually require biopsy. In smoking patients with or without TSC, the diagnoses of pulmonary emphysema and Langerhans cell histiocytosis (pLCH)[136] must be seriously entertained. Serologies for Sjögren's syndrome antibody A (SS-A), SS-B, and alpha$_1$-antitrypsin level should be obtained. Serum VEGF-D is elevated three- to eightfold in patients with LAM[71] but not in patients with pulmonary emphysema, pLCH, lymphangiomatosis, or BHD and, if validated in larger studies, may prove to be useful in differentiating LAM from these disorders.[72]

In addition to an HRCT of the chest, patients with LAM should have a dedicated CT of the abdomen to screen for AMLs, lymphangiomyomas, uterine masses, and chylous ascites. Renal AMLs can be identified radiographically based on the presence of fat; biopsy may be required to rule out renal cell carcinoma in case the renal masses do not contain fat.

Differential Diagnosis

The primary differential in patients with a smoking history includes pLCH and pulmonary emphysema. The morphology of the cysts, which are devoid of distinct walls in emphysema and thicker walled, mid- and upper lung zone–predominant, and more irregularly shaped in pLCH, can be helpful in differentiating these disorders from LAM.[115] Diffuse subcentimeter nodular changes are often present in pLCH, but can also occur in TSC and TSC-LAM, where they represent MMPH.[118] Less common cystic lung diseases that can mimic LAM and should also be considered include Sjögren's syndrome,[137] Castleman's disease, follicular bronchiolitis and lymphocytic interstitial pneumonitis, hypersensitivity pneumonitis,[138] amyloidosis, lymphoma, light chain deposition disease,[139] and bronchopulmonary dysplasia/barotrauma. Thin-walled cystic lung lesions can also be associated with metastatic genitourinary neoplasms including endometrial stromal cell sarcoma,[140] low-grade leiomyosarcomas, and cystic benign metastasizing leiomyoma.[63]

BHD syndrome[141] can be difficult to distinguish from LAM. BHD is a rare tumor suppressor syndrome associated with spontaneous pneumothorax, skin lesions (fibrofolliculomas, trichodiscomas, acrochordons, and angiofibromas), bland, peripheral and subpleural pulmonary cysts devoid of smooth muscle infiltration (Fig. 62-8), and inherited renal neoplasms including oncocytomas, chromophobe adenomas, papillary renal cell carcinoma, and angiolipomas. Mutations in the folliculin gene *17p11.2* cause defects or deficiency in a protein of unknown function called folliculin and result in BHD or familial spontaneous pneumothorax.[142,143] It appears that BHD is also associated with aberrant signaling through

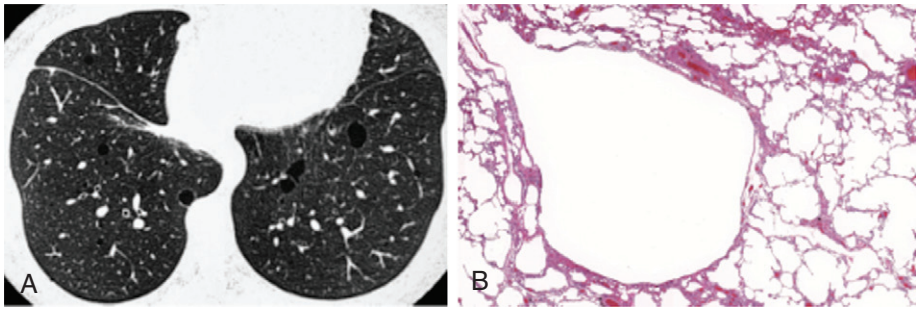

FIGURE 62-8 ■ Birt-Hogg-Dubé syndrome. HRCT (**A**) and histopathologic (**B;** H&E staining) presentation of the lung cysts. This 58-year-old patient had repeated bilateral pneumothoraces, facial fibrofolliculomas, and acrochordons and a family history of pneumothorax in a brother, son, and daughter. the Akt pathway, but the loss of regulation occurs upstream of mTOR.

Chylous diseases that involve the thorax including lymphangiomatosis, lymphangiectasis, and lymphatic dysplasia[144–147] may also be confused with LAM, although they do not typically produce cystic change in the lung.

Lung Biopsy

The diagnosis of LAM is most definitively established by lung biopsy. HMB-45 staining is highly specific for LAM and can be used to differentiate LAM from other causes of smooth muscle proliferation in the lung including idiopathic pulmonary fibrosis, benign metastasizing leiomyoma, and leiomyosarcoma. Successful bronchoscopic diagnoses, using transbronchial biopsies with appropriate immunohistochemical staining, have been reported but are the exception.[148] Video-assisted thoracoscopic lung biopsy is the preferred approach for making the diagnosis of LAM. Although there are few interventions for the most likely diseases in the differential other than smoking cessation, clarity regarding the diagnosis of LAM facilitates discussions regarding life planning, pregnancy, birth control, pneumothorax management, and candidacy for trials.

TREATMENT

There are no well-designed studies upon which to base therapeutic decisions in LAM, and there is no consensus regarding optimal treatment of the disease. The three largest recent series, from Japan,[9] England,[149] and France,[14] reviewed retrospective experiences with multiple therapies that can only be described as inconclusive. The definitions of evaluable treatments and response to therapy vary greatly. Each study reported a few responses, often in the chylous manifestations, but most patients progressed. The few apparent pulmonary responses were often based on soft end points, such as a 15% increase in FEV_1, and none of the studies was statistically powered to adequately address the question of therapeutic efficacy. The CAST trial described earlier suggested a possible beneficial effect of sirolimus on FEV_1, FVC, and residual volume in LAM, but the results will need to be validated in larger trials before the drug can be recommended for clinical use.[91] Multiple case reports of responses of AMLs and LAM (pre- and post-lung transplant) to sirolimus have recently appeared in the literature.[150–156]

The remarkable gender restriction in LAM, although unexplained, has provided the rationale for the empirical anti-estrogen strategies that have dominated the approach to LAM for the last several decades. The results are generally disappointing, and because proper trials with hormonal therapies have never been conducted, there remain no proven therapies for LAM based on antagonism of estrogen action. Bilateral oophorectomy has not been demonstrated to slow the rate of decline in lung function in LAM.[8] Enthusiasm for the use of progesterone, which became the standard of care following a single positive outcome published in a case report in 1987,[94] has likewise waned over time. In a retrospective study of 275 patients, Taveira-DaSilva and associates[101] found that progesterone treatment failed to slow the decline in FEV_1. In fact, in that study, intramuscular or oral progesterone therapy was associated with an accelerated rate of decline in D_{LCO} compared with untreated patients. The rate of decline in FEV_1 and D_{LCO} was also no different in patients treated with the gonadotropin-releasing hormone (GnRH) agonist triptorelin for 3 years compared with a well-characterized cohort of historical controls.[157] Other case series of GnRh agonist treatment have yielded conflicting results.[158–160]

In the face of such uncertainty, decisions of when and how to treat are best made jointly by the patient and physician after thorough discussions of the risks and limited available data. When feasible and available, enrollment in clinical trials should be offered to patients who qualify. Therapies that are most often discussed with patients who suffer progressive decline in lung function or worsening symptoms include progestins (both oral and intramuscular) and GnRH agonists. Oral progestins at doses that are just sufficient to suppress serum estrogen production are preferred over the suprapharmacologic intramuscular progesterone doses that have been propagated in the literature (e.g., Depo-Provera 400 mg intramuscularly every month). Progestins at such high doses can cause fluid retention, depression, and mood swings. GnRH agonists (e.g., leuprolide, buserelin acetate, goserelin) have been used in patients with LAM, but benefits are unproved and induction of early menopause is associated with psychological, vascular, and bony consequences in young women. There is no proven role for corticosteroids, immunomodulatory cytotoxic agents, or ovarian irradiation in the treatment of LAM. Ovariectomy is no longer widely recommended because the benefits are unknown.[8,9,14]

The management issues that should be addressed in patients with LAM are outlined in Table 62-2.

General Recommendations

Estrogen-containing medications may have adverse effects[108] and should be discontinued. A trial of bronchodilators should be considered in patients with LAM, because up to 17% to 25% of LAM patients have bronchodilator-responsive disease.[11,103] Extrapolating from chronic obstructive pulmonary disease populations, it is reasonable to speculate that oxygen use has beneficial effects in hypoxic patients. Oxygen should be administered to maintain oxyhemoglobin saturations of greater than 90% with rest, exercise, and sleep. Bone densitometry should be considered in all patients who are immobilized and/or on antiestrogen therapies, and appropriate therapy instituted for osteoporotic patients. Proper attention should be paid to cardiovascular health following natural or therapeutic menopause. Pulmonary rehabilitation seems to be particularly rewarding in this young, motivated population with obstructive lung disease, but studies to assess improvements in exercise tolerance, conditioning, and quality of life have not been done.

TABLE 62-2. Recommended Interventions, Studies and Immunizations in Patients with LAM

Interventions/ recommendations	• Stop smoking • Stop all estrogen containing medications • Counsel regarding pregnancy and air travel • Inform patient of symptoms/management of pneumothorax, chylothorax • Consider bronchodilator therapy • Consider oxygen therapy • Refer large angiomyolipomas (>4 cm diameter) for possible embolization • Refer for transplant evaluation for FEV_1 < 30%, disabling dyspnea or profound hypoxia
Studies	• High-resolution CT of the chest (every 1–3 yr) • Pulmonary function testing (every 6–12 mo) • $Alpha_1$-antitrypsin level, SS-A, SS-B, consider VEGF-D • Abdominal CT, MRI, or ultrasound for angiomyolipoma (every 6–12 mo) • Rule out TSC with head CT or MRI, dermatologic, and ophthalmologic examinations • Rest, sleep, exercise oximetry, 6-minute walk • Bone densitometry
Indications for lung biopsy	• Cystic pulmonary change without corroborating features of known TSC or angiomyolipomata. In smokers, lung biopsy may be required to distinguish LAM from emphysema and Langerhans cell histocytosis.
Immunizations	• Flu shot and pneumovax

CT, computed tomography; FEV_1, forced expiratory volume in 1 second; LAM, lymphangioleiomyomatosis; MRI, magnetic resonance imaging; SS-A, Sjögren's syndrome antibody A; SS-B, Sjögren's syndrome antibody B; TSC, tuberous sclerosis complex; VEGF-D, vascular endothelial growth factor-D.

Pregnancy

Patients should be advised that pregnancy has been reported to result in exacerbations of LAM in some cases.[109–113] However, the risk of pregnancy in LAM has not been rigorously studied, and decisions regarding the advisability of pregnancy should be made on an individual basis. Women diagnosed with LAM during pregnancy have high rates of pneumothorax, miscarriage, and premature birth.[161] In a survey of 318 patients who indicated on their LAM Foundation intake forms that they had had at least one pregnancy, 163 patients responded to a second inquiry regarding pneumothorax.[162] A total of 38 reported that they had a pneumothorax during pregnancy, consistent with a minimum incidence of pneumothorax in pregnancy of at least 10% (38/318). In a third of patients, the pneumothorax during pregnancy led to the diagnosis of LAM. Pneumothoraces occurred almost twice as frequently on the right as on the left and 4 women presented with bilateral spontaneous pneumothorax. Most pneumothoraces occurred during the second and third trimesters. This study and others[14,21] suggest that pregnancy is associated with pleural complications in patients with LAM. Unfortunately, the more pressing question of whether pregnancy accelerates the decline in lung function in LAM may never be fully addressed, because so few women with LAM choose to become pregnant and patients who are diagnosed with LAM during pregnancy rarely have baseline pulmonary function tests available.

Air Travel

LAM patients may be at increased risk of pneumothorax during air travel. Pollock-BarZiv and coworkers[163] found that 35% of LAM patients have been advised by their physician to avoid air travel, because of the theoretical risk of lung cyst rupture associated with atmospheric pressure changes during flight. In a survey of 276 patients who answered a questionnaire, there were 8 cases of radiographically documented pneumothorax associated with 454 flights. In 5 cases, however, symptoms that were consistent with pneumothorax may have been present prior to boarding. Other symptoms also occurred, including anxiety (22%), chest pain (12%), shortness of breath (14%), cyanosis (2%), and hemoptysis (0.4%) in 10% to 20% of flights. The conclusion from the study was that, although adverse events occurred during flight in patients with LAM, air travel is well tolerated by most LAM patients. A recent study of 281 LAM patients who had routine CXR after traveling to the National Institutes of Health identified 7 with acute pneumothorax. There was no difference in the incidence of pneumothorax in patients who traveled by ground versus air. The conclusion was that the occurrence of a pneumothorax with air travel was related to the high incidence of pneumothorax in the disease rather than the air travel itself.[163a] In advising LAM patients about air travel, it is reasonable to consider several factors, including a history of frequent or recent pneumothorax, extensive cystic disease on HRCT, and the overall extent of cardiopulmonary impairment. Patients with poor cardiopulmonary reserve may tolerate even small pneumothoraces poorly. It is prudent for LAM patients to seek medical evaluation including a chest radiograph prior to boarding a plane if pleuritic chest pain or unexplained persistent shortness of breath is present. Hypoxemia during flight presents independent risks. Patients should consult with their physicians regarding recommendations for on-board oxygen use.

Pleural Disease

Pneumothoraces occur in most patients with LAM and tend to recur, especially after conservative management such as observation, aspiration, or simple tube thoracostomy. Failure rates after pleurodesis are also surprisingly high for reasons that are not well explained; higher than in any other chronic lung disease. Over 65% of patients with LAM develop pneumothorax during the course of their illness, averaging 3.5 pneumothoraces per affected patient over a lifetime.[102] The size of cysts appears to correlate with risk of pneumothorax.[164] We advocate the use of a pleural symphysis procedure on the first pneumothorax, given the greater than 70% chance of recurrence. Chemical sclerosis, mechanical abrasion, talc poudrage, and pleurectomy have all been effective in patients with LAM.

Chyle does not generally cause pleural inflammation or fibrosis, and small stable chylous effusions rarely require intervention once the diagnosis of LAM is made. Shortness of breath may mandate drainage, however, and in some cases, repeatedly. Pleural symphysis may be required to prevent nutritional and lymphocyte deficiencies that can result from repeated taps or persistent drainage. Chemical pleurodesis is generally an effective therapy for chylothorax, as is mechanical abrasion and talc poudrage.[165]

Pulmonary Transplantation

Urban and associates[14] reported the outcome of transplant in 13 patients (associated with renal transplant in 1). The mean interval between time of onset of LAM and transplant was 7.8 ± 5.2 years (range, 2.1–16.8 yr). Mean FEV_1 before transplant was 0.57 ±.15 L. Boehler and colleagues[166] conducted a retrospective survey on 34 LAM patients who had undergone lung transplant. The actuarial survival after 2 years was 58%, which is similar to other lung disease categories. The incidence of perioperative bleeding appeared to be higher, especially in patients with extensive pleural adhesions related to prior pleural procedures, as were complications of pneumothorax and postoperative chylothorax. The United Network of Organ Sharing recorded 126 transplants for LAM from 1989 through 2007, including 77 double-lung transplants and 49 single-lung transplants. The 1-, 3-, and 5-year survival for single- and double-lung transplants were 87%, 73%, and 61%; and 92%, 83%, and 77%, respectively. These survival rates are equal to or better than those for other disease groups transplanted in the same timeframe. There have been four case reports of recurrence of LAM in the donor allograft.[56–58,167] The recurrences did not appear to contribute to death in any of these patients, and at the present time, we do not feel that recurrence should be considered in judging the candidacy of patients for transplant. More than half of LAM patients who have undergone lung transplantation have had a prior history of unilateral or bilateral pleural fusion procedures, and although postoperative bleeding risk is increased, the operative mortality and long-term survival do not appear to be affected.[102,166]

As with other obstructive lung diseases, referral for lung transplantation should be considered as the FEV_1 falls to less than 30% of the predicted value. Some patients that fail to meet this criterion may qualify based on other factors that profoundly affect quality of life, such as disabling dyspnea or problems maintaining oxygen saturation at high levels of supplemental oxygen. Although the question of bilateral versus unilateral transplantation has not been directly studied in LAM, bilateral lung transplantation produces better functional outcomes in other types of obstructive lung disease.[168] However, double-lung transplantation is not always feasible owing to the limited availability of organs and the urgency of the procedure in some patients.

Angiomyolipomas

Renal AMLs may require embolization or cauterization if bleeding occurs, which is thought to be more common when the diameter of the tumor exceeds 4 cm.[169] Others feel that the extent of aneurysmal change determines bleeding risk. Serial abdominal imaging should be performed to assess AML size at 6- to 12-month intervals. Nephron-sparing partial resections may be consider for very large tumors.[170] Nephrectomy is sometimes required for tumors with intravascular extension or other reasons, but is rarely the approach of choice for AMLs that can be managed by less invasive means.

PROGRESSION AND PROGNOSIS

Patients with LAM typically develop progressive airflow obstruction. In a cohort of patients in the United Kingdom, 10 years after symptom onset, 55% of 77 patients were breathless walking on flat ground and 10% were housebound.[171] The average annual rate of decline in FEV_1 and D_{LCO} in 275 patients studied in a single laboratory at the NHLBI was 75 ± 9 mL, and 0.69 ± 0.07 mL/min/mm Hg, respectively.[93] In other series from Europe, the rate of decline in FEV_1 was considerably higher, estimated at approximately 100 to 120 mL/yr.[14,172,173] There was some evidence in these studies that rate of decline in lung function correlates with initial D_{LCO}, with menopausal status, and with progesterone treatment. In patients with mild disease, the development of pneumothorax appears to correlate with a faster rate of decline in FEV_1.[164] A positive bronchodilator response, which was associated with a lower FEV_1, was found to be a predictor of more rapid rate of decline in FEV_1 over time.[12] Survival estimates vary widely, appear to be dependent on mode of presentation, and have generally trended upward over the past few decades, probably due to earlier recognition through more widespread use of CT scanning. The data from early, large case series indicate that 38% to 78% of patients are alive at 8.5 years from the time of disease onset.[8,9] Urban and associates[14] reported a 91% probability of survival at 8.5 years, 79% at 10 years, and 71% at 15 years. Hayashida and colleagues[13] reported that 5-, 10-, and 15-year survival probabilities for Japanese patients who presented with

pneumothorax as the sentinel event were 95%, 89%, and 89%, whereas the survival for those who presented with dyspnea were only 85%, 60%, and 47%. Matsui and coworkers[174] found that the actuarial survival, based on time from lung biopsy to death or transplant, was 85% and 71% after 5 and 10 years, respectively. These investigators also developed a lung histology scoring (LHS) system based on semiquantitative analyses of smooth muscle cell infiltration and cystic change, which correlated with survival. Using the Kaplan-Meier method, they found that patients with LHS scores of 1, 2, and 3 had 5- and 10-year survivals of 100%/100%, 81%/74%, and 63%/52%, respectively. Other negative prognostic indicators that have been reported include a reduced FEV_1/FVC, increased TLC, and a predominantly cystic, rather than smooth muscle hyperplastic, histology.[9] There are no prognostic data available for TSC-LAM, but the survival of patients identified through screening is almost certainly more favorable than that of patients who present with dyspnea.[23,25]

FUTURE CLINICAL TRIALS IN LYMPHANGIOLEIOMYOMATOSIS

Progress in the understanding of the genetic and molecular basis of LAM has suggested a number of potential candidate therapies beyond mTOR inhibitors that may be appropriate for testing in clinical trials (Fig. 62-9). These include Akt inhibitors, Rheb inhibitors (e.g., farnesyltransferase inhibitors and statins), selective estrogen receptor antagonists (e.g., fispemifene), aromatase inhibitors (e.g., letrozole), tyrosine kinase inhibitors (e.g., imatinib mesylate), metalloproteinase inhibitors (e.g., doxycycline), angiogenesis inhibitors (e.g., bevacizumab), Rho inhibitors, and lymphangiogenesis inhibitors (e.g., anti–VEGF-D antibody). Many of these drugs have been approved by the U.S. Food and Drug Administration or are in development for other indications. In the absence of a known effective treatment, participation in clinical trials should be encouraged.

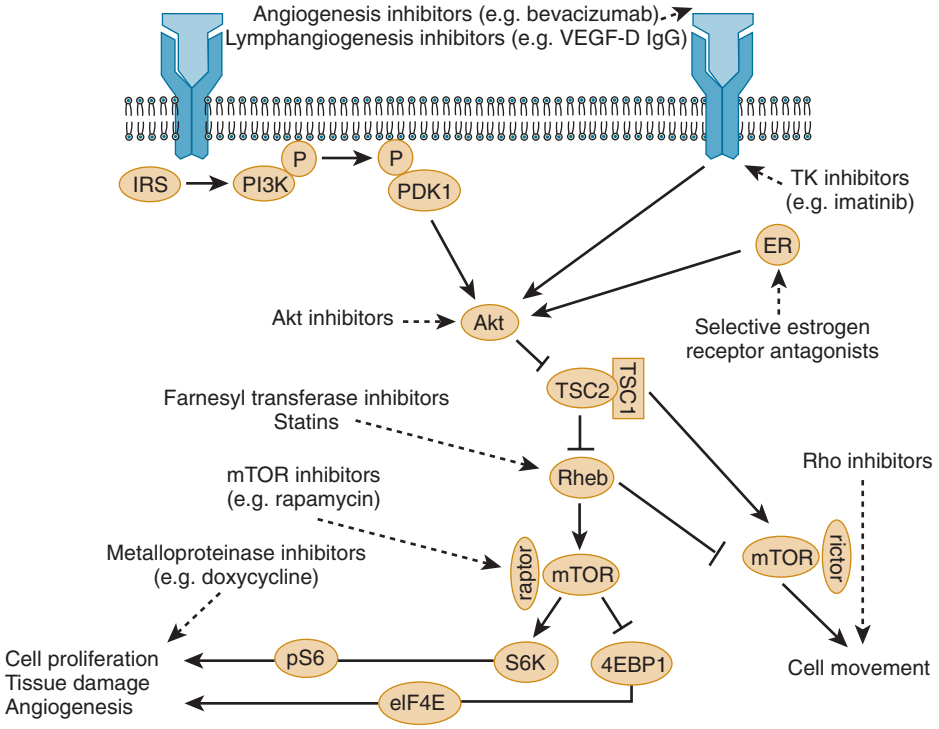

FIGURE 62-9 ■ Future therapeutic targets for LAM. Knowledge of the signaling pathways that are dysregulated in LAM patients has revealed a number of promising molecular targets for intervention. The constitutive activation of mTOR drives the inappropriate phosphorylation of S6 (pS6) when the TSC1 or TSC2 gene is missing or defective, as occurs in LAM patients. pS6 (and eIF4E) drives protein translation and inappropriate cellular proliferation, but also feeds back to inhibit the activation of immunoreactive secretin (IRS) and the downstream effector Akt. This feedback loop control can be defeated by the activation of Akt through other routes, such as the platelet-derived growth factor (PDGF) and estrogen receptor pathways (which may explain the gender restriction in LAM). In this regard, tyrosine kinase (TK) inhibitors such as imatinib and selective estrogen antagonists such as fispemiphene may have special utility in LAM to block alternative activation of Akt. mTOR inhibitors such as sirolimus and everolimus block mTOR signaling through binding to an accessory protein cell FKBP12, and statins and farnesyl transferase inhibitors block Rheb translocation to the membrane by inhibiting the lipid modification of the protein. Patients with LAM express elevated levels of the lymphangiogenic growth factor vascular endothelial growth factor-D (VEGF-D), which is currently being studied as a target in metastatic malignancy trials. Angiogenesis inhibitors such as bevacizumab and anti–VEGF-D antibody may block blood and lymphatic vessel recruitment required for tumor maintainance, respectively, and metalloproteinase inhibitors such as doxycycline may block lung matrix degradation that plays a role in tumor implantation, spread, and tissue destruction. Cell migration, infiltration, and metastasis are controlled by a rapamycin-insensitive mTOR pathway, but may be susceptible to inhibition by rho kinase inhibitors.

KEY POINTS

- LAM is the most gender-restricted illness in medicine, with the exception of diseases of the genitourinary tract. Only a few men with LAM have been reported.
- LAM affects about one third of women with the genetic disease tuberous sclerosis, but most LAM patients who present for pulmonary consultation have S-LAM.
- LAM is caused by mutations in tuberous sclerosis genes, which inactivate the regulatory TSC1/TSC2 complex and result in dysregulated signaling through the Akt growth pathway.
- LAM is characterized by smooth muscle infiltration and cystic destruction of the lung.
- LAM is a neoplasm that spreads through the bloodstream and the lymphatics.
- LAM most commonly presents with dyspnea and pneumothorax and less commonly with chylothorax, hemoptysis, or incidentally discovered abdominal masses or pulmonary cysts.
- The diagnosis of LAM can be established on clinical grounds, but may require tissue confirmation in patients who do not have corroborating features of pneumothorax, chylothorax, or tuberous sclerosis.
- There is no effective treatment for LAM, but clinical trials based on promising molecular targets are under way.
- Pregnancy can result in exacerbation of LAM.
- Pneumothorax in LAM should be aggressively managed, because the incidence of recurrence is exceedingly high.
- The clinical course of LAM is highly variable, but is generally slowly progressive, with 10-year survivals of approximately 80% to 90%.

Conclusion

INTRODUCTION

Pulmonary alveolar proteinosis (PAP) is a rare disorder characterized by progressive accumulation of surfactant within pulmonary alveoli resulting in respiratory insufficiency and, in severe cases, respiratory failure.[1–3] Although the pathogenesis of PAP remained an enigma for much of the past 50 years, contributions from basic science, clinical medicine, and translational research and globalization of the PAP research community have taken this fascinating disorder from obscurity to clarity. Results have advanced our understanding of pathogenesis, epidemiology, clinical subtypes, prognosis, and natural history and have led to new methods to diagnose, evaluate, and treat patients (see references 1, 2, and 4–6 for recent reviews).

PAP is a syndrome and not a specific disease. Further, it is most appropriately considered in the larger context of disorders of surfactant homeostasis, which include disorders of surfactant production and disorders of surfactant clearance. The former include pulmonary surfactant metabolic dysfunction (PSMD) disorders, of which known diseases include genetic mutations in genes that encode surfactant proteins or proteins involved in surfactant lipid metabolism.[7] The latter include PAP, which can be divided into primary and

secondary forms depending on whether an underlying disease associated with development of PAP is absent or present, respectively.

Importantly, research on this rare but fascinating syndrome has illuminated the critical role of the cytokine granulocyte-macrophage colony-stimulating factor (GM-CSF) in the pathogenesis of PAP, pulmonary surfactant homeostasis, and immunity. Further, expanding knowledge about the regulatory role of GM-CSF in inflammation and autoimmunity has ushered in new potential treatment approaches to other more common diseases. This chapter provides an overview of the pathogenesis, classification, epidemiology, and clinical aspects of the PAP syndrome, emphasizing progress occurring since the previous edition of this textbook.

PATHOGENESIS

Surfactant Composition and Homeostasis

Surfactant is a complex mixture of 90% phospholipids and 10% surfactant proteins that functions at the air-liquid–alveolar wall interface to reduce surface tension, thereby preventing alveolar collapse. It is produced in type II alveolar epithelial cells, secreted into the alveolar space, and cleared by either recycling or catabolism in type II cells or uptake and catabolism by alveolar macrophages. Surfactant composition, production, and homeostasis are reviewed in detail in Chapter 9. Our current concepts of the mechanisms by which surfactant homeostasis is disrupted in PAP draw heavily on animal models of PAP in which the pathogenesis has been elucidated. These models and subsequent studies in humans have identified GM-CSF as a critical regulator of surfactant homeostasis (Fig. 63-1).

Granulocyte-Macrophage Colony-Stimulating Factor

GM-CSF is a 23-kD glycoprotein cytokine present in serum and tissues that signals via cell surface receptors comprising a GM-CSF–binding, low affinity α chain (CDw116) and a nonbinding, affinity-converting β chain (CD131).[8,9] While neither α nor β chains have intrinsic activities associated with intracellular signaling capabilities,[10] the β chain constitutively binds Janus activating kinase (JAK),[10] a tyrosine kinase involved in cytokine signaling. Ligand binding causes formation of αβJAK2 multimers and activation of JAK2, resulting in phosphorylation of α[11] and β chains, activation of other kinases,[10] and initiation of signaling via multiple pathways,[10,12] including the signal transducer of activation and transcription (STAT)-5.[13]

Murine Models of Disordered Surfactant Homeostasis

The first real clue to the pathogenesis of PAP was the observation that genetically manipulated mice deficient in GM-CSF developed a phenotype with features similar in nearly every respect to the common form of PAP in humans.[14] Detailed studies of these mice revealed that neither production of surfactant by type II cells nor its uptake by alveolar macrophages was altered.[14,15] Rather, the defect was impaired catabolism of surfactant in alveolar macrophages.[16] Further studies showed that pulmonary GM-CSF was critical for regulation of surfactant catabolism in alveolar macrophages,[17,18] and that this pathway was controlled by the transcription factor PU.1.[19] Many other functions of alveolar macrophages were concomitantly regulated by GM-CSF via PU.1,

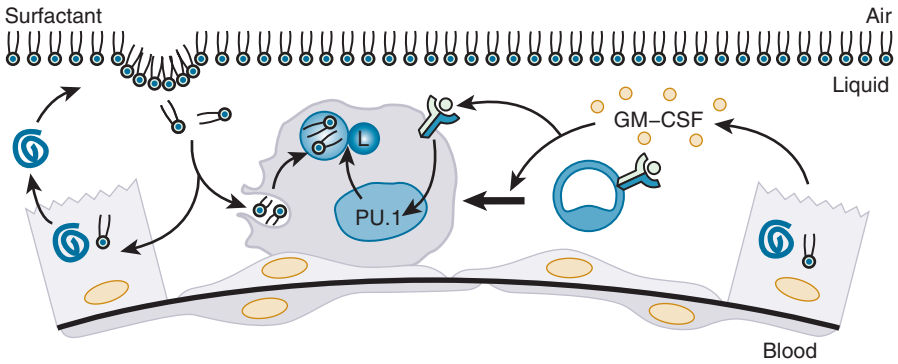

FIGURE 63-1 ■ Schematic of pulmonary surfactant homeostasis within an alveolus of a healthy individual. Surfactant lipids and proteins are synthesized in type II alveolar epithelial cells and secreted into the intra-alveolar space. Extracellular surfactant contributes to the surfactant layer present at the air-liquid-tissue interface, which plays a critical role by reducing surface tension within the alveolus. Surfactant lipids and proteins are removed from the extracellular surfactant by uptake and recycling in type II cells or by uptake and catabolism in alveolar macrophages. Granulocyte-macrophage colony-stimulating factor (GM-CSF), a critical regulator of surfactant catabolism in alveolar macrophages, functions by binding to heterologous receptors on alveolar macrophages and stimulating surfactant catabolism via the transcription factor PU.1. GM-CSF is also critical for stimulating the terminal differentiation of precursors into mature alveolar macrophages.

including cell adhesion; expression of Fc receptors, mannose receptors, and other receptors; phagocytosis; bacterial killing; and Toll-like receptor-4 signaling.[19] The diversity of functions coordinately regulated by GM-CSF via PU.1 indicated that pulmonary GM-CSF is a critical regulator of the terminal differentiation of alveolar macrophages in mice.

Genetically manipulated mice deficient in the β chain of the GM-CSF receptor develop PAP indistinguishable from that of GM-CSF–deficient mice.[20] Transplantation of bone marrow from wild-type mice corrected PAP in GM-CSF receptor–deficient mice, indicating that loss of GM-CSF signaling to myeloid cells (not lung epithelial cells) was the pathogenic lesion resulting in PAP in mice.[21]

Disruption of surfactant homeostasis also occurs in several other mouse models. For example, PAP develops in mice with severe combined immunodeficiency.[22] While the phenotype of this mouse is histologically similar to that of GM-CSF–deficient mice, the mechanism underlying the development of PAP is unknown. Pulmonary surfactant lipidosis occurs in transgenic mice with pulmonary overexpression of either interleukin (IL)-4[23] or IL-13 in airway epithelial cells[24]; however, both these models are phenotypically distinguished from the GM-CSF–deficient mouse by the presence of pulmonary inflammation, which is not a feature in GM-CSF–deficient mice. Surfactant lipid accumulation also occurs in surfactant protein (SP)-D–deficient mice.[25] However, these mice develop significant pulmonary inflammation and emphysema, and thus are phenotypically and mechanistically distinct from GM-CSF–deficient mice.[26] Inhalation of fine particulate silica (silica dioxide) by rodents produces alveolar proteinosis. Thus, silica inhalation serves as a model of secondary PAP (see later).[27]

Genetically modified mice with abnormalities of surfactant production exhibit disordered surfactant homeostasis to varying degrees but have a phenotype that differs markedly from that of GM-CSF knockout mice. For example, mice deficient in SP-B develop respiratory failure immediately after birth. Studies in these mice demonstrated that SP-B is critical to the processing of SP-C precursor protein, the organization of surfactant phospholipids in lamellar bodies, the formation of tubular myelin in the alveolus, the generation of surfactant films capable of reducing surface tension, and lung function during the early postnatal period.[28–30] Expression of mutant SP-C in mice causes a severe interstitial lung disease phenotype[31]; however, it is unclear whether the absence of mature, functional SP-C or the presence of abnormal SP-C is pathologically important for the development of this phenotype. Genetically modified mice deficient in ABCA3, a member of the ATP-binding cassette (ABC) transporter protein family expressed in alveolar type II cells, die from respiratory failure immediately after birth.[32] Studies in these mice have revealed that ABCA3 is a lipid transporter critical to lamellar body formation, and pulmonary surfactant biogenesis.[33] The phenotype of these murine is histologically, biochemically, and clinically distinct from that of GM-CSF–deficient or GM-CSF receptor–deficient mice.

Genetically modified mice deficient in ABCG1, a transmembrane protein, mediate cellular efflux of cholesterol, accumulate cholesterol in alveolar macrophages and type II cells, and develop pulmonary lipidosis, suggesting that ABCG1 is important in surfactant homeostasis.[34] In alveolar macrophages from both GM-CSF–deficient mice and patients with autoimmune PAP, impaired GM-CSF signaling results in reduced expression of ABCG1, and increased expression of a related family member, ABCA1, which is involved in cellular lipid efflux.[35]

Historical Overview of Human Disorders of Surfactant Homeostasis

PAP was initially described by Rosen in 1958 as a disorder characterized by the alveolar accumulation of lipoproteinaceous material, comprised of primarily phospholipids, a smaller amount of protein, and minimal amounts of carbohydrate.[36] The accumulated material was quickly identified as pulmonary surfactant, and a therapeutic approach was devised to remove the excess material by saline lung lavage. Notwithstanding, for 3 decades, it was unclear if the mechanism of surfactant accumulation in PAP involved an abnormality in production or clearance of surfactant. The rarity and heterogeneous nature of the syndrome probably contributed to the difficulty in establishing its pathogenesis. For example, the syndrome was associated with heavy silica inhalation, various hematologic disorders, and infections. However, in most cases, it occurred as an idiopathic disorder in previously healthy individuals with no obvious exposures other than smoking.

In 1976, Golde and colleagues reported that alveolar macrophages from PAP patients had excessive lipid accumulation, giant lysosomes, and impaired adhesion, chemotaxis, microbial killing, and survival.[37] The morphologic abnormalities were reproduced in normal monocyte-derived macrophages cultured with the proteinaceous lavage material from a PAP patient, suggesting that the lung macrophages were defective as a consequence of an abnormal pulmonary environment.

In 1981, Wasserman's group reported that both PAP patient serum and lung lavage fluid contained a substance that inhibited the growth of mononuclear cells in response to mitogens, and that the inhibiting substance did not appear to be immunoglobulin.[38] In 1987, Muller-Quernheim and associates identified a 40-kD protein found in the lavage fluid with macrophage-inhibiting effects.[39] Shortly thereafter, bronchoalveolar lavage (BAL) was reported to improve alveolar macrophage function in PAP. In 1996, prompted by the discovery of PAP in GM-CSF knockout mice, Seymour and colleagues reported that GM-CSF administration resulted in clinical improvement in one individual with idiopathic PAP.[40] Neither this individual nor any other humans have been identified to date as having GM-CSF deficiency,[41] and patients with idiopathic PAP were found to express GM-CSF normally.

In 1999, Nakata's group reported the presence of high levels of polyclonal, neutralizing immunoglobulin

G (IgG) autoantibodies in patients with idiopathic PAP.[42] This was a second important clue about the pathogenesis of PAP that has stimulated research in many areas, including pathogenesis, diagnosis, and therapy of PAP.

The first report of a genetic disturbance of surfactant homeostasis was the report of a PAP-like disease of unknown cause occurring in four siblings in 1981.[43] Subsequently, mutations in the genes encoding SP-B,[44] SP-C,[45] and ABCA3[7] (*SFTPB, SFTPC,* and *ABCA3,* respectively) have been reported to cause a spectrum of lung disease in humans, including variable degrees of disruption of surfactant homeostasis.

Dirksen and coworkers reported PAP in four cases in association with the absence of detectable GM-CSF receptor β chain on peripheral blood monocytes,[46] of which PAP was confirmed in three and SP-C mutation in one. Using biomarkers identified by studies in mice, a familial form of PAP caused by mutations in the gene encoding the GM-CSF receptor α chain (*CSF2RA*) was recently reported.[47]

Role of GM-CSF Autoantibodies

In 1999, Nakata's group identified the presence of neutralizing GM-CSF autoantibodies in the BAL fluid and serum of individuals with idiopathic PAP.[42,48] Subsequently, multiple studies confirmed the presence of GM-CSF autoantibodies with idiopathic PAP but not in secondary PAP, other lung diseases, PSMD disorders, or healthy individuals (Fig. 63-2).[1-3,49,50] GM-CSF autoantibodies are composed of IgG, predominantly of the IgG1, and IgG2 subclasses; are highly specific for GM-CSF; have a very high binding affinity (20 ± 7.5 pM); and are capable of neutralizing GM-CSF at levels up to many thousands times higher than the physiologic concentrations of GM-CSF in vivo.[49] Based on the available evidence, GM-CSF autoantibodies are presumed to be important in the pathogenesis of idiopathic PAP. Published reports have not established a causal role or even that GM-CSF autoantibodies affect alveolar macrophage function (Fig. 63-3). Supporting their potential role in pathogenesis, GM-CSF autoantibodies have been reported to impair neutrophil functions in humans and mice.[51] Endogenous neutrophil functions are impaired in patients with idiopathic PAP and GM-CSF–deficient mice in a remarkably similar pattern (Fig. 63-4). These results have shown that GM-CSF autoantibodies regulate neutrophil functions and suggest that a similar mechanism of control by GM-CSF may be present in humans and mice.

Serum GM-CSF autoantibodies are useful in diagnosis of idiopathic PAP, but levels do not correlate with disease severity,[50] casting doubt about their role in pathogenesis. Further, GM-CSF autoantibodies were detected in 4 of 1258 apparently healthy individuals in one report.[52] In another study, non-neutralizing autoantibodies were detected in 38 patients and neutralizing autoantibodies were detected in 3 of 425 patients with autoimmune diseases without evidence of PAP. The estimated concentrations of total GM-CSF autoantibodies in these latter three patients were 2.9, 8.6, and 17.3 μg/mL.[53] In contrast, the concentration of GM-CSF autoantibodies in 158 patients with idiopathic PAP was 113 ± 7 μg/mL,[1,49] while levels were less than 1 μg/mL in patients with secondary PAP, PSMD disorders, or other lung diseases.[1] GM-CSF autoantibodies are also the dominant anticytokine activity in pharmaceutical immunoglobulin, which is prepared from healthy individuals. Using improved detection methods, GM-CSF autoantibodies were demonstrated in all of 72 healthy individuals with no prior exposure to GM-CSF, albeit at low level (median [interquartile range] = 1.04 [0.63 to 1.7] μg/mL serum).[54] In this study, serum levels of endogenous GM-CSF autoantibodies in healthy individuals correlated inversely with endogenous, unstimulated neutrophil function (phagocytosis), suggesting they may play a physiologic role in healthy individuals. GM-CSF autoantibodies may also scavenge free GM-CSF in blood and tissues because serum GM-CSF concentrations were recently found to be much higher than previously reported, and more than 99% was bound to GM-CSF autoantibodies in healthy individuals and PAP patients.[54]

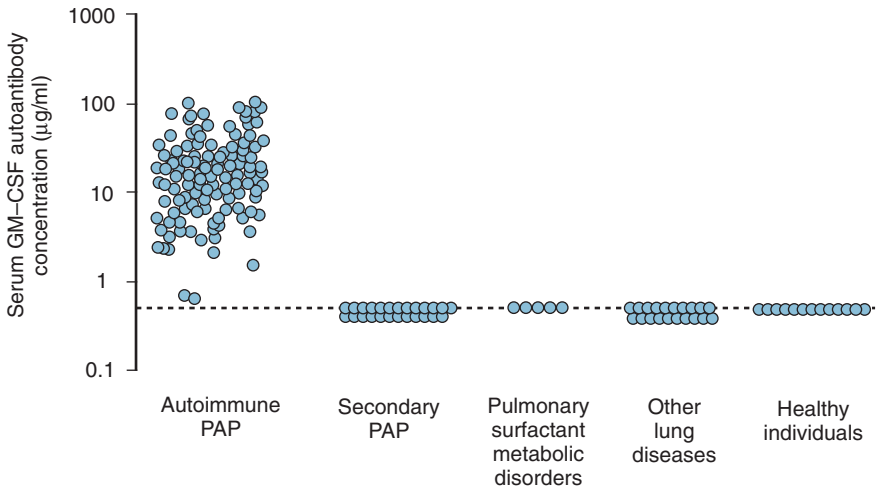

FIGURE 63-2 ■ Serum GM-CSF autoantibody levels in individuals with autoimmune PAP (n = 223), secondary PAP (n = 33), pulmonary surfactant metabolic dysfunction (n = 5), other lung diseases (n = 24), and in healthy controls (n = 13). The detection limit of the assay was 0.5 μg/mL of serum. (Some of these data were reported in Inoue et al.[3])

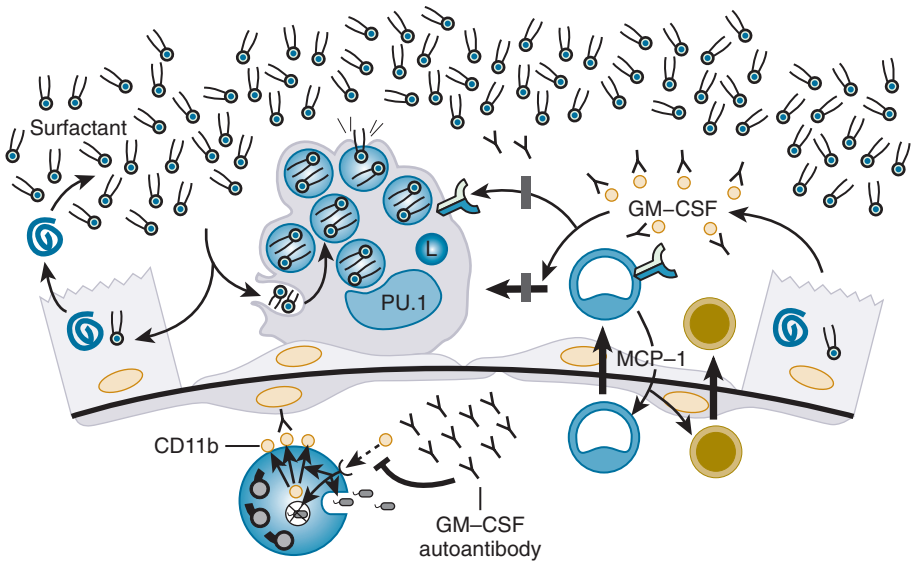

FIGURE 63-3 ■ Schematic of the pathogenic mechanism of autoimmune PAP. High levels of neutralizing GM-CSF autoantibodies bind to GM-CSF, eliminating its bioactivity in vivo. In the absence of GM-CSF, surfactant production continues, as does uptake into alveolar macrophages. However, in the absence of GM-CSF stimulation, levels of the transcription factor PU.1 fall within alveolar macrophages. Without PU.1, alveolar macrophages do not terminally differentiate and are unable to catabolize surfactant. With uptake proceeding and catabolism impaired, alveolar macrophages become engorged with surfactant-filled vesicles, which probably contributes to their dysfunction. Impaired pulmonary clearance of surfactant ensues, eventually leading to impaired gas transfer across the alveolar epithelium. GM-CSF autoantibodies also impair GM-CSF signaling to other cells (e.g., circulating neutrophils), thus impairing their innate immune and other GM-CSF–dependent functions.

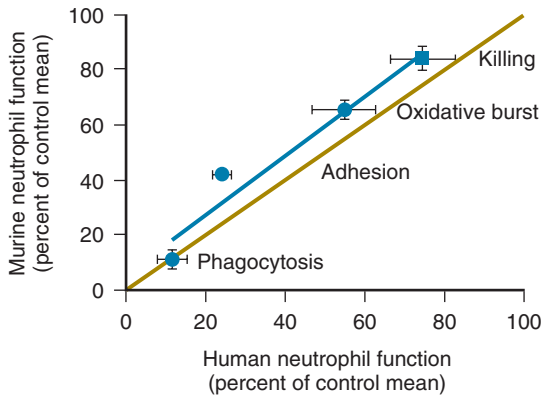

FIGURE 63-4 ■ Similarity of impairment of various corresponding neutrophil functions in GM-CSF–deficient mice and patients with autoimmune PAP. The *brown line* indicates equal impairment. The *blue line* indicates the similarity between the impairment in corresponding mouse and human functions (correlation coefficient = 0.94). (Redrawn from Uchida K, Beck DC, Yamamoto T, et al: GM-CSF autoantibodies and neutrophil dysfunction in pulmonary alveolar proteinosis. N Engl J Med 356:567–579, 2007.)

The apparent discrepancy between the high diagnostic utility of GM-CSF autoantibodies and a lack of correlation between their serum concentration and lung disease severity was reconciled by the hypothesis of a critical threshold level of GM-CSF autoantibodies necessary to reduce GM-CSF bioactivity to a level that impairs myeloid cell functions.[53] This value was calculated from published data to fall between 8 and 22 μg/mL[53] and determined experimentally to be between 10.7 and 19 μg/mL.[54] Together, published reports strongly suggest but do not prove that GM-CSF autoantibodies mediate the manifestations of patients with idiopathic PAP by impairing the functional ability of alveolar macrophages to catabolize surfactant lipids and proteins. Results also show that GM-CSF autoantibodies negatively regulate the basal functions of circulating neutrophils.

Genetic Factors

PAP has been reported in association with the absence of detectable GM-CSF receptor β protein on circulating leukocytes in four children,[46] and in one individual with sequence polymorphism in the gene (*CSF2RB*) encoding this receptor that causes a single amino acid change (isoleucine to threonine) at position 117 of the mature protein.[41] However, these studies did not definitively establish GM-CSF receptor β chain abnormalities as the cause of PAP. Recently, two studies reported PAP in association with abnormalities in the gene encoding the GM-CSF receptor α chain (*CSF2RA*).[47] In one report, biochemical, genetic, and molecular studies demonstrated that a point mutation causing a single, nonconservative amino acid change (glycine to arginine) at position 174 of the mature protein was the cause of reduced GM-CSF signaling in myeloid cells.[47] The defect was reproduced by cloning and expression of the abnormal complementary DNA in cultured cells. In the other study, bone marrow transplantation was successful in treating PAP. However, this patient succumbed to infection 4 months after transplantation. The absence or abnormalities of the GM-CSF receptor resulted in high

serum levels of GM-CSF. This appears to be a useful biomarker of GM-CSF receptor dysfunction, because screening of 122 previously collected serum samples from PAP patients who were negative for GM-CSF autoantibody revealed the presence of 5 cases with elevated GM-CSF levels and GM-CSF receptor α chain mutations.[55] Thus, the combination of an elevated serum GM-CSF level and the absence of detectable GM-CSF autoantibody in a child with PAP may indicate the presence of a GM-CSF receptor defect.

Mutations in three genes of the surfactant synthetic pathway, *SFTPB, SFTPC,* and *ABCA3,* disrupt surfactant production and function and cause respiratory disease in neonates, children, and older individuals.[56–59] SP-B and SP-C are hydrophobic peptides that reside within the surfactant phospholipid layer, which functions to reduce surface tension at the alveolar wall–liquid-air interface,[30] whereas ABCA3 likely transports lipids, including phosphatidylcholine, cholesterol, sphingomyelin, and phosphatidylglycerol, into lamellar bodies in alveolar type II cells where the surfactant complex is assembled, processed, and stored.

SFTPB is a relatively small gene (9.7 kb) encoding a 79–amino acid, hydrophobic protein. Infants homozygous for recessive loss-of-function mutations in *SFTPB* develop respiratory failure and die shortly after birth.[44,60] In contrast, individuals heterozygous for SP-B deficiency alleles have normal lung function.[61] More than 30 mutations have been identified to date in less than 100 infants with SP-B deficiency.[59,62] Two thirds have an insertional frameshift mutation caused by the replacement of a single nucleotide by three nucleotides at codon 121 (designated 121ins2). Among infants with SP-B deficiency, approximately 60% are homozygous for the 121ins2 mutation, 25% are heterozygous for this and another function-altering allele, and 15% have other mutations. SP-B deficiency is associated with the aberrant processing and secretion of an immature SP-C peptide, which may contribute to the respiratory failure associated with hereditary SP-B deficiency.[63]

SFTPC is also a small gene (3 kb) encoding a 35–amino acid hydrophobic protein. Known mutations in *SFTPC* are expressed in a dominant fashion and are associated with interstitial lung disease in neonates, children, and adults.[45,59,64–66] Twenty-five percent of individuals with SP-C–associated lung disease have a point mutation in *SFTPC* causing the substitution of threonine for isoleucine at codon 73 (I73T).[64] Immunohistochemical analysis of lung tissue from an infant with the I73T mutation demonstrated normal staining patterns for pro–SP-B, SP-B, and pro–SP-C. Although infants with this mutation can present with respiratory distress syndrome, most children with the mutation become symptomatic with interstitial lung disease beyond the newborn period.[64,67]

ABCA3 is a large gene (80 kb) encoding a 1704–amino acid protein. Autosomal recessive mutations in *ABCA3* can result in fatal surfactant deficiency in neonates[7,68] and chronic respiratory insufficiency in older children.[69] Function-altering mutations in *ABCA3* result in surfactant that is deficient in phosphatidylcholine and has decreased function, suggesting that ABCA3 has an important role in pulmonary surfactant phospholipid homeostasis.[70] A relatively common missense point mutation in *ABCA3* causing the substitution of a valine for glutamic acid at codon 292 (E292V) is associated with chronic interstitial lung disease in older children who are heterozygous for this and a different function-altering mutation on the other *ABCA3* allele.[69]

While disorders arising from function-altering mutations in *SP-B, SP-C,* and *ABCA3* disrupt surfactant homeostasis to varying degrees, they are easily distinguished from PAP by their surfactant dysfunction, disruption of alveolar wall architecture, and clinical course. Although sometimes referred to as congenital forms of PAP in the medical literature, these disorders are considered as distinct from PAP. In keeping with this concept, the term *pulmonary surfactant metabolic dysfunction disorders* has been proposed for this group of genetic disorders.

Disease Associations

PAP or PAP-like lung diseases have been reported in association with other medical conditions believed to cause PAP. In such cases, the lung disease is commonly referred to as "secondary PAP."[1,2] Systemic disorders associated with PAP include malignant and other hematologic diseases, nonhematologic malignancies, immune deficiency syndromes, chronic inflammatory syndromes, and chronic infections (Table 63-1). Chronic myelogenous leukemia and myelodysplastic syndrome are the most frequently reported hematologic disorders associated with PAP.[2,71–73] In one single-institution study, PAP occurred in 5.3% of patients with hematologic malignancies, and in 8.8% of those who were neutropenic.[72] Among 10 such patients, 5 had acute myeloid leukemia, 4 had chronic myelogenous leukemia, and 1 had acute lymphocytic leukemia. Of potential pathogenic importance, nine of these patients were neutropenic when they developed PAP, three had undergone bone marrow transplantation, and in most, PAP recovered spontaneously with recovery of bone marrow. In another report, a patient with acute lymphoid leukemia developed PAP during a period of neutropenia that resolved after treatment with granulocyte colony-stimulating factor.[74] A different study reported PAP in three patients with acute myeloid leukemia with GM-CSF receptor abnormalities, including reduced levels of the β chain (three of three) and undetectable α chain (two of three).[75]

Secondary PAP has been reported in the context of systemic disorders associated with various forms of immunodeficiency, including thymic alymphoplasia,[76] immunoglobulin A deficiency,[77] solid organ transplantation,[78] and acquired immunodeficiency syndrome.[79]

Although the mechanism(s) responsible for secondary PAP are poorly studied, two common themes emerge when the data are considered together. Medical conditions that reduce either the numbers or functions of myeloid cells may impair pulmonary clearance of surfactant by effects on alveolar macrophage numbers or function (i.e., surfactant catabolism). A reduction in either could alter the capacity of the alveolar macro-

phage pool to clear surfactant from the lung surface. Further studies will be required to determine if this is, in fact, the case.

Environmental Factors

PAP or PAP-like lung disease has also been reported in association with varying degrees of inhalation exposure to environmental factors, including cigarette smoke, a wide variety of organic and inorganic dusts, and fumes and gases (Table 63-2). Epidemiologic studies (see later) have shown that PAP occurs more often in individuals who smoke. Reports linking PAP to other environmental exposures comprise case reports and small retrospective series, and in general, have not established a causal relationship between the exposure and development of PAP. Five of the 27 original patients reported by Rosen and colleagues had been exposed to wood dust.[36]

An early report on 138 PAP patients in one series found that about half had significant exposure to dust and fumes, of which the most common exposure was to inhaled silica, occurring in 10 individuals.[80] With the advent of occupational protective equipment in the workplace, this form of "acute silicoproteinosis"[81,82] is rare. Other case reports have documented the association of PAP with exposure to aluminum dust,[83] cellulose fibers, cement dust, titanium dioxide,[84,85] and nitrogen dioxide. In support of the link between silica and PAP are studies in rats demonstrating that inhalation of silica particles disrupts surfactant homeostasis, resulting in increased surfactant accumulation.[27,86] Further research is needed to determine what role, if any, environmental inhalation exposure plays in the pathogenesis of PAP.

Mechanisms of Disruption of Surfactant Homeostasis

In mice, a series of observations have established GM-CSF as a critical regulator of pulmonary surfactant homeostasis, including the following: (1) surfactant homeostasis requires the presence of GM-CSF in the lung, and PAP develops in the absence of either pulmonary GM-CSF or its receptor; (2) surfactant accumulation in GM-CSF–deficient mice is caused by decreased catabolism by alveolar macrophages, and not an increase in surfactant production; (3) pulmonary GM-CSF is required for normal expression of transcription factor PU.1 in alveolar macrophages, and enforced (i.e., retroviral-mediated) expression of PU.1 restores surfactant catabolism in alveolar macrophages from GM-CSF knockout mice; and (4) surfactant homeostasis can be restored in GM-CSF receptor β–deficient mice by transplantation of bone marrow from a wild-type mouse.

In humans, the pathogenesis is less clear, but recent studies support a similar role for GM-CSF as a critical

regulator of pulmonary surfactant homeostasis. These findings include the following: (1) high levels of GM-CSF autoantibodies are strongly and specifically associated with PAP; (2) GM-CSF autoantibodies are capable of neutralizing vastly more GM-CSF than is present physiologically; (3) in PAP patients, PU.1 expression is reduced in alveolar macrophages and increased by GM-CSF therapy; (4) interruption of GM-CSF signaling by function-altering mutations in the *CSF2RA* gene encoding the GM-CSF receptor α chain disrupt surfactant homeostasis and result in lung histopathology indistinguishable from that of GM-CSF knockout mice and idiopathic PAP in humans; (5) reduced expression of GM-CSF receptor β on leukocytes is associated with PAP in children and with development of PAP in leukemia patients; and (6) various disorders that transiently reduce the number and/or functions of myeloid cells are temporally related to the development and resolution of secondary PAP in humans. Importantly, a recent study involving passive transfer of highly purified GM-CSF autoantibodies into healthy nonhuman primates reproduced the typical pathologic findings of PAP, thus supporting the role of GM-CSF autoantibodies in the pathogenesis of PAP and the role of GM-CSF in surfactant homeostasis in primates.[87]

Available evidence suggests that GM-CSF regulates myeloid cell functions similarly in humans and mice. GM-CSF knockout mice and idiopathic PAP patients have remarkable similarity in (1) pulmonary histopathologic appearance of the lung; (2) cytologic and ultrastructural appearance of alveolar macrophages; (3) elevation of certain cytokines (monocyte chemotactic protein-1, macrophage colony-stimulating factor); (4) the pattern of differential impairment of various neutrophil functions; and (5) the increased occurrence of pulmonary and extrathoracic secondary infections.

A primary mechanism of PAP is the disruption of GM-CSF signaling to alveolar macrophages, either by the absence of GM-CSF (observed in mice, but not yet in humans), disruption of GM-CSF signaling by mutations in the GM-CSF receptor proteins (in mice and humans), or an autoimmune attack targeted at GM-CSF that neutralizes GM-CSF, eliminating GM-CSF bioactivity and myeloid cell stimulation in vivo (in humans and nonhuman primates) (see Fig. 63-3). GM-CSF, via PU.1, regulates catabolism of surfactant in alveolar macrophages (in mice and possibly humans). Surfactant accumulation in PAP is due to reduced clearance (in mice, and likely in PAP associated with GM-CSF autoantibodies or GM-CSF receptor defects in humans). However, the precise mechanism of this control is unknown. Since pulmonary surfactant is internalized into macrophages by endocytosis and catabolized in phagolysosomes, it is possible that interruption of GM-CSF signaling blocks the translocation of endocytosed surfactant to lysosomes. Such a mechanism has been demonstrated for adenovirus internalized by macrophages from GM-CSF–deficient mice, in which PU.1 redirects adenovirus-containing endosomes to lysosomes for destruction. Alternatively, GM-CSF deficiency may result in a key enzyme deficiency. Potentially supporting this possibility are data related to the peroxisome proliferator–activated receptor-γ (PPAR-γ), a ligand-activated transcription factor regulating genes involved in lipid metabolism and other pathways.[88] PPAR-γ messenger RNA and protein are expressed in alveolar macrophages in healthy individuals, decreased in PAP patients, and increased by GM-CSF therapy of PAP patients.[89] CD36, a lipid scavenger receptor regulated by PPAR-γ, is regulated in a similar pattern. However, PPAR-γ deficiency has been noted in several other disorders, including sarcoidosis, acute respiratory distress syndrome, and asthma, where there have been reports of surfactant abnormalities.[90] Further studies are required to determine the mechanism by which interruption of GM-CSF signaling leads to reduced catabolism of surfactant by alveolar macrophages.

Secondary mechanisms of PAP, although less well supported by experimental data, appear to involve a decrease in either the numbers or functions of myeloid cells, including alveolar macrophages. Such abnormalities are expected to decrease the capacity of the remaining alveolar macrophage population to clear pulmonary surfactant, resulting in its accumulation. This model is supported by the temporal relationship of the onset and resolution of PAP with the occurrence and resolution of myeloid cell suppression in hematologic disorders. Other secondary mechanisms of PAP—for example, due to inhalation of toxic fumes and dusts—are less clear. Presumably, they would involve a reduction in the ability of alveolar macrophages to clear surfactant. However, since overexpression of certain cytokines (IL-4, IL-13), or decreased expression of some surfactant proteins (SP-D) also increases surfactant production in mice, other potential mechanisms appear possible.

Mechanisms of PSMD involve mutations in genes of the surfactant synthetic pathway, including *SFTPB, SFTPC, ABCA3,* and likely others, and result in the production of biochemically and functionally abnormal surfactant. These disorders have a lung histopathology and clinical course that is markedly different from PAP caused by interruption of GM-CSF signaling. Further, the pathophysiology arises from surfactant deficiency rather than surfactant excess as in PAP. Thus, it seems appropriate to consider these disorders as distinct from PAP and not part of a spectrum of PAP.

NOMENCLATURE AND CLASSIFICATION

In the 50 years since PAP was first described as a lung disease "that consists of the filling of the alveoli by a PAS-positive proteinaceous material, rich in lipid,"[36] it has become recognized as a syndrome caused by various distinct diseases,[1] and is reported in the medical literature using numerous terms, resulting in a nomenclature that is redundant, inconsistent, and confusing. Terms have been based on the biochemical characteristics of the accumulated material (e.g., alveolar proteinosis, phospholipidosis), pathogenesis (e.g., silicoproteinosis, idiopathic), disease category (e.g., primary vs. secondary), and timing of symptom onset (e.g., congenital, acquired), and are redundant (e.g., idiopathic PAP, acquired PAP, pulmonary alveolar lipoproteinosis,

TABLE 63-3. Classification of Diseases Associated with Disruption of Surfactant Homeostasis

CLINICAL CATEGORY/DISEASE
Primary PAP
GM-CSF autoimmunity
CSF2RA dysfunction
CSF2RB dysfunction

Secondary PAP
Hematologic disease
Nonhematologic malignancy
Immune deficiency syndromes
Chronic inflammatory syndromes
Chronic infections
Pulmonary Surfactant Metabolic Dysfunction Disorders
SP-B deficiency
SP-C mutations
ABCA3 mutations

phospholipoproteinosis, alveolar lipoproteinosis, alveolar proteinosis, alveolar phospholipidosis, and alveolar lipophosphoproteinosis). Confusion arises from use of the same term for different diseases. For example, the term *congenital PAP* is used for the disease caused by mutations in *SFTPB* that is uniformly fatal at birth and caused by surfactant deficiency, and also for the disease caused by GM-CSF receptor deficiency that presents in children, is caused by surfactant accumulation, and can be treated successfully.

The foregoing discussion underscores the need for a classification and nomenclature that will facilitate clear communication about disorders of homeostasis necessary for clinical training, disease management, and research. Based on initial discussions of a global task force assembled by the Rare Lung Diseases Consortium, a simplified classified scheme is proposed (Table 63-3).

Disorders of surfactant homeostasis are separated into disorders of reduced clearance (PAP) or abnormal production (PSMD). PAP is further subdivided into primary and secondary categories, depending whether it is due to a primary disturbance of GM-CSF signaling or secondary to another disease, respectively. Primary PAP is composed of several specific disease mechanisms: an autoimmune disease caused by GM-CSF autoantibodies (autoimmune PAP), or one of several genetic diseases caused by mutations in *CSF2RA* or *CSFR2B.* A third disease, caused by GM-CSF deficiency, occurs in mice and is predicted but not yet observed in humans. Secondary PAP arises in association with several disease categories, including hematologic disorders, malignancy, immune deficiency syndromes, chronic inflammatory disorders, and chronic infections (see Table 63-1), and in association with certain inhalation exposures, especially silica (sandblasters) (see Table 63-2). PSMD disorders are those arising from mutations in genes of the surfactant synthesis pathway, including *SFTPB, SFTPC, ABCA3,* and likely others that have yet to be identified.[57] These disorders are included in a new classification of interstitial lung disease in young children.[91]

The plethora of terms used to report on the PAP syndrome are not recommended for continued use and should be replaced with the term *pulmonary alveolar proteinosis.* Terms referring to clinical presentation (i.e., acquired PAP, congenital PAP) should not be used when the underlying disease is known. For example, "SP-B deficiency" is far more informative than "congenital PAP," and more consistent with its pathogenesis as a disorder of surfactant deficiency (PSMD) rather than excessive surfactant accumulation (PAP). When the cause in unknown, the term *unclassified PAP* is preferred over "idiopathic PAP" because the latter is currently understood to be the disorder associated with high levels of GM-CSF autoantibodies.

EPIDEMIOLOGY

Disorders of surfactant homeostasis are found in worldwide distribution but are quite rare. Since the initial description of PAP, approximately 650 to 700 separate cases of PAP[2–4,36,46,47,92] and substantially fewer cases of PSMD[7,45,56–59,64,69,93–95] have been reported in the medical literature. A comprehensive meta-analysis of 410 separate cases of PAP representing all clinical subtypes and most or all cases of PAP reported in the medical literature through 1998 found that patients were more likely to be male (male:female ratio = 2.65:1.0), and that males predominated among smokers (male:female ratio = 2.78:1.0) but not among nonsmokers (male:female ratio = 0.69:1.0).[2] These results suggested that the high proportion of males among PAP patients may be explained by their higher frequency of tobacco use. This study also found the median age at diagnosis to be 39 years (39 in men and 35 in women). In a smaller study based on ethnic clustering in Israel, the incidence and prevalence of PAP were estimated to be 0.36 and 3.7 per million, respectively.[96] However, this report included only 15 cases, of which one was a PSMD disorder and others appear to be cases of primary and secondary PAP. More recent evaluations have refined these estimates for individual diseases. Consequently, the epidemiology of each is considered individually.

A large national, multicenter, registry-based study of PAP was recently conducted in Japan and identified 223 patients with autoimmune PAP.[3] This study reported a male predominance (male:female ratio = 2.1:1.0), and that males predominated among smokers (male:female ratio = 9.3:1.0) but not among nonsmokers (male:female ratio = 0.6:1.0).[3] The median age at the time of diagnosis was 53 years (52 in men and 55 in women). The prevalence was similar in nine non-overlapping geographic regions encompassing the entirety of Japan, and the case rate correlated closely with the regional population size. This result suggests the absence of an effect of climate on the prevalence. Further supporting this, PAP occurs in a worldwide distribution. An intensive screening

within the Niigata prefecture in Japan (population 2.41 million) estimated the incidence and prevalence of autoimmune PAP to be 0.49 ± 0.13 and 6.2 per million, respectively.[3] This registry found that, among noncongenital cases of PAP, 89.9% of cases were autoimmune, 9.7% were secondary, and 0.4% were unclassified.

Familial PAP caused by genetic mutations in the *CSF2RA* gene was recently reported in two female children ages 6 and 8.[47] The disease was suspected based on a series of biomarkers, including an elevated serum SP-D concentration and increased serum and lung lavage GM-CSF concentrations, and confirmed by biochemical, molecular, and genetic studies and by reproduction of the GM-CSF receptor signaling defect. Since this report, five other children ages 2 to 11 years old have been identified with PAP and genetic defects in the GM-CSF receptor α chain gene. Further, PAP has been associated with abnormalities in the GM-CSF receptor β chain.[41,46]

Secondary PAP accounts for approximately 10% of PAP in adults,[2,3] and occurs as a consequence of an underlying disease (see Table 63-1) or environmental exposure (see Table 63-2). Thus, the prevalence of secondary PAP is estimated to be approximately 0.34 per 100,000 individuals in the general population. The most common cause of secondary PAP is hematologic malignancy, in which PAP is reported to occur in up to 5.3 % of cases.[72] The occurrence of secondary PAP is a function of the underlying clinical condition and, in some cases, can resolve with successful treatment of the underlying disorder.

PSMD disorders occur in individuals with mutations in the genes involved in surfactant synthesis: *SFTPB, SFTPC,* and *ABCA3,* as discussed earlier. The incidence of SP-B deficiency is estimated to be approximately 1 per 1.5 million births. Among infants with respiratory distress syndrome of unknown etiology, mutations appear more commonly in *ABCA3* than in *SFTPB.*[57] The prevalence of the common disease-associated mutations in the *SFTPB* (121ins2), *SFTPC* (I73T), and *ABCA3* (E292V) genes are not well established. However, a recent study in ethnically diverse cohorts from Missouri, Norway, South Korea, and South Africa (n = 420) found the population-based frequencies of these mutations to be rare (<0.4%). Further, E292V was present in 3.8% of newborns with respiratory distress syndrome, suggesting it imparts an increased genetic risk for this syndrome.[56]

CLINICAL PRESENTATION

Autoimmune PAP typically presents as progressive dyspnea of insidious onset unless secondary infection is also present, in which case fever, cough, and rarely hemoptysis may also be present. The frequency of various symptoms was recently evaluated in a large contemporaneous cohort in Japan (Table 63-4). This nonspecific presentation may lead to months or years of misdiagnosis as "asthma" or "chronic bronchitis." The symptoms are frequently milder than expected from the radiographic findings, which should raise the suspicion of PAP. The physical examination is nonspecific.

TABLE 63-4. Frequency of Symptoms among Patients with Autoimmune PAP*

Symptom	Frequency (%)
Dyspnea	54
Cough	23
Sputum	4
Other	4
None (asymptomatic)	31

*Data for a contemporaneous group composed of 220 patients.

Although lung examination is frequently normal despite a grossly abnormal chest radiograph, when findings are present, basilar crackles are most common. Cyanosis is seen in severe cases, while clubbing, hemoptysis, and fever are rare. Importantly, in the national PAP registry cohort in Japan, 31% of patients with obvious radiologic manifestations were asymptomatic.[3]

Familial PAP due to mutations in the GM-CSF receptor genes presented as progressive dyspnea in one of two sisters (age 6 years), while the other sister (age 8 years) was asymptomatic.[47] Others with this disease have presented with dyspnea of insidious onset. Thus, while this disease is newly described, very rare, and poorly studied, it appears quite similar to autoimmune PAP, except that it occurs in children instead of primarily in adults.

Secondary PAP usually arises in an individual with an underlying systemic disorder such as a hematologic malignancy/disease.[71,72,74,92,97,98] It can occur in the context of neutropenia or myeloid cell dysfunction related to the underlying disorder and can resolve with successful treatment of the underlying disorder.

PSMD disorders can present as a spectrum of lung disease ranging from respiratory distress syndrome in neonates and infants to interstitial lung disease in children, adolescents, and adults, depending on the exact nature of the underlying genetic mutations. SP-B deficiency typically presents as respiratory distress immediately after birth.[44,67,99] *ABCA3* mutations can result in fatal respiratory distress syndrome in neonates and interstitial lung disease in infants, children, and adolescents.[7,69,95,100] SP-C mutations can present as interstitial lung disease in children and adults.[45,59,65,66,94]

EVALUATION AND DIFFERENTIAL DIAGNOSIS

Radiographic Appearance

The chest radiograph in autoimmune and secondary PAP classically reveals patchy bilateral air space disease similar in appearance to that of pulmonary edema but without the other radiographic signs of left heart failure.[36,101] Occasionally, other patterns occur, including

mixed alveolar, interstitial, or nodular infiltrates, and asymmetrical or focal abnormalities. Effusions, adenopathy, and cardiomegaly are not features. The chest radiograph in familial PAP is similar except that the disease occurs in children, and it may be normal in mild cases.[47] The diagnostic value of the plain chest radiograph is limited by its lack of specificity.

Conventional 7- to 10-mm collimation chest computed tomography (CT) scans demonstrate bilateral areas of consolidation with poorly defined margins (Fig. 63-5).[102,103] High-resolution chest CT is superior to both conventional CT and chest radiography in the assessment of the pattern and distribution of abnormalities and may demonstrate lesions even when the radiograph is normal. The distribution of disease is variable and may reflect heterogeneity of underlying disease resulting in PAP. Several patterns are noteworthy. Areas of ground-glass opacification (GGO) often have sharply defined straight and angulated margins, giving them a "geographic" appearance. The sharp margination usually reflects lobular or lobar boundaries. A pattern of fine overlapping lines forming 3- to 10-mm polygonal shapes occurs in the majority of cases. Superimposition of these two patterns gives an appearance that has been described as "crazy paving," which is characteristic but not diagnostic of PAP.[104] In an ongoing study within the Japanese national PAP registry, autoimmune PAP was found to more commonly have a geographic appearance with crazy paving compared to secondary PAP.[104a]

Findings on the chest radiograph and high-resolution chest CT correlate with a restrictive ventilatory defect, reduced diffusing capacity, and hypoxemia.[103] Recently, a quantitative algorithm was reported permitting quantitative assessment of longitudinal changes in GGO, lung weight, and gas volume in patients with PAP.[105]

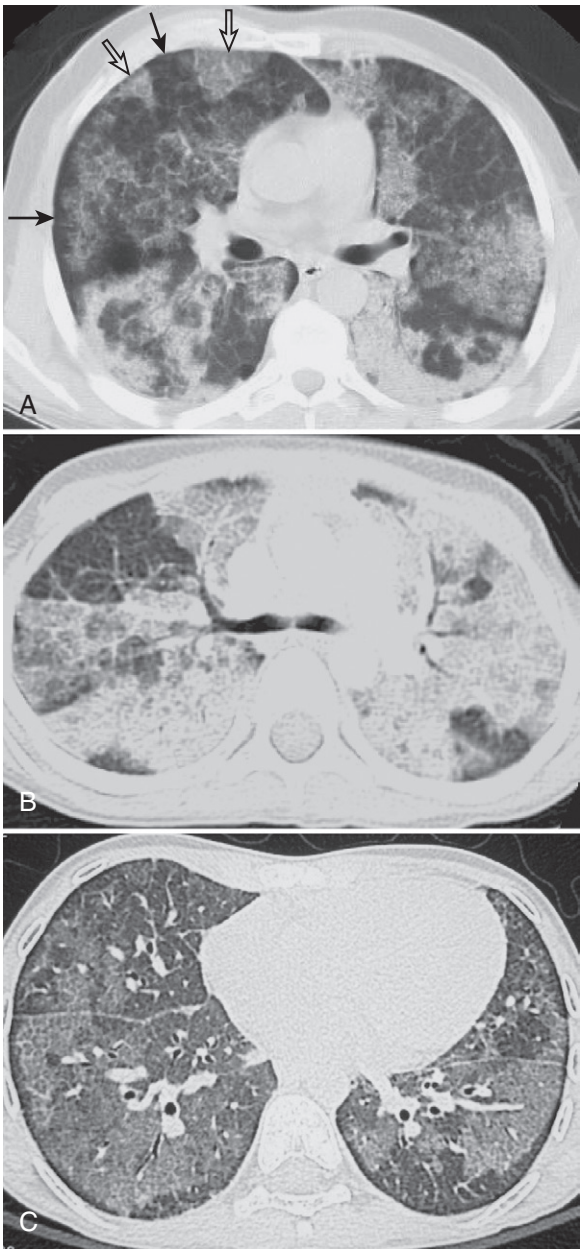

FIGURE 63-5 ■ Computed tomography of the chest illustrating differences in the radiographic appearance of the lungs in autoimmune PAP **(A),** familial GM-CSF receptor (alpha-chain) dysfunction **(B),** and secondary PAP in a child with lysinuric protein intolerance **(C).** Note the juxtaposition of highly abnormal secondary lobules (*open arrows*), adjacent to more normal-appearing secondary lobules (*solid arrows*). This is referred to as a "geographic" pattern and is common in autoimmune PAP, and also present in familial PAP due to GM-CSF receptor dysfunction. Infiltrates that are more homogeneous and less geographic are more common in secondary PAP **(C).**

Pulmonary Function Testing

The results of pulmonary function testing can be normal, but commonly show a restrictive ventilatory defect with mild impairment of the forced vital capacity and total lung capacity, and a disproportionate, severe reduction of the diffusing capacity for carbon monoxide.[2,3] Patients are typically mildly hypoxemic, with an elevated alveolar-arterial P_{O_2} difference and compensated respiratory alkalosis. The shunt fraction is elevated, compared to patients with other diffuse lung diseases.[106]

Bronchoscopy, Bronchoalveolar Lavage, and Transbronchial Biopsy

Bronchoscopic airway examination is typically unremarkable in PAP, and specimens are usually sent to assess the presence of infection or concomitant lung disease. In contrast, BAL specimens usually reveal characteristic gross, cytopathologic, and biochemical findings that are highly suggestive or diagnostic of PAP. In autoimmune, familial, and secondary clinical forms of PAP, the BAL fluid has a "milky" or "waxy" appearance, and upon standing forms sediment (Fig. 63-6). Cytologic examination of Papanicolaou-stained specimens reveal the BAL fluid to comprise granular, acellular, eosinophilic lipoproteinaceous material[107] and the sediment to contain fat globules. The most striking observation from a cytospin preparation or cell blocks of the BAL sediment is the gross appearance of the alveolar macrophage. These

FIGURE 63-6 ■ Gross appearance of the whole-lung lavage fluid from a patient with autoimmune PAP demonstrating the "milky" appearance and dense sediment (*right*) compared to normal saline (*left*). The lavage fluid was allowed to settle overnight in the refrigerator.

cells are enlarged and engorged with lipid material with a foamy, vacuolated appearance under light microscopy (Fig. 63-7). Electron microscopic examination of the sediment reveals the presence of tubular myelin, lamellar bodies, and fused membrane structures characteristic of pulmonary surfactant. The BAL cell differential in autoimmune PAP may be normal or reveal the presence of increased pulmonary lymphocytes composed of increased numbers of $CD4^+$ and $CD8^+$ cells.[108]

Biochemical analysis of BAL fluid reveals increased amounts of phospholipids and proteins, similar in composition to that of surfactant from healthy individuals.[109] Surfactant proteins are variably increased in the BAL fluid in PAP. This accumulated material in PAP has surface-active properties similar to those of normal pulmonary surfactant.

Surgical Lung Biopsy

Macroscopically, the cut surface of lung biopsy specimens in autoimmune and familial PAP reveals a geographic pattern of 2- to 3-cm grayish-yellow regions of firm consolidation that exudes fatty material. Microscopically, alveoli and terminal airways are filled with a fine eosinophilic material (Fig. 63-8) that stains strongly for

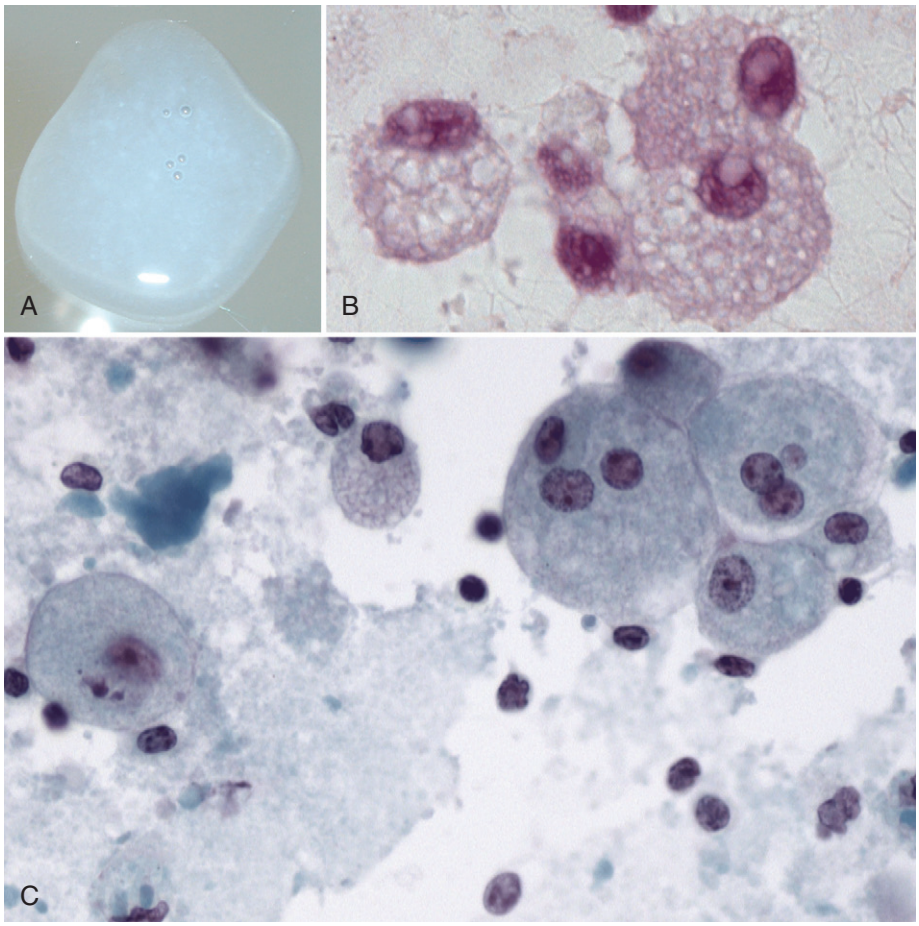

FIGURE 63-7 ■ Appearance of the sputum in autoimmune PAP. **A,** Gross appearance of freshly expectorated sputum from an afebrile patient. **B,** Sputum smear after staining with periodic acid–Schiff reagent. **C,** Sputum smear after staining with Papanicolaou reagent. Note the appearance of very large, foamy-appearing alveolar macrophages in **B** and **C**.

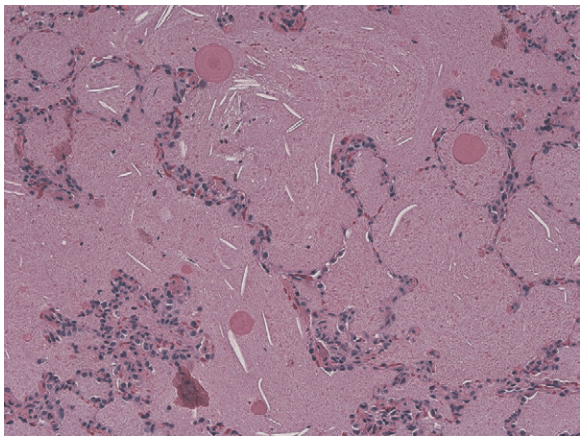

FIGURE 63-8 ■ Histopathologic appearance of the lung in autoimmune PAP. An open-lung biopsy was obtained from a patient with autoimmune PAP. The alveoli are completely filled with amorphous, acellular eosinophilic material contains cholesterol clefts and occasional eosinophilic bodies. The alveolar architecture is well preserved, and the alveolar walls are essentially unremarkable.

surfactant proteins (Fig. 63-9) with periodic acid–Schiff reagent (see Fig. 63-6). The alveolar wall and interstitial architecture are relatively well preserved, but lymphocyte infiltration and, occasionally, fibrosis can be seen. The vasculature appears normal. Electron microscopy, which is seldom necessary, reveals characteristic, concentrically laminated surfactant structures (lamellar body inclusions) within the granular material and in alveolar macrophages.[110]

Laboratory Studies

Routine laboratory studies are usually normal in PAP. Serum lactate dehydrogenase is typically elevated in proportion to lung disease severity, although this finding is nonspecific.[2,106] Serum levels of SP-A, SP-B, SP-D, C-reactive protein, and Krebs von den Lungen protein-6 (KL-6), a mucin-like protein secreted by alveolar epithelium, are increased in PAP and correlate with lung disease severity.[3,50,111] However, all of these biomarkers can be elevated in other lung diseases.[112,113] Thus, while not very helpful in establishing a diagnosis, these biomarkers may be useful in monitoring disease activity in patients with PAP.

In contrast to routine laboratory tests, several disease-specific biomarkers derived from clinical and basic research studies have emerged as useful tests for establishing the diagnosis of PAP as well as the clinical subtype. A high serum level of GM-CSF autoantibodies is helpful for establishing a diagnosis of autoimmune PAP, for which the sensitivity and specificity are reported to approach 100%.[114] Serum values above 3 μg/mL using a polyclonal standard,[1,51,54,114,115] or 0.5 μg/mL using a recently developed monoclonal standard,[116] are diagnostic of autoimmune PAP. Serial dilution is a useful but less well standardized method for titrating abnormal levels. The CD11b stimulation index is a measure of the ability of exogenous GM-CSF to bind to GM-CSF receptors on

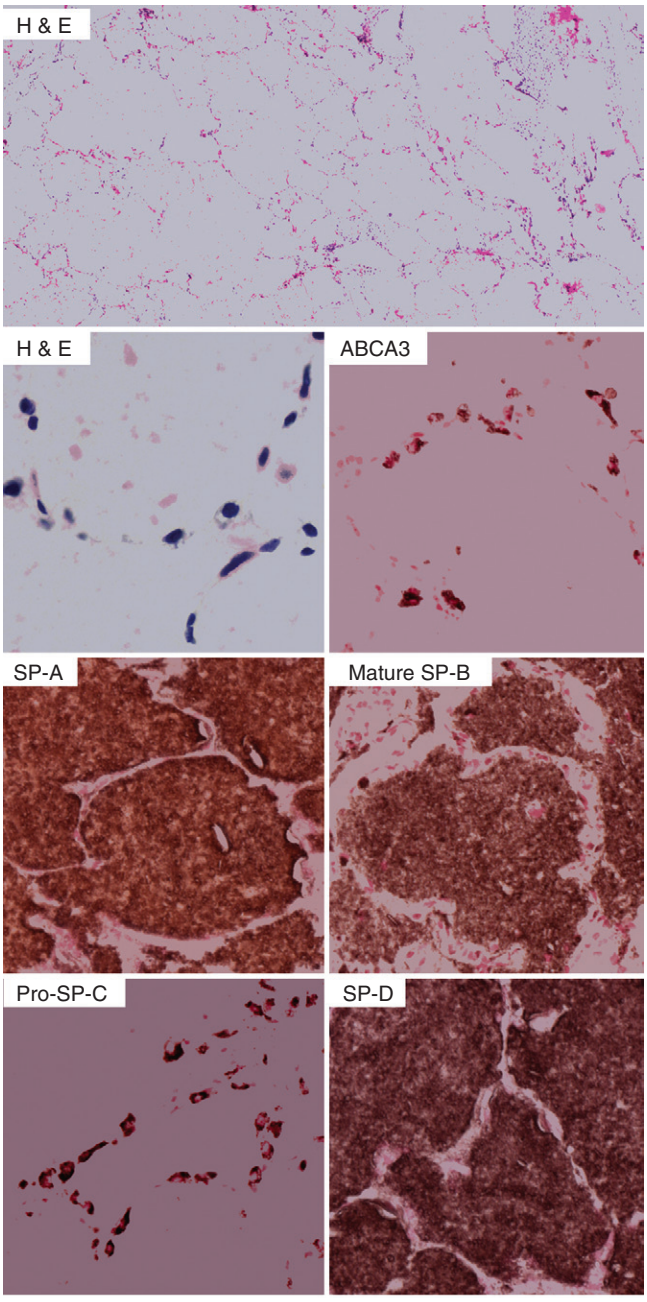

FIGURE 63-9 ■ Histopathologic appearance of the lung in familial PAP caused by function-altering mutations in the *CSF2RA* gene. An open-lung biopsy was obtained and stained with hematoxylin and eosin (H&E), or immunostained for ABCA3, SP-A, mature SP-B, pro–SP-C, or SP-D as indicated. Note the lymphocytosis in the low-powered H&E-stained section. (Data from Suzuki T, Sakagami T, Rubin BK, et al: Familial pulmonary alveolar proteinosis caused by mutations in *CSF2RA*. J Exp Med 205:2703–2710, 2008.)

neutrophils in fresh whole blood and increase the level of the cell surface CD11b.[51] In healthy individuals, the CD11b level rapidly increases at low concentrations of GM-CSF, whereas in patients with autoimmune PAP, the response is blunted or absent due to the presence of neutralizing GM-CSF autoantibodies. In familial PAP patients, who do not have GM-CSF autoantibodies, this test is also abnormal due to genetically impaired GM-CSF

receptor function.[47] In familial PAP, GM-CSF levels are elevated in serum and lung lavage, likely caused by the absence of receptor-mediated clearance.[47] These values range from 40 to 80 in serum and 400 to 1500 in lung lavage fluid.[47]

Approach to Diagnosis

The diagnosis of PAP should be suspected on the basis of a history of dyspnea of insidious onset with or without other symptoms and characteristic radiologic findings on high-resolution CT of the chest. Pulmonary function testing may be helpful if the disease is moderate or severe, but is normal in many patients.[3] In the context of these findings, a elevated serum GM-CSF autoantibody level is sufficient to establish the diagnosis of autoimmune PAP in previously healthy adult patients without other intercurrent illness or significant pulmonary exposures. Bronchoscopy with cytologic analysis of the BAL fluid is helpful and is further supported by transbronchial biopsy findings typical of PAP.[4,92] In many such cases, an open-lung biopsy is not necessary. However, if the diagnosis is still unclear or if secondary PAP is suspected, an open-lung biopsy may be needed. In such cases, it is important to rule out disorders that have radiologic, cytologic, or pathologic features similar to PAP.

In neonatal and pediatric cases of suspected disorders of surfactant homeostasis, it is important to establish if PAP or one of the PSMD disorders is present. The timing and severity of the presentation are helpful. Familial PAP can present between the ages of 1 and 11 years, while SP-B deficiency presents at birth, ABCA3 dysfunction presents over a wide range from neonates to adolescents, and SP-C dysfunction appears to present in children and adults. In familial PAP, the CD11b stimulation index and serum GM-CSF level will be abnormal. In the PSMD disorders, a lung biopsy is frequently needed. Genetic studies are generally a useful part of the workup of pediatric cases.

The diagnostic workup of individuals with disorders of surfactant homeostasis, including PAP and PSMD disorders, consists of routine clinical evaluations, a series of biomarker evaluations, and genetic tests capable of distinguishing among autoimmune PAP, secondary PAP, familial PAP caused by receptor dysfunction, and PSMD disorders (Fig. 63-10).

NATURAL HISTORY

The natural history of PAP has not been well studied. However, the clinical course of autoimmune PAP follows three distinct patterns: progressive deterioration, stable disease, or spontaneous resolution.[2] In Seymour and Presneill's comprehensive meta-analysis of PAP, the actuarial survival rates for 343 patients with acquired PAP were 78% ± 8% at 2 years, 75% ± 8% at 5 years, and 68% ± 9% at 10 years. More than 80% of the deaths attributable to PAP during a 5-year observation period occurred during the first 12 months after diagnosis. This study reported that, of the 69 deaths, death was caused by respiratory failure from PAP in 47 patients (72%), uncontrolled infection in 13 (20%), and unrelated causes in 5 cases (8%). A recent contemporaneous cohort of 223 autoimmune PAP patients reported no deaths over the 5-year period of the study, although it was not designed to report longitudinal results.[3]

Secondary Infections

Multiple studies have reported an unexpectedly increased incidence of secondary infections in patients with PAP.[2] Microbial pathogens include those commonly seen in community- and hospital-acquired infections but more commonly involve *Nocardia* spp. or opportunistic organisms.[2] However, such an increased risk of infections in PAP is controversial and supported by some[51] but not other[3,4] recent reports. GM-CSF–deficient mice also have increased mortality from infection and increased susceptibility to a wide variety of microbial pathogens, including bacteria, fungi, and mycobacteria. Further, myeloid cells from both patients with autoimmune PAP and GM-CSF–deficient mice have defects in innate immune functions, including phagocytosis, generation of reactive oxygen species, inflammatory signaling, and bacterial killing.[19,51,54,114,117] In both GM-CSF–deficient mice and PAP patients, infections can occur in the lungs and at extrathoracic locations, consistent with a systemic immune defect.

Pulmonary Fibrosis

Pulmonary fibrosis has been reported in association with PAP and has been reproduced in animal models of exposure to inhaled silica.[27,110] Further, exposure to oxygen or repeated whole-lung lavage have been suggested as potentially contributing to fibrosis. However, while not adequately studied, "end-stage lung disease" or irreversible scarring of the lung is rarely associated with PAP.

Spontaneous Resolution

Spontaneous improvement was reported to occur in cases of PAP in the initial description[36] and subsequent case series, although documentation is generally poor. In a comprehensive meta-analysis of 303 patients for whom adequate information was available, spontaneous improvement occurred in 24 (7.9%).

TREATMENT

Various therapeutic strategies have been proposed for PAP since its initial description (reviewed in the previous edition of this book). Whole-lung lavage emerged early, underwent multiple refinements to improve therapeutic efficiency, and has served as the standard therapy for nearly 5 decades. More recently, based on an understanding of the importance of GM-CSF in surfactant homeostasis and of neutralizing GM-CSF autoantibodies in the pathogenesis of the common form of PAP, new

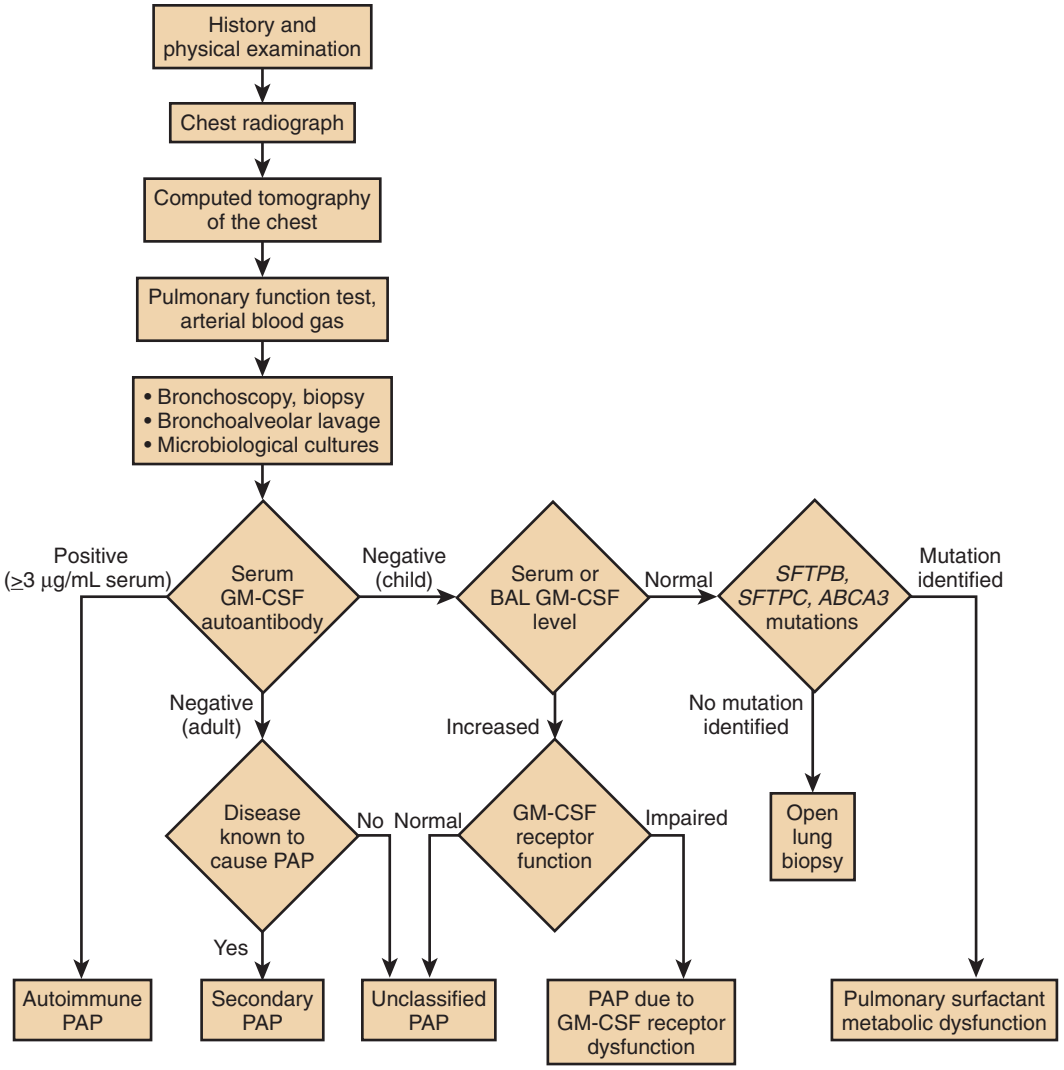

FIGURE 63-10 ■ Diagnostic algorithm for evaluation for individuals with PAP syndrome. In hereditary PAP caused by mutations in GM-CSF receptor genes *CSF2RA* or *CSF2RB,* further GM-CSF receptor function tests are needed to confirm and identify the specific nature of the defect. See text for details.

therapeutic strategies based on pathogenic mechanisms have emerged, including GM-CSF augmentation, plasmapheresis, and anti–B lymphocyte therapy.

Autoimmune PAP

Whole-Lung Lavage

Originally developed by Ramirez in the early 1960s, currently, whole-lung lavage is a procedure performed under general anesthesia in which large volumes (up to 50 L) of saline are infused into each lung to physically "wash out" the accumulated surfactant lipids and proteins while mechanical ventilation is provided to the other lung.[118–120] A number of procedural variations have been introduced, including the use of mechanical chest percussion, prone positioning, variation in the volume of infusate, and use of a hyperbaric chamber. Despite changes, whole-lung lavage has not been standardized with respect to the method (i.e., volume infused, use of mechanical percussion, the end point of an individual lavage procedure), indications for its use, methods for evaluating the treatment effectiveness, or timing of repeated procedures. The end point used clinically for terminating lung lavage in the operating room is a improvement in visual clearing of the lavage effluent. No studies have systematically evaluated the procedure, its utilization in clinical practice, or the efficacy or durability of clinical responses. Notwithstanding, it is widely held among practitioners to improve symptoms, radiographic findings, and gas exchange in PAP patients.[121,122]

Although safe in the vast majority of individuals, complications can include hypoxemia, pneumonia, sepsis, hydropneumothorax, and acute respiratory distress syndrome. The procedure is not performed in a patient with an active bacterial lung infection, since this can result in sepsis and shock. Bronchoscopic segmental or lobar lavage has been proposed as a safe alternative in patients in whom whole-lung lavage under general anesthesia is considered risky due to severe hypoxemia.[123]

TABLE 63-5. Therapeutic Response to Whole-Lung Lavage Therapy of Adults with PAP

Parameter	*n*	Mean Change ± SD	95% CI of the Mean	*P* Value*
Arterial P_{O_2} (mm Hg)	41	20.1 ± 14.3	15.6 to 24.6	<0.0001
(A − a)P_{O_2} (mm Hg)	21	−30.6 ± 18.0	−38.8 to −22.4	<0.0001
FEV_1 (L)	33	0.26 ± 0.47	0.09 to 0.42	<0.0034
VC (L)	40	0.50 ± 0.54	0.33 to 0.67	<0.0001
$D_{L_{CO}}$ (mL/mm Hg per minute)	25	4.4 ± 4.5	2.6 to 6.3	<0.0001

*Value is for the comparison of paired postlavage to prelavage data for individual patients for each parameter for only those patients with available data using a two-sample *t*-test.
(A − a)P_{O_2}, alveolar-arterial difference in oxygen tension; CI, confidence interval; $D_{L_{CO}}$, diffusing capacity of carbon monoxide; FEV_1, forced expiratory volume in 1 second; PAP, pulmonary alveolar proteinosis; VC, vital capacity.
From Seymour JF, Presneill JJ: Pulmonary alveolar proteinosis: progress in the first 44 years. Am J Respir Crit Care Med 166:215–235, 2002.

Other alternatives include performance in a hyperbaric chamber,[124] and use of complete cardiopulmonary bypass.[125]

A comprehensive literature review identified 231 individuals for whom sufficient whole-lung lavage data were available, and reported that lavage was associated with increased overall 5-year survival (94 ± 2% with lavage [n = 146] versus 85 ± 5% without lavage [n = 85]; P = 0.04).[2] This study also reported that the median number of whole-lung lavage procedures performed was two, and that 70% of patients underwent the procedure within 5 years of diagnosis. Among 55 individuals undergoing the procedure, the median duration of benefit was 15 months, and only 20% of patients remained free of recurrence at 3 years. Among 41 patients with adequate available data, arterial P_{O_2} improved by 20.1 mm Hg after whole-lung lavage (Table 63-5). The improvement in other pulmonary function test parameters was less impressive. More than 95% of patients respond to whole-lung lavage; however, a small fraction of patients did not respond despite aggressive lavage. Treatment-related improvement results from the physical removal of the accumulated surfactant and can occur within hours of completion of therapy.

In practice, the indications for whole-lung lavage therapy include dyspnea, exercise intolerance, and a desire to reduce the requirement for supplemental oxygen therapy. Reasonable indications for performing the procedure may include dyspnea limiting activities of daily living, arterial P_{O_2} less than 60 mm Hg while breathing room air, and a shunt fraction greater than 10% to 12%.

Granulocyte-Macrophage Colony-Stimulating Factor

Successful GM-CSF therapy of PAP was first demonstrated in a single patient in 1995.[40] GM-CSF was administered in subcutaneous daily doses of up to 6 μg/kg/day and resulted in reduction of the alveolar-arterial oxygen gradient and improved exercise tolerance within 35 days. Relapse occurred on discontinuance, but the treatment effects were restored on reinstitution of therapy. An international, multicenter follow-up study in 14 autoimmune PAP patients who received GM-CSF by subcutaneous injection in escalating doses (5 to 20 μg/kg/day) over a 3-month period reported an overall response rate of 43%.[126] A subsequent study in 21 autoimmune PAP patients receiving GM-CSF by subcutaneous administration in escalating doses (5 to 18 μg/kg/day) for 6 to 12 months reported an overall response rate of 48% as defined by a 10 mm Hg or greater improvement in room air arterial P_{O_2}.[127] Several single cases of subcutaneous GM-CSF therapy of PAP have reported similar findings. In aggregate, these results indicate that (1) subcutaneous GM-CSF therapy of autoimmune PAP results in objective improvement in about 50% of patients, (2) the therapeutic response is variable among patients, (3) the therapeutic response depends on the dose and duration of treatment, and (4) a lag of about 8 weeks occurs before a therapeutic response is seen. Although controversial, some but not all studies have reported that GM-CSF therapy is associated with a fall in the GM-CSF autoantibody level.

Several case reports and a recently completed larger study have evaluated aerosolized GM-CSF therapy of autoimmune PAP.[128] These studies have evaluated daily inhaled doses of GM-CSF ranging from 125 to 500 μg per patient per day. One recently completed study in 35 autoimmune PAP patients evaluated aerosolized GM-CSF given as induction therapy (250 μg on days 1 to 8 of 14, ×6 cycles) followed by maintenance therapy (125 μg on days 1 to 4 of 14, ×6 cycles). This study excluded patients who improved spontaneously during an initial observation period and thus only evaluated patients with unremitting/progressive disease. The overall response rate was 69%. Results suggested a somewhat higher clinical response rate for aerosol compared to subcutaneous GM-CSF administration. Further, while both routes appeared to be safe, local site reactions and other minor problems occurred in 85% of patients receiving subcutaneous GM-CSF, while no treatment-related side effects have been noted with inhaled GM-CSF.

Other Approaches

Other therapeutic strategies that have been tried in a few patients include plasmapheresis and B-lymphocyte depletion, both of which target the reduction in the level of GM-CSF autoantibodies. No conclusions can yet be drawn about the utility of such theoretically attractive

clinical therapeutic strategies. Lung transplantation has been performed successfully in a 41-year-old patient with PAP (probably autoimmune PAP), but the disease recurred 3 years later.[129]

Familial PAP

Whole-lung lavage and bone marrow transplantation have both been used successfully in familial PAP caused by *CSF2RA* mutations. Further work is needed to determine the safety of the latter, theoretically attractive approach.

Secondary PAP

Secondary PAP, in some cases caused by hematologic disorders, can resolve with resolution of the underlying disorder. Nonresolving secondary PAP can be effectively treated with whole-lung lavage. However, this has not been well studied.

Surfactant Metabolic Dysfunction Disorders

Therapy of these disorders depends on the disease and presentation; care is generally supportive and includes assessment of need for supplemental oxygen and nutritional support. In very young children, whole-lung lavage is extremely challenging and of uncertain efficacy, and an adapted technical approach to airway management is required during lavage.[130] Neonates may show transient improvement with exogenous surfactant administration. Lung transplantation is particularly considered in cases of SP-B deficiency and in severe and progressive disease from *ABCA3* mutations.

GAPS IN KNOWLEDGE AND FUTURE DIRECTIONS

Etiology

While our knowledge of the pathogenesis of the common form of PAP has improved substantially, its etiology remains obscure. Further, while it has been established that GM-CSF, via PU.1, is critical for surfactant homeostasis in humans and that GM-CSF autoantibodies mediate the pathogenesis of autoimmune PAP, the precise mechanism by which loss of GM-CSF signaling reduces surfactant catabolism in alveolar macrophages is not clear. Finally, the immunopathology of autoimmune PAP, while of particular interest, is largely unexplored.

In contrast, secondary PAP is less well studied in terms of pathogenesis, but in some cases, the etiology (i.e., loss of alveolar macrophages in hematologic disorders and after chemotherapy) is more clear. The extreme rarity of this disorder makes its study difficult.

The etiology of familial PAP is clear (i.e., genetic mutations in *CSFR2A*). However, the pathogenesis beyond the loss of GM-CSF signaling is unclear.

Surfactant metabolic dysfunction disorders are clear with respect to etiology, and continue to provide important information regarding surfactant production and processing.

Clinical Practice Guidelines

There are no standardized clinical practice guidelines for pulmonary alveolar proteinosis. While whole-lung lavage has been in use for nearly 5 decades, no studies have prospectively evaluated the indications for, timing of, or methods to monitor outcomes of the procedure. Nor has the procedure itself been standardized with respect to volume of infusate, use of mechanical percussion, hyperbaric oxygen, position or repositioning of the patient during the procedure, or objective methods for terminating the procedure. The Rare Lung Diseases Consortium has recently assembled a task force to address this unmet need and is developing a clinical consensus document.

Novel Therapeutic Approaches

Results of clinical trials show that inhaled GM-CSF in patients with autoimmune PAP is safe and effective. Current results show that the treatment effect is dependent on the dose and duration of therapy. However, existing results have not defined the optimal dose, timing, or duration of administration, which could potentially improve the current response rate. The mechanism of the therapeutic effect is also unclear with respect to lowering GM-CSF autoantibody levels. Further research is needed to evaluate other therapies, including plasmapheresis, anti–B lymphocyte therapy, and combination therapies. Examples of the latter include combining whole-lung lavage with aerosolized GM-CSF to reduce time to clearing and combining plasmapheresis and anti–B lymphocyte therapy to deplete GM-CSF autoantibodies.

Conclusion

PAP is a rare syndrome characterized by the accumulation of surfactant in the lungs and a variable clinical course ranging from respiratory failure to spontaneous improvement. It occurs in association with various disorders, but 90% of cases are caused by the presence of increased levels of neutralizing autoantibodies that block GM-CSF signaling to myeloid cells in vivo. The name of this common clinical form of PAP has been recommended to be changed to “autoimmune” in recognition of the new understanding of its pathogenesis. A new genetic disease, familial PAP, has been identified and has implicated GM-CSF as critical regulator of human surfactant homeostasis. A number of biomarkers have been developed to diagnose and manage individuals with various clinical forms of PAP. Current therapy with whole-lung lavage is effective in most patients with autoimmune and familial PAP. GM-CSF treatment of autoimmune PAP shows promise as safe and effective therapy, yet further clinical trials are needed to optimize the therapy.

KEY POINTS

- PAP is a rare syndrome with a prevalence of 6 to 7 per million in the general population that occurs in men, women, and children and in all ethnic backgrounds.
- Ninety percent of cases of PAP occur in individuals with high levels of GM-CSF autoantibodies, which eliminate GM-CSF bioactivity and presumably impair surfactant catabolism by alveolar macrophages. Nine percent to 10% of cases occur in individuals with an underlying disease associated with PAP that is presumed to impair surfactant catabolism in resident alveolar macrophages by reducing their number or functions.
- New diagnostic biomarkers are helpful in the differential diagnosis of clinical subtypes of PAP and pulmonary surfactant metabolic dysfunction disorders.
- Inhaled recombinant GM-CSF is a promising new pharmacologic approach that appears to be effective in individuals with autoimmune PAP.

IRRITANT-INDUCED ASTHMA AND REACTIVE AIRWAY DYSFUNCTION SYNDROME

INTRODUCTION

Asthma affects 5% to 10% of people and about 10% of these individuals report that their symptoms are worse when they are at work and improve when they are away from work.[1] In addition, asthma in the workplace can provide important information on certain aspects of asthma, including physiopathology, diagnosis, and management.[2] Occupational asthma (OA) has the elements of an experiment, in which at-risk individuals can be examined before exposure starts and serially thereafter, during and after cessation of exposure. For example, apprentices starting work with exposure to high-[3,4] and low-molecular-weight[5] agents have been studied before and after their apprenticeship periods and, more recently, after several years in a working environment where they are either still or no longer exposed to the sensitizing agents.[6] It is also possible to examine workers with confirmed OA after they stop being exposed to see whether the asthma persists or is cured.[7] For instance, bronchial biopsies have recently been obtained and examined in workers with OA who were apparently cured.[8] This study showed that airway inflammation and remodeling were still present on average 14 years after exposure had stopped, which is instructive to our understanding of other forms of asthma.[9] OA can be reproduced by using specific inhalation challenges, which give information on late asthmatic reactions, a concept introduced by Professor Jack Pepys, who has been called the father of OA.[10]

DEFINITION AND CLASSIFICATION

Asthma in the workplace includes several types of asthmatic conditions (Fig. 64-1). This first includes OA or asthma caused by the workplace. In a recent re-edition of a textbook on *Asthma in the Workplace*, OA was defined as: "a disease characterized by variable airflow limitation and/or hyperresponsiveness and/or inflammation due to causes and conditions attributable to a particular occupational environment and not to stimuli encountered outside the workplace." Two types of OA are distinguished by their appearance following a latency period:

1. After a latency period (allergic): This category is characterized by work-related asthma appearing after a latency period and encompasses: (a) OA caused by most high- and certain low-molecular-weight agents for which an allergic (IgE-mediated) mechanism has been proved; and (b) OA induced by specific occupational agents (e.g., Western red

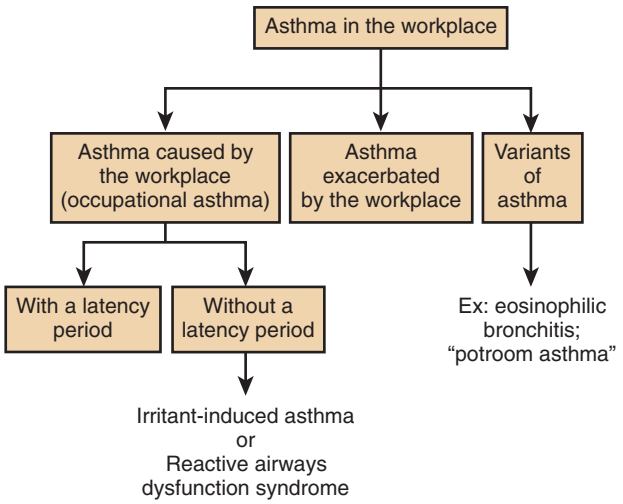

FIGURE 64-1 ■ Asthma in the workplace.

cedar) but the allergic mechanisms responsible have not yet been fully characterized.

2. Without a latency period (nonallergic): This category includes irritant-induced asthma or reactive airway dysfunction syndrome (RADS), which may occur after a single or multiple exposures to nonspecific irritants at high concentrations.[11]

OA, therefore, shares all functional and inflammatory features of common asthma. The first type of OA that occurs after a latency period is initiated in adult life and is caused solely by the workplace where, generally, a specific agent can be identified in its etiology. The other type of OA is rarer and is related to one (generally) or more inhalational accidents clearly identified by the worker at the workplace.

Besides OA, the majority of cases of asthma in the workplace are represented by asthmatic subjects who report that their symptoms are aggravated by exposure to the workplace. Little is known about this condition. Criteria for identification have been proposed by the Sentinel Event Notification System for Occupational Risks (SENSOR) project sponsored by the National Institute of Occupational Safety and Health (NIOSH).[12] These include (1) a physician's diagnosis of asthma; (2) an association between symptoms and work; (3) the onset of asthma symptoms or treatment within a period of 2 years before entering a new occupation; (4) increase in asthma symptoms or treatment upon entering a new occupation. As it is, this condition is mainly diagnosed through exclusion; that is, after excluding OA in a subject with asthma, the symptoms and the need for medication increase at work. This condition encompasses a socioeconomic burden that is equivalent to OA.[13] Indeed, even following confirmation that a worker does not suffer from OA, many frequently leave their workplace. Lemière and coworkers[14] have shown that the investigation of these subjects is more likely to show an increase in sputum neutrophils while at work, whereas, in the case of OA, there is an increase in eosinophils. Also, these subjects experience more important changes in peak expiratory flows (PEFs) while at work than what is found in well-controlled non–work-aggravated asthma, though of lesser magnitude than what is found in OA.[15]

There are variants of asthma in the workplace. Potroom asthma is an asthma-like condition that occurs in aluminum potroom workers, the cause being unknown. In recent years, many cases of occupational eosinophilic bronchitis have been described.[16] Workers affected by this condition principally report coughing. Airway responsiveness is normal. The only abnormality is the increase in eosinophils in induced sputum.

TABLE 64-1. Important Dates in the History of Asthma in the Workplace

Date	Event and Contributor
16th century	Olaus Magnus (Scandinavia) and Bernardino Ramazzini (Italy) first describe OA.
19th century	Thackrah in England and Patissier in France publish a more detailed account of OA.
First half of the 20th century	Castor beans, various gums, metal salts, and anhydrides incriminated as causes of OA.
1951	Fuchs and Valade identify isocyanates as a cause of OA.
1970s	Epidemics of OA due to enzymes in detergent workers.
	Development of specific inhalation challenges by Pepys.
1977	OA can cause permanent impairment even after removal from exposure, as shown by Chan-Yeung.
1979	Peak expiratory flows as a diagnostic tool proposed by Burge.
1985	Reactive airway dysfunction syndrome labeled by Brooks, Weiss, and Bernstein.
1990s	Epidemics of OA due to latex.
	Development of tools and scales to assess permanent impairment.
End of 20th century	Monitoring of airway inflammation as a diagnostic tool.

OA, occupational asthma.

HISTORICAL ASPECTS

Some of the important dates in the history of asthma and the workplace are listed in Table 64-1. In the 16th century, the Scandinavian physician Olaus Magnus and the Italian Bernardino Ramazzini first described difficult breathing occurring in grain handlers.[17] In the 19th century, Thackrah in England and Patissier in France described the occurrence of chronic bronchitis in workers exposed to malt, coffee, and flax. Castor beans, various gums (acacia, tragacanth), metal salts, and anhydrides were the first occupational sensitizing agents clearly identified in causing asthma in reports made in the beginning of the 20th century.[17] Diisocyanates, a still important cause of OA, were incriminated in 1951.[18]

Although the condition of irritant-induced asthma had been recognized a long time before as reviewed,[19] it was in 1985 that the label "reactive airway dysfunction syndrome" was first proposed.[20] The epidemics of OA due to enzymes incorporated in soaps in the 1970s[21] and due to the latex in gloves used by health professionals[22] have clearly demonstrated that the degree of exposure plays a key role and that the control of exposure can result in rapid diminution of sensitization and disease.

Various objective diagnostic means have been developed over recent years. Professor Pepys[23] proposed an experimental type of simulated exposure to agents suspected to cause OA. Monitoring of PEFs for periods at work and away from work were later proposed by Burge and colleagues.[24] More recently, monitoring of airway inflammation through induced sputum and exhaled nitric oxide has started being used.[25] Its usefulness in the diagnosis of OA is being evaluated at present. Although objective means are available and guidelines have been proposed,[26] it is known that the diagnosis is still principally based on clinical history,[27,28] which has a higher sensitivity than specificity.[29]

Chan-Yeung[30] was the first to show that workers with OA are often left with permanent asthma in 1970s, a relatively new concept because it was thought that removal from exposure would lead to a cure. Tools and scales to assess impairment were proposed in the 1990s.[31]

ETIOLOGIC AGENTS

OA can be caused by proteinaceous, high-molecular-weight, or chemical, low-molecular-weight agents. There are differences in the mechanisms, clinical manifestations, and means of diagnosis between these two classes of agents (Table 64-2). There are over 250 reported workplace sensitizers and there are many workplaces with such sensitizers. It is difficult for a physician to know all possible exposures that a patient could have. Fortunately, several websites—http://www.asmanet.com; http://www.csst.qc.ca; http://hazmap:nlm.nih.gov/; and http://toxnet.nlm.nih.gov/—and the appendix in the textbook *Asthma in the Workplace* contain up-to-date information on sensitizers and irritants causing asthma in the workplace.[32]

GENETIC, PHYSIOPATHOLOGIC ASPECTS, AND ANIMAL MODELS

Genetics

Because not all individuals exposed to the same levels of sensitizers develop asthma, host susceptibility factors are important, although little is known about this. Human leukocyte antigen (HLA) class II antigens (DR, DQ, DP) play a key role in antigen presentation to T lymphocytes and influence the specificity. They are also highly polymorphic. Their role has been examined in the development of OA due to a number of agents: high-molecular-weight allergens such as laboratory animals and low-molecular-weight compounds such as platinum salts, acid anhydride, diisocyanates, and plicatic acid as shown in Table 64-3. Some of the HLA class II antigens are associated with susceptibility whereas others are associated with protection.[33-39] It should be noted that in most occupational studies, the sample size is small and the magnitude of association illustrated by the odds ratio (OR) is low, suggesting that they are not major genetic determinants. However, HLA associations provide evidence of a specific immunologic response in asthma caused by low-molecular-weight sensitizers.

Many occupational agents such as welding fumes and ozone cause oxidative stress. However, even occupational sensitizers such as diisocyanates also cause oxidative stress by inducing monocytes to produce reactive oxygen species.[40] The presence of the GSTP1Val/Val genotype was found to confer protection against both

TABLE 64-2. Characteristics of High- and Low-Molecular-Weight Agents as a Cause of Occupational Asthma

	High-Molecular-Weight Agents	Low-Molecular-Weight Agents
Structure	Proteins, polysaccharides	Chemicals, metals
Duration of the latency period before receiving "sensitization"	Generally longer (e.g., flour)	Generally shorter (e.g., isocyanates)
Oculonasal symptoms	+++	+
Accompanying dermatitis	Rare	Possible
Immunologic mechanism	IgE-dependent	Generally not IgE-dependent. IgG, MCP-1 (isocyanates)
Cellular component	Eosinophils	Eosinophils and neutrophils
Feasibility of skin testing to elicit immediate reactions	Yes	No
Type of asthmatic reaction after challenge	Immediate, dual	Isolated late or atypical
Frequency of referral	One third	Two thirds
Diagnostic means	Numerous	More limited

Ig, immunoglobulin; MCP, macrophage chemotactic protein.

TABLE 64-3. HLA Antigen and Occupational Asthma from Selected Studies

Exposure	HLA Antigen	Cases	Controls	OR (95% CI)	Reference No.
Laboratory animal allergy					
Sensitization	HLA-DR7			1.82 (1.12–2.97)	33
	HLA-DR3			0.55 (0.31–0.97)	
Work-related chest symptoms	HLA-DR7			2.96 (1.64–5.37)	
	HLA-DR3			0.71 (0.35–1.45)	
Sensitization and work-related chest symptoms	HLA-DR7			3.81 (1.90–7.65)	
	HLA-DR3			0.57 (0.24–1.32)	
Complex platinum salts					34
All	HLA-DR3	18 (41)	15 (26)	2.3 (1.0–5.6)	
Low exposure		6 (55)	4 (22)	Infinite	
High exposure		12 (36)	11 (28)	1.6 (0.6–4.1)	
All	HLA-DR6	16 (36)	34 (60)	0.4 (0.2–0.8)	
Low exposure		2 (18)	12 (67)	0.1 (0.02–1.1)	
High exposure		14 (42)	22 (56)	0.5 (0.2–1.3)	
Acid anhydride					
Trimellitic anhydride	HLA-DR3	8/11	2/14		35
Phthalic anhydride		2/12	2/14		
Tetrachlorophthalic anhydride		5/7	0/0		
Total		15/30 (50)	4/28 (14)	16 $P < .05$

asthma and nonspecific bronchial hyperresponsiveness induced by diisocyanates.[41] Another study found that the *N*-acetyltransferase slow acetyl genotype posed an eight-fold risk of toluene diisocyanate (TDI) asthma.[42]

A more recent study investigated the relationship between polymorphisms of interleukin-4 receptor antagonist (IL-4Ra), CD-14, and IL-13 in 62 inhalation-positive patients using 75 inhalation challenge–negative patients as controls. Among individuals exposed to hexamethylene diisocyanate, those with IL-4Ra II were at increased risk for asthma (OR 3.29, 95%, confidence interval [CI] 1.33–8.14). However, the combination of IL-4-Ra II and IL-13-receptor (IL-13RR) or IL-4Ra II and CD 14 CT genotypes as well as the triple combination of IL-4Ra II, IL-13RR, and CD 4 CT genotypes further increased the risk.[43]

Physiopathology

Occupational Asthma with a Latency Period

Irrespective of the etiology, the pathology in the airways of subjects with OA with latency is similar to what is found in non-OA. There is extensive epithelial desquamation associated with epithelial cell ciliary abnormalities, smooth muscle hyperplasia, presence of airway inflammation with increased numbers of total inflammatory cells, eosinophils, and lymphocytes in the airways of these subjects and presence of airway remodeling with subepithelial fibrosis.[44] Removal from exposure for a period ranging from 5 to 21 months in subjects with diisocyanate-induced asthma was associated with a reduction in subepithelial fibrosis, but also with persistence of inflammatory cell infiltration of the airways.[45] It

has recently been shown that airway eosinophilic inflammation and remodeling persist 10 years or more after cessation of exposure in subjects apparently cured, that is, without symptoms and with normal airway caliber and responsiveness.[8]

Immunologic, Immunoglobulin E–Mediated. High-molecular-weight agents, such as animal proteins and flour, act as complete antigens and induce the production of specific immunoglobulin E (IgE) antibodies. Certain low-molecular-weight occupational agents, such as platinum salts, trimellitic anhydride, and other acid anhydrides, also induce specific IgE antibodies by acting as haptens and binding with proteins to form functional antigens. As with common allergens, the inhaled occupational sensitizer binds to specific IgE antibodies on the surface of mast cells, basophils, and possibly macrophages and eosinophils, leading to a cascade of events that results in an influx of inflammatory cells into the airways as well as the release of inflammatory mediators. Clinically, an inhalational challenge with these agents in sensitized individuals leads to one of the following types of reactions: isolated early reaction (an asthmatic reaction that occurs in the first hour and that is maximum 10 to 20 minutes after end of exposure), isolated late (an asthmatic reaction that occurs 4 to 8 hours after ending exposure), biphasic reaction (combination of an early and a late reactions), or atypical (other patterns) reactions.

Immunologic, Non–Immunoglobulin E–Mediated. Many low-molecular-weight chemicals, including diisocyanates and plicatic acid, cause OA but do not induce specific IgE antibodies. In patients with Western red cedar asthma, specific IgE antibodies were found in only 20%.[46] These antibodies may reflect only prior red cedar exposure because they do not passively sensitize human lung fragments.[47] Specific IgE antibodies to TDI have been reported in 0% to 50% of workers with TDI-induced asthma.[48] This variation has been attributed to several reasons: the short half-life of the specific IgE antibodies to TDI of about 2 days,[49] the appearance of new antigenic determinants after the binding of specific IgE to TDI-human conjugate,[50] and the different methods of conjugation as well as the measurement of specific IgE antibodies. A conjugate of TDI vapor–exposed albumin was found to detect specific IgE antibodies in 40% to 50% of TDI-induced asthma, much higher than the conjugate prepared from the liquid phase of isocyanate.[51] The inability to detect specific IgE antibodies to such low-molecular-weight compounds as plicatic acid or diisocyanates may be due to the use of the wrong carrier protein, human serum albumin, which is the protein often used. Keratin in the lungs and skin was found to conjugate with hexamethylene diisocyanate through in vitro (human epithelial cell line) and in vivo (endobronchial biopsy samples) exposure.[52] The role of these proteins in the pathogenesis of diisocyanate-induced asthma needs to be assessed. Specific IgG antibodies are also demonstrated in diisocyanate-induced asthma.[53,54] Although they are sensitive in the diagnosis of TDI-induced asthma, their specificity is poor and their pathogenic significance unclear.

The characteristics of the inflammatory process in diisocyanate-induced asthma and Western red cedar asthma are similar to those of an IgE-dependent reaction. In both types of OA, evidence of cell-mediated immunity has been provided by bronchoalveolar lavage (BAL), bronchial biopsy, and induced sputum studies because the T lymphocytes showed markers of activation.[44,55] In isocyanate-induced asthma, an increase in $CD8^+$ cells and eosinophils was found in the peripheral blood of subjects during a late asthmatic reaction induced by challenge with the agent.[56] One study found that the majority of T cells from bronchial biopsies of these subjects exhibited the CD8 phenotype and produced interferon-γ (IFN-γ) and IL-5 with very few clones producing IL-4, suggesting that CD8 cells play a central role in OA without the production of IgE antibodies.[57] There is considerable controversy as to whether diisocyanate-induced asthma is due to a non-IgE or an IgE mechanism.[48] In a recent study, bronchial biopsies of patients with diisocyanate-induced asthma showed absence of both bronchial C-epsilon and IL-4 RNA message, which should be present if an IgE-mediated reaction had taken place, after an inhalation challenge with diisocyanate irrespective of the test response, suggesting that this is a non–IgE-mediated disease.[58]

The role of neutrophils in OA is unclear but could be important. Neutrophils are increased in the BAL fluid during the late asthmatic reaction,[59] and they are found when individuals with diisocyanate-induced asthma are exposed to a very low dose of TDI, levels much lower than would induce an asthmatic reaction.[60] In non-OA, the presence of neutrophils in the airways usually indicates severity of asthma in the absence of infection.[61] This could be due to oxidative stress with formation of reactive oxygen species arising from persistent airway inflammation.[62]

The sensitizing compound, when present in high levels, may also act as an irritant. Diisocyanates, for example, have been shown to stimulate sensory nerves to release substance P and other neuropeptides and inhibit the neutral endopeptidases that normally inactivate these substances.[63] Neuropeptides affect a variety of cells in the airways, resulting in cough, smooth muscle contraction, and mucus production.[64] These sensitizing chemicals may also have pharmacologic effects. High concentrations of plicatic acid have been shown to activate the classic complement pathway,[65] with generation of chemotactic factors leading to inflammatory response in the airways. The working environment is complex and workers are often exposed to multiple substances in the workplace. It is very likely that the airway inflammation found in patients with OA is the result of different mechanisms of exposure to an offending agent or to different substances.

Occupational Asthma without a Latency Period

Irritant-induced asthma is an example of nonimmunologically induced asthma or OA without latency. Subjects with RADS showed denudation of the mucosa and

fibrinohemorrhagic exudate in the submucosa,[66] followed by regeneration of the epithelium with proliferation of basal and parabasal cells, subepithelial edema, and marked thickening of the airway wall.[67] The underlying mechanism of irritant-induced asthma is not known, but in an animal model, extensive denudation of the epithelium[68,69] may result in airway inflammation because of a loss of epithelium-derived relaxing factors. Exposure of the nerve endings leads to neurogenic inflammation and nonspecific activation of mast cells with release of inflammatory mediators and cytokines. Epithelial damage, a key feature of the acute phase of the process, may also result in the marked airway remodeling that is probably responsible for the reduced reversibility of airflow obstruction in patients with RADS.[67]

Role of Irritant Exposure in Sensitization

There is increasing evidence that exposure to low levels of irritants may enhance specific sensitization to occupational agents. Combined ozone and platinum salt exposure significantly increased specific (platinum) and nonspecific bronchial hyperresponsiveness more often than did exposure to either ozone or the platinum salt alone.[70] The airway inflammation, epithelial damage, and modification of cellular tight junctions from ozone exposure lead to greater penetration of platinum salt into the subepithelial tissue and, thus, enhance the inflammatory response to platinum salt exposure.

Because, in many industries, exposure to low levels of irritant gases commonly occurs simultaneously with exposure to specific asthmagens, there greater emphasis should be put on reducing exposure to these gases as well as to the specific agents.

Animal Models

In OA, animal models are used: (1) to investigate exposure determinants, such as the route of exposure, respiratory or dermal, the dose, and the exposure duration and frequency; (2) to determine the role played by the immune system in order to reproduce the disease phenotype and to determine its pathogenesis; (3) to study potential interactions between allergens and pollutants; and (4) to identify novel agents or new modalities for treatment.

Occupational Asthma with a Latency Period

Table 64-4 shows some of the selected animal models of asthma due to occupational agents.[71–79] Some are high-molecular-weight allergens whereas others are low-molecular-weight compounds. All of them induce asthma with latency to indicate that some forms of immunologic mechanisms are involved. Interested readers should consult two recent reviews on animal models, one for protein respiratory sensitizers[80] and the other for low-molecular-weight chemicals.[81]

TABLE 64-4. Animal Models of Occupational Asthma

Agent—Purpose	Species	Exposure	Elicitation	Parameter Evaluated	Reference No.
HMW ALLERGENS					
Bacillus subtilis—to establish threshold limit value	Guinea pigs	Inhalation	Inhalation	Respiratory response—rapid shallow breathing	71
New enzyme protein in detergent industry	Guinea pigs	Intratracheal	Blood	Amount of antibodies produced	72
Latex—to identify the most active immunogenic fraction	Guinea pigs	Injection	Blood	PCA, passive systemic anaphylaxis	73
Latex—HEV b5	Mice	Intraperitoneal	Blood Lung lavage	Specific antibodies; IL-5 in lavage fluid	74
LMW COMPOUNDS					
Diisocyanate—to establish a model of TDI asthma	Guinea pigs	Inhalation—vapors	SIC with TDI-GPSA	Changes in pulmonary function	75
Diisocyanate—to determine the role of dermal exposure in TDI asthma	Guinea pigs	A single epicutaneous injection	SIC with TDI	Changes in pulmonary function Antibodies in blood	76
Diisocyanate—to study role of $CD4^+$ and $CD8^+$ T lymphocytes in TDI asthma	Mouse: Deficient in $CD4^+$ or $CD8^+$ T cells	Epicutaneous	SIC	BALF—eosinophils Skin—contact hypersensitivity	77
Acid anhydride—to establish a model of TMA lung	Guinea pig	Inhalation	SIC with TMA or TMA GPSA	Respiratory response Antibodies detection	78
Plicatic acid—Western red cedar—to establish a model	Rabbit	Plicatic acid-ovalbumin and adjuvant	Plicatic acid—OA conjugate	Respiratory response frequency and resistance	79

BALF, bronchoalveolar lavage fluid; GPSA, guinea pig serum albumin; HEV, hepatitis E virus; HMW, high-molecular-weight; IL, interleukin; LMW, low-molecular-weight; OA, ovalbumin; SIC, specific inhalation challenge test; T cells, T lymphocytes; TDI, toluene diisocyanate; TMA, trimellitic anhydride.

Guinea pigs, rats, and mice are commonly used, but occasionally, rabbits, monkeys, and dogs are also used. The mouse model has advantages because the IgE-mediated responses in mice and their antigenic repertoire are similar to those of humans. Sensitization can be initiated by either systemic or local (inhalation or dermal) exposures. Systemic sensitization is usually done through intraperitoneal injections whereas respiratory exposures can be done through inhalation, intratracheal, or intranasal route. The animals are usually challenged by the respiratory route when respiratory frequency and pulmonary resistance are measured. Measurement of nonspecific bronchial hyperresponsiveness can also be assessed by response to methacholine challenges. Blood samples and lung lavages can be collected for immunologic assessment such as measurement of specific antibodies, inflammatory cytokines, or chemokines. The tissue can be used to assay messenger RNA and the lung pathology assessed.

Animal models have been very helpful in increasing our understanding of the pathogenesis of OA. Studying the dose relationship between exposure and response may allow the determination of a threshold limit value of human exposure, as in the case of detergent enzymes.[72] However, one needs to be cautious in interpreting the results because most of the exposure situations in humans are quite different from laboratory conditions and the response in humans could be different from that in animals.

Occupational Asthma without a Latency Period

In an animal model of irritant-induced asthma caused by a single exposure of rats to chlorine 1500 ppm, it was shown that maximum changes in lung resistance and nonspecific bronchial hyperresponsiveness occurred in the first 3 days and persisted after 1 week.[68] These functional changes corresponded to the maximum pathologic changes when complete epithelial denudation was found. Neutrophils were increased in BAL. When lung tissue is exposed to chlorine, oxidation of component proteins is found with increased concentration of 3-nitrotyrosine and inducible nitric oxide synthase, along with the hypothesis that irritant-induced asthma is induced by an oxidative process.[69]

FREQUENCY

The frequencies of asthma in the workplace can be assessed by several means in either cross-sectional and longitudinal studies, and they are presented in Table 64-5.[3,4,6,12,82–86] First, several population-based studies have been carried out. Blanc and Toren,[1] in an often quoted review, proposed a median estimate of 9% to 15% of attributable risk of asthma due to work exposure. Becklake and associates[7] reviewed selected studies in which the population attributable risk (%) ranged from

TABLE 64-5. Means for Assessing the Frequency of Asthma in the Workplace and Examples

Type of Study*	Strengths	Weaknesses	Examples (Ref. Nos.)
POPULATION-BASED			
Epidemiologic surveys	Large samples. Subjects exposed to a vast number of agents. Possibility of using a job-exposure matrix. Avoid the "healthy worker" effect.	Mostly based on questionnaires. Very little objective confirmation. Costly.	82
Registers	Large samples. Subjects exposed to a vast number of agents. Not costly.	Indirect information. Misclassification likely.	83
OCCUPATION-BASED			
Epidemiologic surveys	Well-defined populations in high-risk workforces with possibility of control groups. Objective testing can be done. Possibility of obtaining information on preexposure host factors. Characterization of environment feasible.	Survivor bias. (Healthy worker effect.)	104 6 4
PATIENT- OR CLAIMANT-BASED			
Sentinel projects	Subjects assessed by specialists.	Referral biases Clinical impression not necessarily based on objective testing.	84 12
Patients referred to specialist clinics	Subjects assessed by specialists. Objective testing likely with firm diagnosis.	Referral biases.	85
Medicolegal registers	Diagnosis confirmed.	Referral biases.	86

*The design can be cross-sectional or longitudinal.

The authors are grateful to Denyse Gautrin, PhD, for her precious advice in the preparation of this table.

3% in studies from Spain[87] and New Zealand[88] to 23% in Canada[89] and 33% in Singapore.[90] An important survey in the general population recently proposed that 10% to 25% of new cases of asthma confirmed by assessment of bronchial responsiveness were attributable to the workplace.[82] A source of controversy in the ascertainment of the condition is that it can be defined as either new-onset asthma or work-aggravated asthma and not necessarily OA.[91,92]

The prevalence of work-related respiratory symptoms suggestive of OA and of OA have been investigated in several different workplace surveys where workers were exposed to agents known to cause OA.[7] Highly variable prevalence figures have been proposed, depending on the way the cases were defined. Obviously, using only a questionnaire results in higher figures. Studies in which objective tests have been carried out to better ascertain cases have shown that as a rule of thumb, the prevalence is lower than 5% in workers exposed to high-molecular-weight agents and is between 5% and 10% in workers exposed to low-molecular-weight agents. The well-known survivor effect affects prevalence estimates.

Prevalence figures can also be obtained from registers. A population-based incidence study included the entire employed Finnish population. The cohort was followed for 10 years, using two registers, one of clinically established persistent asthma, the other of census data (for information on employment).[83] A total of nearly 50,000 incident cases of asthma were recorded and the fraction attributable to work was 29% for males and 17% for females. The proportion attributable to work was approximately 5%.[93] Higher frequencies of asthma and use of antiasthma medications have been found in workers of various trades—health care professionals,[94] cleaners,[95,96] electrical machinery workers,[97] and construction workers[90] being the most consistently reported ones. Recent figures from Surveillance of Work and Occupational Respiratory Disease (SWORD), the sentinel project based in the United Kingdom, show stabilization and even a reduction in the number of new cases of OA.[98] Similar surveillance systems have been initiated in the Canadian provinces of Quebec[99] and British Columbia,[100] in France,[101] and in South Africa.[102] Another means of collecting relevant information on frequency is by soliciting physicians to report possible cases with a sentinel-based approach. The SWORD[84] and the SENSOR[12] projects, respectively based in the United Kingdom and the United States, the most well-known and long-lived ones, reflect not only changes in frequencies but also changes in causal agents. Frequency can also be examined by consulting patient files in specialized referral clinics.[85] Finally, medicolegal statistics can be used. Figures from Finland and Quebec are particularly illustrative in this regard as they are probably less likely to be affected by underreporting because the system offers satisfactory compensation to workers with OA. Moreover, objective tools are used to diagnose the condition.[86]

Several prospective cohort studies have been carried out in selected high-risk professions to assess the incidence and determinants of probable OA among apprentices newly exposed to high-molecular-weight agents[3,4,103–107] and low-molecular-weight sensitizers.[5,108] The incidence is particularly high in apprentices exposed to animal-derived allergens, more so than in bakers and dental hygienists exposed to latex.[109] It is also higher during the apprenticeship period and diminishes during later exposure at the time of employment.[6]

Risk determinants for developing sensitization and disease have been examined in various studies.[7] Clearly, exposure and the degree of exposure, as shown by dose-response analysis, are the most significant determinants in most studies, having therefore an important impact on the prevention strategy in surveillance programs. Most occupational studies have shown that the higher the level of exposure, the higher the prevalence of sensitization. Table 64-6 shows some of these studies from

TABLE 64-6. Studies of Exposure-Response Relationships of Occupational Agents and Exposure Limits

Allergen	Source (Ref. No.)	No. Subjects	Lowest Effective Allergen Level	Exposure-Response Relationship	OEL in BC
Flour dust	110	230	1–2.4 mg/m^3	Sensitization	4 mg/m^3 for grain dust
	111	279	1.7 mg/m^3	Sensitization	
				Symptoms, PD20	
Alpha-amylase	112	178	0.25 ng/m^3	Sensitization	
Western red cedar	113	243	0.2–0.4 mg/m^3	FEV_1 decline	
Latex—NRL	114	145	0.6 ng/m^3	Sensitization, symptoms	1 ng/m^3
Acid anhydride					
TCPA	115	52	0.1–0.39 mg/m^3	Symptoms	0.04 mg/m^3
TMA	116	17	0.82 mg/m^3	Symptoms	
TMA	117	49	<0.04 mg/m^3	Symptoms, sensitization	
Isocyanates	118	84	5–10 ppb	Symptoms, lung function decline	0.005 ppm
Colophony	119	88	<0.01 mg/m^3	Asthma, lung function decline	
Platinum salts	120	78	≤2 µg/m^3	Sensitization, asthma	0.002 mg/m^3

FEV_1, forced expiratory volume in 1 second; NRL, natural rubber latex; OEL in BC, occupational exposure limits in British Columbia, Canada; ppb, parts per billion; ppm, parts per million; TCPA, tetrachlorophthalic anhydride; TMA, trimellitic anhydride.

which the lowest observed effective allergen levels were derived as well as the occupational threshold limit values in British Columbia, which were based on time-weighted averages.[110-120]

In OA, once sensitized, the degree of exposure is also a major determinant in the development of symptoms. However, the level of exposure required to induce symptoms is significantly lower after sensitization. Thus, the classic notion of time-weighted average exposure, short-term exposure limits, and ceiling limits for agents that are responsible for occupational diseases may not be relevant in OA.[121] For example, in diisocyanate exposure, it is not clear at this time whether peak levels of exposure are more important than the cumulative dose of exposure because one case report indicates the importance of intermittent high levels of exposure[122] whereas another indicates the level of continuous exposure.[123] In the case of high-molecular-weight agents only, personal factors that influence risk are atopy and, inconsistently, depending on the causal agent, smoking.[108] In a study of animal laboratory workers, the risk of sensitization in atopic subjects was found to increase when levels of exposure were low but the risk did not further increase with increasing exposure. In nonatopic subjects, the risk of sensitization increased with increasing exposure.[124] Some investigators suggested that genetic susceptibility is important when levels of exposure are low.[34]

DIAGNOSIS

The diagnosis of OA is a stepwise procedure that uses several tools (Fig. 64-2). Unfortunately, although guidelines have been proposed, objective confirmation of OA is often still not or only partially carried out.[125] The diagnosis of OA is too often made on clinical history alone, which is unacceptable when one considers the availability of objective tests for making the diagnosis.

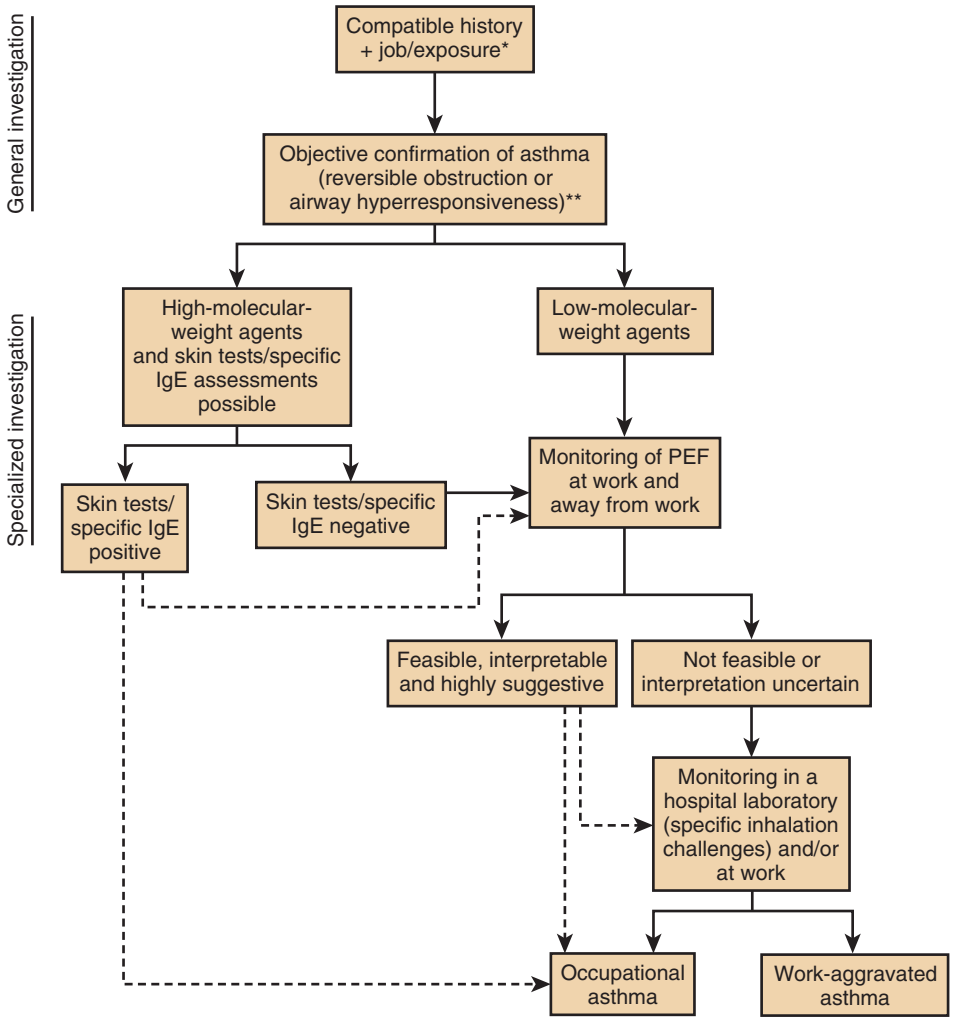

FIGURE 64-2 ■ The diagnosis of occupational asthma (OA). *Either the job or the exposure can result in increased risk. **Airway responsiveness can be ideally assessed at a time the worker is at work and has been symptomatic recently; even if a worker is no longer at work, airway responsiveness can persist in 75% of workers with OA. The *dashed lines* indicate that there are two possibilities. For example, even if interpretation of peak expiratory flow is suggestive of OA, some would prefer to carry on monitoring of airway function and inflammation.

The clinical questionnaire is the first step. It should obtain information on job title and exposure. For example, health care professionals represent a group at risk and a patient with asthma working in this field should be questioned on the products he or she may be exposed to at work. Information on products handled at work can be obtained by consulting material safety data sheets. However, these might not reveal the complete content of a product because manufacturers in the United States do not have to report on content that represents less than 1% of the total content of a product. If there is suspicion that a product can cause OA, the manufacturer needs to be contacted. In some instances, "walk-through" visits of the workplace need to be done to obtain more information on exposure. Often, workers can be exposed to several products that are known to cause OA.

Typically, respiratory symptoms begin to appear only on workdays and improve or disappear on weekends and vacations. However, with the progression of symptoms, patients may still be symptomatic on weekends. Workers should be questioned not only on the presence of classical asthma symptoms such as wheezing but also on nasal (i.e., the "united airway" concept) and ocular symptoms, especially in the case of exposure to high-molecular-weight agents for which the allergic mechanism is IgE-mediated.[126] A list of key symptoms to include has been published.[126] It has been shown that "open questionnaires" used by clinicians demonstrate satisfactory sensitivity but lack specificity.[29] Therefore, they should not be used alone in making a diagnosis that has considerable psychosocioeconomic impact (e.g., wrongly suggesting that a young worker leave his usual work for which he has been trained) and health consequences (e.g., wrongly suggesting that a worker stay at work with worsening asthma and the possibility of long-term sequelae).

If a worker has a history suggestive of asthma and has a job/exposure history compatible with OA, it is mandatory to confirm the diagnosis of asthma by objective testing, confirming either partial or complete reversibility of airway obstruction or airway hyperresponsiveness in the event that normal airway caliber is present. This assessment is best carried out toward the end of a week spent at work (i.e., on the Thursday or Friday afternoon of a normal week at work). Even if the worker is no longer at work, objective confirmation of asthma is still required because airway hyperresponsiveness is often still present after many exposure-free years in as much as 75% of workers affected with OA. If assessment of airway inflammation using induced sputum is available, this should also be examined. Workers may have normal function but airway inflammation can be present, especially in the case of eosinophilic bronchitis.

After confirming that a symptomatic at-risk worker has asthma, it is mandatory to refer her or him to a specialized center. Skin testing with some high-molecular-weight occupational allergens is feasible with cereals, in the case of bakers, or latex, for health professionals using gloves. If a technician exposed to laboratory animals has confirmed asthma and a positive skin test to rat urine, there is an 80% chance that exposure to rat urine in the laboratory will result in an asthmatic reaction.[127] Unfortunately, extracts of high-molecular-weight agents are rarely standardized and skin tests cannot be done with low-molecular-weight agents.

Serial monitoring of PEF can be initiated for periods at work and away from work. Such monitoring is complex. Workers need to be exposed and symptomatic at the time that this is carried out and meticulously and honestly record their breathing at least four times a day. Graphs have to be plotted and interpreted. The availability of computer-based reading may help the specialist.[24] This monitoring can be coupled with assessment of nonspecific bronchial hyperresponsiveness during periods at work and away from work as well as with monitoring of inflammatory parameters. Induced sputum adds information to monitoring of PEF[14] but monitoring of exhaled nitric oxide still has to be validated in the investigation of OA. In many instances, even after completing this investigation, the diagnosis is still uncertain and further testing is required. Finally, one should consider serial monitoring of airway function (forced expiratory volume in 1 second, forced vital capacity, airway responsiveness to methacholine) and inflammation (induced sputum) on days of controlled exposure to the potential causal agent in a hospital laboratory[128] or at work.[129] This monitoring that should be offered only in specialized centers and carried out in a standardized way, in a dose-response curve fashion, under the close supervision of an experienced technician.

EXPOSURE AND ENVIRONMENTAL MONITORING

Environmental monitoring is important in OA for identification of causative agents, determination of exposure dose-response relationship, establishment of threshold limit values, and subsequent control of exposure.

Traditional environmental monitoring has been carried out for chemicals and gases, but many agents causing OA are high-molecular-weight allergens such as proteins and polysaccharides. Progress and advancement in particle collection methods and immunochemistry since 1980 have enabled the characterization of complex mixtures of proteinaceous material and increased our understanding of bioaerosol exposure and its link to allergic lung disease.[121]

Exposure is the most important determinant in the development of OA (see "Frequency," earlier). Most occupational studies have shown that the higher the level of exposure, the higher the prevalence of sensitization. In OA, once sensitized, the degree of exposure is also a major determinant in the development of symptoms. However, the level of exposure required to induce symptoms is significantly lower after sensitization. Thus, the classic notion of time-weighted average exposure, short-term exposure limits and ceiling limits for agents that are responsible for occupational diseases may not be relevant in OA.[121] For example, in diisocyanate

exposure, it is not clear at this time whether peak levels of exposure are more important than the cumulative dose of exposure; one case report indicates the importance of intermittent high levels of exposure[122] whereas another indicates the level of continuous exposure.[123] In the case of flour, an exposure threshold has been proposed at 2 mg/m^3, at which risk of sensitization is significantly lower.[110]

Employers must ensure the availability of copies of the material safety data sheet for all materials used in the workplace. Moreover, an employer is required by law to make this information available to all workers in the workplace. Material safety data sheets are also available at the following websites: http://ccinfoweb.ccohs.ca/msds/search.html and www.ehs.cornell.edu/lrs/internetMSDS.htm. In the United States, the Occupational Safety and Health Administration (OSHA) requires suppliers to include information regarding a sensitizer if its concentration represents 1% or greater (≥0.1% in Canada) in a chemical product and to be listed as a hazardous ingredient.

MEDICOLEGAL ASPECTS AND COMPENSATION ISSUES

Numerous studies have shown that patients with documented OA may not recover after removal from exposure.[7] Even those apparently cured using clinical and functional criteria still have airway inflammation and remodeling 10 years or more after cessation of exposure.[8] Moreover, patients with OA (as well as with work-aggravated asthma) often become unemployed and suffer a loss of income after removal from exposure.[13,130–133] Even those workers who remain employed in the same workplace may suffer a reduction in income and an increase in medication costs over time.[132]

Given the permanent impairment and the economic loss from OA, the treating physician should support his or her patients in Workers' Compensation claims once the diagnosis has been established. Workers' Compensation is generally a no-fault compensation system paid for by employers or by insurance companies and differs from country to country. This variation is at times due to different ways of defining OA. In some industrialized countries, compensation of OA is based on a list or schedules of covered diseases. In others, objective evidence of work-relationship is necessary. It is in the patient's interest for the physician to obtain as much objective diagnostic information as possible before submitting the application so as to assist those with OA to change jobs and to avoid loss of employment for workers who do not have OA. Work-aggravated asthma is generally not accepted for compensation by medicolegal agencies unless unexpected working conditions occurred (e.g., an atopic asthmatic subject exposed to various molds as a result of dampness in a workplace and who reports that asthmatic symptoms worsened at work during a specific period or a lifeguard with asthma who has been exposed to higher than usual concentrations of chlorine in a swimming pool and who reports that the asthmatic condition worsened during this period).

In Quebec, Canada, the first level of compensation allocated at the time of diagnosis provides for an income replacement indemnity and complete costs for rehabilitation. This process lasts 1 to 2 years. The second level is based on a permanent disability indemnity that is allocated 2 years after diagnosis because, although improvement can still occur at a later stage, maximum improvement occurs in the first 2 years after cessation of exposure.[134] The criteria used for the determination of permanent impairment are the degree of airway obstruction, the degree of nonspecific bronchial hyperresponsiveness, and the need for medication as proposed by the American Thoracic Society[31] and the American Medical Association.[135] As a result, disability, that is, the impact of functional impairment and the psychosocial burden as a whole, is probably less than in other jurisdictions[136] with more than 80% of workers being employed when assessed 2 years after diagnosis, for a median direct cost recently estimated at $61,000 Canadian dollars (CAD) per claimant, this covering both readaptation and impairment/disability (including drugs for asthma).[137]

Whereas most industrialized countries have recognized OA as a compensable disease, work-aggravated asthma is not. Because the loss of income and suffering are the same irrespective of whether asthma is caused or exacerbated by work, the management and approach to compensation of work-aggravated asthma should be reconsidered.

PREVENTION AND SURVEILLANCE

Primary Prevention

Reduction of exposure is the key to primary prevention of OA and work-exacerbated asthma. This could be accomplished by substitution of the known hazardous substance with one that is less harmful, by improving ventilation, by enclosing the process, by modifying the process or the agent to reduce risk sensitization, and by improving housekeeping and work practices. There are many examples of successful reduction in OA and allergy due to reduction of exposure. In natural rubber latex allergy, avoiding use of the sensitizer by replacing latex gloves with nonlatex gloves and reducing the powder and the content of latex protein of gloves are measures that have led to a decline in the incidence of both OA and allergies to latex[22] as reflected in compensation data reported in Ontario[138] and in national statistics in Germany.[139] Encapsulation of detergent enzymes to reduce exposure was very successful in reducing sensitization and asthma.[21] In Ontario, Canada, the introduction of a surveillance program in 1983 for diisocyanates to include monitoring of diisocyanate concentrations in the workplace with a maximum allowable 8-hour time-weighted average of 5 ppb combined with a medical surveillance program was associated with a decline in new diisocyanate-induced asthma compensation

claims,[140] although similar declines have been noticed in other parts of the world where surveillance programs do not exist. The use of personal protective equipment such as respirators, gloves, coveralls, and goggles by the worker to reduce exposure is less desirable because compliance is poor.

The second measure in primary prevention is to identify susceptible workers and relocate them to areas free of known sensitizers. Atopy has been shown to be the most important personal risk factor for OA, whereas smoking is relevant in some types of OA owing to high-molecular-weight agents and some low-molecular-weight compounds such as acid anhydrides and platinum salts.[7] However, the prevalence of atopy in the general population is very high, close to 40%, and the rate of sensitization to the occupational agent is relatively low. Considering the high frequency of atopy, it is unrealistic to exclude atopic individuals from the workforce. Conversely, many countries now prohibit smoking in the workplace.

Another possible measure is to screen chemicals for respiratory sensitizing potential before their introduction into the market. As some low-molecular-weight compounds possess chemical structures that are more potent sensitizers than others, studies have been carried out to assess whether it is possible to develop quantitative structure-activity relationship models to predict the sensitizing potential of these compounds.[141,142] However, so far, there has been no validated protocol.

Secondary Prevention

Secondary prevention aims at early detection in workers with disease and removal of workers from further exposure to prevent the progression of the disease process with increasing morbidity and disability. Secondary prevention consists of a medical surveillance program together with environmental monitoring usually in high-risk industries. For high-molecular-weight allergens, a reasonable medical surveillance program of OA may include a symptom questionnaire, skin prick testing, and spirometry every 6 months for 2 years and once every year thereafter. In the detergent enzyme industry, such medical surveillance has proved to be very successful.[21] Workers who developed rhinitis or lower respiratory symptoms at work and had positive skin tests were removed from exposure. The rate of OA was significantly reduced as a result of these measures.

In asthma due to platinum salt allergy, skin prick testing using platinum salt in medical surveillance to detect and remove sensitized workers from further exposure resulted in a reduction of asthma.[143] However, when skin testing is not available, as in most low-molecular-weight compounds, the medical surveillance program is dependent on symptom questionnaires and spirometry. In Ontario, such a program was mandated by the Department of Labour—a questionnaire every 6 months and spirometry, if indicated by the questionnaire, as well as follow-up at least every 2 years thereafter. A referral was made for further investigation if the worker had symptoms of asthma or if there was a 15% drop in spirometry. This program initially increased the number of compensation claims followed by a progressive reduction.[140]

Tertiary Prevention

Tertiary prevention is directed at reducing the degree of impairment/disability in those with established disease. For OA with latency, the best prognosis is complete avoidance of further exposure to the sensitizing agent. An air-supply helmet respirator has been used by some sensitized workers when exposure is intermittent. Its use on a continuous basis may not be tolerated by workers.

IRRITANT-INDUCED ASTHMA AND REACTIVE AIRWAY DYSFUNCTION SYNDROME

It had long been thought that inhalational accidents resulted only in lung injury, causing edema and alteration of the alveolocapillary membrane, an example being the deleterious effect of toxic gases used in World War I.[19] It was only in 1983 that authors described the airway effect of inhalational accidents with development of airway hyperresponsiveness and irritant-induced asthma.[144] The label "RADS" and criteria for diagnosis were later proposed.[20] Whereas the label "RADS" is reserved for a single inhalational accident, Irritant-induced asthma may include more than one accident. The most mediated RADS events occurred at Bhopal in 1987 where methylisocyanate was responsible for the deaths of 2000 civilians[145] and at the World Trade Center site where firemen and civilians were exposed to dust.

RADS occurs after accidentally inhaling an agent generated at high concentrations. Theoretically, all types of agents can cause RADS but chlorine and ammonia are the most commonly reported agents. Vapors and aerosols are more likely to cause RADS than dry particles. The degree of exposure and the proximity of the emission are the most important determinants.[146] and there is no personal determinant. Table 64-7 compares some features of OA with a latency period and irritant-induced asthma. Although irritant-induced asthma is a type of OA, there are several differences between the two conditions (see Table 64-7). Coughing is the principal symptom and, commonly, the nose is also affected, workers complaining of acute burning in the nose. Workers typically arrive at the first aid unit or at the emergency department. Unfortunately, too often spirometry is not assessed and treatment with a bronchodilator and oxygen is initiated without giving parenteral and inhaled steroids, which should be the recommended course of action as early as possible after an inhalational accident.[147] Airway responsiveness should be part of the assessment. Typically, there is a discrepancy between the severity of symptoms and the low degree of airway hyperresponsiveness. If a worker is still symptomatic after 3 months, improvement will be minimal afterward.

TABLE 64-7. Differences between Occupational Asthma with a Latency Period and Irritant-Induced Asthma

	OA with a Latency period	IrIA
Latency period	Variable but at least a matter of weeks	Onset of symptoms within minutes or hours
Mechanisms	Immunologic sensitization	?
Physiopathology	Like common asthma	Massive epithelial desquamation with early deposition of collagen. No role of eosinophils. Oxidative process.
Frequency	85%–90% of all cases of OA	10%–15% of all cases of OA
Symptoms	Wheeze predominant	Cough predominant
Function	The degree of airway hyperresponsiveness to methacholine reflects severity.	Severity not reflected by the degree of responsiveness to methacholine.
Response to bronchodilator	+++	++
Response to inhaled steroids	+++	++
Improvement with time	Good in general	Moderate, little or absent

IrIA, irritant-induced asthma; OA, occupational asthma.

Irritant-induced asthma represents 10% to 15% of all cases of OA compensated by medicolegal agencies in Ontario[148] and Quebec.[149] Animal models in rats[68] and mice[69] exposed to chlorine have shown that early epithelial desquamation is massive, followed by an important generation of epithelial basal cells, edema, and early collagen deposition in the submucosal space. Inflammatory cells are minimally present. Although one study has shown that 25% of subjects with RADS had normal responsiveness approximately 2 years after an inhalational accident,[150] generally, the clinical, functional and pathological improvement is less than what is found in OA with a latency period.[151,152]

ACKNOWLEDGMENTS

The authors are grateful to Ms. Cynthia Demedash for reviewing this manuscript.

KEY POINTS

- OA is caused by the workplace and may be associated with a latency period necessary for acquiring sensitization. OA can occur without a latency period, usually after inhalation of an irritating substance. This has different characteristics from asthma associated with latency.
- Asthmatic persons who report that their symptoms are aggravated by exposure in the workplace may also suffer significant disability.
- Asthma in the workplace can be suspected in 1 out of 10 adult-onset asthmatic subjects.
- OA can be caused by high-molecular-weight (proteins) and low-molecular-weight (chemicals) agents.
- OA caused by high-molecular-weight agents is IgE-mediated whereas the mechanism of OA caused by low-molecular-weight agents is generally unknown, although it is immunologically mediated.
- The diagnosis of OA should be confirmed by objective testing in addition to clinical questionnaires.
- The nature and intensity of exposure are the principal determinants of OA and are more important than personal determinants.
- OA should be diagnosed early to avoid permanent sequelae.
- Satisfactory compensation should be offered to claimants, the emphasis being on proper readaptation programs.
- Prevention should be focused on adequate environmental control.

FLOCK WORKER'S LUNG

INTRODUCTION

Definitions

The *Encyclopedia of Occupational Health and Safety* of the International Labour Organization (ILO)[1] defines pneumoconiosis as "the accumulation of dust in the lungs and the tissue reactions to its presence." The main reaction to mineral dust in the lungs is fibrosis. Not included in the definition of pneumoconiosis are conditions such as asthma, chronic obstructive pulmonary disease (COPD), and hypersensitivity pneumonitis in which there is no requirement for dust to accumulate in the lungs in the long term.

Accumulation of Dust in the Lung and Tissue Reactions

The *deposition* of dust in the lungs depends on the size and geometric and aerodynamic properties of the particles. Particle clearance is determined by the mucociliary escalator and cellular mechanisms, in particular, the macrophage (see Chapter 12). Dust *accumulation* in the lungs is determined by deposition and clearance. The biologic *response* depends upon the amount and duration of the accumulation and the nature of the dust. Tissue responses to inorganic dusts depend on particle size and the biologic activity of the dust, which in turn depends on its surface chemical and physical properties.[1] Some dusts, such as coal, are relatively inert and may accumulate in considerable amounts with minimal tissue response; others, in particular silica and asbestos, have potent biologic effects. Parenchymal responses include nodular fibrosis (the classic example is the silicotic nodule), diffuse fibrosis (the classic example is asbestosis), and macule formation with focal emphysema (the classic example is the coal dust macule).[2] Irregular and mixed fibrotic patterns also have been described as a consequence of mixed exposures involving other mineral dusts or fibers in addition to silica dust exposure.[3] For any given dust exposure, the severity of the tissue reaction appears to be related to the cumulative lung dust burden.

Exposure-Response Relationships

In epidemiologic studies, the dust burden in the lung can be assessed only indirectly. However, at an individual level, exposure can be estimated more directly from the job history, from the engineering history of the plant, including the efficiency of dust control, and from environmental measurements. Based on these estimates, convincing exposure-response relationships for pneumoconiosis can invariably be demonstrated in work force studies (Fig. 65-1; see also Fig. 65-9). At the public health level, the demonstration of exposure-response relationships is supportive evidence that the abnormality, dysfunction, or disease in question is causally related to the exposure.

The demonstration of exposure-response relationships also has implications for clinical practice. For instance, a clinical diagnosis of pneumoconiosis is strengthened greatly when there has been exposure to dust levels known to be associated with an increased risk of disease. Although exposure-response relationships generally describe the events in a work force, there may be heavily exposed individuals who remain unaffected and lightly exposed individuals with disease. Thus, environmental standards such as threshold limit values set by the American Conference of Government and Industrial Hygienists (ACGIH) are levels that if respected throughout an individual's working life, are unlikely to be associated with disease. However, dust sampling may be problematic and even in a workplace where average dust concentrations are below the threshold limit value, nearly half the samples exceed this value.[4] Thus, a clinician should not reject the diagnosis of pneumoconiosis solely on the grounds that exposure was too remote, too short, or in a workplace where the threshold limit value was maintained. The subject in question may be unusually susceptible, may have had an unusual exposure profile, or may retain more dust than others similarly exposed.

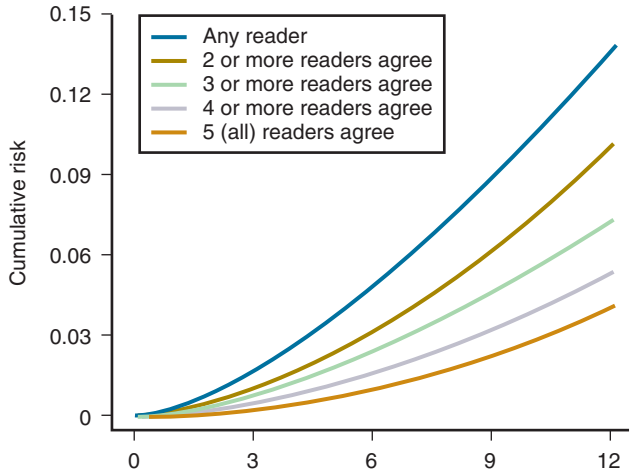

FIGURE 65-1 ■ The cumulative risk of developing silicosis in relation to cumulative exposure to respirable silica ($mg/m^3 \times yr$), lagged by 5 yr, among hard rock miners. The cohort consisted of all miners on the Ontario Workmen's Compensation Board's master file of miners who started work between 1941 and 1959 and were followed by chest radiography until their dust exposure ended or until 1982, whichever came first. The figure shows fitted Weibull models for one to five levels of reader consensus. The criterion for silicosis was a chest radiograph reading of small rounded opacities of profusion 1/1 or greater, using the International Labour Organization (ILO) standard reference films, on the miner's most recent film. The films of 32 of 2109 miners were considered by one or more readers to have silicosis and were retained for the purposes of this analysis. (Redrawn from Muir DCF, Shannon HS, Julian JA, et al: Silica exposure and silicosis among Ontario hardrock miners: III. Analysis and risk estimates. Am J Ind Med 16:29–43, 1989.)

Chest Imaging

The ILO standard films for the descriptive interpretation of the radiologic appearance of diffuse parenchymal lung

disease[5] were originally developed for epidemiologic studies of occupational lung disease but may also be used for clinical interpretation. Apart from improving consistency in the reading of parenchymal disease, which is notoriously subject to reader variability, they enable the clinician to set an individual case in the context of the available epidemiologic information.[5] Small opacities in the parenchyma are classified by shape and size: *p*, *q*, or *r* for rounded opacities (diameter, <1.5 mm, 1.5-3 mm, or >3 mm, respectively) and *s*, *t*, or *u* for irregular opacities (width, <1.5 mm, 1.5-3 mm, or >3 mm, respectively). Profusion category (or concentration) is next read on a 12-point scale (0/–, 0/0, 0/1, up to 3/2, 3/3, and 3/+) in comparison with the standard radiographs. Large opacities are classified as category A (for one or more such opacities with a diameter of 1 cm but not exceeding a combined diameter of 5 cm), category B (one or more opacities > 10 cm in diameter and whose combined area does not exceed one upper zone), and category C (>B). Provision is made to grade pleural thickening for width ($a \leq 5$ mm, $b > 5$ mm but < 10 mm, and $c \geq 10$ mm) and extent (*1* = up to one quarter, *2* = one quarter to one half, and *3* = over one half of the lateral chest wall). The extent of pleural calcification also is graded, and there are provisions for comment on other features.

In the United States, the National Institute of Occupational Safety and Health (NIOSH) administers the National Coal Workers' Health Surveillance Program, which provides coal miners with the opportunity of a periodic medical examination. The program incorporates quality control in terms of radiographic technique and reading procedures using the ILO classification and reader training. This involves training seminars for physicians who may qualify as "A" readers (i.e., attended the seminars) or "B" readers, who passed a comprehensive examination on the basis of 120 radiographs read into the ILO classification.

Chest radiographs are the cornerstone of surveillance for pneumoconiosis in the workplace. Computed tomography (CT) and high-resolution computed tomography (HRCT) have revolutionized clinical case evaluation. CT and HRCT are able to characterize lung and pleural lesions and their extent and confluence and are considerably more sensitive than the conventional chest radiograph. However, the chest radiograph remains the accepted method for surveillance and assessment because of its wide availability, acceptable cost and radiation dose, and the standardization of its reading.

Clinical Issues, Lung Function, and Principles of Management

The clinician is faced with two main tasks when evaluating a case of suspected pneumoconiosis. *First* to assess the nature of the disease process, including its site (airways or pulmonary parenchyma or pleura) and its extent, and to determine whether it has decreased the individual's performance in particular for his or her current job (evidence of impairment or disability). Assessment of impairment is based on symptoms and measurements of pulmonary function at rest and during exercise where indicated (see Chapter 27). Pneumoconiosis may be associated with apparently normal lung function or with a predominantly obstructive, restrictive, or mixed pattern of dysfunction. In the individual case, interpretation of results in terms of lung function profiles is usually done by the use of reference or predicted values. These may, however, be misleading given that those who undertake dusty occupations on average have higher initial spirometry and lung volumes than the general population, on whom most predicted values are based.[6] Thus, it is not appropriate to minimize the functional significance of pneumoconiosis on the grounds of apparently normal lung function. Assessment of disability is made in the wider context of whether the subject is fit for his or her job and, thus, requires expert knowledge of the job content. *Second*, is the need to determine whether there has been environmental or occupational exposure of duration, intensity, and character sufficient to account in full or in part for the patient's present condition. For this task, the key tool is the occupational history, which can be completed with the addition of the often extensive knowledge that the worker can provide concerning his or her occupations, the materials handled, and the processes involved. Because pneumoconiosis is a reaction to retained dust, it may appear and progress after exposure has ceased[7]; hence, the importance of a complete exposure history, including student summer jobs, military service, and short-term jobs. In addition, in industrialized countries, between 25% and 60% of men and up to 30% of women report exposure to dust or fumes at work,[8] further testimony to the fact that an occupational history is as essential as the smoking history in the practice of respiratory medicine. On occasions, it may be necessary to establish occupational exposure on the basis of analysis of biologic material (sputum, bronchoalveolar lavage (BAL), transbronchial or open-lung biopsy specimen) for the putative dust or its breakdown products. This is particularly so in cases in which the exposure is remote and the exposure history incomplete or unreliable. Figure 65-2 presents examples of cases in which the putative dust was demonstrated in the pathologic specimens. The case record in Figure 65-11 is an example of the use of lung dust burden measurements in establishing attributability.

Tuberculosis was a common complication of pneumoconiosis in the early part of the 20th century, when infection levels were high in parent populations from which work forces were drawn and drug therapy was not yet available. Although now relatively rare in industrialized countries, tuberculosis remains an important issue in industrializing countries and has increased dramatically, especially in South Africa, in response to the human immunodeficiency virus (HIV) epidemic.[9]

Pneumoconiosis does not regress and may appear and progress only after work exposure ceases.[7] In general, there should be no doubt that a worker with pneumoconiosis should have no further occupational dust exposure.[10] A rare exception would be in an older worker who is close to retirement for whom early retirement

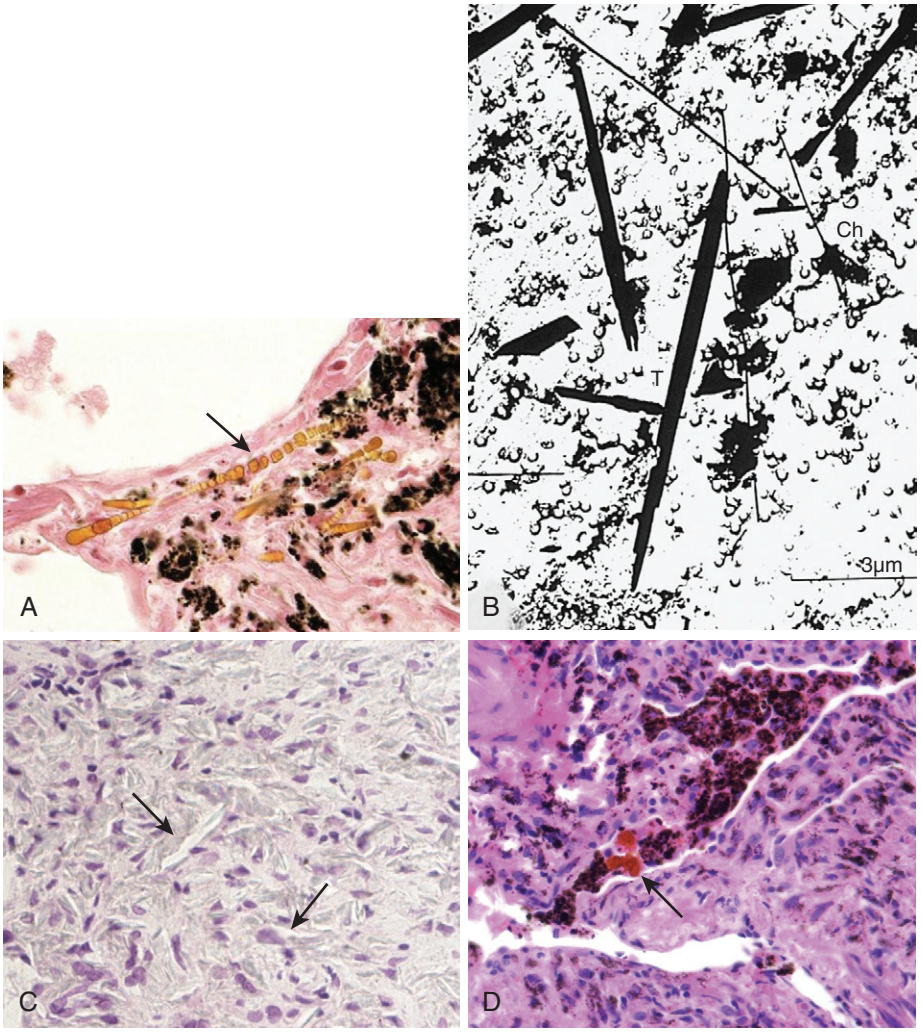

FIGURE 65-2 ■ The putative agent in the lung tissue in four cases of pneumoconiosis is demonstrated. **A,** Typical asbestos body (*arrow*) in the lung of a crocidolite asbestos miner with asbestosis, from South Africa. **B,** Lung digest from the case of a 67-year-old long-term chrysotile miner with asbestosis from the Thetford area, photographed on a filter of pore diameter 0.2 mm (pores are evident as small punched-out areas in the photograph). The thin fibers labeled *Ch* were identified as chrysotile using morphologic criteria and energy-dispersive x-ray spectrometry (EDS). The thick fibers labeled *T* were identified as tremolite by EDS. In this mining area, there is a small amount of tremolite in the mined ore that accumulates preferentially in the lung tissue.[142] Amphiboles such as crocidolite, amosite, and tremolite most frequently form the core of asbestos bodies. For each asbestos body found in lung tissue, the number of uncoated fibers is at least several orders of magnitude greater. **C,** Lung section from a 53-year-old man who worked in a mica milling factory. The mica (*arrows*) appears as birefringent (*bright white*) elongated particles. **D,** Lung from a foundry worker shows amorphous black carbon particles and a cluster of rounded iron-coated particles (*arrow*). Particle clusters like this frequently are seen in the lung sections of welders and of foundry workers who have had exposure to iron dusts and fumes. Fraser, Department of Pathology, and Dr. Patrick Sébastien, formerly of the School of Occupational Health, McGill University, Montreal.)

would cause significant economic loss not covered by a compensation package.

The physician should be aware that each time the diagnosis of pneumoconiosis is substantiated, it carries with it several important public health implications. In many jurisdictions, the physician has the legal responsibility to report all cases of pneumoconiosis.[7] The diagnosis of pneumoconiosis reflects a failure of environmental controls in the workplace that may require intervention by an appropriate authority. There are differences in disease notification practice and compensation legislation among states and among countries, and physicians should be aware of the appropriate procedure in the location of their practice.

Epidemiology and Implications for Clinical Practice

Information on the distribution of these diseases within and between work forces and the factors that influence distribution provides the scientific base that the physician uses to reach a diagnosis, set prognosis, and plan management. Thus, knowledge of pneumoconiosis rates

in the industries located in the local area assists the physician in diagnosis. Likewise, determining prognosis depends on work force–based information, on knowing which factors influence disease progression favorably and unfavorably, and the likely effect of further exposure even at low levels.

In the discussion that follows, the various types of pneumoconioses are considered separately with respect to occupations at risk, pathophysiology and epidemiology, as well as the clinical issues of diagnosis, prognosis, and management. On all continents and in many countries, there are a substantial proportion of individuals exposed to dust at work and therefore potentially at risk for pneumoconiosis.[8] Lists of occupations and jobs at risk are never exhaustive (Table 65-1) but are a guide for use in general office practice, where it may be more important to raise the suspicion of a diagnosis of pneumoconiosis than to be knowledgeable about the particular exposures a given job title implies. Indeed, the latter often falls into the expertise of the industrial hygienist. For those in occupational health or occupational medicine practice, reference should be made to one of the more specialized texts that describe the occupations at risk in greater detail.[1,2,4,11]

TABLE 65-1. Industries and Occupations at Risk for Silicosis

Industries with Examples	Occupations Implicated
Mining, tunneling, and excavating	
Underground: gold, copper, iron, tin, uranium, civil engineering projects	Miner, driller, tunneler, developer, stoper
Surface: coal, iron, excavation of foundations	Mobile rig drill operator
Quarrying	
Granite, sandstone, slate, sand, chinastone/clay	Driller, hammerer, digger
Stonework	
Granite sheds, monumental masonry	Cutter, dresser, driller, polisher, grinder, mason
Foundries	
Ferrous and nonferrous metals	Molder, knockout man, fettler, coremaker, caster
Abrasives	
Production: silica flour, metal polish, and sandpapers, fillers in paint, rubber, and plastics	Crusher, pulverizer, and mixer; workers in the manufacture of abrasives
Sandblasting: oil rigs, tombstones, denim	Operators of high-speed jets
Ceramics	
Manufacture of pottery, stoneware, refractory bricks for ovens and kilns	Workers at any stage of process if products are dry
Others	
Glass making, boiler scaling, traditional crafts, stone grinders, gemstone workers, dental technicians, concrete reconstruction	

SILICOSIS

Definition

Silicosis is a fibrotic lung disease attributable to the inhalation of crystalline silica usually in the form of quartz and, less commonly, as cristobalite and tridymite.[1,12] Amorphous silica is relatively nontoxic; silicates such as asbestos, mica, and talc evoke a different type of pulmonary response and are considered separately.

Industries and Occupations Still at Risk

Silicosis is an ancient disease that continues to be a major disease worldwide in men and women exposed to silica dust in a variety of occupations.[1,13] Table 65-1 provides some common examples of industries in which workers are at risk for silica exposure. Construction and surface and underground rock drilling have all been subjects of Alert documents from NIOSH. Foundries are also a main source of silica dust.[1,7,14] More recent reports have shown a silicosis risk for workers involved with the repair, rehabilitation, or demolition of concrete structures[15] including roads.[16] Less common occupations associated with silicosis include workers producing stressed denim by sandblasting,[17] stone carvers,[18] and jewelers using chalk molds.[19]

Many of the current cases of silicosis come from industries using relatively new technology that, if unaccompanied by modern controls, may result in exposures to finer dust particles than in traditional industries and jobs. New types of pneumoconiosis often turn out to be silicosis in an industry not previously thought to be at risk or a mixed dust pneumoconiosis in which silica is implicated with other dusts.[20,21] Silicosis is often the result of exposure in the remote past and not in the current workplace. The risks for silicosis depend upon the levels of exposure, and although this can be controlled, there is evidence that dust levels may be monitored inappropriately and that the sampling accuracy may be poor in many workplaces.[14]

Outbreaks of silicosis and death from the disease continue to be reported worldwide,[7,14,18] even in countries with developed legislative systems and environmental surveillance programs, such as the United States,[22] Canada,[23] Europe,[24] and South Africa.[25] Recent U.S. data show a reduction in the rate of decline in deaths from silicosis after 1995 with an increased proportion of deaths in the age group younger than 45 years. These data indicate "that intense overexposures to respirable crystalline silica continue to occur despite the existence of legally enforceable limits."[26] In the United States, NIOSH has estimated that at least 1.7 million workers are exposed to silica, of whom between 1500 and 2360 will develop silicosis each year. Cases of silicosis have also been reported following general environmental exposure[27,28] and in agricultural workers.[29,29a]

Pathology

Three clinicopathologic types of silicosis have been described (Table 65-2): *chronic silicosis*, which typically

TABLE 65-2. Diseases Associated with Exposure to Silica Dust

follows exposure, measured in decades rather than years, to respirable dust usually containing less than 30% quartz; *accelerated silicosis*, which follows shorter, heavier exposure; and *acute silicosis* (silicoproteinosis), which follows intense exposure to fine dust of high silica content, such as that found in sandblasting industries, for periods measured in months rather than years.[2,12]

Chronic silicosis is the most common form of the disease. The hallmark of chronic silicosis is the silicotic nodule, one of the few agent-specific lesions in pathology (Fig. 65-3A and B). The mature lesion is characterized by a central area of whorled hyalinized collagen fibers with a more peripheral zone of dust-laden macrophages. Birefringent particles can be seen in the nodule with light microscopy. Early in the course of the disease, dust-filled macrophages may be the most prominent finding. Silicotic nodules develop first in the hilar lymph nodes[30] and may be confined to this area; they may become encased in calcification and impinge on or erode into airways. The disease process next involves the lung parenchyma, where the nodules are discrete (3–5 mm in diameter), palpable and grayish-black in color. They are usually bilateral, involving the upper zones. Similar nodules can be found in the visceral pleura and often develop in the lymphatic drainage channels of the lung, particularly in the perivascular sheath.

In accelerated silicosis, the changes are similar to those seen in chronic silicosis. However, the nodules develop sooner (after 3–10 yr of exposure) and are more cellular than fibrotic.

With disease progression in both chronic and accelerated silicosis, the nodules may become confluent, leading to the development of *progressive massive fibrosis* (PMF) (see Fig. 65-3C), also known as *complicated silicosis*. These lesions, which are at least 1 cm in diameter (and often larger), usually involve the upper lobes. They tend to obliterate lung structure and may cavitate, which may be an indication of tuberculosis.[2] *Rheumatoid nodules* may also occur in the setting of silicosis and may be seen in subjects with rheumatoid arthritis or high levels of circulating rheumatoid factor.[2] These nodules may be larger than the usual silicotic lesion (≤5 cm in diameter) and have light gray necrotic centers surrounded by palisading histiocytes, fibroblasts, collagen, and neutrophils.[2] There may be silicotic nodules in the background. Rheumatoid nodules are less frequently associated with silica than with coal dust exposure (see subsequent discussion).

Acute silicosis shows all the features of pulmonary alveolar proteinosis (see Chapter 63). Silica particles and various biomarkers of tissue reaction can be identified in the proteinaceous material from the alveolar spaces as well as in lavage material.

The lungs of exposed individuals, whether or not they show silicosis, also may demonstrate the features of other diseases associated with occupational dust exposure, such as chronic bronchitis and emphysema. The pathologic features are similar whether associated with occupational exposure to dusts and fumes encountered in the workplace or with exposure to tobacco smoke. Small airway abnormalities, including fibrosis and pigmentation of respiratory bronchioles (see Fig. 65-3D), are seen in association with exposures to a variety of mineral dusts including those responsible for silicosis.[31] An association between silica exposure and idiopathic pulmonary fibrosis has also been noted.[32]

Silicotic nodules may also develop in the cervical and abdominal lymph nodes and, occasionally, in the liver, spleen, and bone marrow.[7]

Pathogenesis

The pathogenicity of silica dust is dependent on the physical, mechanical, and chemical properties of the particles. A review of this topic summarizes the processes whereby silica produces inflammation and fibrogenesis in the lung.[33] Silica-induced inflammation and fibrosis result from complex interactions between the particles and the lung macrophages, alveolar epithelial cells, fibroblasts, neutrophils, lymphocytes, and complex networks, stimulating the production of oxidants, chemokines, and cytokines. However, the cell mechanisms that initiate and drive the process of inflammation and fibrosis are not fully understood. The surface characteristics of the silica particles determine their redox potential and ability to react with hydrogen, oxygen, and nitrogen. There is agreement that freshly fractured silica, such as that generated during sandblasting, is more toxic to the alveolar macrophages than is "aged" silica, presumably because of its increased redox potential. Other minerals, particularly clay components, may adhere to the surfaces of silica particles, producing "coated" silica that is less toxic than uncoated silica dust. This may explain the relatively nonfibrogenic response to silica in

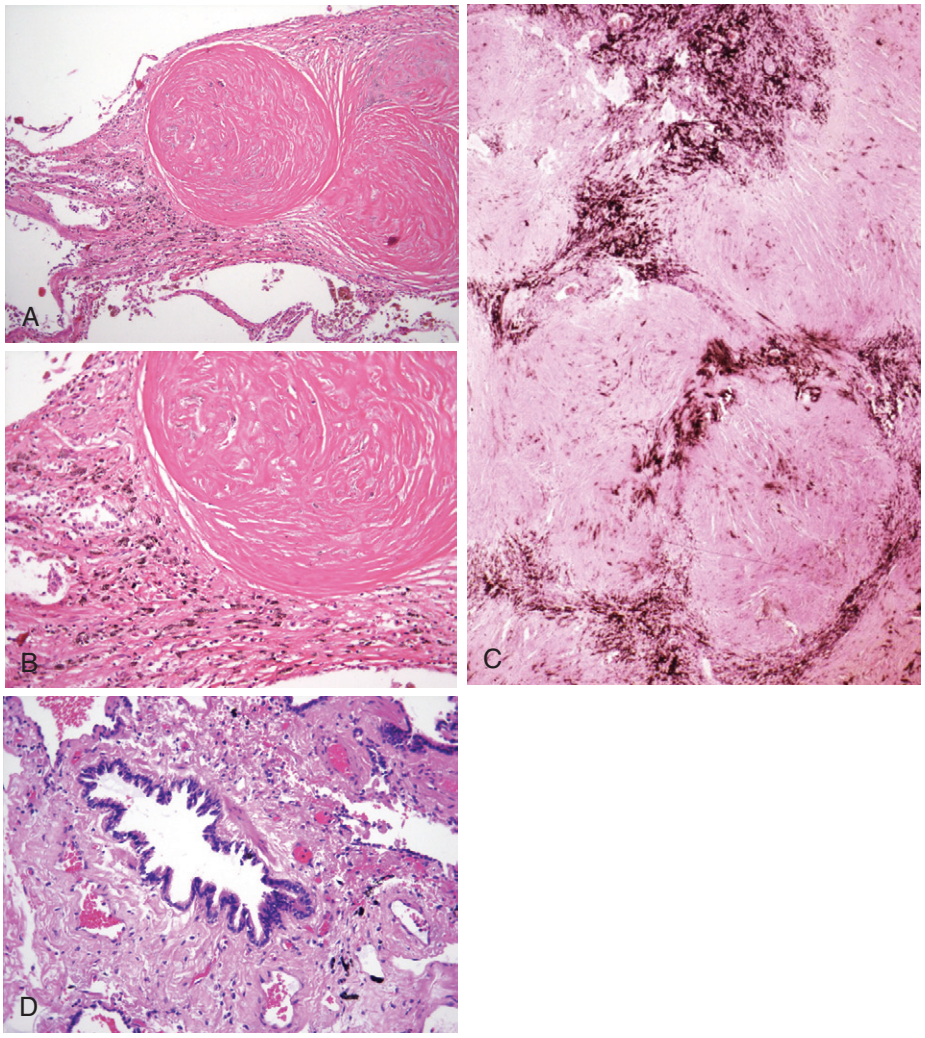

FIGURE 65-3 ■ Pathologic lesions of chronic silicosis. **A,** Silicotic nodule characterized by a central zone of a cellular hyalinized collagen with a whorled appearance and a peripheral zone of dust-laden macrophages. **B,** Silicotic nodule at higher magnification to show these characteristics to better advantage. **C,** Progressive massive fibrosis shows confluent silicotic nodules and aggregates of dust-laden macrophages. **D,** Mineral dust small airway disease characterized by peribronchiolar fibrous tissue containing a moderate amount of pigment. (Courtesy of National Institute for Occupational Health, South Africa.)

coal and hematite miners and the observation that the incidence of silicosis is decreased by concomitant exposure to other dusts. Silica particles smaller than 5 μm reach the lower respiratory tract and may enter the alveoli. There is some debate as to whether the fibrogenicity of the particles is dependent on their actual size. The intensity of the exposure determines the nature of the lung injury. Low-intensity exposure generally produces aggregates of fibrosis with relative sparing of the lung architecture, whereas high-intensity exposure has been shown in rats to cause widespread pulmonary inflammation and collagen deposition.

Tumor necrosis factor-α (TNF-α) and interleukin 1 (IL-1) play an important role in the initiation of silicosis, and experimental inhibition of these cytokines has been shown to prevent silicosis. Growth factors, including transforming growth factor-β (TGF-β), are important in fibrogenesis (and also have been implicated in carcinogenesis) in association with silica.[34,35] A review describes the immune response to silica in more detail and the role of innate and adaptive immunity.[36] Although the major determinant of silicosis is the level of exposure to silica-containing dust, individual susceptibility to the disease may play a role in its development and severity.[37,38]

Epidemiology: Secular Trends and Their Implications for the Clinician

Over the course of the 20th century, silicosis changed from a rapidly fatal disease to an indolent and disabling disorder. Reasons include improved environmental controls, falling rates of tuberculosis, and the advent of drug therapy for tuberculosis. Nevertheless, there is still well-warranted concern that this avoidable disease will remain

a significant cause of morbidity[7] and mortality in the 21st century.[39,40] The prevalence of silicosis is difficult to estimate, given the large number of industries at risk (see Table 65-1), the transient labor force in industrializing as well as in industrialized countries, and the frequent appearance (and progression) of disease after the worker has left the work force.[41,42] Despite the progress made, silicosis has been reported in workers from a variety of industries in persons starting work after 1970, and reported cases have been estimated to represent only a third of the total cases of silicosis.[13] The prevalence of silicosis in South Africa has been rising.[25] In calculating an individual's risk for silicosis, duration and intensity of exposure are of primary interest but peak exposure also may be important.[43] The physician should never dismiss the diagnosis of silicosis when that diagnosis is suggested by clinical and radiologic features, even when exposure appears to have been insignificant or in an occupation not known to be associated with silicosis.

Tuberculosis

The association between silicosis and tuberculosis has long been recognized. Rates for active tuberculosis in silicotic subjects range from 2- to 30-fold more than those in the same workforce without silicosis.[44] Factors that influence the development of tuberculosis in the subject with silicosis include the severity and type of disease (the risk is considerably higher in patients with acute and accelerated silicosis),[12] the prevalence of tuberculosis in the population from which the work force was drawn, as well as their age, general health and HIV status.[44–46] Exposure to silica, without silicosis, may also predispose individuals to tuberculosis.[44,45]

Tuberculosis is characterized by necrotizing epithelioid granulomas. These are never seen with silicosis alone. Although *Mycobacterium tuberculosis* is the usual organism, nontuberculous mycobacteria account for a large proportion of the mycobacterial disease in populations in which nontuberculosis mycobacterial disease is common.[7,47]

Airflow Obstruction and Chronic Bronchitis

Chronic obstructive pulmonary disease (COPD) and chronic bronchitis are common manifestations of long-term occupational exposure to environments contaminated by silica dust and can develop in silica-exposed individuals with or without silicosis.[7,48–50] Small airway abnormalities, including fibrosis and pigmentation of respiratory bronchioles (see Fig. 65-3D), are also seen in association with exposures to a variety of mineral dusts, including those responsible for silicosis.[31] In a study of adolescents and young adults working in a stone crushing plant, lung function changes were interpreted as evidence for impaired lung growth that was attributed to their very high respirable crystalline silica exposure.[51] Smoking can potentiate the effect of silica dust on airflow obstruction.[49]

Connective Tissue Diseases and Renal Disease

Associations have been reported between exposure to silica and certain connective tissue diseases including progressive systemic sclerosis, systemic lupus erythematosis, and as previously mentioned, rheumatoid arthritis.[7] Epidemiologic evidence indicates that the prevalence of rheumatoid arthritis is increased in those with exposure to silica as well as in those with silicosis.[52] It has also been suggested that rheumatoid arthritis may initiate or aggravate silicosis. Systemic sclerosis has been shown to be associated with silicosis[52] but may also be associated with silica dust exposure without silicosis.[7] The evidence for an association between lupus erythematosus and silicosis is strongest for acute or accelerated silicosis but is inconclusive for chronic silicosis.[7,52]

Renal disease has also been reported in silica-exposed workers. Some studies have implicated an immune complex glomerulitis or a direct toxic effect of silica.[7,11,52] A recent report has linked silicosis with ANCA positivity and possibly with vasculitis.[53]

Lung Cancer

In 1996, the International Agency for Research in Cancer (IARC)[54] classified silica dust as "carcinogenic to humans." The association between silicosis and lung cancer has been difficult to establish because of the high prevalence of smoking in silica-exposed workers and because of frequent concomitant radon exposure.[7] Studies of non-radon–exposed, nonsmoking workers with silicosis suggest a clear relationship between silicosis and lung cancer, but there remains some doubt as to whether silica exposure, in the absence of silicosis, carries an increased risk for lung cancer.[7,52,55–57]

Clinical Features

The symptoms and signs of chronic silicosis may be minimal. The main symptom is breathlessness, but in chronic silicosis, in the absence of other respiratory disease, even this symptom may be absent. It is not unusual for a patient with chronic silicosis to present without symptoms for assessment of an abnormal chest radiograph. The appearance of breathlessness may mark the development of a complication such as PMF or tuberculosis or may reflect associated airway disease. Cough and sputum production are common symptoms and usually relate to chronic bronchitis but may reflect the development of tuberculosis or lung cancer. Chest pain is not a feature of silicosis nor are systemic symptoms such as fever and weight loss, which should be attributed to tuberculosis or lung cancer until proved otherwise. Clubbing is also not a feature of silicosis and should raise concern about lung cancer.

In accelerated and acute silicosis, the time scale of symptom evolution is in years or months rather than in decades. In acute silicosis, breathlessness may become

disabling within months, followed by impaired gas exchange and respiratory failure.

Radiographic Features

Uncomplicated silicosis is characterized by the presence of small rounded opacities on the chest radiograph,[1,12,58] as graded in the ILO classification (as described previously).[5] In general, there is a good correlation between dust exposure, the amount of dust in the lungs, the lung pathology, and the chest radiograph.[59] However, occasionally, even advanced silicosis, determined by histology, may not be apparent on a chest radiograph.[60]

Silicotic nodules are usually symmetrically distributed and tend to occur first in the upper zones (Fig. 65-4), later, although not invariably, involving other zones. Occasionally, they are calcified, resembling microlithiasis. Enlargement of the hilar nodes may precede the development of the parenchymal lesions.[58] Eggshell calcification, when present, is strongly suggestive, although not pathognomonic, of silicosis (Fig. 65-5; see also Fig. 65-4). Pleural plaques may occur but are not a common feature.

PMF is characterized by the coalescence of small rounded opacities to form larger lesions; they are graded on the ILO scale according to size and extent (categories A-C). CT assessment is superior to the chest radiograph not only in assessing the presence and extent of silicotic nodulation but also in revealing early conglomeration (see Fig. 65-5).[61] With time, the mass lesions tend to contract, usually to the upper lobes, leaving hypertranslucent zones at their margins and often at the lung bases.

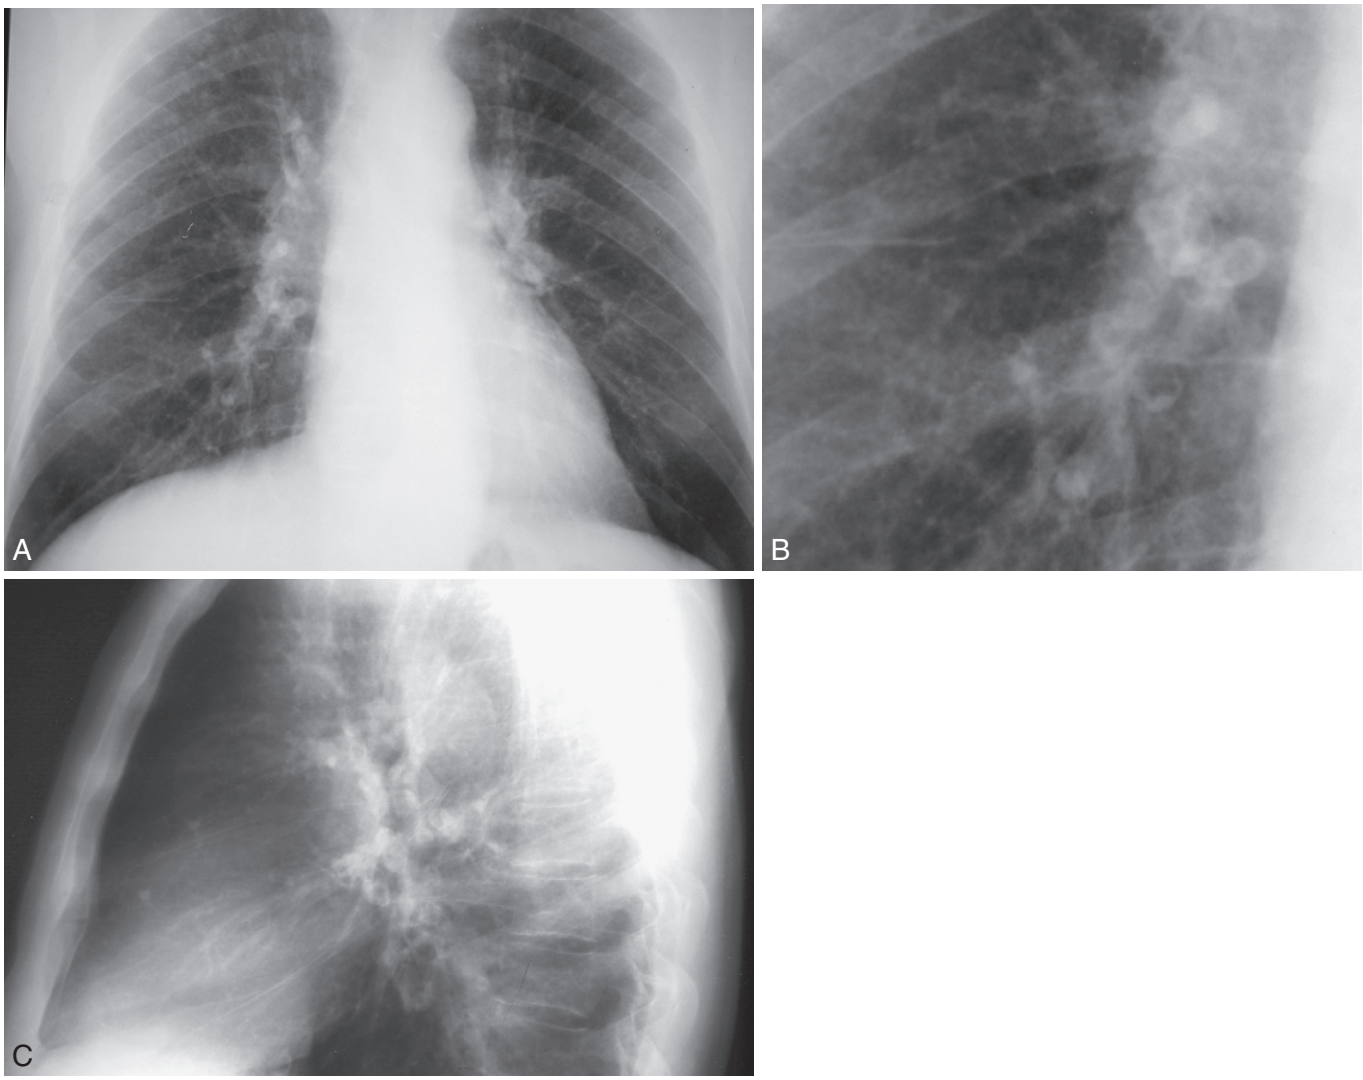

FIGURE 65-4 ■ **A,** Posteroanterior radiograph shows predominantly upper zone but, atypically, asymmetrical nodularity in keeping with silicosis. **B,** Close-up shows the right upper zone nodularity and "eggshell" calcification of the hilar lymph nodes. This latter feature strongly suggests that this radiograph represents silicosis, notwithstanding the patient's history of 30 years of underground work in a coal mine. **C,** Lateral view shows the eggshell calcification and also a larger and probably calcified nodule situated anteriorly. This latter feature is compatible with a healed primary tuberculous focus, and if this is supported by a positive test for tuberculosis, a course of treatment for latent tuberculosis infection should be offered. (Courtesy of Dr. J. H. M. MacGregor, University of Calgary.)

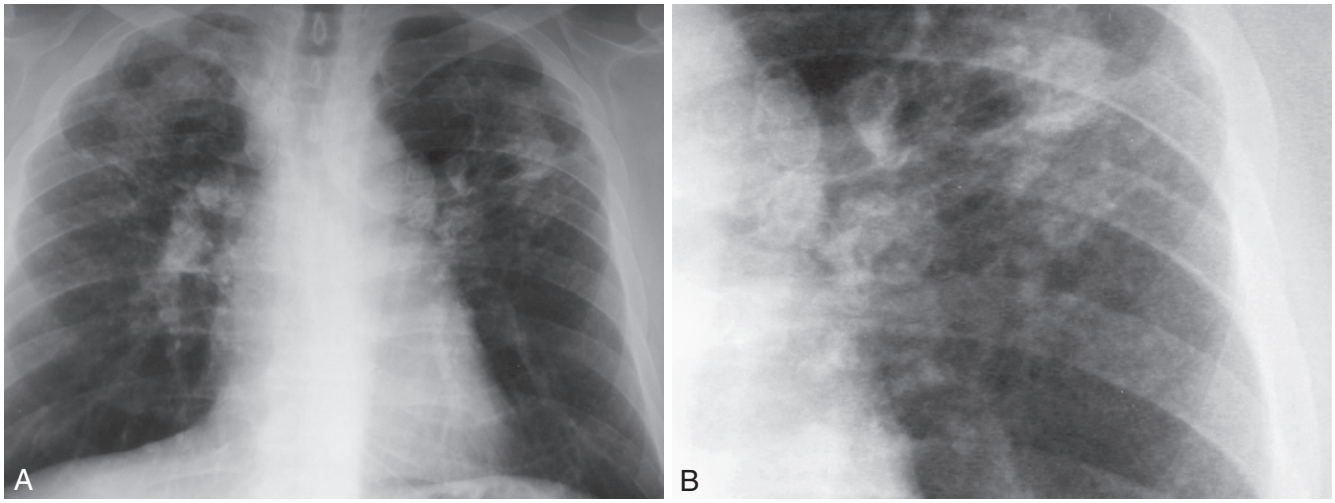

FIGURE 65-5 ■ **A,** Posteroanterior radiograph shows features of progressive massive fibrosis (PMF) with "eggshell" calcification of the hilar nodes, in keeping with complicated silicosis, in a man who had shoveled sand in a glass factory. **B,** Close-up view shows the PMF with a background of smaller nodules and the eggshell calcification. (Courtesy of Dr. J. H. M. MacGregor, University of Calgary.)

In this process, small rounded opacities, previously evident, may disappear, resulting in a picture that must be distinguished from tuberculosis. The rapid development of several large lesions suggests rheumatoid silicosis, but new lesions, especially if cavitated, should be regarded as evidence of mycobacterial disease. Acute silicosis is characterized radiologically by diffuse changes that usually display an air space and interstitial pattern rather than the usual nodularity.[1,62]

Lung Function

The lung function profile is determined by the extent of silicosis as well as associated or concomitant airway and vascular changes. In chronic silicosis, spirometric tests (forced expiratory volume in 1 second [FEV_1], FEV_1/FVC [forced vtital capacity], and maximal midexpiratory flow[31]) usually reflect airflow limitation.[7] Reduction in diffusing capacity of carbon monoxide (D_{LCO}) is generally apparent in more advanced chronic silicosis and probably reflects associated emphysema.[63]

In the accelerated and acute forms, functional changes are more marked and progression is more rapid. In acute silicosis, lung function shows a restrictive defect and impairment of gas exchange, which leads to respiratory failure and eventually to death from intractable hypoxemia. Interpretation of pulmonary function tests is discussed in Chapter 24.

Diagnosis and Complications

Silicosis is diagnosed on the basis of a history of exposure and the characteristic radiographic changes.[12] Problems arise when the history of exposure is remote, forgotten, or missed or has occurred outside of a recognized occupation. Occasionally, the radiologic features are unusual; examples include the presence of hilar lymphadenopathy or of large lung opacities in the absence of typical small nodules. Detection of silica in BAL material may suggest the diagnosis. Lung biopsy may be necessary to distinguish progressive massive fibrosis or other atypical features from lung cancer, tuberculosis, and other diagnoses. Biopsy material should be submitted for microanalysis for dust, including silica.

Less common complications include cor pulmonale, spontaneous pneumothorax, broncholithiasis, and tracheobronchial obstruction from enlarged calcified hilar nodes.[12] The diagnosis of active tuberculosis in the silicotic subject may be more difficult than in the nonsilicotic subject, but in general, a good sample of sputum or sputum induced by nebulized hypertonic saline sent for mycobacterial culture provides the diagnosis. The presence of cough, hemoptysis, weight loss, fever, or any new radiologic feature should be pursued with culture of sputum or BAL fluid or with culture and histologic examination of tissue. In many instances, it is the chest radiograph rather than the clinical features that gives the first indication of tuberculosis in the presence of silicosis, but it should be noted that those with silicosis are also at risk for extrapulmonary tuberculosis.[44]

Management and Control

Once established, the fibrotic process of chronic silicosis is thought to be irreversible. Management of the individual case is thus directed toward preventing progression and the development of complicated disease. A change in occupation to an environment free of silica-containing dust should be advised. The disease will generally progress even without further exposure,[41,42] but the rate of deterioration may be reduced.

Interventions to interrupt the inflammatory process that leads to chronic silicosis including the inhalation of aluminum or polyvinylpynidine-*N*-oxide and oral tetrandine have not been shown to be successful. There is currently interest in the use of lung lavage to remove

silica from the lung, but a favorable impact on progression of acute or chronic silicosis has not been demonstrated. Treatment of all forms of silicosis should be directed toward control of mycobacterial disease. This is especially true for acute and accelerated silicosis and silicosis in workers with HIV infection.[12,46] All subjects with silicosis should have a tuberculin skin test or an interferon-γ (IFN-γ) release assay[64] and, if positive in the absence of evidence of tuberculosis, be offered treatment for latent tuberculosis infection (see Chapter 34).

The interaction between silica exposure and smoking in the development of COPD,[49,50] tuberculosis,[65] and lung cancer makes it important to implement smoking-cessation programs in the workplace.

Because acute and accelerated silicosis carry such a poor prognosis and tend to occur in younger subjects,[66] consideration should be given for lung transplantation in such cases. (For lung transplantation, see Chapter 95.)

The most important aspect of the management of silicosis relates to its prevention. To achieve this, a sustained effort must be made to increase awareness of silicosis. Recent deaths from silicosis in younger subjects in the United States have occurred after exposure in the construction and manufacturing sectors, with none from mining.[66] Deaths of young people sandblasting denim[17] is a reminder that there is often a lack of awareness of the hazards of silica outside the traditional occupations associated with silicosis.[26]

COAL WORKERS' PNEUMOCONIOSIS

Definition and Occupations at Risk

Coal workers' pneumoconiosis (CWP) is a distinct pathologic entity resulting from the deposition of coal dust in the lungs.[1,2,4] The tissue reactions to deposits of dust include the *coal macule* and the *coal nodule* (simple CWP) and PMF (complicated CWP)[2] (Fig. 65-6).

The main occupation at risk for CWP is coal mining, an industry that in the 1970s, employed approximately 250,000 people in the United Kingdom and a comparable number in Western Europe.[8] Approximately 175,000 coal miners were employed in the United States in 1986; since then, there has been a steady decrease in the number to approximately 80,000 in 1999.[22] Coal is also mined in Eastern Europe, India, and China and on the African, Australian, and South American continents. With mechanization, output and potential for dust exposure have increased. Former as well as current coal workers are likely to continue to be seen with CWP.

Coal mine dust contains a variable amount of quartz depending on the nature of ore-bearing rock, the size of the coal seam, and the processes used to mine the seam (including the degree of mechanization). Coal miners may also develop silicotic nodules when the coal seams are in hard rock. Silicosis is more common in mines with a high grade of coal and in workers such as roof bolters who work outside of the coal seams.[2,4] Current evidence shows that coal mining, even in the absence of CWP, is associated with chronic bronchitis, chronic airflow limitation,[4,67,68] and emphysema.[2,4,68a]

Other occupations at risk for exposure to coal or carbon dust include coal trimming (which involves loading and stowing coal in stores or ships' holds), the mining and milling of graphite in carbon plants, the manufacture of carbon electrodes, and the manufacture and use of carbon black.

Pathology

The primary lesion in CWP is the *coal macule*, which can be seen (although not palpated) on macroscopic examination as a small (≤4 mm) pigmented lesion, distributed initially in the upper lobes, although the lower lobes may subsequently become involved.[2] On microscopic examination, the coal macule consists of a stellate aggregation of dust and dust-laden macrophages around respiratory bronchioles, with reticulin fibers and a variable amount of collagen (see Fig. 65-6).[2] *Focal emphysema*, a form of centriacinar emphysema, occurs within and around the coal macule, and together they form the characteristic lesion of CWP.[2] The *coal nodule* is a palpable lesion that, in addition to dust-laden macrophages and reticulin, contains a substantial number of haphazardly arranged collagen fibers.[2] Coal nodules, which

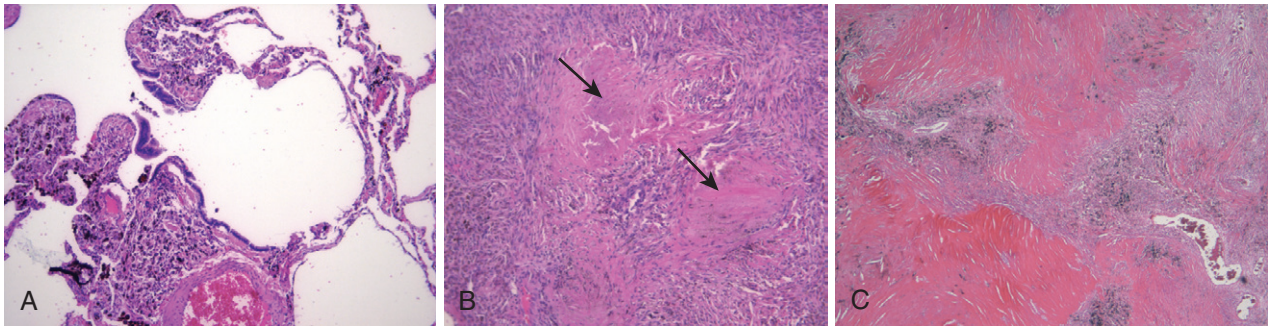

FIGURE 65-6 ■ Pathologic lesions of coal workers' pneumoconiosis: examples from South African coal miners. **A,** Coal macule shows an aggregation of dust and dust-laden macrophages in the wall of a distal airway in which reticulin and a few collagen fibers were demonstrated. **B,** Coal nodule consists of dust and dust-laden macrophages and dense, irregular depositions of collagen (*arrows*). This lesion would be palpable. There also was associated focal emphysema. **C,** Progressive massive fibrosis with coalescence of nodules and dense collagen deposition. (Courtesy of National Institute for Occupational Health, South Africa.)

result from exposure to coal dust admixed with silica, usually occur in association with coal macules.[1] Classic silicotic lesions are seen in approximately 12% of U.S. coal miners[2] and form when lung dust residue contains 18% or more quartz. Other features include subpleural dust deposits, enlargement of the hilar and mediastinal nodes, and on occasion, tattooing of the parietal pleural lymphatic channels by coal dust.

PMF (complicated CWP) is defined as a fibrotic pneumoconiotic lesion 1 cm or greater in diameter. These bulky, often irregular, well-defined, heavily pigmented rubbery black tissue masses usually occur in a background of severe simple CWP. PMF usually develops in the posterior segment of the upper lobes or apical segments of the lower lobes and is typically bilateral (Figs. 65-7 and 65-8). Microscopically, the lesions contain the

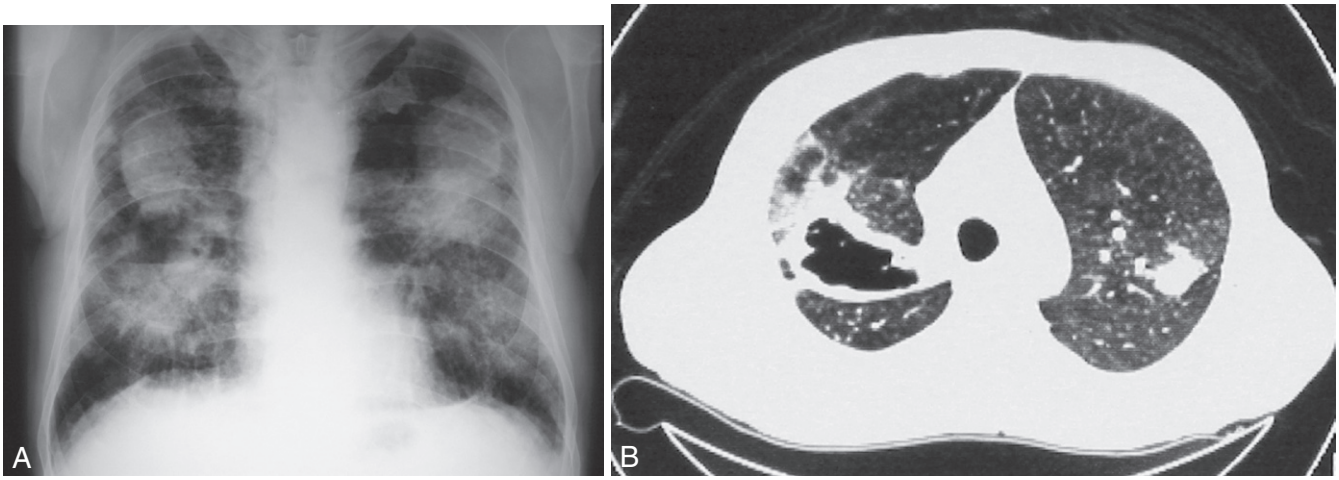

FIGURE 65-7 ■ **A,** Chest radiograph shows PMF with evidence of cavitation in the right lower zone. The film represents complicated coal worker's pneumoconiosis. **B,** Computed tomography scan shows the background nodularity and the lesions of PMF with cavitation on the right. (Courtesy of Dr. J. H. M. MacGregor, University of Calgary.)

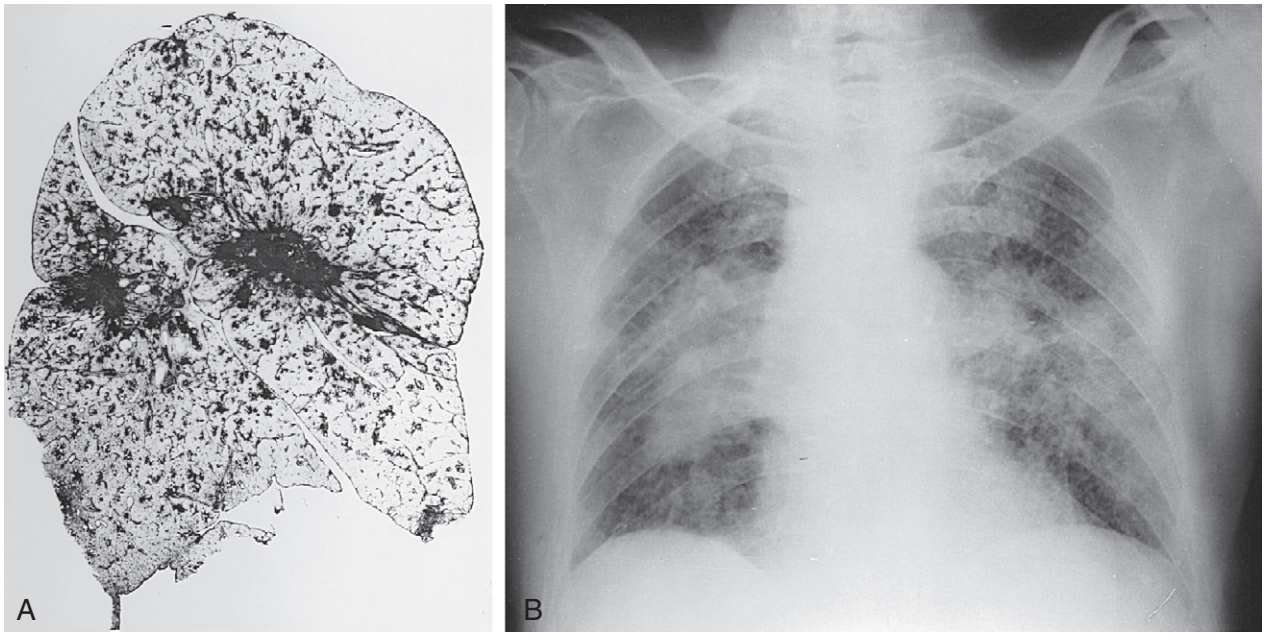

FIGURE 65-8 ■ **A,** Whole-lung section of a 71-year-old Appalachian coal miner. The miner was a nonsmoker and had worked for 28 years underground, primarily at face work. The midsagittal section of the left lung shows massive lesions in the superior segment of the lower lobe and in the central area of the upper lobe. PMF is seen against a background of simple nodular and macular coal workers' pneumoconiosis. In several areas, there is evidence of coalescence of nodules. There is mild focal emphysema associated with the coal dust macules. **B,** Chest radiograph shows features of PMF against a background of nodularity. The mass lesion on the right shows the propensity of PMF to move toward the hilum. The opacities are somewhat atypical for their predominantly lower zone situation. (Case from the National Institute of Occupational Safety and Health [NIOSH] W. Laqueur collection, courtesy of Drs. V. Vallyathan and F. H. Y. Green.)

same elements as the coal nodule (see Fig. 65-6C). They may impinge on and obliterate airways and vessels and cross interlobar fissures. Cavitation is not uncommon, probably as a consequence of ischemic necrosis.

Rheumatoid pneumoconiosis,[2] one variant of which is called Caplan's syndrome, is a form of CWP associated with rheumatoid arthritis or a rheumatoid diathesis. It is characterized by nodules that are larger than coal nodules (≤5 cm in diameter) and have smoother borders. Pigmentation is arranged in concentric laminations, and relative to PMF lesions, they contain little dust. These lesions may cavitate or calcify. The microscopic features are similar to those described for the rheumatoid silicotic lesion (see the discussion under the "Pathology" of "Silicosis"). Active areas in the nodules contain dust-laden macrophages, lymphocytes, polymorphonuclear leukocytes, and plasma cells. When activity ceases, they may collapse or calcify. Vasculitis is seen in vessels within and surrounding these lesions. Rheumatoid pneumoconiosis lesions were originally described in Welsh coal miners and are reported in Belgian coal miners, but are uncommon in North American coal miners.

Diffuse interstitial fibrosis has also been reported in coal miners; the fibrosis may contain black carbon pigment but is otherwise pathologically indistinguishable from usual interstitial fibrosis. However, it has a relatively benign clinical course compared with that of the same condition in the general population.[2]

Pathogenesis

The risk for CWP increases with the intensity and duration of exposure to coal dust. The effect of coal on the lung is also related to its rank, which is based on its carbon content. Anthracite ranks highest (93% carbon), followed by bituminous, subbituminous, and the lowest ranked lignite with the lowest carbon content.[2,4] In epidemiologic studies, CWP is more common in mines of high-rank coal than in those of low-rank coal. This may relate to the greater relative surface area of the coal dust particles, higher surface free radicals, and silica in the high-rank, rather than the low-rank, coal.[4] The coal dust macule and nodule are ascribed to the accumulation of large amounts of relatively inert dust in the lung. As the lung burden of dust increases, alveolar macrophages are activated and reactive oxygen species are released. These in turn trigger the release of cytokines, including interleukins and TNF, which set in motion the processes of inflammation and fibrogenesis that are responsible for the development of pneumoconiosis, and the release of proteases, which contribute to the associated emphysema. The fibrosis, however, is considerably less intense and extensive than that evoked by the more bioactive dusts, such as silica and asbestos.

Although the exact pathogenic mechanisms underlying the development of PMF remain in doubt, these lesions are thought to relate to the amount of coal dust accumulated in the lung, the proportion of inhaled silica in the dust and its surface bioactivity, individual immunologic and genetic factors, and whether tuberculosis is present.[2,4,38] Of these factors, the total dust burden appears to be the most important. In addition, there are striking differences in rates of simple pneumoconiosis and PMF between different coal pits, mining areas, and countries,[2,4] suggesting that other characteristics of the dust particles, including their shape, size, composition, bioactivity, and durability in lung tissue, also make a contribution to the risk of developing CWP and PMF.

Epidemiology and Natural History

Early studies of coal miners suggested that the occupation of coal mining and even the presence of CWP were not associated with higher mortality rates. These studies probably did not take the healthy worker effect into account, and more recent studies have shown that exposure to coal dust is associated with increased mortality.[69] Overall, in the United States, the mortality associated with CWP decreased by 36% between 1982 to 2000 compared with 1968 to 1981.[70]

Although the rates of CWP have been falling steadily in the United States and Europe, new cases continue to be detected.[1,22,71] The presence of PMF is associated with more severe adverse effects on the health and life expectancy of coal miners than those of simple CWP. Risk factors for PMF include the presence and stage of CWP, the intensity of dust exposure, and the age of the subject.[72] The role of silica in the development of PMF is controversial but is generally believed to be important.[2,4,72a] A study of coal miners with rapidly progressive CWP suggests that this might be a marker for the development of PMF. Risk factors for rapid progression of CWP included working at the face in smaller mines, younger age, and mining in eastern Kentucky and western Virgina.[71]

Rheumatoid Pneumoconiosis

Rheumatoid pneumoconiosis (Caplan's syndrome) was originally described as a variant of PMF in coal workers on the basis of its distinctive radiologic features. Active arthritis or circulating rheumatoid factor were commonly associated with rheumatoid pneumoconiosis.[1] At present, most evidence suggests that the presence of rheumatoid arthritis, a rheumatoid diathesis, or both, is a host factor that modifies the response of an individual to coal mine dust exposure. Conversely, dust exposure does not appear to be a risk factor for rheumatoid arthritis.[1] CWP does not appear to have an association with other connective tissue disorders.

Role of Silica

Although it is recognized that silica does not play a primary role in the causation of CWP, coal miners, especially those mining anthracite, may develop the lesions of silicosis. When present, silicosis is usually associated with CWP.[2] Although combined exposure to silica and coal dust may produce less silicosis than would a similar pure exposure to silica, silica exposure is nevertheless thought to contribute to the risk of developing PMF.[4]

Airflow Obstruction and Chronic Bronchitis

With the generally decreasing rates for CWP in most countries, the focus of interest has shifted to an examination of the relationship of coal mining exposure with chronic bronchitis and emphysema.[67,68a,73] Earlier studies demonstrated an association between occupational exposure and airflow limitation, but the confounding effects of smoking were not uniformly taken into account. The association between coal mining and obstructive lung disease has now been confirmed by several longitudinal studies that show that airflow limitation from coal dust exposure can occur independently from CWP and that the effect becomes comparable with that of smoking at exposure levels at which there is a risk for CWP.[50,74]

Mucus hypersecretion (chronic bronchitis) is common in coal workers but does not appear to play a direct role in their development of COPD. Mucus hypersecretion will generally resolve after withdrawal from dust exposure as it does after smoking cessation. Bronchial hyperresponsiveness appears to predispose coal workers to develop COPD. Longitudinal studies have shown that those with persistent airway hyperresponsiveness to methacholine over a 5-year period show a greater FEV_1 decline compared with those whose airway hyperresponsiveness reverses over the same time period.[75]

Tuberculosis and Cancer

Mycobacterial infection, either by *M. tuberculosis* or nontuberculous mycobacteria, has not been demonstrated to be more common in association with CWP in the absence of silicosis.[76] Most evidence suggests that the occupation of coal mining is not associated with lung cancer. An increased risk of stomach cancer has been documented,[2,4,77] but this was not apparent in a 23 year follow-up study of 8,899 coal miners.[69]

Clinical Features

Simple CWP is regarded as a disease state without symptoms or physical signs. The diagnosis is based on the radiologic features. The symptoms of cough and sputum reported by most coal miners are likely to be the consequence of dust-induced chronic bronchitis.[50] Breathlessness on effort is usually caused by associated chronic airflow limitation or by the development of PMF.[4] Respiratory impairment and disability develop as PMF progresses, although patients with category A PMF (lesions 1-5 cm in diameter) may be symptom free. Lesions of PMF that impinge on airways may cause abnormal breath sounds. Large or bilateral PMF lesions may be associated with hypoxemia and right heart failure. The presence of new lung lesions with rheumatoid arthritis, subcutaneous rheumatoid nodules, or positive rheumatoid factor raises the possibility of rheumatoid pneumoconiosis. The lung lesions may or may not develop concomitantly with joint disease.

Chest Radiography

The hallmark of simple CWP on the chest radiograph is the presence of small rounded opacities in the lung parenchyma.[1,58] (See the discussion of chest radiographs in the "Introduction" to this chapter.) Coal macules are usually associated with small (<1.5 mm) p nodules on the chest radiograph, but the radiograph may show no nodularity with mild to moderate grades of CWP. Large amounts of coal dust in the lungs are found in association with small, rounded p nodules. When the larger q and r nodules are visible radiologically, this usually reflects the presence of coal nodules and a higher proportion of quartz in the lungs.[78]

Because the chest radiograph has been shown to be insensitive to the presence of macules and nodules,[78] in individual cases, CT may be useful. Small rounded opacities are usually seen first in the upper zones and involve the other zones at a later stage; all lung zones are unlikely to be involved unless profusion category 3 is present.[1,58] The nodule profusion is closely related to the lung dust content at autopsy. Small irregular opacities also occur in a profusion up to 1/0 in association with increasing age and smoking and, in coal workers, may relate to coexisting fibrosis and emphysema. Small rounded opacities probably never regress but the presence of emphysema appears to reduce the reading of profusion on the chest radiograph. Some enlargement of hilar nodes is usual, but eggshell calcification is unusual.

PMF is diagnosed radiologically when the parenchymal opacities exceed 1 cm in diameter, a cutoff point that is arbitrary in what is obviously a continuous process, as shown by the pathologic demonstration of PMF without associated radiologic features.[78] Conversely, approximately one third of cases diagnosed as PMF on the radiograph have been shown, at autopsy, to represent other lesions, including tumors, rheumatoid nodules, or tuberculosis scars.[78] PMF lesions are more common in the upper lobes, are situated posteriorly, and are usually well demarcated from the adjacent lung. As PMF becomes more advanced, the lesions are nearly always bilateral (see Figs. 65-7 and 65-8). They may take on bizarre shapes, cavitate, or calcify. As the lesions shrink toward the hilum or to the apex, bullous lesions may be seen in the surrounding lung.

Lesions seen on the chest radiograph in rheumatoid pneumoconiosis are similar to those of PMF but are usually multiple and peripherally located. The lesions, which range in diameter from 0.5 to 5.0 cm, may appear within weeks. These lesions generally appear in the presence of lesser degrees of nodule profusion than are usual for PMF. They may cavitate, contain fluid levels, and show some calcification surrounding the cavity. In some cases, the lesions disappear, often completely, but may be followed at a later date by a fresh crop of lesions. The ILO classification of radiographs provides a

special notation for lesions thought to be rheumatoid pneumoconiosis.[5]

Lung Function

The controversy regarding the association between simple CWP and abnormal lung function has persisted largely because coal dust has been shown to cause both obstructive lung disease[79] and pneumoconiosis. In general, it is probably true that simple CWP is a condition with little demonstrable effect on lung function. In part, this may be due to the health selection effect into a dusty job.[50] Small irregular opacities and PMF have each been shown to be associated with abnormal lung function.[4,80] Lung function deficits in complicated CWP include reduction in FVC and FEV_1, increased total lung capacity (TLC) and residual volume, and decreased D_{LCO} (particularly in the presence of mixed rounded and irregular opacities). Similar changes have also been noted in nonsmoking coal miners without CWP.[4] Pulmonary hypertension may develop in proportion to the reduction of the vascular bed associated with advanced PMF.

Diagnosis, Complications, and Management

A history of occupational exposure to coal and a chest radiograph are the fundamental elements in the diagnosis of CWP. A CT scan of the chest may be used to demonstrate evidence of CWP when the features on the radiograph are inconclusive.

There are no data to suggest that CWP alone carries an increased risk for mycobacterial infection, either tuberculous or nontuberculous, but treatment of latent tuberculosis infection should be considered for coal workers who are thought to have had significant silica dust exposure or who have evidence of silicosis. Other complications include rheumatoid nodules, which are associated more commonly with coal mining than with gold mining exposure, and scleroderma, in which the opposite is true. Most evidence suggests that the occupation of coal mining is not associated with a risk of lung cancer, but there are some data to suggest and some to refute an increased risk of stomach cancer.[4,69]

The principles of management are those summarized in the "Introduction" to this chapter and elaborated in the section on "Silicosis." Younger subjects with radiologic disease of profusion category 1 or greater should be advised to change their occupation to one in which they are no longer exposed to dust because of their risk of developing PMF. Management of other dust-related, smoking-related, or dust- and smoking-related diseases, such as chronic bronchitis and emphysema, is less straightforward. Smoking-cessation counseling should be given on general principles. Although there are no data to show any interaction between smoking and CWP, both coal mining and smoking have the capacity to cause COPD.[68a]

ASBESTOS-RELATED FIBROSIS OF THE LUNGS (ASBESTOSIS) AND PLEURA

Asbestos Minerals

History and Uses

Asbestos is an ancient mineral exploited by humans from prehistoric times because of its durability and heat resistance and its fibrous nature, which enabled it to be spun.[1,81] Commercial use of asbestos, which started in the 19th century with open-pit mining, grew as mechanization replaced hand cobbing[1] and growth was exponential between the two world wars. Annual production peaked over 5 million tons in 1976 and stabilized at approximately 4 million tons in the early 1980s. Production began to fall in Europe and North America only in the late 1980s, when the ill health effects of exposure became a matter of increasing public concern.[1] By contrast, annual world production of the nonasbestos mineral silicates is almost eightfold greater (~30 million tons) than that of the asbestos mineral silicates.[82] The use of substitutes has increased proportionately as the use of asbestos has been restricted or banned, although in 2008, only 40 countries had banned or severely restricted the use of asbestos. On the African, Asian, and South American continents, asbestos continues to be in demand as a cheap, durable material for use in water reticulation and in housing projects for their rapidly urbanizing populations, and in many countries, the consumption of asbestos remains high and is increasing.[83]

The word *asbestos* (meaning "unquenchable" in Greek) is used currently as a collective term for naturally occurring mineral silicates of the serpentine and amphibole group. Despite different origins and physical and chemical properties, these silicates have in common a fibrous habit, that is, they occur naturally in bundles from which fibers can be easily separated.

What is meant by the term *fiber* is of more than academic importance because their dimensions are determinants of biologic potency. The mineralogist defines a fiber as a particle whose length to diameter (called "aspect") ratio is equal to or greater than 10:1, whereas the definition used by the Occupational Safety and Health Administration (OSHA) as a basis for standard setting is a particle more than 5 μm in length with an aspect ratio equal to or greater than 3:1.

Table 65-3 lists some of the mineral silicates found in human lung tissue and gives a general (but not exhaustive) indication of their commercial uses. From the point of view of health effects, the most important are asbestos fibers and man-made mineral fibers. Biologic potency (and disease-producing potential) depends in general on dose delivered to the target organ, fiber dimensions, and durability in the lung tissue. The role of each of these parameters may not be the same for all fibers and all disease entities.[82] Nonfibrous particles greater than 10 μm seldom reach the lung parenchyma, whereas fibers up to 200 μm can be found in the lungs if their diameter is less than 3 μm.[2]

TABLE 65-3. Mineral Silicates That Have Been Found in Human Lung Tissue*

Mineral: Group and Form	Location of Major Deposits, Commercial or Other	Main Commercial Uses and/or Other Sources of Human Exposure
ASBESTOS MINERALS		
Serpentine		
Chrysotile† (white asbestos)	Canada (Quebec, British Columbia, Yukon, Newfoundland‡), Russia, China (Szechwan), Brazil, Mediterranean countries (Cyprus, Corsica, Greece, Italy), southern Africa (South Africa, Zimbabwe, Swaziland)	Brake lining, shipbuilding and repair, polishing of precious stones, stone cutting, whetstone cutting, foundry operations (mainly for insulation) Asbestos cement products (pipes, gutters, tiles, roofing); insulation, fireproofing, reinforced plastics (fan blades, electric switchgear); textiles; friction materials; paper products; filters, spray-on products
Amphibole		
Crocidolite (blue asbestos)	South Africa (Northwest Cape‡), western Australia‡	Used in combination, mostly in cement but also in some of the products listed above
Amosite (brown asbestos)	South Africa (Northern Province, former Transvaal) Finland‡	
Anthophyllite		Filler in rubber and plastics
Tremolite	Contaminates ore in certain asbestos, talc, iron, and vermiculite mines; also found in some agricultural soils	May or may not be removed in processing; has rural domestic uses (e.g., stucco)
Cummington-grunerite	Contaminates ore in certain iron mines (often not fibrous)	No commercial use
NONASBESTOS MINERAL SILICATES		
Clay minerals (usually fine-grained, powder-like) such as kaolin and montmorillonite (bentonite)	40 countries, including China, United States (Georgia, North Carolina), United Kingdom (Cornwall), Czechoslovakia, Germany, Egypt, Japan	Functional filler in paper, plastic, bricks and cement, rubber, paint, etc.; fire clays, refractories, ceramics, lubricants
Attapulgite and sepiolite	United States (Georgia, Florida), Spain, Australia, South Africa	Oil absorbants; pesticide carriers; pet litter
Talcs (usually platelike but can roll into scrolls)	United States (Vermont, Montana, New York, California), Italy, Spain, Norway, China, Japan, Korea, Canada	Ceramics; paper making; cosmetics; pharmaceuticals; animal feed; fertilizer; anticaking; paints; varnishes; plastic reinforcer
Micas (usually flaky)		
Muscovite	United States (North Carolina, Georgia, and other states), France, Spain, China, India, Italy	Filler in plastics, drill sites, special paints; refractories; semiconductors; insulation; anticorrosion materials; welding rods
Vermiculite (expands when heated)	South Africa, United States (Montana, Virginia), Australia, Kenya	Absorbants (horticulture); plasters; boards; insulation; fire resistance
Wollastonite (occurs as needles or fibers in limestones)	United States (California, New York), Japan, former USSR, Finland, Mexico, Australia	Filler/flux in ceramic industry; used in latex and oil-based paint; in welding fluxes; asbestos substitute in hardboard, insulation, and brake linings
Zeolite (fibrous), e.g., Erionite§	Turkey (Cappadocia and Anatolia regions)§: noncommercial deposits	Houses constructed in erionite rock; soil-containing fibers mixed with tremolite; sepiolite used in stucco and plaster
Other (mainly nonfibrous)	Worldwide (in filling of lava cavities); mined in 16 countries, including several in Europe, in the United States, and in Japan	Pollutant and radioactive waste control; also used in catalysts, adsorbants, conditioners
MANMADE MINERAL FIBERS		
Glass wool and filament, rock wool, slagwool, ceramic fiber	Production in factories around the world	Many uses previously reserved for asbestos: glass filament used in mats, lamination, yarns; glass-rock and slagwool used as insulation in buildings and in car and naval construction; ceramic fiber used in reinforced cloth, disks, brakes, gaskets, board, and paper; high-performance ceramic fiber used in jet engines, spacecraft

*The list is not exhaustive, and the reader should consult other sources[1,2,84,151,152] for further information. Asbestos minerals invariably exhibit the fibrous habit; nonasbestos mineral silicates also may do so. Most silicate deposits are mineralogically heterogeneous, as are most of the commercial forms of the minerals.[151]

†Accounts for more than 90% of the world's commercial production; other fibers still used in combination with chrysotile.

‡Mining no longer in operation.

§One of three epidemics of mesothelioma in Turkish villages implicated erionite; in the other two, tremolite and/or chrysotile were implicated.[91] As of 2008, 40 countries have prohibited the use of asbestos or severely restricted its use, but in all countries, exemptions are allowed for certain uses. A prohibition decree was adopted to be enforced in the European Community in 2005. Currently, the Jeffrey Mine in Canada suspends its mining operations intermittently depending on demand.

Sources of Human Exposure

Given its many uses, the potential sources for human exposure to asbestos are legion, even today.[1] The list given in Table 65-3 should be regarded as a short guide for clinical use. The discussion that follows deals mainly with exposure to asbestos fibers; the principles, however, apply equally to exposure to other fibers.

In industrialized countries, and increasingly in industrializing countries, human exposure is most likely to be *occupational* and may occur in mining, milling, transporting, manufacturing, and applying or using raw fiber or manufactured products. In World War II, a major source of exposure was in the naval shipbuilding, repair, or refitting industries; in the post–World War II period, major sources of exposure were in the construction and transport industries, although exposures in shipbuilding, repair, or refitting continued to pose risks. Asbestos-containing materials in post–World War II buildings include boards, panels, surfacing, insulation, tile and floor covering, roofing, and caulking. Exposure also occurs in maintenance operations or demolition of plants and buildings in which asbestos-containing materials have been used. Other sources of human exposure occur during the removal of asbestos lagging or insulation from ships or buildings and the disposal of industrial waste, such as the dumps of defunct asbestos plants. In most industrialized countries, these sources of exposure have diminished in response to heightened public awareness and control regulations.[1,84] However, as recently as 2004, the U.S. Department of Labor estimated that 1.3 million workers remained exposed to asbestos in the workplace, notably in construction and general industry in the United States.[85] Data do suggest that asbestos exposure has decreased, although a recent study from the United States comparing those examined between 1980 and 1992 and those examined between 1993 and 2005 found an unexplained increase in crocidolite fibers in the lungs from 819 subjects with lung cancer, malignant mesothelioma, and asbestosis.[86]

Indirect occupational exposure, also called *bystander exposure*, describes the exposure of those whose trades require them to work in the vicinity of others who were working directly with asbestos or asbestos-containing materials. Examples are carpenters and welders who may work in close contact with insulators and laggers who mix asbestos on site, often in closed spaces. These exposures often occurred in the shipbuilding, repair, and refitting industries and the construction industries.

Domestic exposure occurred primarily as a consequence of fiber-laden work clothes being brought home. Domestic exposure still accounts for a small proportion of cases of asbestos-related disease, mainly pleural, and is reported to have accounted for up to 15% of malignant mesothelioma in one U.K. study.[87] Given the long incubation period of this tumor (from 20-40 yr), domestic exposure is likely to be the source of cases presenting well into the 21st century.[1,2]

Environmental and residential exposure occurs as a consequence of living in the neighborhood of asbestos mines, mills, or plants.[88] This source of exposure was first dramatically brought to medical attention in 1960 in a report of a cluster of 31 cases of malignant mesothelioma among residents and crocidolite asbestos miners of the Northwest Cape, South Africa.[89] New cases were reported from this area until 1995, and because occupational and environmental exposure continued until the 1970s, cases are expected to continue and to increase up to and beyond 2010.[90] A cohort study comparing the mortality experience of more than 4500 women living in the vicinity of the Quebec chrysotile mines with that of 1.375 million women from 60 reference areas in the province found 7 deaths from mesothelioma in women living in the asbestos mining area and none in the reference population.[88] Environmental exposures from nonindustrial sources have been documented among residents of rural areas in Eastern Europe where the soil is contaminated with various fibers.[91] In addition, epidemics of asbestos-related pleural disease, nonmalignant as well as malignant, have occurred among residents of Turkish villages whose homes were constructed in erionite tuff rock or who used erionite and tremolite in stucco and plaster[91] and in Da-yao, southwestern China, where crocidolite is present in the soil.[88,92] A major concern since the 1980s has been the potential risk of exposure to occupants of public buildings (including schools), commercial, and residential buildings constructed during the post–World War II period, when asbestos-containing materials were widely used in construction. A health review, mandated by the U.S. Congress concluded that exposure in buildings was less by an order of magnitude than that encountered in the workplace except for custodians and others responsible for building maintenance.[93] The report also provided estimates of lifetime cancer risk (see "Asbestosis, Asbestos Exposure, Lung Cancer, and Mesothelioma," later).

The Fate of Inhaled Fibers

Accumulation of fibers in the lung is the outcome of exposure, deposition, clearance, and retention, all processes that depend on fiber dimensions and the level, intensity, and profile of exposure.[94,95] Clearance of fibers from the lung is greater for short and for chrysotile fibers than for long and for amphibole fibers.[96] Retention of fibers is inhomogeneous, with more fibers being found in the lung regions with shorter pathways and greater accumulations of longer fibers with asbestosis than in lungs in which only airway lesions have developed.[96] Fibers equal to or less than 3 μm are phagocytosed by activated macrophages, then translocated to lymphatic channels, and eventually drained to the pleural space. Longer fibers are incompletely phagocytosed, often by more than one macrophage, and become the core of what were originally called *asbestos bodies* because of their association with asbestos exposure. Although most coated fibers in human lungs have been shown to contain asbestos (usually amphibole) when subjected to radiographic diffraction analysis,[2,81] the term *ferruginous bodies* has been suggested to underline the fact that other mineral fibers may undergo coating in human lungs. The mechanism by which fibers transmigrate to the parietal pleura to produce pleural plaques remains uncertain.[97]

In the lungs of exposed individuals, the number of uncoated, or bare, fibers (visible only on electron microscopy) exceeds the number of coated fibers (*asbestos* or *ferruginous* bodies), visible by light microscopy, by 5- to 10,000-fold.[82,98] For many years, the coated asbestos fiber, *asbestos body*, has been considered the hallmark of exposure, past or current, no doubt because of its distinctive structure and because it was readily visible under the light microscope. The presence of more than one coated fiber has been cited (and challenged) as a necessary criterion for the pathologic diagnosis of asbestosis even in a subject with an appropriate exposure history.[98] Asbestos bodies may be found in sputum or in BAL fluid when lung tissue levels are very high. They are also more commonly found when exposure has been recent and to amphibole rather than chrysotile fibers.[2,99,100] BAL fluid may also show characteristic cellular, biochemical, and mineralogic features in workers exposed to asbestos and especially in those with asbestosis.[101]

Exposure versus Dose-Response Relationships

Epidemiologic studies have consistently demonstrated exposure-response relationships for asbestos-related parenchymal lung fibrosis (Fig. 65-9).[102] There are differences in the slopes of the exposure-response relationships between industrial sectors, which probably reflect the fiber size (smaller fibers causing more disease) and the nature of the fibers, their retention, and their biopersistence in lung tissue (amphiboles causing more disease than chrysotile). For asbestos-related pleural disease, exposure-response relationships can also usually be demonstrated, but the residence time of the dust in the lungs is more important than the cumulative exposure.[95,97] Mineralogic analysis has also shown that the degree of fibrosis correlates with fiber concentration, both in chrysotile- and in amosite-exposed workers. The toxicity of mineral fibers is determined by their physical and aerodynamic properties, which determine deposition and retention. Also relevant in fibrogenesis and probably in carcinogenesis is the solubility of the fibers (which determines their survival in lung tissue) and their surface properties and electrical charge (which may affect their toxicity for cell membranes and the formation of free radicals).[2,33]

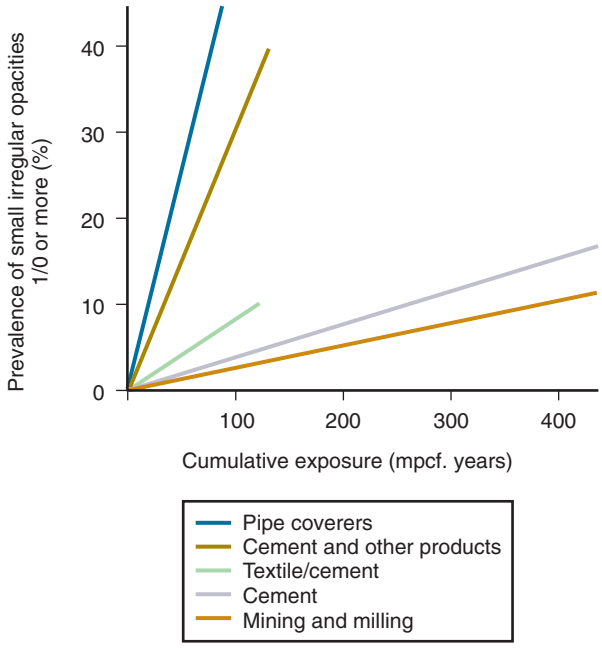

FIGURE 65-9 ■ The prevalence (%) of small irregular radiographic opacities (≥1/0) in relation to cumulative exposure in millions of particles per cubic foot × years (mpcf years) in different work forces exposed to asbestos. Idealized exposure-response relationships are shown for various sectors of the asbestos industry, including mining and milling, cement, and textile production (studies carried out in Quebec), and cement and other products and pipe covering (studies carried out in the United States). Further details are given elsewhere.[136] (Redrawn from Becklake MR: Occupational lung disease: Past record and future trend using the asbestos case as an example. Clin Invest Med 6:305–317, 1983.)

Asbestosis (Pulmonary Parenchymal Fibrosis)

Pathology and Pathogenesis

Asbestosis tends to be prominent in the lower lobes and in the subpleural areas. When disease is advanced, the lungs are small, streaks of fibrosis outline lobar and interlobar septa, and the visceral pleura is invariably thickened. Honeycombing may be prominent subpleurally and in the lower lobes. Unlike in silicosis, the tracheobronchial lymph nodes do not show characteristic changes and progressive massive fibrosis is unusual.[98] Advanced asbestos-related fibrosis is distinguishable from advanced fibrosis due to any other cause only by the presence of asbestos bodies or uncoated asbestos fibers (Fig. 65-10B).[2] At the other end of the disease spectrum, the lesions of mild asbestosis tend to occur at scattered sites and usually consist of foci of peribronchiolar fibrosis[103] with local chronic interstitial inflammation, accumulation of macrophages in the air spaces, and proliferation of type II pneumocytes. Second- and third-order bronchioles and alveolar ducts tend to be involved as the disease progresses and the fibrosis spreads to involve the alveolar interstitium (see Fig. 65-10A).

In general, the grade of pulmonary fibrosis relates to the fiber burden carried by the lungs.[2] On the basis of animal and human data,[33,104,105] the sequence of events leading to asbestosis is thought to commence with an alveolitis that may resolve if the fiber burden is low and the fibers are cleared. If the fiber load is low but retained, a nonprogressive distal airway lesion, mineral dust-induced peripheral airway disease, may develop.[33,96,103–105] If the dust load retained is high and phagocytosis of fibers by alveolar and interstitial macrophages is incomplete, fibronectin is released together with other proinflammatory and cytotoxic agents such as free oxygen radicals. These interact with and recruit fibroblasts to the site of the injury, where they proliferate and lay down collagen. If sustained, this leads to irreversible damage, loss of alveolar spaces, and the development of chronic interstitial lung fibrosis, asbestosis.[96]

Epidemiology and Natural History

Clinical asbestosis, like clinical silicosis, is becoming less frequent and less severe as exposure levels in workplaces around the world are increasingly meeting currently recommended control levels.[95,106] However, in the United States, although mortality rates for the other pneumoconioses (CWP and silicosis) are declining, the rate for asbestosis has increased possibly by as much as tenfold between 1968 and 1999,[22,70] and are not expected to decrease before 2024,[70a] a similar trend was apparent in Australia,[107] while in the United Kingdom and Canada, rates of certification of death or disability from asbestosis are falling.[108,109] With low-level exposure to asbestos, the interval between exposure and disease increases.[95] The pattern of exposure also determines the nature of the disease. In occupations in which exposure is intermittent but of high intensity, the ratio of pleural to parenchymal radiologic abnormalities may exceed 20, whereas a 2:1 pleural-to-parenchymal ratio is more usual in occupations in which workers are more consistently exposed.[95,110] Exposure at a young age is an independent determinant of both attack and progression rates of parenchymal and pleural radiologic abnormalities, suggesting that residence time of dust in the lung is important in their pathogenesis.[95,110,111] Other determinants of progression are level and duration of exposure, cumulative exposure, and fiber type (more frequent after exposure to the amphiboles crocidolite and amosite or mixtures of amphibole and chrysotile than to chrysotile alone) (see Fig. 65-9).[95] Once established, radiologic asbestosis may remain static or it may progress; rarely has regression been recorded.[110] Radiologic asbestosis may appear and progress long after exposure ceases; in a study of chrysotile miners and millers in Quebec, appearance and progression rates of 31% and 9%, respectively, were recorded for pleuroparenchymal disease over an average follow-up period of 17 years after exposure.[95,110] Progression in the absence of further exposure relates to cumulative exposure up to the time of quitting.[95,111] Genetic features appear to play a role in determining the occurrence and extent of asbestos-induced lung fibrosis.[95,112,113]

Smoking deserves comment because of its role as a universal risk factor for respiratory disease, both malignant and nonmalignant. There is some evidence that the milder grades of radiologic small irregular opacities on the ILO classification may be caused by smoking. Pathologic studies do not show evidence of an association between asbestosis grade and smoking,[114] although there is evidence to suggest that smoking enhances the retention of fibers in the lungs.[2,114]

Clinical Features

Asbestosis has been called a monosymptomatic disease because the earliest, most consistently reported, and most distressing symptom is dyspnea. Dyspnea often precedes other evidence of disease and, therefore, may be underrated by the physician because of its subjective nature. However, the consistency of its relationship to exposure levels[95] suggests that it is related to early parenchymal asbestosis. Persistent dry cough is reported commonly, almost as frequently as dyspnea in some series,[97,115] and has been attributed to the stimulation of lung receptors. Chest tightness or pain, or both, are not uncommon and may be caused by acute asbestos-associated pleural reactions.

Basal crackles, an early and distinctive feature of asbestosis, are fine crisp persistent sounds, often heard first over axillary and basal regions and then more generally as the disease advances.[85] Other sounds, including coarse crackles and rhonchi, reflect airway disease that may be related to cigarette smoking or to dust in the occupational environment.[73] Clubbing of the fingers and, occasionally, the toes develops in some subjects. Late manifestations include respiratory and circulatory failure, and these, with cancer, are common causes of death.

Radiographic Features

The posteroanterior chest radiograph remains a key tool in the initial clinical diagnosis of asbestosis and in the health surveillance of exposed workers. The ILO classification[5] uses the term "small irregular opacities" to describe the irregular linear shadows that develop in the

lung parenchyma and obscure the normal bronchovascular arborization pattern seen in disease-free lungs. The parenchymal opacities are usually seen first in the lower lateral zones. As their profusion increases, the borders of the heart are obscured. Small rounded opacities are unusual when the exposure has been primarily to fibers but are more likely to be seen in workers who also have had silica exposure: for instance, asbestos cement workers.[1,16]

Early fibrotic changes are better visualized by HRCT with supplementary prone images,[101] particularly for subpleural parenchymal changes that may be obscured by overlying pleural fibrosis on the chest radiograph.[116] Visceral pleural thickening of the interlobar fissures is common.[97] Changes in the parietal pleura (see later) are also common, and the presence of pleural plaques (particularly if they are bilateral) or of pleural thickening provides additional evidence that the parenchymal disease is asbestos related. Hilar node enlargement is not a feature of asbestosis, and PMF lesions, including rheumatoid pneumoconiosis, are less common than in workers exposed to coal or silica. The radiologic features of well-developed disease seldom present a diagnostic problem; interpretation of the less marked changes is much more subjective, and hence, the use of ILO films and of HRCT are proportionately more valuable.[116,117] The CT scan is also useful in characterizing localized pleuropulmonary lesions, including rounded atelectasis, which must be distinguished from lung cancer because it usually presents as a solid localized lesion (Fig. 65-11). HRCT can also identify coexisting lung disease such as emphysema and distinguish subpleural fat from pleural thickening and plaques.

Lung Function

Established asbestosis is often, but certainly not always, associated with a restrictive lung function profile (see Chapter 24).[95] With less advanced radiologic disease, FVC and the D_{LCO} are reduced, and reduction in flow at low lung volumes ($FEF_{25\%-75\%}$ [mean forced expiratory flow between 25% and 75% of the FVC]) is a common finding in keeping with small airway abnormality.[31,97] In studies of exposed populations, a substantial proportion of subjects (up to half in some series)[110] exhibit a mixed or obstructive function profile in keeping with the parallel development of airway and parenchymal effects of working in dusty occupations contaminated by mineral dusts.[67] When repeated lung function tests are used to assess evolution of disease, simple volume measurements such as FVC appear to be the most useful.[81,110,118]

Diagnosis and Complications

Criteria for diagnosis depend on the purpose for which a diagnosis is required. Clinical diagnosis depends on establishing the presence, extent, and nature of pulmonary fibrosis and that the exposure has been of a duration and intensity sufficient to put the individual at risk for developing asbestosis. The fewer the features, the less certain the diagnosis; the more trivial the exposure, the less likely that it is causal. When radiologic or lung function changes are marginal, other imaging, including CT or HRCT, may be helpful. In the absence of what appears to be an adequate exposure history, it may be appropriate to perform a biopsy of the lung to establish the nature of the disease and the presence and burden of asbestos in the lung. Sputum analysis may be useful for identifying asbestos bodies as an indication of lung dust burden but is far less sensitive than BAL.[85,101,119] Diagnosis of asbestosis for the purpose of legal attributability calls for greater certainty and the use of criteria that vary according to the legal administrative system involved. Most published criteria consider histopathology as the best means of establishing the diagnosis.[96] In its absence, the following criteria are proposed: (1) a reliable history of asbestos exposure; (2) an appropriate lag time between exposure and detection; (3) evidence of lung fibrosis on the chest radiograph or HRCT scan; (4) a restrictive pattern of lung function; (5) bilateral fixed inspiratory crackles; and (6) clubbing of the fingers or toes, or both. Of these, history of exposure and radiographic evidence are considered essential and the others confirmatory.[96]

The individual with asbestosis is at increased risk for cancer of the lung[120,121] and, by virtue of asbestos exposure, is also at risk for mesothelioma. Working in a dusty occupation also puts the worker at risk for developing COPD.[67] Tuberculosis and rheumatoid pneumoconiosis are uncommon complications of asbestosis.

Asbestosis, Asbestos Exposure, Lung Cancer, and Mesothelioma

The observation reported in 1951 that lung cancer occurred more frequently in association with asbestosis than with several other types of pneumoconiosis was responsible for first directing attention to the potential of asbestos exposure for carcinogenesis.[122] Mortality studies of exposed workforces confirmed the excess lung cancer risk and showed it to be related to the intensity and duration of exposure[2,123] and to decrease after exposure ceases, thus providing evidence for causality.

In 1977, the IARC classified asbestos as a human carcinogen, the target sites being lung, larynx, and pleura.[1,121] The report stated that there is "no scientific documentation indicating that these entities [asbestosis and lung cancer] are interrelated in any way other than [by their being] associated causally with exposure to asbestos." Since that date, a considerable body of evidence has accumulated in support of this view that lung cancer is associated with asbestos exposure with or without asbestosis,[124–126] although there are still dissenting views.[2] Experimental studies (cellular and molecular) support this view and suggest that asbestos may have multiple roles in the pathogenesis of malignancy, a question that touches on the whole issue of the interrelationship of inflammation, fibrogenesis, and carcinogenesis because profibrotic mediators may promote carcinogenicity.[33] The lung cancer risk is enhanced by cigarette smoking (although the previously held multiplicative model has more recently been challenged[127]) but is also demonstra-

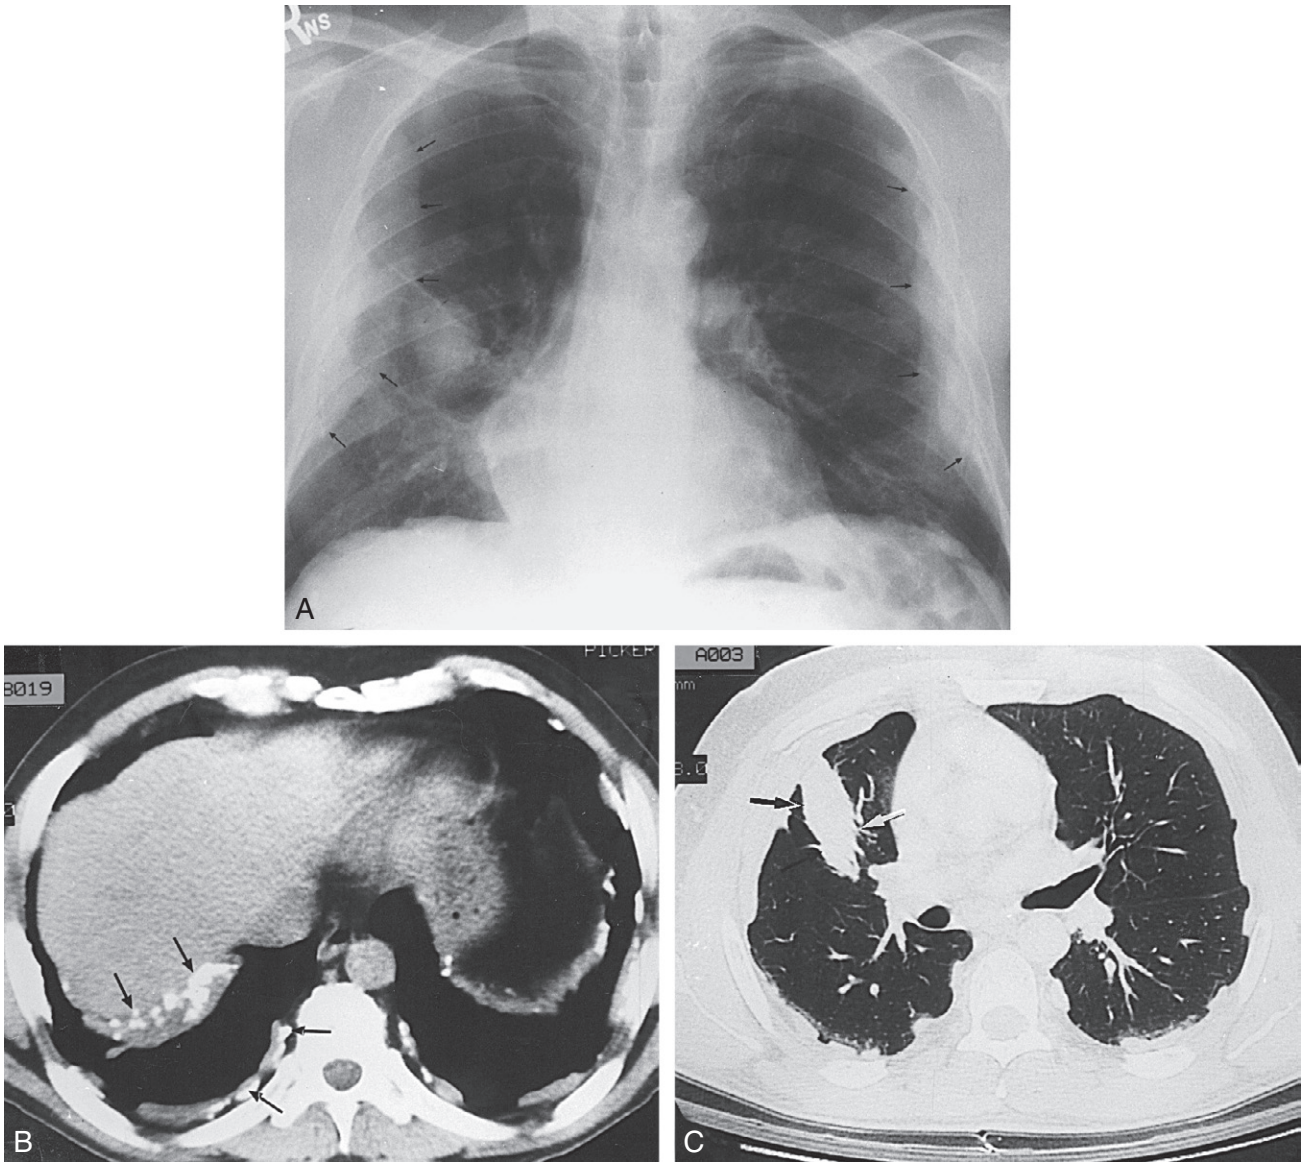

FIGURE 65-11 ■ Asbestos-related pulmonary parenchymal and pleural disease (bilateral pleural fibrosis and rounded atelectasis) in a 50-year-old man. The patient had worked as an electrician since the age of 17 years, first in construction for 10 years (with known exposure to asbestos), then briefly on naval ships during World War II, and in a chemical plant (with known exposure to talc) for the past 20 years. His exercise tolerance was excellent and his only complaint was a dry cough. Chest radiographic abnormalities had been noted 4 years previously. **A,** Posteroanterior chest radiograph shows bilateral diaphragmatic plaques, extensive bilateral pleural thickening (category c3 using the ILO reference radiographs), and a circumscribed lesion in the right mid-lung zone that had increased in size over the past year. **B,** On the computed tomography scan, the pleural plaques were shown to be much more extensive than appeared from the posteroanterior chest radiograph. Many plaques (*arrows*) were calcified. In addition, high-resolution computed tomography scan at multiple levels revealed bands of subpleural fibrosis related to the pleural plaques or thickening, or both. Lung volumes and carbon monoxide diffusing capacity were greater than 100% and 98% of predicted values, respectively. Because the circumscribed lesion (*arrows* in **C**) had enlarged over the past year, it was removed surgically. The lesion, which was nonmalignant and pleural based, consisting of pleural, subpleural, and interstitial fibrosis. Analysis of lung digest revealed the following: 36,000 asbestos bodies/g of dry lung tissue, and 7570 fibers/mg of dry lung tissue, more than half of which were asbestos fibers and less than 1% of which were talc. These findings implicated his earlier rather than his more recent occupational exposures as the cause of his pleural disease. (Dr. J. Kosiuk, Department of Radiology, Royal Victoria Hospital, Montreal, carried out the radiographic studies; Dr. A. Dufresne, School of Occupational Health, McGill University, carried out the lung dust analyses.)

ble in nonsmokers.[93,101,128] A 1999 analysis estimated the attributable proportion due to synergy to be as high as one third.[129] Other factors influencing the risk of lung cancer in exposed workforces include industry (risk greater in the textile vs. the asbestos cement industry), fiber type (risk greater when exposure is to amphibole-crocidolite, amosite or tremolite, or mixed amphibole-chrysotile than when it is only to chrysotile), and fiber dimensions (longer fibers are more carcinogenic than shorter fibers).[96,130]

The emergence of cancer as an important cause of death in asbestos-exposed individuals can be attributed

in part to workplace controls, introduced in the 1970s and implemented over the latter half of the 20th century, resulting in a decrease in the competing risk from asbestosis and greater chance of survival into the cancer age group. Lung dust burden studies in workers coming to autopsy with different asbestos-related diseases have confirmed that the dust burden associated with asbestosis is on average severalfold greater than that associated with asbestos-related lung cancer.[131] For instance, in chrysotile miners in Quebec, the fiber concentrations in those dying of asbestosis versus those dying of lung cancer versus nonexposed were 30 versus 13 versus 2 million chrysotile fibers per gram dry lung tissue; for those engaged in trades with asbestos exposure in the Pacific Northwest, where amosite was the dominant fiber, the equivalent figures were 10.0 versus 1.0 versus 0.7 million fibers per gram of dry lung tissue.[114] All histologic cell types of lung cancer have been shown to be associated with asbestos exposure, which further supports the direct role of asbestos, independently from asbestosis, as a carcinogen.[101] In addition to its biologic importance, the question is also of practical interest in terms of legal attributability, and this varies between jurisdictions. There is obviously a much stronger case for attributing lung cancer in a particular individual to asbestos exposure in the presence of asbestosis and in the absence of a smoking history than in the absence of asbestosis and in the presence of a smoking history. Despite the methodologic variation in asbestos fiber and body counting, all available information about exposure, including any measures of asbestos fiber in BAL or biopsy material, should be assembled in such evaluations; in other words, the presence of asbestosis should not be used as the only indicator of important occupational exposure.

Of great concern to the public has been the risk of cancer from attending school or working in a building constructed with asbestos-containing materials. The lifetime risk for premature cancer death from exposure at school from age 5 to 18 years has been estimated at 6 per million exposed, and for working in an office building with asbestos-containing material, at 4 per million exposed, compared with a risk of 2000 per million for 20 years employed in a workplace conforming to 0.1 fiber/mL, that is, in compliance with the current permissible exposure limit proposed by OSHA.[93] Malignant mesothelioma has been reported in 16 teachers from different parts of the United States, 12 of whom had no identified exposure outside of school employment, but other population studies have failed to show an increase in the incidence of mesothelioma in relation to the use of asbestos in buildings.[93] Residential environmental exposure has, however, been implicated in mesothelioma production.[88]

Pleural Plaques

Pathology and Pathogenesis

Pleural plaques are distinctive, smooth, white, raised, irregular lesions usually found on the parietal and rarely on the visceral pleura. They may vary from small to extensive ($\leq 50\,cm^2$) and are usually nonadherent. Common sites are the posterolateral mid-zones, where they may follow the rib contour, and on the diaphragm. They are less commonly found on the pleura adjacent to the mediastinum and pericardium and, rarely, in the apices and costophrenic sulci.[97] On microscopic section, pleural plaques consist of avascular, acellular, laminated collagen fibers arranged parallel to the surface or in whorls, with hyaline changes and occasional fibroblasts (Fig. 65-12). Macroscopic calcification is common, and microscopic calcification extremely common, especially in the parietal lesions. The lesions are usually covered by mesothelium. Fine asbestos fibers are seen on electron microscopy.[97] The lungs of patients from the general population who have plaques have been shown to contain a 50- to 250-fold excess of long, thin, mainly amphibole fibers.[2] In asbestos miners and millers in Quebec and in those engaged in the Pacific Northwest trades that involve exposure to asbestos, the lung burden is similar to that seen in association with lung cancer (see earlier).[114] Pleural plaques are thought to develop from the release of fibers into the pleural space by mechanisms open to conjecture.[2] Release or escape probably occurs from subpleural accumulations of usually short, fine fibers that are able to penetrate the deeper lung spaces and are cleared via subpleural lymphatic channels.[2] Within the pleural space, macrophage and cellular interactions may determine fiber localization and plaque formation. In the absence of macrophages, the pleural reaction tends to be disorganized and diffuse.[132] The parietal location may be due to the fact that for fibers, as for macrophages, the only exit from the pleural space is via stomas that communicate directly with the parietal pleural lymphatic channels. Pleural fibrosis and pleural plaques may have the same pathogenesis.[2]

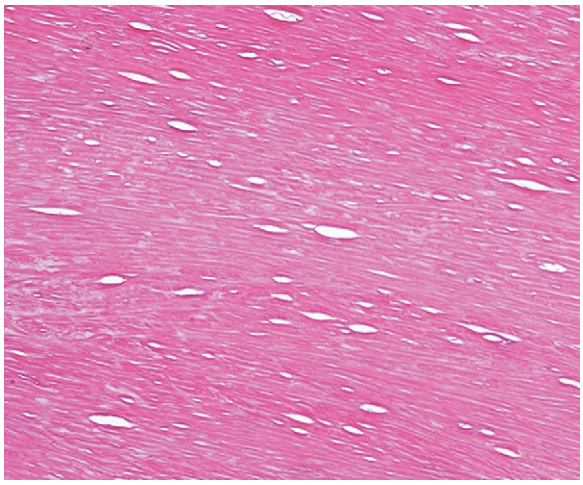

FIGURE 65-12 ■ Asbestos pleural plaque shows parallel acellular collagen fibers.

Clinical Features

Pleural plaques, in the absence of parenchymal disease, often do not cause signs and symptoms and are usually detected as an incidental finding on a routine chest radiograph. Their visualization depends on their thickness and the orientation of the x-ray beam. Only a modest proportion of those seen at autopsy are detected

on posteroanterior chest radiographs; oblique views increase the yield. CT and HRCT scans can identify plaques at an earlier, less well-developed stage and can differentiate plaques from extra pleural fat pads. In the past, pleural plaques have been labeled as "visiting cards" for asbestos exposure, implying that they had no impact on lung function at rest or on effort. In fact, in epidemiologic studies, lung volumes (mainly vital capacity and FVC) are on average modestly but consistently reduced. The DL_{CO} is generally normal and the diffusion constant Kco (DL_{CO}/TLC) may be increased because of the reduction in lung volume.[97,110,118] Increasingly too, it is recognized that in some individuals, pleural plaques may be associated with disability[133]; the underlying mechanism may be inhibition of inspiratory capacity during exercise resulting in an increase in the work of breathing.

Epidemiology

Pleural plaques continue to be the most frequent and often the only manifestation of asbestos exposure,[97,109,134] and asbestos exposure is the most common cause of pleural plaques. For instance, for the period 1996 to 1998, pleural plaques constituted 28% of 4393 incident cases of occupational respiratory disease reported to the Surveillance of Work and Occupational Respiratory Disease (SWORD) study, which has been operating in the United Kingdom since 1989.[134] Bilateral pleural plaques are more likely to be associated with occupational exposure than unilateral plaques, for which other causes should be considered.[85] Age and residence time of dust in the lungs are determinants of these distinctive pleural lesions[97]; smoking is considered to be a determinant by some[1] but not in general.[97] Domestic and residential exposures have been implicated in the production of pleural plaques (see earlier, the discussion of human exposure in the section on "Asbestos Minerals"), with remarkably high rates for pleural calcification (≤30%) being described in some rural communities in the eastern Mediterranean countries of Corsica, Greece, Cyprus, and Turkey.[91] Of greater concern to the patient and the clinician is the prognostic significance of plaques: in one study, they were associated with alveolitis, as reflected in bronchoalveolar cell counts,[132] and by implication, with an increased likelihood of developing parenchymal disease. The results of a Swedish cohort mortality study involving 1596 men were interpreted as showing that pleural plaques on the chest radiograph indicated significant exposure to asbestos, as well as an increased risk of mesothelioma and possibly also for lung cancer.[135] This risk raises the question of screening chest radiographs in those with pleural plaques, a topic that remains controversial in the absence of clear evidence of benefit.[85,135]

Pleural Fibrosis and Visceroparietal Reactions

Pathology

Like pleural plaques, pleural fibrosis and visceroparietal pleural reactions may be localized or diffuse and may vary in thickness from a milky discoloration of the lung surface to a thick, white peel encasing much of one or both lungs. The interlobar fissures are commonly involved.[101] Even severe visceral pleural disease may occur in the presence of minimal parenchymal reaction.[97,98] Occasionally, a localized pleural reaction may fold on itself and the surfaces synthesize, trapping the underlying lung and leading to a well-defined pleuroparenchymal lesion or pseudotumor, also called *rounded atelectasis*[97] (see Fig. 65-11). Asbestos bodies and fibers are usually found in the visceral pleura, the underlying parenchyma, or both,[97] and the lung dust burden usually reflects the occupational exposure but with electron microscopy fiber counts considerably less than those seen in asbestosis.

Epidemiology

Like pleural plaques, pleural fibrosis and visceroparietal reactions may occur in the absence of radiologic parenchymal fibrosis and are increasing in frequency.[97] The exposures implicated (see Table 65-3) are often short, heavy, remote, and related to amphiboles. Latency is usually long (>20 yr), reflected in the fact that these reactions relate to time since first exposure (a proxy for residence time of dust in the lung) and not to cumulative exposure dose.[97,110] In the United States, radiographic pleural abnormality has been reported in approximately 1% of men without known exposure.[97] Pleural fibrosis has been reported in association with environmental exposures from mining operations (see previous discussion under "Sources of Human Exposure") in Finland and South Africa and from nonmining (agricultural) operations in Bulgaria, Czechoslovakia, Poland, Greece, and Turkey. Epidemiologic studies are also consistent in showing that the presence of pleural fibrosis is associated with reduction in lung function, after any associated parenchymal fibrosis has been taken into account.[97,110,118]

Diagnosis

Pleural fibrosis is less specific for asbestos exposure than pleural plaques, and other causes need to be considered in the differential diagnosis. Diagnosis of asbestos-related pleural thickening is usually based initially on the chest radiograph. Clinical presentation, like that of pleural plaques, is often as an incidental abnormality detected on a routine chest radiograph. After careful inquiry, a remote history of exposure, often quite brief but usually heavy, can be obtained from the subject. Rounded atelectasis may present as a radiologic abnormality in an asymptomatic subject, usually with a clear history of exposure. Conversely, some subjects present with breathlessness[97] or chest pain, or both, with or without a history of acute episodes, attributed to benign pleural effusions (see later). Pleural fibrosis restricts the movement of the lungs; in the absence of associated parenchymal disease, clinical signs may be minimal, even though functional impairment is detectable. Impairment may be modest even in the presence of severe pleural disease.[97,110,136] In one study, any pleural abnormality was associated with an

average deficit of 0.22 L and 0.40 L for FEV_1 and FVC, respectively,[133] but pleural fibrosis occasionally becomes severe enough to precipitate respiratory and cardiac failure and to require pleurectomy.[97,137]

The radiologic and CT features of pleural fibrosis are discussed under "Pleural Plaques." Given a history of exposure, obliteration of the costophrenic angle is likely to represent the residuum of asbestos pleural effusion.[97] In rounded atelectasis, the CT scan is particularly useful in delineating the relationship of the rounded lesion to other pleural changes.[116] Nevertheless, the differential diagnosis of rounded atelectasis includes lung cancer, and in some cases, the diagnosis can be established only by surgery.

Benign Asbestos-Related Pleural Effusions

Benign asbestos-related pleural effusions may occur in lungs free of other stigmata of asbestos exposure or may mark an increase in the extent or severity of an already present pleural reaction. The term "benign" does not imply a lack of clinical significance but rather that the effusion is not associated with mesothelioma.[97] Benign asbestos-related pleural effusions usually occur within 15 years of the first exposure and may occur after exposure has ceased.[97] They are more common in persons in their 20s and 30s and may be the most common manifestation of asbestos pleural disease in that age group. The episodes are usually transient and may be silent but may be associated with chest tightness and, occasionally, pleural pain, fever, and dyspnea.[97] A pleural rub may be heard. The effusion is usually small, exudative, and blood-stained[2] and contains leukocytes. Asbestos bodies are rarely found in the fluid, but they may be seen in the underlying parenchyma on biopsy.[138] The sedimentation rate often is raised.[138] Diagnosis is by exclusion, and suggested criteria include (1) an exposure history; (2) the absence of other causes; and (3) absence of tumor on a 3-year follow-up.[96] Because cytologic examination of the pleural fluid is rarely conclusive, a thoracoscopic biopsy is usually required to exclude other causes; to establish the presence of fibers in the pleural fluid (rarely demonstrable), pleura (sometimes demonstrable), or the underlying lung parenchyma (not infrequently demonstrable); and to rule out malignancy, in particular malignant pleural mesothelioma. The usual pathologic findings in benign asbestos-related pleural effusion are those of chronic fibrous pleurisy with minimal cellularity.

The prognosis of benign asbestos-related pleural effusions is generally good; most clear spontaneously, whether it be the first episode or a recurrence. Recurrence may be on the opposite side. Although pleural effusion is a common form of presentation for mesothelioma (see Chapter 75), there is no evidence that a benign effusion signals a future pleural malignancy. It appears rather to represent a stage in the evolution of asbestos-related pleural fibrosis and also carries a risk of developing parenchymal fibrosis (asbestosis).[95] The pathogenesis is unknown.[2] Both mechanical irritation by fibers permeating the pleura and a direct cytotoxic effect on the surface mesothelial layer have been invoked.[97]

Management, Prevention, and Health Monitoring

The principles guiding clinical management of all asbestos-related lung and pleural conditions are no different from those guiding this management when there is no history of asbestos exposure. It is important to make the appropriate notification of a case of asbestos-related disease. Notification, together with any procedure related to compensation, depends on the local jurisdiction. Employment advice should be guided by knowledge of the impact of further exposure on the natural history of the disease processes[97,98,110] and by the risks for developing additional asbestos-related disease. It is important to emphasize that even in the absence of any further exposure, progression of all nonmalignant asbestos-related diseases may occur on the basis of dust load already in the lungs. Once there is definite parenchymal or pleural radiologic abnormality, the prudent option is to avoid all further exposure. Furthermore, continued exposure is likely to be associated with persistent industrial bronchitis, if present, and an increase in the risk of chronic airflow limitation.[73] The possible role of smoking in the initiation and progression of fibrotic parenchymal disease and its established role in multiplying the risk of lung cancer are strong indications for smoking-cessation advice to be given to the individual and for instituting smoking-cessation programs for workers in workplaces contaminated by asbestos dust.

No active treatment measures have been shown to influence the course of asbestosis. Corticosteroids and other anti-inflammatory and cytotoxic agents advocated for other interstitial lung diseases are less effective in asbestosis, possibly because the responsible agent remains in the lungs. Patients with end-stage asbestosis have been the recipients of lung and heart-lung transplants but technical difficulties may arise because of the associated pleural disease.

For the nonmalignant asbestos-related pleural disorders, the evidence is now reasonably clear that those with pleural fibrosis are at greater risk for parenchymal fibrosis in the future.[95] The presence of pleural fibrosis or pleural plaques is associated with increased risk for malignant pleural mesothelioma and lung cancer.[135]

Control and prevention of asbestos-related lung diseases are a public health issue reviewed elsewhere.[1] An international ban on asbestos has been advocated for its control as a public health measure.[139] However, issues associated with an international ban, imposed by the industrialized world, include the lack of inexpensive alternatives for asbestos, especially important in the industrializing world, which currently accounts for much of the asbestos use, and the lack of studies comparable with those conducted on asbestos to examine the safety and effectiveness of substitutes, including man-made fibers.[140] Concern certainly still exists about the potential ill health effects of the man-made substitutes[140,141] even though the most recent data do not suggest that those

exposed occupationally have an increased risk of lung cancer or mesothelioma.[142–144] A document from the American College of Chest Physicians highlights areas in which there is and is not consensus regarding the health effects of asbestos exposure.[138a]

Successful public control requires control of the work environment, setting and enforcing of standards, and preemployment or in-service health examinations for exposed workers as part of a health-monitoring program. Implicit in the latter examination, which has the elements of a screening examination, is the hope that early detection might avoid later damaging disease, a hypothesis still to be tested. Nor is the interpretation of small changes between examinations (in physical signs and in radiologic, lung function, and cytologic examinations) an easy task. Such examinations are best regarded as biologic monitoring (for the purpose of detecting average trends within a workforce) rather than as a method of case identification. Nevertheless, some individuals seek this type of health examination from their personal physician or clinic, and the clinician must make a best judgment on the basis of available information. For the current worker with no evidence of disease, whose exposure has occurred only since the present control levels (0.1 fiber/mL for a 50-yr working life) have been in place, ill-health effects are unlikely to be demonstrable by any practicable method of study, but for those with more than 10 years of exposure, a chest radiograph every 3 to 5 years is recommended.[85] Only a minority of those exposed are likely to develop radiologic changes, and only a minority of those with radiologic changes develop clinical manifestations and any degree of disablement. Furthermore, the additional chance of developing a carcinoma of the lung in the face of frank asbestosis is likely to be considerably lower than the 10% to 30% quoted on the basis of case data from subjects exposed before the 1960s when exposure levels were higher and asbestosis was, as far as can be judged, a more severe disease.[115] Quitting cigarette smoking should benefit the asbestos-exposed individual even more than the nonexposed individual because of the interaction of these two agents.[129,145] The mesothelioma risk, perhaps more disquieting for those with past occupational exposure, may also be expected to decline with time. Although in Europe and Australia, it had been estimated that this would occur only by the second decade of the 21st century,[146,147] a 2003 report from a British naval dockyard indicates that rates had already peaked in 1991 and have since fallen.[148] Similar trends have been observed in Sweden, where the rate in men peaked in 1995 and has subsequently fallen,[149] and in the Netherlands.[150] This improvement is attributed, at least in part, to the introduction of asbestos safety guidelines in the 1970s in the countries concerned.

NONASBESTOS MINERAL SILICATES AND LUNG DISEASE

Exposure to some of the nonasbestos mineral silicates listed in Table 65-3 has been associated with lung disease. Silicate dust particles are found in the lungs of most urban dwellers,[81] and in general, they appear to have low biologic activity.[151] Disease may develop after long, heavy exposure; initially, it is characterized by accumulation of dust-laden macrophages around respiratory bronchioles and, later, by fiber deposits with little mature collagen; the disease appears to progress in relation to lung dust overload.[91,151,152] Silicates are used widely as filling materials (kaolin, talc, and chlorite), as insulation (mica, vermiculite), and as absorbents (attapulgite, sepiolite), among other uses.[151] The clay minerals, talcs and mica (also called phyllosilicates because of their sheet structure),[151] constitute an important group. World production and use (estimated in 1991 as 5.3 million tons for talc alone) considerably exceeds that of the asbestos minerals, which peaked at 5 million tons in the late 1970s. Before a 1989 NATO Workshop, their toxicity as a group for humans had been studied little,[151] although three (talc, attapulgite, and sepiolite) had been evaluated for carcinogenic risk for humans by the IARC.[151] The information in this section is derived from the report of this workshop[151] and other sources.[2,105,153] Talc and, more often, mica particles may form the core of ferruginous bodies. In general, the nonfibrous silicates have pulmonary effects similar to those caused by coal, unless they contain fibrous forms of these minerals or are contaminated by asbestos fibers, in which case their effects are closer to those produced by asbestos. The biologic effects of silica (quartz) may be modulated by the presence of silicates.

Kaolin Pneumoconiosis

The lesions of kaolin pneumoconiosis tend to be cellular and dust packed.[151] In its simple form, this pneumoconiosis is not usually associated with clinical or lung function changes, but rarely. interstitial fibrosis or PMF may occur and be associated with impairment.[2] In 10 surveys of kaolin-exposed workforces, the radiologic prevalence of simple pneumoconiosis (mostly small round opacities) ranged from less than 1% to 26.3%, whereas complicated pneumoconiosis and pleural change were unusual.[153] In general, prevalence was related to level and duration of dust exposure and probably contamination by other materials, including silica. Although lung cancers have been mentioned in relation to kaolin exposure,[154] no cohort mortality studies have been reported.

Talc Pneumoconiosis

The lesions of talc pneumoconiosis include peribronchial and perivascular interstitial accumulations of dust-filled macrophages, ill-defined nodular lesions in which birefringent talc crystals can be seen, and foreign body granulomas.[2,151] In general, the disease evolves slowly, and progressive massive fibrosis occurs infrequently; tuberculosis may complicate the condition but might reflect concomitant silica exposure. Interstitial fibrosis also may occur. A granulomatous arteritis caused by talc embolism is described in drug addicts who use an

intravenous route for talc-containing drug tablets. Pleural changes, including plaques, are common; they are usually associated with mining exposures and may be due to contamination of mine dust by fiber (tremolite or anthophyllite).[2,151] Reactions to talc can be difficult to distinguish from those caused by silica or by asbestos, which often contaminate or even predominate in industrial grade talc.[2] In six surveys of talc-exposed workforces, prevalence of small opacities ranged from less than 1% to 37.2%, the latter in long-time workers and the lower rates in some studies in which exposure was to pure talc.[153,155] In three of seven cohort mortality studies in talc-exposed workers, excess deaths were recorded from nonmalignant respiratory disease, including pneumoconiosis. In addition, an excess of respiratory cancer mortality was found in five of the seven cohorts, but these findings must be interpreted with caution because they were based on only 13 or fewer deaths in each cohort. In four of these, coexposure to other carcinogenic agents (mineral fibers, radon, silica) could have been implicated.[153] Several cases of mesothelioma were reported, but all in cohorts exposed to fiber-contaminated dusts.[153]

Mica Pneumoconiosis

The lesions of mica pneumoconiosis comprise dust particles surrounded by reticulin but usually with relatively little cellular reaction, although there are case reports of interstitial fibrosis[156] in which granulomas also have been described.[153] In three surveys of mica-exposed workforces, the prevalence of radiologic pneumoconiosis ranged from 1% to 44%, the latter workforce being exposed to quartz-contaminated mica.[153] No mortality studies have been reported, but there has been one case report of a peritoneal mesothelioma in a mica-exposed worker.[153] Vermiculite, also a mica, does not appear to be toxic to the lungs of animals. However, in four surveys of vermiculite-exposed mine workers, the prevalence of radiologic pneumoconiosis ranged from less than 1% to 18% and of pleural changes from 3% to 28%; in a processing plant, rates were higher and were related to cumulative exposure.[151,153] Pleural effusions and pleural thickening have been reported in mica-exposed workforces but are thought to relate to amphibole contamination of vermiculite. Vermiculite mined in Libby, Montana, has been found to be contaminated with asbestos and to be associated with asbestosis, mesothelioma, and lung cancer in former miners, millers, and processors. The material has been widely used as insulation in buildings, which has raised concern for those exposed through building maintenance and renovation.[157] A case report of fatal asbestosis occurring 50 years after exposure to vermiculite from Libby in a California expansion plant emphasizes the risk from even brief but intense exposure to this material.[158] The lung biopsy fiber analysis showed 8 million fibers per gram of dry lung, a level certainly compatible with the diagnosis of asbestosis, of which 68% were tremolite. Pleural plaques had been noted on his chest film 10 years before evidence of interstitial lung disease became apparent.

The authors of a 1990 review[153] concluded that (1) there is little evidence that occupational exposure to pure kaolin, talc, mica, or vermiculite carries any important risk for health; (2) long and heavy exposure to kaolin and mica may result in low-grade radiographic changes, but clinically important pneumoconioses in workforces exposed to these phyllosilicates are likely to be the result of contamination by silica or asbestos fiber; (3) pleural lesions are common in talc-exposed workers but are probably caused by fiber contaminants; and (4) the increased rates of lung cancer or mesothelioma recorded in several exposed workforces probably result from exposure to fiber or silica contaminants of the ore or milled products.

Man-made Vitreous Fibers

The production of man-made vitreous fibers (MMVFs; including glass fibers and mineral wool, and refractory ceramic fibers as well as man-made mineral fibers such as carbon graphite, Kevlar-Aramid, silicon carbide, and aluminum oxide) has increased markedly since the restriction or banning of asbestos in several countries. As with asbestos fibers, determinants of MMVF toxicity are (1) their dimensions (greatest risk with fine, long fibers < 0.25 μm in diameter and > 8 μm in length); (2) their biopersistence, which can be altered in the production process according to the end use; and (3) dose to the target organ. MMVFs differ from asbestos fibers in being more soluble, less durable, and less biopersistent along a gradient: glass > rock > ceramic fibers.[159] Fibers are also coarser along a gradient: continuous glass filament > insulation wool > ceramic fibers > special purpose.[159] Airborne levels in plants manufacturing MMVFs are commonly lower than 1 fiber/mL and lower in most applications except the application of insulation in confined spaces.[159] Airborne fiber diameters, with the exception of ceramic fiber, are generally large (1 mm) and thus nonrespirable. Despite their intensely irritating effects on skin and mucous membranes, there is no firm evidence that these fibers produce lung fibrosis, pleural lesions, or nonspecific respiratory disease in humans. Refractory ceramic fibers may, however, enhance the effects of smoking in producing airway disease.[159,160] An increased standardized mortality ratio for lung cancer in several cohorts exposed to MMVFs is now thought to have been attributable to smoking[142,144] Nevertheless, several agencies have recommended exposures of 0.5 to 1 fiber/mL based on apparent excess working lifetime risk for lung cancer.[101] There is no evidence of an increased mesothelioma risk for MMVF workers.[143]

OTHER PNEUMOCONIOSES, OLD AND NEW

The pneumoconioses already discussed account for the majority of cases in most countries of the world. They exemplify a range of pulmonary reactions from minimal reaction to a large lung particulate dust load as in CWP

to a very specific fibrotic reaction to a comparatively small lung dust particulate load as in silicosis. In the case of mineral fibers, the pulmonary reaction appears to be determined by lung fiber load of a particular size range (the long, fine fiber) as well as by fiber durability.

Several long-recognized, well-catalogued but less common pneumoconioses, which fall into the group in which the dust load is heavy but pulmonary reaction minimal, have not yet been mentioned. They include the pneumoconioses resulting from inhalation of iron in welding fumes or in iron or hematite mine dust (siderosis), those that result from the inhalation of barytes by barium miners or workers (baritosis), and those that result from exposure to tin dust (stannosis). Other dusts that fall into this category include bismuth, manganese, Fuller's earth, and titanium. A more comprehensive list can be found elsewhere.[101] At the other end of the scale, lung disorders originally described as unusual or new forms of pneumoconiosis often turn out to be silicosis, which escaped recognition because exposure levels to quartz were higher than originally appreciated or the features of the pulmonary response were modified by the presence of other dusts. Examples include Labrador lung (after exposure of iron miners to ore dust containing silica and some anthophyllite fibers)[20] and disease in bentonite workers that also turned out to be silicosis.[161] The pneumoconiosis of foundry workers is also an example of a response to mixed dust, in which the proportion of quartz is a key determinant to the character of the response. Careful case reports by observant clinicians continue to identify interstitial lung disease associated with various exposures such as those associated with indium-tin oxide recently reported from Japan[162] and provide information to stimulate the epidemiologic studies necessary to place them in proper context.

BERYLLIUM LUNG DISEASE

Beryllium: Uses, Human Toxicity, and Exposures

Beryllium is a rare metal that has many applications in modern industry because of its light weight, tensile strength, high melting point (1500°C), excellent alloying properties (beryllium-copper are the most widely used), good thermal and electrical conductivity, resistance to corrosion, and ability to reduce the speed of nuclear fission.[1] Major sources are Argentina, Brazil, India, Zimbabwe, South Africa, and the United States. Its toxicity for humans was first recognized in Europe in the 1930s. In the United States, an epidemic of chronic beryllium disease (CBD) occurred as a result of exposure in the fluorescent light industry during the 1940s, leading to discontinuation of its use in that industry and the institution of engineering controls in other industries handling beryllium.[1] However, the number of cases continued to increase and, in 1987, reached 904 in a U.S. case registry.[163] Initially, a large number of cases of acute berylliosis, an acute, toxic pneumonitis, were documented but acute cases are now uncommon. Chronic berylliosis, a disease with features similar to those of sarcoidosis, continues to be reported. Cases arise from beryllium exposure in a wide variety of industries including the manufacture of alloys, ceramics, radiographic equipment, and vacuum tubes and in the extraction and smelting of beryllium. The number of individuals potentially exposed in the United States in 1987 was estimated between 30,000 and 800,000 in the following industries: aerospace, electronics, ceramics, metal, including refining of scrap metal, nuclear (reactors, weapons), telecommunications, tool and die, and welding.[163] A survey of 646 workers in a beryllium metal alloy and oxide production plant showed that 9.4% were sensitized to beryllium on the basis of their positive beryllium lymphocyte proliferation test (BeLPT) and 4.6% had evidence of disease.[164] A British registry of deaths from beryllium exposure found that most cases had been exposed as machinists or in the manufacture of fluorescent lamps.[165] Survival rates ranged from 1 to 29 years.[165] Cases of berylliosis have also been reported in residents living near a beryllium manufacturing facility[166] and in a wife who laundered her exposed husband's clothing.[167] Beryllium contamination inside the personal vehicles of workers has also been documented.[168] Sarcoidosis-like granulomatous lung disease in firefighters involved with rescue work at the World Trade Center is of uncertain origin and might suggest berylliosis or another environmental cause for granulomatous lung disease.[169]

Pathology and Immune Pathogenesis

Acute beryllium disease in humans has been attributed to toxic, dose-related lung injury characterized by acute inflammatory reactions in the upper airways, bronchiolitis, pulmonary edema, and chemical pneumonitis. Recovery is usual, but 17% of cases progress to CBD.[163] CBD is a multisystem disorder characterized by noncaseating granulomas that occur throughout the body, although their primary manifestation is in the lung.[2,163] On pathologic examination, CBD is characterized by the presence of a lymphocytic (helper/inducer T cells) alveolitis as well as noncaseating epithelioid granulomas indistinguishable from those of sarcoidosis. There is a variable amount of fibroblastic activity that progresses to interstitial fibrosis as the lesions mature. Granulomatous lesions may occasionally be found in other sites, including thoracic and abdominal lymph nodes, spleen, liver, kidneys, and adrenal glands.

Beryllium enters the body by inhalation and, occasionally, via the skin, where it acts as a specific antigen (alone or as a hapten through an IL-2 receptor pathway), leading to a proliferation of specific CD4 lymphocytes, release of lymphokines, and granuloma formation.[1] Because the agent persists in the lung, its slow release over time explains the appearance and progression of disease, even without further exposure.[1,2] There is evidence for an underlying genetic basis for susceptibility to beryllium disease, linked to a major histocompatibility complex (MHC) class II marker (human leukocyte antigen [HLA]-DPβ-1^{Glu69}) carrier status, which adds to the effect of the process (exposure) risk factor.[170,171]

Evidence for delayed hypersensitivity to beryllium may be assessed by the in vitro BeLPT on lymphocytes from blood or BAL.[172] Although these reactions are thought to indicate exposure and sensitization, not disease, in one series, six of eight sensitized individuals had granulomas on transbronchial biopsy.[173]

Beryllium is now considered to be a human carcinogen, especially in the presence of beryllium lung disease; in 1993, the IARC classified beryllium as a class 1 human carcinogen.[174]

Clinical Features

The clinical features of acute beryllium disease include cough, chest pain, blood-tinged sputum, crackles, and patchy airspace disease on the chest radiograph. The disorder is associated with high, and usually accidental, exposure and may present with an acute syndrome with features of acute respiratory distress syndrome or in a subacute form with features of pneumonitis.[175] High levels of exposure to beryllium may also cause irritation and inflammation of the upper respiratory tract and conjunctivitis.[163] Although resolution generally occurs within a year, historically, the acute form was associated with death in 10% of cases and 17% progressed to chronic berylliosis.[163] CBD may follow an acute beryllium pneumonitis but more usually develops without antecedent events. The clinical features of CBD are similar to those of pulmonary sarcoidosis, although extrapulmonary manifestations including hilar and mediastinal lymphadenopathy and splenomegaly are not as commonly observed.[163,176] There may be no associated symptoms,[172] but symptoms often include dyspnea, cough, chest pain, weight loss, fatigue, and arthralgias. Physical signs may include crackles, but signs of lung disease are often absent. Radiographic changes may precede the development of symptoms. The usual finding is ill-defined nodular or irregular opacities; hilar adenopathy is seen in approximately 40% of cases but is usually mild.[163] In the later stages of the disease, patchy fibrosis occurs with adjacent hyperinflation or distortion and extensive honeycombing. In CBD, pulmonary function usually shows a restrictive defect in advanced disease, but features including obstruction or isolated reduction in $D_{L_{CO}}$ may occur with mild or moderate disease.[177] The clinical course of CBD is variable. Some cases remain stable, some relapse and remit, and some progress inexorably.[163]

Diagnosis and Management

The diagnosis of CBD is based on documented exposure to beryllium, evidence of lung disease compatible with the diagnosis, and a positive BeLPT performed on blood or BAL fluid.[178] The BeLPT allowed for the introduction of three categories of beryllium-associated disorders: beryllium sensitization (positive blood or BAL BeLPT but negative biopsy), subclinical beryllium disease (positive BeLPT and biopsy but no clinical or radiologic features of the disease), and chronic berylliosis (positive BeLPT and biopsy with clinical and radiologic features of disease).[178]

Given the potentially long latency time for CBD and despite the generally lower exposures that have occurred since the 1950s and its decreasing frequency, CBD still should remain in the differential diagnosis of sarcoidosis. Clusters of sarcoidosis occurring in a workplace should alert the clinician to the possibility that these represent examples of chronic berylliosis. In this context, note should be made of the very wide range of occupations associated with potential exposure to beryllium

The most important step in case management is complete cessation of further exposure to beryllium, and this advice should also be given to exposed workers with a positive BeLPT, even in the absence of clinical and radiologic signs of disease, because of the high prevalence of lung granulomata associated with that finding.[173] Corticosteroid therapy has been recommended in CBD, and long-term steroid therapy is believed to alter the course of the disease favorably, although there are no reports of permanent cure.

HARD-METAL DISEASE

Hard-metal disease, first described in Germany in the 1940s, has now been reported from many countries. Hard metal is manufactured by a sintering process that involves pressurization plus heating to 1500°C a mixture of tungsten carbide powder (often with tantalum carbide or titanium carbide added) and 10% cobalt.[1] Because of their diamond-like hardness, extreme strength, and heat resistance, "hard-metal" products have wide application in industry as drill tips (from dental to engineering drilling and diamond polishing), cutting and tunneling tools, grinding wheels, molds, jet engines, and ferromagnets. Human exposure occurs in the manufacturing of hard-metal products and in their maintenance and use. The grinding of sintered pieces generates high dust and cobalt concentrations.

Work-related illness in hard-metal workers may be acute (rhinitis and asthma), subacute (fibrosing alveolitis), or chronic (diffuse and progressive interstitial fibrosis).[179] The interstitial fibrosis is characterized by unusual multinucleated giant cells comprising alveolar type II cells and macrophages that can be recovered from BAL. The interstitial lung disease which has been described with exposure to both tungsten carbide products and in diamond polishers[180] is thought to be a hypersensitivity pneumonitis to cobalt, which reacts with metallic carbides to produce active oxygen species.[181] A genetic association with some HLA-DP alleles may also be implicated.[182] This affords a plausible explanation of why only a small proportion of those exposed develop disease. A 1998 industry-wide cohort study in 10 facilities in France documented an increased mortality from lung cancer associated with simultaneous exposure to cobalt and tungsten carbide.[183] A review of workplace surveys indicates that interstitial disease is quite rare, whereas airway diseases including bronchitis and asthma are more frequent.[179,184] Both interstitial and airway disease may of course occur in the same individual. Diagnosis is based on an exposure history, a compatible clinical

presentation, and pathologic and mineralogic features on biopsy.[179,185] Both tungsten carbide and cobalt have now been identified in the centrilobular fibrotic lesions associated with hard-metal lung disease.[186] Prompt diagnosis and removal from exposure may reverse acute disease, including asthma, and prevent the development of chronic disease. There have been several reports of response to withdrawal from exposure and treatment with corticosteroid.[2] Prevention requires control of exposure; for monitoring workforce exposure, urinary cobalt may be useful.

SILICON CARBIDE (CARBORUNDUM) PNEUMOCONIOSIS

Carborundum pneumoconiosis is associated with exposure in the manufacture of carborundum, which is used as an abrasive because of its hardness. Under current exposure levels, this is generally a mild and nonprogressive disorder.[187] There is, however, some evidence that those exposed to this material, which has a silica and a fibrous component, are at risk for pneumoconiosis associated with lung dysfunction[188,189] and, possibly, for lung cancer.[190]

FLOCK WORKER'S LUNG

A specific interstitial lung disorder characterized by lymphocytic bronchiolitis and peribronchiolitis with lymphoid hyperplasia[191] has been described in workers involved with the manufacture of nylon flock.[192–194] The disorder appeared to be related to a specific form of cutting machine, but recent reports have shown restrictive lung disease in workers manufacturing rayon flock–coated cards[195] and workers exposed to polypropylene flock.[196]

KEY POINTS

General

- Chest radiography and occupational history are the mainstays for the diagnosis of pneumoconiosis, although CT and lung biopsy may be necessary, especially for asbestosis.
- Because of the many interactions between smoking and dust, it is important to implement smoking-cessation programs in the workplace.
- The treatment for most pneumoconiosis is removal from the workplace. Despite this, disease may progress and regression is not expected.

Silica

- Silicosis occurs in a wide range of new and older but less classical industries such as concrete rehabilitation, stone carving, and the sandblasting of denim jeans.
- Silica dust is a risk factor for tuberculosis and other mycobacterial lung diseases, lung cancer, COPD, and connective tissue diseases.
- Chronic silicosis may not be associated with respiratory symptoms even in the presence of extensive radiologic changes.
- Silicosis and HIV infection multiplicatively increase the risk of tuberculosis.

Coal

- Exposure to coal dust is not associated with an increased risk of tuberculosis or cancer of the respiratory system.
- Workers exposed to coal dust are at risk for developing COPD and chronic bronchitis.

Asbestos

- Asbestos-related diseases will occur for many decades because of the long latent period between exposure and disease and because asbestos is still widely encountered.
- Asbestos causes both benign and malignant disease.
- Pleural plaques, the most common manifestation of exposure, are generally an asymptomatic incidental radiologic finding but may be associated with an increased risk of malignant mesothelioma and lung cancer.
- Asbestos exposure is not a risk factor for the development of tuberculosis.

PREVENTION

INTRODUCTION

Hypersensitivity pneumonitis (HP), also known as extrinsic allergic alveolitis, constitutes a spectrum of granulomatous, interstitial, bronchiolar, and alveolar-filling lung diseases resulting from repeated inhalation of and sensitization to a wide variety of organic aerosols and low-molecular-weight chemical antigens. Increasing recognition of the ubiquity of environmental antigen exposures and improved diagnostic tools has led to identification of cases and outbreaks of HP in a wide variety of occupational and environmental settings. Disease typically is characterized by a lymphocytic alveolitis and granulomatous pneumonitis on pathologic examination.

HP remains a diagnostic challenge because of the spectrum of clinical findings and the lack of a simple "gold standard" for diagnosis. The diagnosis depends on a strong clinical index of suspicion, a careful exposure history, and the integration of a constellation of imaging, physiologic, and histopathologic findings that, by themselves, are nonspecific and mimic a variety of other chest illnesses. HP is both treatable and preventable if exposure is recognized and antigen abatement is effective. Unrecognized or untreated, the illness may lead to permanent sequelae including airway reactivity, emphysema, and interstitial fibrosis. Confirmation of the diagnosis often generates broader public health implications regarding potential risks from ongoing antigen exposure to others sharing the environment. Diagnosis of a case of HP should prompt a search for additional cases in the shared environment as well as initiation of measures to eliminate further exposure.

ETIOLOGY

The list of specific agents that cause HP is extensive, and new exposure circumstances and disease entities continue to be described. The distinctive and often colorful disease names for HP can be organized more simply into three major categories of causal antigens: microbial agents, animal proteins, and low-molecular-weight chemicals (Table 66-1). There are also an increasing number of pharmacologic agents that have been shown to cause hypersensitivity reactions in the lung, but these are beyond the scope of this chapter and are covered under the subject of drug-induced lung diseases (see Chapter 72).

TABLE 66-1. Etiologic Categories of Hypersensitivity Pneumonitis, with Examples

MICROBIAL AGENTS

Bacteria

Examples: Thermophilics, *Bacillus subtilis*, *Klebsiella*, *Epicoccum nigrum*, nontuberculous mycobacteria

Fungi

Examples: *Aspergillus*, *Penicillium*, *Cladosporium*, *Trichosporon*, *Alternaria*, *Aureobasidium*, *Cephalosporium* species, *Absidia corymbifera*, *Eurotium amstelodami*, *Wallemia sebi*

ANIMAL PROTEINS

Examples: Bird proteins, fish meal, rat urine, mollusk shell, wheat weevil, silkworm larvae

CHEMICAL SENSITIZERS

Examples: Isocyanates, acid anhydrides, pyrethrum, Pauli's reagent (sodium diazobenzene sulfate)

Microbial Agents

Microbial organisms, including bacteria and fungi, are common in indoor environments and probably cause many more cases of HP than are recognized clinically. Warm, moist environments often provide ideal circumstances for the amplification and proliferation of microbial antigens that, if aerosolized into the environment and inhaled, can cause sensitizing lung disease.

Bacteria

Bacteria are unicellular prokaryotic organisms that have adapted to a wide variety of ecologic habitats and segregate under different physical and chemical conditions in indoor and outdoor environments. Thermophilic actinomycetes are associated causally with the prototypical example of HP, farmer's lung disease (FLD), first described in 1932. These bacteria are found ubiquitously in the environment year round, thrive at 50°C to 55°C temperatures, and with moist conditions, secreting enzymes that cause decay of vegetable matter such as hay (FLD), sugar cane (bagassosis), and mushroom compost (mushroom worker's lung). They often are found contaminating ventilation and humidification systems (humidifier lung) where temperatures reach 60°C and stagnant water is present. Indoor bacteria that prefer lower temperatures also can cause HP, and case reports have been associated with *Bacillus* spp. in contaminated wood dust, *Klebsiella* spp. in humidifiers, and *Epicoccum* spp. associated with moisture from a basement shower. Metalworking fluid (MWF) aerosols may cause HP from exposure to mycobacterial antigens contaminating these fluids.[1-3] Recreational as well as occupational exposures to bacterially contaminated water aerosols can cause HP. Case reports and outbreaks have occurred in indoor swimming pools, termed "lifeguard lung,"[4] and from exposure to nontuberculous mycobacteria contaminating hot tubs.[5]

Fungi

Fungi are nonmotile, eukaryotic organisms that reproduce by means of spores designed for airborne transport (disseminators). Components of fungi capable of becoming airborne include spores, mycelial fragments, metabolites and partially degraded substrates, and toxins. Among the interior sites for mold growth are garbage containers, food storage areas, wallpaper, upholstery, areas of increased moisture such as shower curtains, window moldings, window air conditioners, damp basements, and emissions from cool mist vaporizers. Many fungal species have been associated causally with HP.[6] *Aspergillus* spp. have been associated with HP in soy sauce brewers; bird breeders; farmers; compost, sawmill, mushroom, greenhouse, tobacco, cane mill, grain, and brewery workers; and in those exposed to contaminated esparto grass used in the production of ropes, canvas, sandals, mats, baskets, and paper paste. Similarly, *Penicillium* spp. may cause HP in cork workers, cheese workers, peat moss processors, laboratory workers, farmers, onion and potato sorters, and tree cutters.[7] *Alternaria*, *Cladosporium*, *Aureobasidium*, *Paecilomyces*,[8] and many other fungal species have been associated with HP in sawmill workers, tree cutters, hardwood processors, and other wood handlers.

Fungal antigens often are implicated in HP cases associated with microbial contamination in homes.[9] Summer-type HP, the most prevalent form of the disease in Japan, is caused by seasonal mold contamination (mainly *Trichosporon asahii*, formerly *T. cutaneum* serotype II) in the home environment.[10,11] Domestic fungal exposure associated with decaying wood and damp walls in inner city dwellings is the most common cause of HP in Australia.[12] Multiple fungal species were identified in the homes of individuals with disease, suggesting that sensitizing microbial exposures may be complex mixtures and disease is not always attributable to a single, well-defined antigen.

Animal Proteins

Particulates from a variety of animal sources can cause HP when inhaled. Exposure to bird protein antigens, first described in 1960, is the most clinically important and well recognized and is referred to as "bird breeder's" or "bird fancier's lung." Avian antigens are complex high- and low-molecular-weight proteins found in the feathers, droppings, and serum of turkeys, chickens, geese, ducks, parakeets, parrots, budgerigars, pigeons, doves, love birds, canaries, and even native birds and are highly immunogenic.[13] Immunoglobulins, particularly IgA and IgG, are secreted from and coat birds' feathers, creating a fine dust called "bloom." Flying birds such as pigeons and parakeets produce the largest amount of bloom and are the birds most often associated with HP.[14] Pigeon fancier's lung may also be caused by IgG secreted on pigeon intestinal mucin.[15,16] Highest exposures to respirable avian antigens are associated with cleaning out bird lofts, cages, and coops.

Animal handlers, including laboratory and veterinary workers, are at risk for HP from exposure to inhaled animal proteins (including rats and gerbils) in pelts, serum, and excreta. Inhalation of grain infested with the wheat weevil *Sitophilus granarius* can cause a form of HP known as "miller's lung." Sericulturists engaged in silk production can develop HP from exposure to larval secretions and cocoon particulates.[17] Production workers exposed to mollusk shell dusts during cutting and polishing to make buttons may develop HP.[18]

Chemical Sensitizers

HP from inhalation exposure to low-molecular-weight chemicals is probably less common than the other causes, although some of these inorganic chemical antigens are widely used in industry. Isocyanates are used for large-scale production of polyurethane polymers in the manufacture of flexible and rigid foams, elastomers, adhesives, and surface coatings and are becoming increasingly recognized as a cause of HP. Acid anhydrides used in plastics, paints, and epoxy resins have been associated with an HP-like syndrome often accompanied by anemia.[19] Rare case reports of HP have been described from exposure to the pesticide pyrethrum; from Pauli's reagent (sodium diazobenzenesulfate) used in chromatography; and from copper sulfate used in Bordeaux mixture to spray vineyards. Other chemical exposures reported to cause HP include formaldehyde, dimethyl phthalate, and styrene, the latter used in boat manufacturing.[20,21]

EPIDEMIOLOGY

The worldwide prevalence of HP is unknown. Reported disease incidence, prevalence, and attack rates vary widely and depend on the populations studied, the nature and intensity of antigen exposure, the case definition chosen, and variable host factors. In Europe, HP constitutes 4% to 13% of all interstitial lung diseases.[22] Epidemiologic studies of agricultural workers and bird fanciers suggest that HP is quite common in some high-risk occupational settings. Early questionnaire surveys of farming communities found prevalence rates ranging from 2.3% to 20%. Country-wide reporting systems that collect data on clinically confirmed HP in Finnish farmers showed a mean annual incidence rate of 44 per 100,000,[23] similar to the Swedish rate of 23 per 100,000. The reported prevalence of pigeon breeder's disease varies between 1 and 100 per 1000 breeders.[24] Rates of avian HP in the United Kingdom averaged 0.9 cases per 100,000 person-years between the years 1991 and 2003.[25] Fewer data exist on the prevalence of HP in workers exposed to chemical antigens. Isocyanate-induced HP was identified in 8 (4.7%) of 167 workers employed in a wood chipboard manufacturing plant.[26] In a European survey of chest physicians reporting on acute work-related respiratory diseases between 1992 and 2001, there was an annual average HP incidence of 2 cases per million. Of the cases in which a causative agent was identified, 17% were due to various chemical agents, with isocyanates the most frequently reported.[27]

OCCUPATIONAL AND ENVIRONMENTAL EXPOSURES

Although the acute symptoms of HP are often attributed to intense, intermittent antigen exposure while more subtle, insidious symptoms are thought to result from lower level, more prolonged exposure, the paucity of environmental exposure data provides little insight into dose-response relationships. Insight into exposure-response relationships is further complicated by the fact that the latency period between exposure to an environmental antigen and onset of HP symptoms may vary from a few weeks to years.

Environmental risk factors—including antigen concentration, exposure duration, frequency and intermittency, particle size, antigen solubility, use of respiratory protection, and variability in work practices—may influence disease prevalence, latency, and severity. FLD is most common in late winter, when stored hay is used to feed cattle, and in regions with heavy rainfall and harsh winter conditions where feed is likely to become damp and, therefore, an ideal substrate for microbial proliferation. A seasonal variation in specific antibody levels has been described in patients with pigeon breeder's disease, with a peak in antibody production during late summer when highest exposures were associated with the sporting season. Thus, the most common forms of HP show both seasonal and geographic variation.

Indirect and apparently trivial antigen exposures have been associated with avian HP. Goose feather duvets, down comforters and pillows, feathers used for making fishing lures, and those contained in decorative wreaths have all been associated with cases of HP. These findings suggest that avian antigens are extremely potent inducers of immunologic lung disease, and a careful search for their presence must be included in the history taking of patients with suspected HP.

HOST FACTORS

Whereas many individuals may develop precipitating antibodies following antigen inhalation, fewer develop HP. Susceptibility to or protection from HP may be explained in part by genetic polymorphisms.[28] Polymorphisms in the major histocompatibility complex and in tumor necrosis factor-α (TNF-α) are associated with the development of HP.[29-31] Several polymorphisms have also been associated with decreased disease risk. Overexpression of GATA-3, a regulator of Th2 differentiation, attenuates disease by correcting the Th1 immune response.[32] Variants in the tissue inhibitor of metalloproteinase-3 appear to be protective against bird fancier's lung.[33,34]

HP occurs more frequently in nonsmokers than in smokers. Compared with former and never smokers, pigeon fanciers who smoked had a lower incidence of

precipitating antibodies to pigeon antigens and lower serum IgG and IgA antibody levels to pigeon proteins; this suggests that cigarette smoking depresses both T-independent and T-dependent responses to inhaled antigens.[35] Investigations into the biologic mechanisms by which smoking inhibits the development of granulomatous diseases have shown that nicotine exposure leads to a reduced cellular response, with reduced total bronchoalveolar lavage (BAL) cell count and lymphocyte count and decrease in lung tissue inflammation.[36] Other studies have shown that smoking induces relative increases in macrophages and decreases in lymphocytes and dendritic cells, perhaps promoting more effective clearance of antigens from terminal airways.[37,38] Although HP appears to occur more commonly in nonsmokers, prognosis is poorer in those with HP who smoke. Smokers with FLD had more frequent illness recurrence, were more likely to have insidious than acute symptoms, had lower percent predicted vital capacities, and had poorer 10-year survival in comparison with nonsmokers with FLD.[39]

HP can occur in infants and children, although incidence and prevalence are unknown. Avian proteins are the most common antigen associated with HP in the pediatric population. In one study of 86 pediatric HP cases, 70 were caused by birds.[40] Children are more likely to present with the subacute or chronic forms of HP than with acute illness.[41] Differential cell counts on BAL fluid of children with HP show a predominantly lymphocytic subpopulation; however, the CD4/CD8 ratio is usually within the normal range and an increased human leukocyte antigen (HLA)-DR expression may be found.[42] HP should be considered in the differential diagnosis of children with recurrent febrile respiratory illnesses and in those with unexplained interstitial lung disease. Parents should be questioned carefully regarding potential antigen exposures in the home, school, and avocation.

IMMUNOPATHOGENESIS

HP is characterized by the presence of activated T lymphocytes in BAL and an interstitial mononuclear cell infiltrate. The pathogenesis of HP is complex and involves (1) repeated antigen exposure; (2) immunologic sensitization of the host to the antigen; and (3) immune-mediated damage to the lung (Table 66-2). Repeated exposure to inhaled antigens usually results in a Th1 and $CD8^+$ T-lymphocyte–predominant inflammation.[43] Compared with sarcoidosis, the ratio of $CD4^+/CD8^+$ cells in HP is often less than 1. However, these ratios vary widely in patients with HP, with some having normal or increased $CD4^+/CD8^+$ ratios. Reasons for this variability are unclear, but the forms of HP (inflammatory vs. fibrotic) and the timing of last antigen exposure in relation to BAL may affect cellular phenotypes.

TABLE 66-2. Unifying Pathogenic Characteristics of Hypersensitivity Pneumonitis

Repeated antigen exposure
Immunologic sensitization of host
Lung is portal of entry and target organ
Immune inflammatory pulmonary infiltrate (T lymphocytes)
Chronic cellular immune response with ongoing antigen exposure

In humans, the cellular and inflammatory mediators that characterize HP have been examined using BAL and provide insights into the immunologic and inflammatory mechanisms that occur in the lung.[44] The BAL cellular profile of HP following antigen exposure begins with an influx of neutrophils, peaking 48 hours after exposure, and is followed by an increase in activated T cells ($CD4^+$).[45] An influx of macrophages and lymphocytes is seen between 48 and 72 hours. This cellular profile is associated with increases in inflammatory mediators. Macrophage inflammatory protein-1α, a chemotactic factors for lymphocytes, peaks early after exposure, between 4 to 6 hours, whereas monocyte chemoattractant protein-1 peaks later, between 48 and 72 hours.[46] Both cellular redistribution from peripheral blood to lung and in situ lymphocyte proliferation contribute to the increased number of lung T cells. Reactive oxygen species produced by macrophages contribute to alveolar damage.[47]

Several cytokines contribute to the development of granuloma formation including interferon-γ (IFN-γ), interleukin (IL)-12, IL-18, and TNF-α.[48] The development of a Th1 T-cell immune response is driven primarily by the cytokine IL-12, produced mainly by macrophages. Th1 cells secrete IL-12, IFN-γ, TNF-α, and TNF-β. Mouse models support the requirement of Th1 responses for the development of HP, whereas Th2-responsive mice are resistant to HP.[49] Natural killer cells also are increased in BAL from patients with HP in comparison with nonsmokers and those with sarcoidosis. Natural killer T cells augment the development of HP by secreting IL-4 and IFN-γ, modulating the Th1/Th2 balance.[50]

The cellular phenotype in chronic, fibrotic HP appears to be different from that of the acute or inflammatory form of disease. BAL from patients with chronic HP shows a loss of effector T-cell function and a higher $CD4^+/CD8^+$ ratio.[51] There is a skewing to Th2 activity associated with the development of fibrosis.[52,53]

Individual genetic factors may drive susceptibility to developing HP. Several genetic polymorphisms of HLA subtypes have been associated with HP.[30,54–56] However, the evidence is variable, and other studies have found no association with certain HLA subtypes. Polymorphisms in tissue inhibitor of metalloproteinase-3 have been shown to confer resistance to the development of HP.[33,34] The strongest evidence for the role of genetic factors in the pathogenesis of HP comes from gene expression profiles.[57] Lung biopsies from patients with idiopathic pulmonary fibrosis (IPF), nonspecific interstitial pneumonitis, and HP were profiled using microarray techniques. The gene expression profile from HP was easily distinguished from that of IPF and was found to

be enriched with genes that are functionally associated with inflammation, T-cell activation, and a heightened immune response. Many of the genes that were found to have a higher expression profile in HP have previously been implicated in the pathogenesis of HP.[58–60] Although gene expression profile studies provide strong evidence for individual susceptibility to the disease, more research is needed to confirm their functional role in the pathogenesis of HP.

HISTOPATHOLOGY

Irrespective of cause, the histopathologic changes of HP are similar but vary depending on the stage of illness at the time of biopsy. The classic histologic triad of HP includes (1) cellular bronchiolitis (airway-centered inflammation), (2) interstitial mononuclear cell infiltrates, and (3) scattered, small, non-necrotizing granulomas. Because the histopathologic findings of HP vary and overlap with other diseases such as usual interstitial pneumonitis (UIP), fibrosing nonspecific interstitial pneumonitis, organizing pneumonia, and centrilobular fibrosis,[61–64] additional clinical data must be considered in confirming the diagnosis.

Features of the inflammatory and acute forms of HP include a lymphocytic interstitial inflammatory cell infiltrate, poorly formed non-necrotizing granulomas, and cellular bronchiolitis[65,66] (Fig. 66-1). The interstitial infiltrates can closely resemble those found in nonspecific interstitial pneumonitis.[63] Granulomas may resolve after a period of antigen exposure avoidance.

Fibrotic and chronic forms of HP are characterized by airway-centered interstitial fibrosis and giant cells, often with minimal granulomatous inflammation (Fig. 66-2). Bridging fibrosis occurring between peribronchiolar and perilobular areas may provide evidence of chronic HP. In a review of 13 cases of chronic HP, three patterns were found: (1) a UIP-like pattern in a patchy subpleural distribution with obliteration of the lung architecture, often with fibroblast foci; (2) a homogeneous linear fibrosis similar to that of fibrotic nonspecific interstitial pneumonitis; and (3) irregular fibrosis in a peribronchiolar distribution.[64]

CLINICAL FEATURES

Signs and Symptoms

A thorough and detailed history is the cornerstone of HP diagnosis. It is also essential for planning exposure intervention (Table 66-3). A clinical history suggesting a temporal relationship between symptoms and certain activities is often the first clue to the diagnosis of HP, although such a pattern does not always occur. The work history should include a chronology of current and previous occupations, with a description of specific work processes and exposures. Antigen exposures capable of causing HP can occur in almost any indoor environment under appropriate circumstances, and a simple job title cannot be used to exclude potential risk.

The environmental history should explore exposure to pets and other domestic animals, particularly birds; hobbies such as gardening and lawn care, which may involve sensitizing chemical exposures like pyrethrins; recreational activities, for example, use of hot tubs and indoor swimming pools from which microbial bioaerosols can be generated; use of humidifiers, cool mist vaporizers, and humidified air conditioners, which can be sources of microbial bioaerosols; moisture indicators such as leaking, flooding, or previous water damage to carpets and furnishings; and visible mold or mildew contamination in occupied spaces. Use of medications (both prescription and nonprescription) should be elicited to assess possible drug-induced lung disease.

The classification of HP into distinct acute, subacute, and chronic forms can be misleading because clinical manifestations frequently overlap. Nevertheless, the varying presentations are associated with variable clinical findings. Acute HP typically begins 4 to 12 hours after exposure, with abrupt onset of viral-like respiratory and constitutional symptoms of cough, dyspnea, chest tightness, fevers, chills, malaise, and myalgias. Symptoms

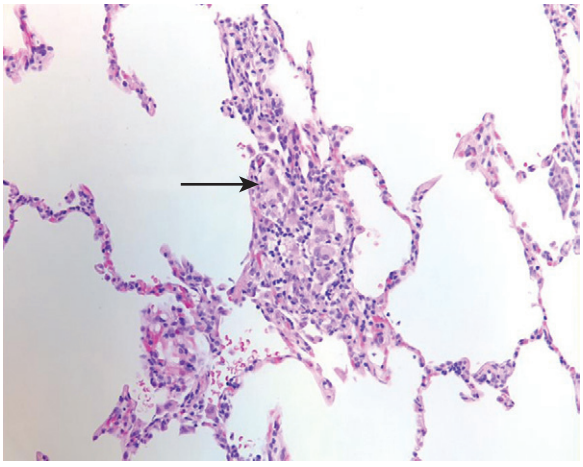

FIGURE 66-1 ■ Highlights of one of several poorly formed non-necrotizing granulomas (*arrow*) in the right middle lobe biopsy.

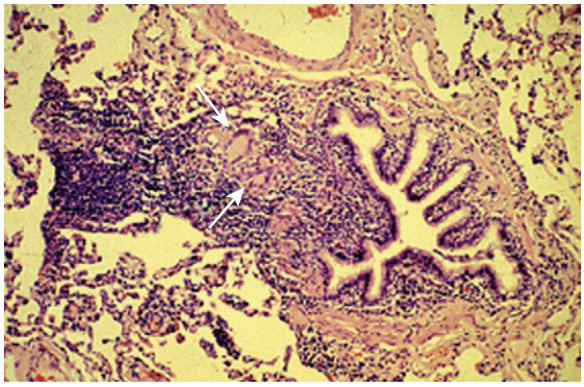

FIGURE 66-2 ■ Airway-centered interstitial fibrosis and giant cells (*arrows*), with granulomatous inflammation.

TABLE 66-3. Components of an Occupational and Environmental History for Patients with Suspected Hypersensitivity Pneumonitis

OCCUPATIONAL HISTORY
Chronology of current and previous occupations
Description of job processes and specific work practices
List of specific chemicals, dusts, and other aerosol exposures (e.g., grain dust; animal handling; food and plant processing; cooling towers, fountains, and other water sprays; metalworking fluids)
Review of material safety data sheets (MSDS) to identify known chemical sensitizers
Reports of industrial hygiene evaluations or environmental testing at the workplace
Symptom improvement away from work or symptom worsening with specific workplace exposures
Presence of persistent respiratory or constitutional symptoms in exposed coworkers
Use of respiratory protection at work
ENVIRONMENTAL AND RESIDENTIAL HISTORY
Pets and other domestic animals (especially birds)
Hobbies and recreational activities (especially those involving chemicals, feathers or fur, plant materials, and organic dusts)
Presence of humidifiers, dehumidifiers, evaporative coolers, clothes dryers vented indoors, and other humidity sources
Use of hot tubs or saunas
Leaking or flooding indoors
Water damage to carpets or furnishings
Visible fungal growth
Feather pillows, comforters, or bedding
Similar symptoms in other family members or home occupants

may be accompanied by physical findings of fever, tachypnea, tachycardia, and lung inspiratory crackles. Peripheral blood leukocytosis with neutrophilia and lymphopenia may be present. Eosinophilia is unusual. Symptoms of acute HP typically resolve spontaneously. Recurrent acute symptom episodes should prompt consideration of hypersensitivity lung disease and a careful historical search for relevant exposures.

The more insidious subacute presentations of illness also require a high degree of clinical suspicion to confirm the diagnosis and initiate appropriate management. Dyspnea and cough are the most commonly reported clinical symptoms. Patients frequently report sputum production, fatigue, malaise, chest tightness, and weight loss. Pulmonary examination findings often include basilar crackles, though in two large studies of HP, nearly 20% of patients with HP had a normal lung examination.[67,68] Wheezing may occur in some patients and likely reflects an antigen-mediated inflammatory effect on the airways. Cyanosis and right-sided heart failure occur with severe fibrotic disease. Digital clubbing is associated with a poorer prognosis.

Precipitating Antibodies

The finding of specific IgG-precipitating antibodies in the serum of a patient with suspected HP indicates exposure sufficient to generate a humoral immunologic response and may be a helpful diagnostic clue. Once thought to be the hallmark of HP, precipitating antibodies are unfortunately neither sensitive nor specific.[69] This is especially true if used as a screening tool.[70] In a large series of patients with bird fancier's lung, 92% had positive serum IgG antibodies, whereas 87% of controls also had positive precipitins.[68]

Despite advances in detection of serum antibodies, challenges in their use and interpretation persist.[71] False-negative results may occur because of poorly standardized antigens, improper quality controls, insensitive immunologic techniques, the wrong choice of antigen, or underconcentrated sera. More sensitive assays such as enzyme-linked immunosorbent assay for specific IgG antibodies may lead to confusion because of decreased specificity. Serum precipitins may disappear over time after exposure ceases. In cases associated with complex microbial bioaerosol exposures, disease may not be a reaction to one organism alone but a cumulative reaction to a number of airborne antigens, which may not be reflected in available laboratory antigen panels.

Other Laboratory Studies

Mild elevations in erythrocyte sedimentation rate, C-reactive protein, and immunoglobulins of IgG, IgM, or IgA isotypes are occasionally evident, reflecting acute or chronic inflammation. Antinuclear antibodies and other autoantibodies rarely are detected and, if found, suggest an underlying connective tissue disease. Skin tests for both immediate and delayed-type hypersensitivity reactions are not helpful in the diagnosis of HP.[70,72,73]

There is increasing evidence for Krebs von den Lungen-6 (KL-6) as a potential biomarker for HP. KL-6 is a mucin-like high-molecular-weight glycoprotein produced mainly by pulmonary epithelial cells. It is often elevated in the serum and BAL fluid of patients with diseases involving the small airways.[74-77] KL-6 has been studied in FLD and bird fancier's disease as a marker of disease activity and may correlate with pulmonary physiologic abnormalities.[78,79]

Physiology

Complete pulmonary function tests (PFTs), including lung volumes, spirometry, and diffusing capacity of carbon dioxide (D_{LCO}), should be obtained in all patients with suspected HP. Lung function abnormalities in acute HP are classically restrictive, with a decrease in forced vital capacity, total lung capacity, and diffusion capacity.[80,81] Hypoxemia is often present, and an exercise-induced decrease in arterial oxygen tension is an early sign of functional impairment. PFTs may be normal if performed after resolution of an acute episode.

PFTs may also fall within normal limits in subacute forms of HP, and findings may be misleading if no premorbid PFT values are available for comparison. Restrictive, obstructive, and combined defects in pulmonary function occur in subacute and chronic HP. Decreased

diffusion capacity also is commonly observed. Gas exchange abnormalities, particularly with exercise, may be marked. Nonspecific bronchial hyperreactivity measured by methacholine challenge has been described. HP should be considered in the differential diagnosis of nonsmokers presenting with physiologic findings of emphysema and in patients with airflow limitation and nonspecific bronchial hyperreactivity. Once diagnostic confirmation of HP is obtained, serial PFTs should be followed to assess response to therapy and to guide treatment decisions until recovery or stability of lung function is achieved.

Radiography

The chest radiograph in acute HP typically reveals a fine micronodular pattern or diffuse ground-glass opacities (Fig. 66-3A).[82,83] Hilar or mediastinal adenopathy rarely is seen on the plain radiograph. The chest film may be normal, particularly in early disease stages, and is a poor screening tool in populations at risk for HP. Radiographic abnormalities in acute illness regress or resolve over 4 to 6 weeks if further exposure is avoided. Radiographic manifestations of fibrotic HP include linear reticular opacities, volume loss, and honeycombing.

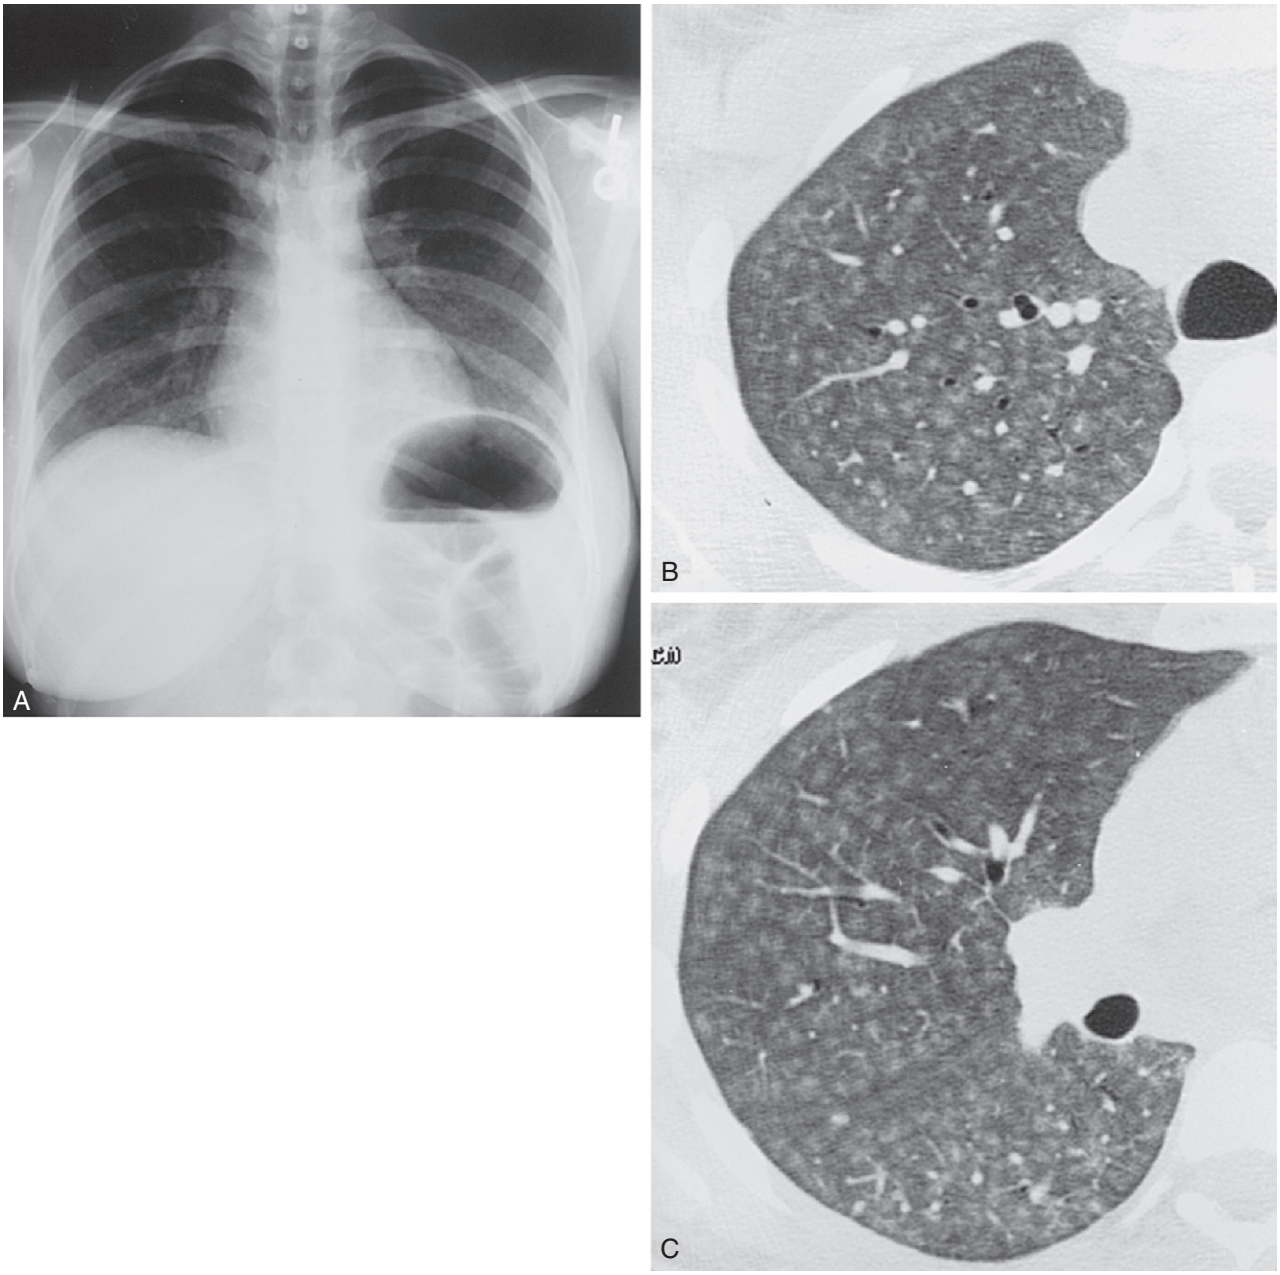

FIGURE 66-3 ■ **A,** Chest radiograph of a patient with hypersensitivity pneumonitis (HP) shows diffuse upper zone predominant micronodules. **B,** High-resolution (1.5-mm thin section) computed tomography (HRCT) image through the lung of the same patient shows profuse centrilobular micronodules. **C,** HRCT scan of a patient with chronic bird breeder's lung shows diffuse ground-glass attenuation with reticular opacities and centrilobular micronodules.

Chest computed tomography (CT) scanning is more sensitive than chest radiography in the diagnosis of HP and is useful in differentiating infectious and noninfectious parenchymal lung diseases.[84,85] The classic CT findings of HP include mosaic attenuation, ground-glass abnormalities, and centrilobular micronodules.[86,87] The finding of centrilobular micronodules probably reflects a cellular bronchiolitis (see Fig. 66-3B).[88] Diffuse ground-glass attenuation may be the predominant or only CT abnormality in some cases. The CT appearance of HP may be normal if disease is diagnosed early.[89] HP-associated effects on small airways are best assessed by expiratory imaging modalities that show areas of decreased attenuation.[90] In chronic HP, chest CT findings include fibrosis, reticular opacities, lobar volume loss, and honeycombing (see Fig. 66-3C). Focal areas of hyperlucency (mosaic pattern), perhaps due to bronchiolocentric inflammation with associated air trapping, may be a prominent feature[91] (Fig. 66-4). Mild reactive mediastinal lymphadenopathy is a common CT finding typically involving only a few nodes with a maximal short axis diameter less than 15 mm. The degree of fibrosis found on CT reflects a poorer prognosis in patients with HP[92,93] (Fig. 66-5). Notably, emphysema is a more common radiographic finding than fibrosis in chronic FLD.[94,95] Lung cysts have been reported in cases of subacute HP.[96] The use of CT scan alone to differentiate chronic HP from other fibrotic interstitial lung diseases is unreliable, with accurate diagnosis in 50% of patients in one series.[97]

Inhalation Challenge

The use of laboratory inhalation challenge in the diagnosis of HP is limited by the lack of standardized antigens and techniques. Inhalation of an aerosolized antigen suspected to be causative is most helpful when acute symptoms and clinical abnormalities are part of the disease presentation and likely to occur within hours after exposure. In some patients with acute symptoms, exposure to the suspect environment with postexposure monitoring of symptoms, temperature, leukocyte count, spirometry, DL_{CO}, and chest radiograph may be preferable to laboratory challenge. Inhalation challenge testing may be useful in distinguishing between insidious versus fluctuating types of chronic bird fancier's lung.[98] Interpretation of results is often difficult, and routine inhalation challenge is not recommended in most patients with suspected HP.[80]

Bronchoalveolar Lavage

BAL is a generally safe and sensitive tool to confirm the presence of alveolitis in patients with HP. Typically, a marked BAL lymphocytosis (30%–70%) without eosinophilia or neutrophilia is found, often with a $CD8^+$ lymphocyte predominance. Total white blood cell numbers are increased, often up to fivefold normal. The absolute number of macrophages is similar to that in controls, although their percentage in BAL is reduced because of the high percentage of lymphocytes.

The BAL cellular profile may vary considerably, depending on the stage of illness and the time interval between BAL and last antigen exposure. Cellular profiles provide insight into possible mechanisms of disease, particularly in chronic HP where effector T-cell function is lost, with shift toward a profibrotic Th2 profile.[51] The BAL lymphocytosis of HP may persist for years after apparent removal from antigen exposure and despite improvement in other clinical parameters, limiting its utility as a tool to follow the course and progression of disease or to assess adequacy of antigen avoidance.[99] Individuals exposed to HP antigens but without reported symptoms or other clinical abnormalities may develop a lymphocytic alveolitis, further limiting the diagnostic specificity of BAL. There appears to be little correlation between BAL findings and other clinical abnormalities, including radiographic changes, pulmonary function, and the presence of precipitating antibody.

FIGURE 66-4 ■ Chronic HP. Bilateral, diffuse ground-glass opacities with mosaic perfusion.

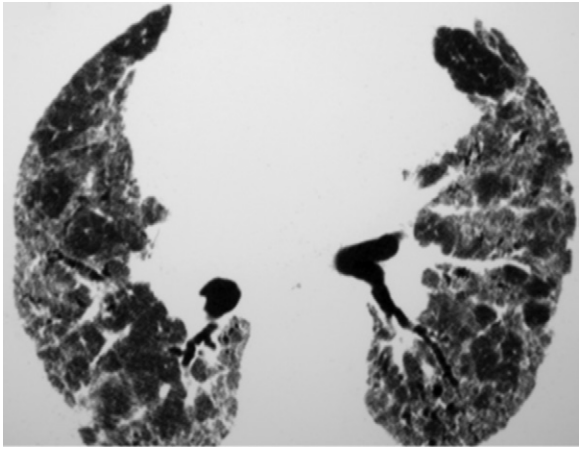

FIGURE 66-5 ■ Chronic HP. Chronic HP is manifest as lung fibrosis, with areas of reticulation, traction bronchiectasis, and architectural distortion, with a mid-lung predominance. (Courtesy of Dr. Michael Gotway.)

Lung Biopsy

Lung biopsy is indicated in patients without sufficient clinical criteria for definitive diagnosis or to rule out other diseases that require different management. In one study, transbronchial biopsies were found to have a relatively low yield of 38% in the diagnosis of interstitial lung disease.[100] Use of transbronchial biopsies should be considered in those patients who decline surgery or are at higher surgical risk. Interstitial lymphocytic inflammation, granulomas, and bronchiolar inflammation can be seen on transbronchial biopsy; however, appreciation of the prototypical airway-centered inflammation usually requires a surgical lung biopsy. Special stains and cultures are important to distinguish HP from infectious granulomatous conditions, including fungal and mycobacterial diseases. HP differs from sarcoidosis in the finding of inflammatory infiltrates at interstitial sites distant from granulomas, whereas in sarcoidosis, such infiltrates generally are found in and around the granulomas. Surgical lung biopsy is often necessary to confirm a diagnosis of subacute HP and is helpful when differentiating HP from other interstitial lung diseases.[62,64,101,102] Fibrotic HP may be difficult to distinguish from UIP. The diagnostic yield increases if biopsies are taken from multiple lobes.[103] Fibroblast foci commonly seen in UIP can also be seen in chronic HP.[61] The histopathologic finding of chronic bronchiolitis with or without peribronchiolar metaplasia in the setting of other findings consistent with UIP should raise the possibility of chronic HP.[103] Given the substantial overlap in the histologic appearance of these inflammatory processes, pathology without clinical correlation is often insufficient for diagnosis.

Diagnostic Approach

A thorough review of potential exposures to known antigens is essential as the cornerstone of treatment is elimination of further exposure. Diagnostic studies that should be considered on all patients with suspected HP can be found in Table 66-4. In patients with exertional dyspnea and normal or minimally abnormal PFTs, exercise physiology is often helpful in defining impairment and important in guiding treatment decisions, including the need for supplemental oxygen. Serum precipitins are helpful when positive in confirming the diagnosis in bird breeder's lung and in other circumstances in which the putative antigen has been identified. However, negative precipitins should not be used to exclude the diagnosis.

TABLE 66-4. Diagnostic Approach to the Patient with Possible Hypersensitivity Pneumonitis

Obtain detailed occupational and environmental exposure histories, along with regular clinical history
Physical examination, with attention to pulmonary findings
Pulmonary function, including spirometry, lung volumes, D_{LCO}
Chest radiograph
Chest high-resolution CT scan if chest film is negative or nonspecific
Assess exercise ventilatory and gas exchange parameters if exertional dyspnea is prominent
Consider serum precipitin analysis; negative results do not rule out HP, but a positive precipitin result helps confirm relevant antigenic exposures
FOB with BAL if diagnosis is in doubt; surgical lung biopsy may be indicated if FOB is nondiagnostic

BAL, bronchoalveolar lavage; CT, computed tomography; D_{LCO}, diffusing capacity of carbon dioxide; FOB, fiberoptic bronchoscopy; HP, hypersensitivity pneumonitis.

DIAGNOSTIC CRITERIA

A number of diagnostic criteria for HP have been proposed, but most lack validation.[104,105] Most criteria include the requirements of appropriate exposure, dyspnea on exertion, inspiratory crackles, and lymphocytic alveolitis (if BAL is done). Supportive criteria include recurrent febrile episodes; opacities on chest radiograph; decreased D_{LCO}; precipitating antibodies to causative antigens; granulomas on lung biopsy (usually not required); and improvement with contact avoidance. Stringent diagnostic criteria may underestimate milder cases of HP in which the chest radiograph is normal or when symptoms are subtle or insidious. Because a positive exposure history is part of the case definition for disease, absent or inadequate occupational and environmental history taking probably results in underrecognition of disease. Moreover, in up to 30% of cases with more complete exposure histories, no causal exposure is identifiable. The likelihood that unrecognized HP occurs also is based on several other factors: (1) the signs and symptoms of illness and clinical diagnostic findings are nonspecific and mimic many other diseases (Table 66-5); (2) early disease may be accompanied by a normal lung examination and resting pulmonary function as well as a normal chest radiograph; (3) many of the microbial antigens that cause HP proliferate in common environmental niches and relevant exposures may be difficult to elicit historically; and (4) precipitating antibodies are often negative and may disappear after exposure ceases, so that a patient with fibrotic lung disease from previous episodes of HP may not be recognized as such

NATURAL HISTORY AND PROGNOSIS

In acute HP, symptoms of fever, chills, and cough usually disappear within days after exposure ceases. Malaise, fatigue, and dyspnea may persist for several weeks. There is usually rapid improvement in lung vital capacity and D_{LCO} in the first 2 weeks after an acute attack, but mild abnormalities in pulmonary function often persist for several months. In general, single acute episodes are self-limited and do not require treatment other than avoidance of repeated exposure. Rarely, the disease may progress despite removal from exposure. Continued symptoms and progressive lung impairment have been

TABLE 66-5. Differential Diagnosis of Hypersensitivity Pneumonitis*

reported after recurrent acute attacks and even after a single severe attack.

The subacute and chronic forms of HP, with insidious symptoms and more subtle, progressive clinical abnormalities, are often recognized later in the course of illness and consequently have a poorer prognosis than acute disease. Overall, patients with HP appear to have an increased mortality rate when compared with the general population.[25] Patients with imaging evidence of fibrotic HP have a significantly worse prognosis overall when compared with those with nonfibrotic chronic HP.[86,93] The risk of death from HP increases with increased age.[92,101] Fatal diffuse alveolar damage has been described as a complication of chronic bird fancier's lung.[106]

Both emphysema (more common in late-stage FLD) and fibrosis (more common as an outcome of bird breeder's lung) are potential sequelae of HP. In a case-control study of 88 farmers with FLD,[107] emphysema was found significantly more often (23%) in those with FLD compared with matched control farmers (7%), occurring in 18% of nonsmoking and 44% of smoking FLD patients. Recurrent attacks of FLD were associated in this study with risk for emphysema. In another follow-up study of farmers with a history of FLD,[108] obstructive abnormalities from emphysema were the most common findings in those whose disease did not completely resolve; only 50% had no residual disease. In a study of Finnish farmers meeting strict diagnostic criteria for FLD,[109] the risk for asthma necessitating medication was found to increase within the first 3 years after a diagnosis of FLD, with significantly higher asthma prevalence rates in the population with FLD at 5-year follow-up compared with the reference population. Patients with HP from avian antigens appear to have a higher risk of developing fibrotic lung disease compared with those with FLD, with a poor 5-year survival similar to that of patients with IPF. Thus, although some patients with HP recover completely, permanent sequelae of the disease include asthma, emphysema, and (sometimes progressive) interstitial fibrosis.

No functional or biochemical marker exists to predict resolution or progression of disease. The BAL lymphocytosis associated with HP may persist for years after removal from exposure and despite clinical recovery. Age at diagnosis, duration of antigen exposure after onset of symptoms, and total years of exposure before diagnosis seem to have predictive value in the likelihood of recovery from pigeon breeder's lung disease.[110] A 23-year population-based study undertaken to investigate the mortality of HP showed that overall age-adjusted death rates increased between 1980 and 2002.[111] The authors suggest that this may be due to the concomitant decline in smoking rates in the United States and better disease recognition from use of thoracoscopic lung biopsy for diagnosis.[111] Wisconsin has the highest percentage of FLD-related deaths (81.9%), twice that of the nation as a whole. Death also increased with age, with rates of 0.01 per million in the 15- to 24-year-old group, compared with 0.80 per million in the 65-year-old and older group of patients with HP.[112]

TREATMENT

An accelerated decline in lung function with continued antigen exposure has been demonstrated for most forms of HP. Thus, early diagnosis and avoidance of exposure are the mainstays of treatment, with pharmacologic therapy an important adjunct in some cases.

Antigen Avoidance

Elimination of a causative antigen from the patient's environment not only is the first step in treatment but also prevents occurrence of hypersensitivity diseases in others exposed. For example, maple bark disease and bagassosis are now quite rare in the United States after changes in the handling of organic material, resulting in diminished opportunity for microbial growth. Removal of damaged and colonized areas, disinfection, and elimi-

nation of conditions leading to seasonal mold contamination have been effective in preventing recurrence of summer-type HP in Japan.[113] Outbreaks of HP traced to microbial contamination of ventilation systems were controlled by extensive modification and replacement of the systems and corresponding work areas.[114] In cases of home humidifier and hot tub lung, removal of the contaminated source is usually straightforward in eliminating ongoing exposure.

On-site investigation of the implicated work or home environment by an experienced industrial hygienist may be helpful in cases in which the exposure history is uncertain, particularly when disease is progressive. However, quantitative bioaerosol sampling for indoor microbial antigens is time-consuming, expensive, and not readily available to most clinicians and requires an experienced industrial hygienist and analytical laboratory. Even when properly performed, results are often difficult to interpret. Negative results should not be used to disprove disease or exposure. Avoidance of exposure by eliminating the offending antigen from the environment may be difficult in some circumstances. In five homes monitored serially after bird removal, antigen levels measured by inhibition enzyme-linked immunosorbent assay declined gradually despite extensive environmental control measures, with high levels still detectable at 18 months in one home.[115] Avian antigens can be found in homes without birds if wild bird excrement is deposited heavily outside the house and tracked in on shoes.

When elimination of the antigen is not feasible or the etiologic agent is not identified, exposure avoidance may be accomplished by removing the affected individual from the likely antigen-containing environment. This approach may be simple and adequate for recovery. However, the social consequences and economic disruption to the affected individual may preclude strict abstinence from exposure. When antigen exposure avoidance is likely to be inadequate, regular follow-up of pulmonary function, chest imaging, and symptoms is essential to assess response to treatment and to direct efforts to mitigate ongoing antigen exposure.

Pharmacologic Therapy

There are anecdotal reports of the beneficial effects of systemic steroids in acute attacks of HP, but controlled clinical trials are lacking. In cases in which pulmonary function abnormalities are minor and spontaneous recovery is likely with removal from exposure, steroids are probably unnecessary. More severe attacks may necessitate treatment with prednisone, typically beginning at 60 mg/day, plus supplemental oxygen for hypoxemia and other appropriate supportive measures. Prednisone usually is continued until there is significant symptomatic and functional improvement. Pulmonary function should be monitored within the first 4 weeks after initiation of treatment. If there is objective improvement, a gradual taper to minimum sustaining doses should follow; otherwise, steroids should be tapered and discontinued. Given the paucity of treatment studies and the known side effects of systemic corticosteroids, clinical judgment and careful medical follow-up must guide individual patient management.

The effect of corticosteroids on the long-term course of various forms of HP has received limited study. In one study, 36 patients, most having suffered only one acute attack of FLD, were assigned randomly to receive prednisolone or placebo for 2 months.[116] The steroid-treated group showed more rapid improvement in physiologic abnormalities (particularly D_{LCO}) at 1-month follow-up, but no differences were found between the treated and the untreated groups 5 years later. In a study of pigeon breeders with HP, there were no significant clinical outcome differences between cases who were treated with steroids and those who were not; the mean time for improvement or normalization of pulmonary function after treatment and removal from exposure was 3.4 months.[110]

Inhaled steroids and β-agonists may be helpful in patients with HP manifested by symptoms of chest tightness and cough and with airflow limitation on pulmonary function. There are as yet no data from controlled clinical trials on the efficacy of inhaled steroids in the treatment of HP. Cytotoxic agents such as cyclophosphamide, cyclosporin A,[117] and azathioprine have been used in patients with refractory progressive HP, but their efficacy is largely unexplored. Lung transplantation may be a last resort in patients unresponsive to medical therapy.

PREVENTION

Recognition of an index case of HP is often a sentinel health event, indicating the need for further investigation and intervention in the environment where others may be at risk and where opportunities for prevention may be identified. For example, indoor microbial contamination often is related to problems with control of moisture. Source dilution and administrative controls should be used when appropriate to reduce these indoor contaminants. Source control includes preventing leaking and flooding; removing stagnant water sources; eliminating aerosol humidifiers, hot tubs, and vaporizers; and maintaining indoor relative humidity below 70%. If humidifiers are used, frequent cleaning and water changes minimize the risk of microbial growth. Dilution of contaminants can be affected by increasing the amount of outdoor air in a building, and high-efficiency filters can be added to the ventilation system to clean recirculated air.

Work practices recommended to reduce the prevalence of FLD include efficient drying of hay and cereals before storage, use of mechanical feeding systems, and better ventilation of farm buildings. Education of potentially exposed workers in antigen avoidance and early symptom recognition may be helpful.

The efficacy of various types of respirators in preventing antigen sensitization and disease progression once sensitization has occurred is poorly studied. Helmet-type powered air purifying respirators have been used to

prevent episodic exposure in individuals with previous acute episodes of FLD. Respiratory protection has been examined in bird breeders with HP.[118] Serum antibody levels declined by 65% over 14 months in those wearing respirators in comparison with no decline in antibody levels in those without respirators; no data were reported on changes in symptoms or pulmonary function in the two groups. Prolonged wearing of respiratory protection is limited by the fact that most respirators are uncomfortable and cumbersome and interfere with communication. Dust respirators offer substantial, but in some cases incomplete, protection against organic dusts and are not recommended as preventive measures once sensitization has occurred.

KEY POINTS

- HP is a complex syndrome of varying clinical presentations, intensity/severity, and natural history.
- Many persons with mild or subclinical HP escape detection or are misdiagnosed as suffering from viral illnesses or asthma.
- Only a small proportion of exposed individuals develop clinically significant HP.
- Genetic factors are postulated to play a major role in determining an individual's risk of disease.
- HP occurs more frequently in nonsmokers than in smokers.
- Correct diagnosis is based upon: exposure history, clinical assessment, radiographic and physiologic findings.
- Absent or inadequate occupational and environmental history taking probably results in underrecognition of disease.
- The presence or absence of serum precipitins is of limited usefulness in the diagnosis of HP.
- HP is characterized by several histologic patterns of lung injury (in combination or alone).
- Removal from exposure to the suspected etiologic agent can be diagnostic and therapeutic.
- HP is both treatable and preventable if exposure is recognized and antigen abatement is effective.

INTRODUCTION

Catastrophic air pollution events in the Meuse Valley of Belgium (1930), Donora, Pennsylvania (1948), and London, England (1952), occurred when air stagnation caused very high levels of ambient pollutants, especially sulfur dioxide and particles. In each case, there was a marked increase in respiratory symptoms and mortality. These "fog disasters" provided incontrovertible evidence that air pollution can have immediate lethal consequences. Since this time, scientific investigations have uncovered a myriad of adverse respiratory health effects of air pollution, ranging from asthma exacerbation to respiratory mortality.

The respiratory system, because it is the portal of entry for air pollutants, suffers the major consequences of air pollution. This chapter reviews the key air pollutants, which are termed *criteria pollutants* by the U.S. Environmental Protection Agency (EPA), and how they affect the airways and lungs (Table 67-1). Both indoor and outdoor air pollution are considered. Respiratory health conditions that are most strongly linked with air pollution are reviewed.

AIR POLLUTANTS

Pollutants—What They Are and Why They Matter

Pollutants are substances that are present in the environment that can damage the physical environment or the living organisms that reside within it. Although pollution can include energy, such as noise, heat, or light, we

consider only chemical pollution in this chapter. Chemical pollution, which includes gas and particles, consists of either foreign substances introduced into the environment or naturally occurring substances that exceed levels that occur in nature in the absence of human intervention. Air pollution, which is a subset of chemical pollution, originates from mobile sources (e.g., vehicular traffic), stationary sources (e.g., factories, power plants, and refineries), and indoor sources (e.g., building materials, gas stoves, passive smoking, and cleaning products).[1–3]

Toxic air pollutants (air toxics) are a subset of air pollutants that may cause cancer or other serious health effects such as birth defects. These substances, such as benzene and cadmium, produce primarily nonrespiratory effects despite having the respiratory tract as a major portal of entry.

The major types of air pollutants that affect the respiratory system are sulfur dioxide (SO_2), nitrogen dioxide (NO_2), particles, and ozone (O_3) (Table 67-2). The principal sources of these pollutants are mobile and stationary sources. Ozone is a secondary pollutant that arises from the action of sunlight on nitrogen oxides and hydrocarbons present in motor vehicle exhaust. It is a major component of photochemical pollution or "smog." The respiratory health effects of these pollutants are considered later in the chapter. Carbon monoxide, which also enters via the respiratory tract, has primarily nonpulmonary toxicity and is not considered further in this chapter.

Indoor air quality has assumed increasing importance. As levels of outdoor ambient air pollution have decreased in many areas throughout the United States, the relative impact of indoor air pollution has increased. Moreover, North American residents spend the majority of their time indoors, increasing their exposure to indoor air pollutants.[4,5] At the same time, changes in home and office building construction have resulted in lower air exchange rates, increasing the levels of pollutants emitted indoors.[6] To adequately characterize personal exposure to air pollution, indoor air quality must be taken into account (see Fig. 67-1 later).

TABLE 67-1. National Primary Air Quality Standards in the United States (Criteria Pollutants)

Pollutant	Standard	Averaging Period
Carbon monoxide	9 ppm (10 mg/m^3)	8 hours
	35 ppm (40 mg/m^3)	1 hour
Nitrogen dioxide	0.053 ppm (100 μg/m^3)	1 year
Ozone	0.12 ppm	1 hour
	0.075 ppm	8 hours
Particulate matter <10 μm (PM_{10})	150 μg/m^3	24 hours
Particulate matter <2.5 μm ($PM_{2.5}$)	15 μg/m^3	1 year
	35 μg/m^3	24 hours
Sulfur dioxide	0.03 ppm (80 μg/m^3)	1 year
	0.14 ppm (365 μg/m^3)	24 hours
Lead	0.15 μg/m^3	Rolling 3-month average
	1.5 μg/m^3	3 months

General Properties, Sources, and Distribution of Pollutants

Sulfur oxides, particulate matter (PM), O_3, and NO_2 are the most widely encountered pollutants that cause adverse pulmonary health effects.[1–3] Sulfur dioxide is produced by the combustion of sulfur contained in fossil fuels such as coal and crude oil. The major sources of SO_2 pollution are power plants, oil refineries, smelters, and paper pulp mills. In the United States, SO_2 levels are generally higher in the northeastern and midwestern states, because sulfur-containing coal is used in power plants. Sulfur dioxide itself is a clear, highly water-soluble gas, so it is effectively absorbed by the mucosal surfaces of the upper airways. A very small proportion of inhaled SO_2 reaches the distal regions of the lungs, but susceptible persons with asthma may still suffer adverse respiratory health effects.[7,8] The SO_2 released into the atmosphere does not, however, remain uniquely in the form of a gas; rather, it undergoes chemical reactions with water, trace metals, and other pollutants to form

TABLE 67-2. Major Pollutants Associated with Adverse Pulmonary Effects

Pollutant	Outdoor Sources	Indoor Sources	Adverse Effects
Sulfur oxides	Power plants, oil refineries, smelters	Kerosene space heaters	Bronchoconstriction
Oxides of nitrogen	Motor vehicle exhaust, power plants, oil refineries	Gas stoves and furnaces, kerosene space heaters	Airway injury (respiratory bronchiolitis), impaired lung defenses, enhanced response to allergens
Ozone	Motor vehicle exhaust	Aircraft cabins, welding, copiers, ozone generators	Airway injury (respiratory bronchiolitis), decreased lung function, exacerbations of asthma, enhanced response to allergen
Particulate matter	Motor vehicle exhaust, power plants	Tobacco and wood smoke	Exacerbations of asthma and chronic obstructive pulmonary disease, increased cardiopulmonary mortality
Radon		Residential basements	Lung cancer
Polycyclic hydrocarbons	Diesel exhaust	Tobacco smoke	Lung cancer

particulate aerosols. The nature of particles generated from sulfur-containing fuels varies geographically, but sulfuric acid and various metallic, acidic, and ammonium sulfates are commonly present. The mixture of sulfur oxides and small particles may be blown great distances from its site of production, undergoing continuous transformation from gas to particle phase and ultimately becoming "acid rain" capable of profoundly affecting flora and fauna.[9]

In the western United States and many other areas of the world, particulate pollution is not driven by the combustion of sulfur-containing fuels. Atmospheric particulate air pollution arises from a variety of sources, including both natural (e.g., sea spray, windblown dust) and synthetic (e.g., power plants, motor vehicles) sources.[10,11] Moreover, particulate material that enters the atmosphere can be primary (particles emitted directly) or secondary (particles that form by complicated chemical reactions that occur in the atmosphere and involve gas-phase precursors such as SO_2 and nitrogen oxides). In North America, secondary particles comprise most of the fine-particle pollution.

Epidemiologic studies have focused on the size of particles in terms of aerodynamic diameter. Most particles have irregular shapes with geometric diameters that cannot be easily measured. The aerodynamic diameter is the diameter of a perfect sphere of unit density (1 g/mL) that has the same aerodynamic properties (e.g., settling velocity) as the particle in question. Larger particles are filtered in the nose and throat, but particles less than 10 μm in diameter (i.e., PM_{10}) can be deposited in the respiratory tract.[10,11] Fine particles, which are less than 2.5 μm in diameter ($PM_{2.5}$), penetrate the alveoli, and ultrafine particles ($PM_{0.1}$) can pass through the alveoli and spread to other organs.

Particle size also determines how far they travel and persist in the environment. Particles classified as "fine" (<2.5 μm) can travel for long distances and remain in the atmosphere for days to weeks; "coarse" particles (>2.5 μm) travel for rather short distances and have atmospheric half-lives of minutes to hours.[12] "Ultrafine" particles (<0.1 μm) are typically generated from combustion processes and have short atmospheric half-lives. For example, the concentration of ultrafine particles emitted from motor vehicles on a major roadway has a rapid falloff with distance from the roadway; the concentration is back to the background level at or beyond 300 m.[12]

Coarse particles (PM_{10}) are composed primarily of crustal (rock, soil), biologic (pollen, spores), and industrial components; they are formed primarily by mechanical processes that produce small particles from larger particles. Fine particles ($PM_{2.5}$) are composed mainly of varying amounts of water and six major components (sulfates, acids, nitrates, elemental carbon, organic carbon, and trace metals), several of which can be further subdivided on the basis of chemical constituents and sources.[13] They are formed from gases by nucleation, condensation, or liquid-phase reactions.

Ozone and nitrogen oxides arise primarily from the action of sunlight on emissions from internal combustion engines used by motor vehicles.[14] The most important of these products are unburned hydrocarbons and NO_2, which is an oxidation product of nitrogen oxide. In turn, nitrogen oxide arises from the fixation of atmospheric nitrogen with oxygen under conditions of high-temperature combustion. Ultraviolet irradiation of this mixture in the atmosphere results in a complex series of chemical reactions, producing O_3, alkyl nitrates, peroxyacyl nitrates, alcohols, ethers, acids, peroxyacids, and other organic and inorganic compounds that exist in both gas and particulate aerosol phases.[14] This mixture of pollutants typifies the "smog" found in areas with large numbers of automobiles and abundant sunlight, such as the Los Angeles basin.

Because O_3 and NO_2 are the gases present in highest concentration and they clearly cause toxic effects in animals and humans, they have been the oxidant pollutants most extensively studied. Both gases are relatively insoluble and poorly absorbed by the upper airways. A high proportion of the inhaled dose therefore reaches the peripheral portion of the lungs and can cause injury at any site from the upper airways to the alveoli.[15,16]

Outdoor urban air contains a number of known carcinogens, including polycyclic hydrocarbons, *n*-nitroso compounds, and asbestos. The concentrations of these carcinogens in ambient air, however, are quite low. Diesel exhaust, in particular, contains particles with polycyclic hydrocarbons as constituents. Epidemiologic studies have provided consistent evidence of an excess risk of lung cancer in workers exposed to diesel exhaust; it is a probable carcinogen in humans.[17–20] Several large population-based epidemiologic studies also have also linked lung cancer to long-term exposure to particulates, SO_2, and O_3 pollution.[21–25]

Although most attention has been given to pollutants present in outdoor air, it is now apparent that elevated concentrations of airborne contaminants are common inside homes, public buildings, and other indoor microenvironments.[6,26] There are two reasons why indoor air pollution has become an important determinant of health risk: (1) residents of the United States and other developed countries spend the majority of their time indoors, and (2) there are point sources of pollution indoors, such as secondhand cigarette smoke and gas stove use, that greatly increase the concentration of pollutants compared to outdoor air. Both indoor and outdoor pollution must be considered when assessing the total health effects of air pollution.

MECHANISMS OF DEFENSE AGAINST AIR POLLUTION–RELATED RESPIRATORY EFFECTS

The respiratory system, which encounters a myriad of particles and gases daily, has evolved an effective defense system for removing impurities from inhaled air. The various mechanisms of defense are interrelated and work in a coordinated manner. A perturbation of any defense mechanism, whether because of congenital deficiency, disease, or the effect of an inhaled pollutant itself, may

result in the breakdown of the coordinated defense system and the development of disease.

Deposition of and Clearance of Particles

The size of particles determines their site of deposition in the respiratory tract.[27] Large particles (diameter > 10 μm) are efficiently removed in the nose by simple filtration via the cilia. Those particles that are not removed by filtration will largely be deposited by a process termed *impaction.* The pathway through the nose, mouth, and branching airways is tortuous. Because inhaled particles cannot easily change direction to follow the abrupt changes in the pathway of airflow, they impact on the mucosa of the upper and lower respiratory tract. Airway bifurcations are especially prone to particle impaction. The complementary mechanisms of filtration and impaction are very efficient, so that few particles more than 10 μm reach the lower respiratory tract.

Smaller particles are less affected by filtration and impaction; the sites of their deposition are more determined by the processes of sedimentation and diffusion.[27] Sedimentation is the tendency for particles to fall at a constant rate under the influence of gravity. It is strongly influenced by particle density, particle diameter, and the viscosity of the surrounding gas. As air moves deeper into the lung, the airflow rate decreases and particles fall out of the air stream under the influence of gravity. Sedimentation is the predominant mechanism for deposition of particles of intermediate size (0.5 to 3.0 μm) in the smaller bronchi, bronchioles, and alveoli.

The smallest particles (<0.5 μm), however, are deposited by the mechanism of diffusion. These particles have random (brownian) motion and will impact the airway mucosa in the terminal bronchioles and alveoli, removing them from the stream of inspired air.

The pattern of breathing can influence the deposition of particles. A higher respiratory rate increases the velocity of airflow, promoting impaction of particles in the more proximal airways. Conversely, increased tidal volume results in deeper lung penetration by particles; because the respiratory rate is usually slower, there is more time for diffusion and sedimentation to deposit particles in the distal airways and alveoli.

After particles are deposited in the tracheobronchial tree, cough and mucociliary clearance are the most important mechanisms of defense. Cough is most effective for clearing particles that are deposited in the larger, more central airways. It is provoked by stimulation of afferent nerves that are most densely present in the mucosa of the larynx and branching points of the tracheobrochial tree, at which particles are most likely to be deposited.[28]

The "mucociliary escalator" is a critical system for clearing particles that are deposited in the trachobronchial tree; it operates over the respiratory tract from the proximal trachea to the terminal bronchioles. The mucus blanket is the product of secretion by goblet cells and serous cells of the epithelium and by the mucus cells and serous cells of the submucosal glands. The mucus blanket is propelled mouthward by the coordinated beating of epithelial cell cilia. The effective removal of particles by the mucociliary system thus requires secretion of glycoproteins by specialized secretory cells, maintenance of liquefaction by the transport of water and solute by airway epithelial cells, and coordinated function of airway cilia. Impairment of any of these functions, whether by congenital or acquired diseases affecting mucus or water secretion (e.g., cystic fibrosis, chronic bronchitis) or ciliary function (e.g., dysmotile cilia syndrome), leads to longer residence of particles in the airway and a greater likelihood of adverse health effects.

Some particles will be deposited in the distal airway and alveoli, beyond the reach of the mucociliary escalator. The central mechanism for clearing these particles involves the alveolar macrophage, which phagocytoses particles that are deposited in the gas-exchanging parts of the lung and either digests them or migrates to the respiratory bronchiole and ascends the mucociliary escalator. A smaller number of particle-laden macrophages migrate to peribronchial or perivascular connective tissue, which is a slow method of clearance that takes many weeks. Because macrophages are the primary phagocyte for inhaled PM, the carbon content of macrophages has been used as a biomarker of exposure to particulate pollution in epidemiologic studies.[29]

Gases—Deposition and Damage Is a Function of Solubility

For gaseous pollutants such as O_3, NO_2, and SO_2,the site of deposition in the respiratory tract is largely a function of its water solubility. For highly soluble gases, the nose serves an important defensive function, because the air inhaled transnasally is passed over the large, irregular surface of the turbinates. The promotion of turbulent flow prolongs contact with the mucosal surface, increasing adsorption. Under conditions of quiet breathing, when most air is inspired transnasally, this is an efficient system for removal. For example, the concentration of SO_2 that reaches the glottis is less than 2% of the concentration inspired at the nose.[30] Under other circumstances, the importance of the nose diminishes. The more rapid the inspiratory flow rate, the smaller the proportion of SO_2 removed. Furthermore, the mouth is substantially less efficient at absorbing gases than is the nose, and the proportion of air inhaled through the mouth increases as the ventilatory demands of exercise rise. Therefore, the dose of a soluble pollutant delivered to the lower airways is increased by exercise for three reasons: the inspiratory flow is higher, the proportion inhaled through the mouth is increased, and the total quantity inhaled over time is greater. The importance of the level of ventilation, which depends on the level of exercise, and of the oral-nasal distribution of breathing has perhaps best been shown in studies of the bronchoconstrictor response to SO_2, in which the greatest responses occur during oral breathing and the smallest responses during nasal breathing.[31] In addition, people with obstructive nasal disease also appear to be at greater

risk for adverse respiratory effects of soluble pollutant gases.

Oxidative Stress

Air pollution, especially particles and O_3, can increase the oxidative burden of the lung. To minimize oxidant damage to biologic molecules, the human lung has an integrated antioxidant system of enzymatic and expendable soluble antioxidants. This system includes several antioxidant defense mechanisms that detoxify reactive products or convert them to products that are quenched by other antioxidants. If the oxidant burden is sufficiently great, the reactive species may overwhelm or inactivate the antioxidant system. An imbalance between the production of reactive oxygen species (ROS) and reactive nitrogen species and antioxidant capacity leads to a state of "oxidative stress" that contributes to the pathogenesis of several respiratory diseases.[32,32a]

When imbalance occurs, the excess oxygen species induce a cellular stress response that activates a number of the redox-sensitive signaling cascades. This initial response is mediated in large part through the transcription factor nuclear factor erythroid 2–related factor 2, which leads to transcriptional activation of more than 200 antioxidant and detoxification enzymes that are collectively known as the phase 2 response.[33] Examples of phase 2 enzymes include heme oxygenase 1, glutathione-*S*-transferase isoenzymes, NADPH quinone oxidoreductase, catalase, superoxide dismutase, and glutathione peroxidase. If phase 2 responses fail to prevent a further increase in ROS production, damage to major cellular components, including membrane lipids, protein, carbohydrates, and DNA, will occur and inflammation and tissue damage may ensue.

There is also a connection between oxidative stress and inflammation in the lung. Proinflammatory effects are mediated by the redox-sensitive mitogen-activated protein kinase and nuclear factor-κB cascades that are responsible for the expression of cytokines, chemokines, and adhesion molecules.[34] Cytotoxic effects are associated with mitochondrial membrane damage, which leads to release of factors that induce apoptosis of lung cells.[35] Pathophysiologic consequences of pollutant-induced oxidant injury include airway inflammation leading to clinical exacerbation of asthma, increased susceptibility to infection, enhanced allergic responses and, if repetitive or chronic, airway remodeling.

METHODS OF STUDYING THE HEALTH EFFECTS OF AIR POLLUTION

In order to develop sound public policy aimed at protecting the public from the adverse health effects of pollutants, scientific studies are necessary both to elucidate the health effects of various pollutants and to define the threshold level at which the risk substantively increases. The scientific basis of public policy is based on several lines of evidence: epidemiologic studies of the association between air pollution exposure and occurrence of disease in the population, controlled human exposure studies conducted in the laboratory, effects of pollutants on lung structure and function in animals, and in vitro studies of toxicity. Each of these study types has advantages and disadvantages, and none alone can provide irrefutable proof of harmful effects from a particular pollutant under naturalistic conditions of exposure (Table 67-3). Standards are based, therefore, on the coherence of evidence provided by epidemiologic, clinical, animal, and in vitro research and are set to provide a margin of safety. Even so, it is recognized that harmful effects may occur in sensitive subgroups of the population even with exposure to lower levels of pollution.

Epidemiologic Studies

Epidemiologic studies have a special role in the evaluation of air pollution–related health effects, because they are the only method for studying the impact of air

TABLE 67-3. Methods for Studying Air Pollution

Method	Strengths	Weaknesses
Epidemiologic study	• Representative sample of general population • Naturalistic exposure • Broad range of pollutants • Wide range of health outcomes • Study of susceptible subgroups	• Chance, bias, confounding are threats to study validity • Difficulty separating effects of individual pollutants when they occur as multipollutant mixtures • Usually no information on biologic mechanisms
Controlled human exposure study	• Rigorous experimental design • Elimination of bias and confounding • Systematic control of exposure levels • Study of susceptible subgroups	• Acute effects do not necessarily predict chronic effects • Limited range of exposures and outcomes evaluated
Animal study	• Best method for evaluating impact of pollutants on structure and function of lung • Dose-response relationship (from minimal level producing health effects to death)	• Large interspecies response to pollutants • Applicability to humans often uncertain
In vitro study	• Elucidate cellular mechanisms • Rigorous experimental control	• Limited to available cell lines • Applicability to intact human organism often uncertain

pollution, as it is actually encountered, on large populations. Consequently, the strengths are the evaluation of a broad range of pollutants, a wide array of health effects, and a representative sample of the larger population. Epidemiologic studies, however, have to adequately address threats to study validity, principally chance, confounding, and other sources of bias. Moreover, epidemiologic studies, while they play a key role in support for regulatory intervention, must be supplemented by clinical, animal, and toxicology data before conclusions can be formulated about the risks of a specific pollutant.

For each putative pollution-related health effect, evidence must be compiled from published literature, synthesized, and evaluated for the likelihood of a causal effect. Typically, the criteria for evaluating whether a particular pollutant (e.g., particulate pollution) causes a specific respiratory disease (e.g., chronic obstructive pulmonary disease [COPD]) are those enumerated by Sir Austin Bradford Hill[36] and used by the U.S. Surgeon General beginning in 1964. These include strength of the association, consistency of the association, specificity of the association, temporal relationship, coherence, biologic plausibility, and exposure-response gradient. In this way, the totality of evidence can be evaluated and conclusions enumerated that provide the basis for regulatory decisions.

The issue of confounding is particularly complex in epidemiologic studies. A confounding variable is one that is associated with both the exposure under study and the outcome and creates the erroneous impression of a causal effect when none actually exists. For example, one might observe an association between a diet low in fruits and vegetables and lung cancer. An important confounder would be smoking, which is associated with both poor diet and lung cancer. In fact, it is smoking, and not poor diet that is the principle cause of lung cancer. Careful control of confounding is necessary to draw the correct conclusions from observed associations in epidemiologic studies.

Modern epidemiologic studies of air pollution–related health effects do account for potential confounding by age, cigarette smoking, occupational exposures, socioeconomic influences, and underlying medical illnesses. However, it is often difficult to be sure that all confounders have been identified and controlled. Since 1990, the use of daily time-series studies has increased, and these studies provide superior control of confounders that do not change over relatively short time periods.[37,38] These studies have led to important advances in the scientific understanding of what respiratory health effects are due to air pollution.

A major difficulty for large-scale epidemiologic studies is that most outdoor environments include a complex mixture of pollutants. Consequently, the several pollutants may interact to promote disease causation. Studying individual pollutants, one by one, might miss important health effects of exposure to the mixture of pollutants. A related issue is "multi-collinearity," which arises because air pollutant concentrations are correlated with one another, making it difficult to parse out the individual health effects of each pollutant. The modern use of multipollutant statistical modeling addresses these issues, but they remain challenges to valid epidemiologic inferences.[39,40]

In epidemiologic studies, the assignment of individual exposures still poses challenges. Many studies estimate individual exposure by mapping each individual subject's home (and sometimes workplace) relative to stationary pollution monitors. Recent advances have also allowed investigators to conduct personal direct monitoring of exposure to specific pollutants, but expense and other logistical considerations remain difficulties of these methods.[41] Another challenge is choosing the metric of exposure that is most relevant to disease causation, because area-based measures can provide multiple exposure metrics (e.g., hourly peaks, hourly averages, and 24-hour averages) for a wide variety of pollutants.

Controlled Human Exposure Research

Experimental studies expose human subjects to pollutants under carefully controlled conditions. Such studies can rigorously evaluate the impact of single or multiple pollutants on acute responses such as lung function or bronchial hyperresponsiveness. In addition to documenting the acute health effects of pollution, controlled human exposure studies can evaluate the minimal concentration of pollutants that causes reduction in lung function or other acute responses. They can also evaluate the effects of exercise, and consequently minute ventilation, on respiratory effects of pollution exposure. Controlled studies can also evaluate the effects of pollutants on susceptible subgroups of the population, such as adults with asthma. Moreover, measurement of biomarkers of inflammation, oxidative stress, and other pathophysiologic processes can provide mechanistic insights.

A major advantage of controlled human exposure studies is the (near) elimination of confounding and bias, because exposures are experimentally induced and carefully controlled. Because these studies evaluate acute effects, however, they cannot, by themselves, be easily extrapolated to the effects of more chronic or recurrent exposure. The finding that a brief exposure to O_3 causes acute decrements in lung function does not, for example, necessarily indicate that prolonged or repeated exposure will lead to the development of COPD. Controlled human exposure studies, when combined with epidemiologic and other study designs, can provide important data for establishing the causal effect of pollution on a respiratory health outcome.

Animal Research

Animal studies offer the most effective opportunity to elucidate the impact of air pollution on changes of lung structure and function. In addition, animal studies permit assessment of the effects of a range of concentrations, so that a dose-response curve can be constructed for outcomes ranging from the first measurable change in lung structure or function to death. Animal studies also afford a unique opportunity to dissect the pathogenetic mechanisms of pollution-related health effects.

The major limitation of animal studies is the large interspecies variations in response to pollutants. As such, applicability of animal studies to humans, especially for dose-response relationships, may not always be clear. Dogs, for example, can tolerate up to 200 ppm of SO_2 without developing significant bronchoconstriction, whereas guinea pigs appear to be especially sensitive to these bronchoconstriction effects.[42] Moreover, common human lung diseases, such as asthma and cystic fibrosis, do not occur in animals, precluding study of these susceptible subgroups for pollution-related effects.

In Vitro Research

Exposure of cell cultures to specific air pollutants has helped to elucidate the mechanisms of lung injury, inflammation, and other adverse respiratory health effects. Specifically, cell culture systems have been used to study the impact of particulate and other air pollutants on inflammatory cytokines, oxidative stress, DNA damage, and cytotoxicity.[43–49] Cultures of bronchial epithelial cells, monocytes, dendritic cells, and other cell lines have been useful for studying the mechanisms of air pollution on the respiratory system.

Air Pollution Studies—Putting It All Together

In sum, there is no single study design or discipline that can establish the health effects of air pollution and provide the basis for regulation. Epidemiologic studies are required, because they evaluate the impact of naturalistically occurring air pollution respiratory health outcomes on members of the general population. The previously mentioned limitations and pitfalls of epidemiologic study design require careful controlled human exposure studies, animal studies, and in vitro studies in order to formulate a conclusion that a specific pollutant causes a specific disease and what level of pollution begins to confer excess risk.

INDOOR AIR POLLUTION

Indoor air quality has been increasingly recognized as an important determinant of air pollution exposure. As levels of outdoor ambient air pollution have decreased in many areas throughout the United States, the relative impact of indoor air pollution has increased. Because North American residents spend the majority of their time indoors, exposure to indoor pollution may have substantive effects on health.[5] To adequately characterize personal exposure to air pollution, indoor air quality must be taken into account (Table 67-4).

Sources of Indoor Pollution

The concentration of indoor air pollutants depend on both indoor and outdoor emission sources (Fig. 67-1).[6,26,50]

TABLE 67-4. Indoor Air Pollutants

Category of Pollutant	Indoor Pollution Source
Combustion	Secondhand smoke
	Gas stoves, ovens, heaters, and fireplaces
	Wood smoke (stoves, fireplaces)
	Kerosene heaters
	Candles and incense
Building materials (emit volatile compounds)	Plywood
	Particle board
	Carpeting
	Paints
Cleaning materials	Bleach, ammonia, detergents

Outdoor emission sources determine outdoor pollution concentrations, which, in turn, can affect indoor air quality. The Six Cities Study clearly demonstrated the impact of outdoor air pollutant concentrations on indoor pollutant concentrations.[51] In addition to outdoor air pollution concentrations, the degree of penetration of outdoor pollution into the indoor environment depends largely on the rate of air infiltration from outdoors to indoors.[52] The rate of air infiltration is a complex function of the "tightness" of building construction and insulation, building location and orientation, number of exterior walls and windows, surrounding terrain and barriers, wind speed and direction, indoor-outdoor temperature gradient, and ventilation system type (e.g., heating, ventilation, and air-conditioning system) and efficiency.[6,26,52]

Time-activity patterns will influence personal exposure. The relative time spent indoors versus outdoors will affect the contribution of indoor pollutants to total personal exposure. Time spent in specific locations within the home will affect exposure to particular pollutants, as the distribution of indoor pollutant concentrations will vary among different zones of a building, especially for pollutants generated indoors.[52] In addition, activity level will affect metabolic rate and ventilatory rate, which will also influence personal exposure to indoor pollutants.[53]

Indoor Combustion: the Major Source of Indoor Air Pollution

Earlier in the chapter, the specific health effects of NO_2, SO_2, particulates, and O_3 were discussed. The major source of indoor pollution is from combustion, particularly secondhand smoke (SHS) exposure, gas stove use, and wood burning in stoves and fireplaces. Kerosene space heaters are also an important source of indoor air pollution. Table 67-4 shows the major indoor pollutants that are released from these sources and are associated with adverse pulmonary effects.

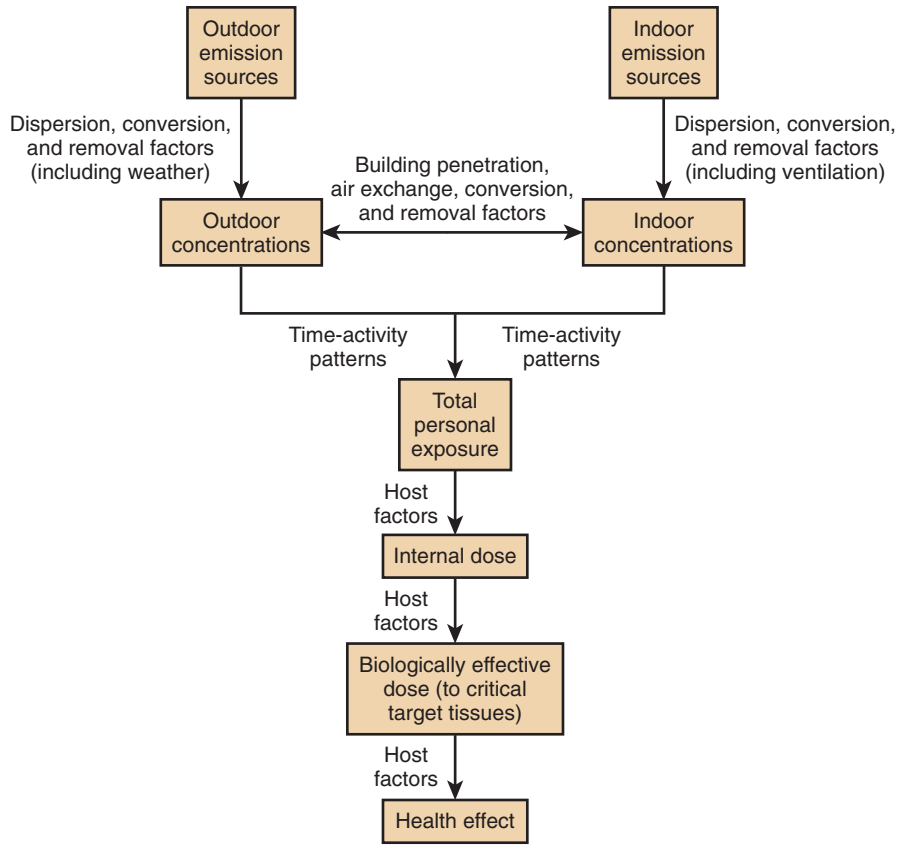

FIGURE 67-1 ■ Relationships among outdoor pollution, indoor pollution, and health effects.

Secondhand Smoke and Obstructive Lung Disease

SHS exposure is perhaps the best known and studied indoor pollutant. Strong evidence implicates it as a cause of lung cancer, coronary heart disease, and decreased life span.[54,55] In addition to these adverse health effects, SHS contains respiratory irritants, such as SO_2, ammonia, acrolein, and formaldehyde.[5] Passive smoking has also been linked with allergic phenomena, such as elevated serum immunoglobulin E levels.[56] As a consequence, SHS has the potential to induce new cases of asthma through irritant or sensitizing mechanisms. Among persons with established asthma, SHS exposure could adversely affect asthma control.

SHS is a complex mixture containing thousands of gas-phase and particulate substances. Of particular note, recent data indicate that passive smoking results in high levels of particulate air pollution. Homes where smoking is allowed have $PM_{2.5}$ levels up to 10 times higher than nonsmoking homes.[57] Workplace exposures can be even higher, especially in bars and casinos.

Numerous studies have evaluated the impact of SHS exposure on childhood asthma induction.[58] The 1997 California Environmental Protection Agency (CalEPA) report included a meta-analysis of 37 studies conducted between 1975 and 1995 that evaluated SHS exposure as a risk factor for induction of childhood asthma. The pooled relative risk for asthma was 1.44 (95% confidence interval [CI], 1.27 to 1.64). These data supported a causal association between environmental tobacco smoke and new onset of childhood asthma cases.[5] Since the CalEPA report, nearly 50 additional studies strongly support the original conclusion that SHS exposure is causally associated with new-onset asthma among children.[59]

SHS exposure also appears to be associated with new-onset asthma in adulthood. Cross-sectional, case-control, and cohort studies have suggested a link between SHS exposure and adult-onset asthma.[60–67] Workplace SHS exposure, in particular, appears to be related to adult asthma induction.[67] The CalEPA report, which was updated in 2006, concluded that the evidence was sufficient to implicate SHS as a cause of adult-onset asthma.[59]

SHS exposure may also cause other respiratory symptoms, such as wheezing, and impaired lung function.[64,68–71] In a cohort of older adults, lifetime home and workplace exposure to SHS was associated with a more rapid decline of lung function during a decade of follow-up.[72] Studies of bartenders, who have high occupational exposures to SHS, have revealed a strong link between SHS and poorer respiratory health. After smoke-free workplace laws were implemented in California, bartenders experienced a reduction of respiratory symptoms, such as cough, wheezing, and dyspnea, and improved lung function.[73] These findings have been replicated in studies from around the world.[74,75]

Beyond asthma induction, SHS exposure is a likely cause of asthma exacerbation in both children and adults. A previous review by the EPA (1992) concluded that: "There is now sufficient evidence to conclude that passive smoking is causally associated with additional episodes and increased severity of asthma in children who already have the disease."[5] Numerous subsequent studies indicate that SHS exposure, which is mostly due to parental smoking, causes increased symptoms, poorer pulmonary function, and other indicators of worsened asthma control among children with established asthma.[59] Similarly, SHS exposure, both at home and at work, appears to cause asthma exacerbation among adults.[69,76–81] Moreover, the negative impact of SHS exposure on pulmonary function appears to be greater among adults with asthma than in the general population.[69,74]

Emerging evidence now suggests that SHS exposure may also be a cause of COPD independent of personal cigarette smoking. A population-based study from the United States found that both cumulative home and work SHS exposure were associated with a greater risk of COPD, controlling for potential confounders.[82] A recent study from China found that self-reported cumulative lifetime SHS exposure at home and work was related to a greater risk of COPD, as defined by spirometry (Global Initiative for Chronic Obstructive Lung Disease [GOLD] stage I or greater).[83] Other epidemiologic studies also support an association between SHS exposure and the development of COPD, as defined by different metrics.[64,84–88] Among patients with established COPD, SHS exposure may increase the risk of respiratory symptoms, poor health status, and disease exacerbations.[89,90,90a,90b]

Gas Stove Exposure: A Cause of Asthma Exacerbation?

Because they have chronic airway inflammation, persons with asthma may be susceptible to the effects of NO_2 and other combustion products released by gas stoves. Few studies have examined the health effects of gas stove exposure among adults with asthma. Cross-sectional epidemiologic studies demonstrate an increased risk of prevalent childhood asthma cases in gas stove homes compared with electric stove homes,[91,92] although this has not been observed in adults.[65] In adults with established asthma, a prospective panel study found an association between gas stove use and increased risk of respiratory symptoms, restricted activity, and emergency department visits.[93] Another time-series analysis found a negative impact of gas stove use on daily peak expiratory flow and respiratory symptoms.[94] In contrast, a longitudinal U.K. cohort study found no effect of gas stove exposure on persistence of adult asthma or on respiratory symptoms among asthmatics[95]; the European Community Respiratory Health Survey investigators also found no clear link between gas stoves and asthma symptoms.[96] In a prospective cohort study of adults with asthma, we found no impact of gas stove exposure on asthma severity or other aspects of asthma status.[80] Moreover, there was no association between gas stove exposure and pulmonary function impairment in a population-based sample of U.S. adults.[97] There was also no relation between gas stove use or measured NO_2 level and lung function in adult asthma.[98] Overall, the evidence has not been sufficient to implicate gas stove use as an exacerbating factor in preexisting adult asthma. Among children with asthma, however, there is stronger evidence of a deleterious effect of indoor NO_2 exposure and poorer asthma control.[99,100]

Wood Smoke Exposure—Respiratory Health Effects

Wood smoke, which is produced from domestic fireplace or wood stove use, contains potent respiratory irritants such as formaldehyde, acrolein, nitrogen oxides, and SO_2. It is also a major source of particulate air pollution.[101] In previous studies, exposure to extremely high wood smoke levels has been linked with respiratory problems. After a work shift, forest firefighters experienced an acute decrement in pulmonary function.[102] Similarly, Florida wildfires were associated with increased emergency department visits for asthma and acute bronchitis.[103] In developing countries, where prolonged wood stove use in poorly ventilated homes occurs, wood smoke exposure has been associated with chronic respiratory symptoms and airway obstruction.[6,104,105] The exposure levels in such settings, however, are much higher than those encountered in modern buildings. Burning of other biomass fuels, such as crop residues or dung, can also lead to chronic respiratory symptoms and airflow obstruction in developing countries.

The respiratory health effects of residential wood smoke exposure in developed countries, which occurs at lower levels, are not as clear. Epidemiologic studies have examined respiratory symptoms, lung function, and asthma outcomes with mixed results.[80,93,99,106–110] Consequently, it remains unclear whether domestic wood smoke causes respiratory symptoms and asthma in developed countries.

Respiratory Effects of Kerosene Heater Use

Although kerosene heaters are less commonly used than other indoor heaters in developed countries, they can substantially increase indoor levels of fine particles ($PM_{2.5}$), sulfate aerosol ($SO4^{2-}$), and acidic aerosol (H^+), which have been linked with respiratory symptoms.[111] The existing evidence, however, is inconclusive about whether kerosene heater use is a cause of respiratory and asthma symptoms in developed countries.[91,99,112–115]

Other Indoor Pollutants—The "Toxic" Indoor Environment

Besides indoor combustion, there are many other sources of indoor pollutants. Building materials, such as plywood

or particle board, and carpeting can emit formaldehyde; furniture may release formaldehyde and volatile organic compounds (VOCs); paints, cleaning compounds, and photocopiers may release VOCs; and radon can arise from soil sources.[6,26] Cleaning with bleach and other compounds can release chlorine and ammonia gas, which are airway irritants. Combination of bleach and ammonia or other nitrogen sources can also produce choramine, which may induce upper and lower respiratory tract symptoms.[116] Of these substances, radon exposure has been associated with lung cancer.[117] Exposure to chlorine, chloramine, and VOCs may be linked with respiratory symptoms, some of which suggest asthma, but further evidence is needed before final conclusions can be drawn.[116,118,119]

OUTDOOR AIR POLLUTION—ADVERSE RESPIRATORY EFFECTS OF SPECIFIC POLLUTANTS

Particulate Matter

Since the catastrophic air pollution events of the Meuse Valley, Donora, and the London Fog, hundreds of epidemiologic studies have examined the health impacts of particulate air pollution. There is strong and consistent evidence that particulate pollution causes premature death, which is principally from cardiovascular and respiratory causes.[21,25,120–124] Both short-term exposure, measured as daily fluctuation of particulate pollutant levels, and longer term chronic exposures have been linked with mortality. In particular, the Harvard Six Cities Study and the American Cancer Society study have provided key insights into the long-term health impacts of particulate air pollution. Evidence linking PM_{10} and $PM_{2.5}$ to mortality is robust, but particularly strong for $PM_{2.5}$. Although particulate pollution is strongly correlated with other pollutants, such as SO_2, it has a strong independent effect on mortality.

Reduction in fine particulate air pollution translates into a longer life span for the population. A recent study examined 211 metropolitan counties throughout the United States to elucidate the impact of declining $PM_{2.5}$ levels on mortality from approximately 1980 to 2000.[122] A decrease in $PM_{2.5}$ of 10 $\mu g/m^3$ was associated with a mean increase in life expectancy of 0.61 years after taking into account measures of sociodemographic and smoking factors. During the 2 decades of the study, the average life expectancy increased 2.72 years. The authors estimated that up to 15% of this improvement in life span could be attributed to declining particulate pollution levels.

Particulate air pollution has a negative effect on respiratory health. Exposure to PM has been associated with lower respiratory tract symptoms, such as cough, wheezing, or shortness of breath.[125–127] Persons with asthma are particularly susceptible to developing lower respiratory symptoms after exposure to particulate pollution.[127a]

Particulate pollution is also associated with poorer lung function throughout the life span. The Children's Health Study conducted in Southern California, which followed thousands of children over many years, found that fine particulate pollution was linked to a reduced rate of lung function growth.[128–130] Another study used carbon content of airway macrophages as a biomarker of individual exposure to PM derived from fossil fuel; there was a dose-dependent inverse association between the carbon content of airway macrophages and lung function, including forced expiratory volume in 1 second (FEV_1), in children.[29] This study, because it used an airway-related biomarker of particulate exposure, provides key support for the connection between particulate exposure and impaired lung function in children.

Particulate pollution has also been linked to poorer lung function among adults, which may reflect decreased growth of lung function in childhood or accelerated decline subsequently.[128,131] In the German SALIA study, higher PM_{10} exposure during the past 5 years was negatively associated with forced vital capacity (FVC), FEV_1, and FEV_1/FVC.[132] This study also provided rare insight into the impact of particulate pollution on the risk of COPD. Higher PM_{10} was also related to an increased risk for COPD as defined by the GOLD criteria (stage I or greater; odds ratio, 1.33 per 7 $\mu g/m^3$; 95% CI, 1.03 to 1.72).[132] In support of a link between particulate pollution and COPD, other studies have linked ambient particle exposure to a greater risk of hospitalization and death from COPD.[133–137]

Importantly, declining particulate air pollution has translated into improved pulmonary function. A recent analysis of the SAPALDIA cohort examined the association between the 11-year change in air quality and lung function decline among 8047 adult subjects (4742 had complete follow-up).[138] Due to a broad range of air quality policies implemented in Switzerland, residential PM_{10} declined over this time period. An 11-year reduction of PM_{10} of 10 $\mu g/m^3$ was associated with a decreased rate of annual decline of lung function (9% for FEV_1, 6% for FEV_1/FVC ratio, and 16% for forced expiratory flow rate between 25% and 75% of the forced vital capacity [$FEF_{25-75\%}$]). The Harvard Six Cities Study also showed that declining fine particle levels were associated with reduced mortality in the United States.[120]

Asthma confers a particular vulnerability to the effects of particulate air pollution. Persons with asthma who are exposed to higher levels of particulate pollution have increased respiratory symptoms, poorer lung function (including peak expiratory flow and FEV_1), and a greater risk of exacerbations (emergency department visits, hospitalizations).[134,136,139–142]

Another important component of particulate pollution is diesel exhaust. Diesel exhaust from heavy-duty trucks and diesel-engine cars is a major contributor to particulate air pollution in many parts of the world. Diesel exhaust particle exposure has been linked with both oncologic and allergic diseases.

Diesel exhaust particles have a central carbon core and adsorbed organic compounds, including polycyclic aromatic hydrocarbons and other known carcinogens. Occupational exposure to diesel exhaust has been associated with an elevated risk of lung cancer; railroad

workers and truck drivers were at highest risk.[17,20,143–145] Toxicologic studies have confirmed the carcinogenic properties of diesel exhaust.[20]

Diesel exhaust exposure can cause acute deterioration of lung function among persons with asthma. A randomized crossover study randomly assigned adult subjects with mild to moderate asthma to walk along Oxford Street in London at lunchtime (the busiest shopping street, in which only diesel powered buses and taxis are allowed) or in Hyde Park for approximately 6 km.[146] Fine and ultrafine particle levels were approximately three times higher on Oxford Street than in Hyde Park. The maximal decline in FEV_1 was much greater for subjects walking on Oxford Street than in Hyde Park (−6.1% vs. −1.9%). These changes were accompanied by increases of biomarkers of neutrophilic inflammation and airway acidification. In sum, this study showed acute deleterious effects of diesel exhaust exposure on adults with asthma in a naturalistic setting. Other studies indicate that diesel exhaust may favor a Th2 immune response, further connecting this form of particulate pollution with allergic disease and asthma.[147]

Sulfur Dioxide

The major source of sulfur oxides in the ambient environment is the combustion of sulfur-containing fossil fuels such as coal and crude petroleum. Sulfur dioxide (SO_2) is the most important of the gas-phase sulfur oxides (SO_x) in terms of both atmospheric chemistry and health effects. Sulfur oxides are usually considered to include sulfur trioxide (SO_3) and gas-phase sulfuric acid (H_2SO_4), but neither is present in the atmosphere in concentrations that result in substantial human exposures except when there are industrial or transportation accidents. Sulfur dioxide is regulated by the EPA as a criteria pollutant.

Bronchoconstriction is the primary acute effect of SO_2 and is likely mediated by chemosensitive receptors in the tracheobronchial tree. In particular, persons with asthma are most sensitive to the effects of SO_2, which may result from preexisting airway inflammation that leads to enhanced release of mediators, alterations in the autonomic nervous system, and exaggerated response of the chemosensitive receptors.[148,149] Multiple controlled human exposure studies have observed symptomatic bronchoconstriction in exercising asthmatics following 5- to 10-minute exposures to SO_2 at concentrations that are similar to those found in ambient air.[150,151] In the published studies, 5% to 30% of relatively healthy asthmatic subjects experienced moderate or greater decrements in lung function (≥100% increase in specific airway resistance or ≥15% decrease in FEV_1) with exposures to SO_2 concentrations of 0.2 to 0.3 ppm during exercise.[31,151] At concentrations of 0.4 ppm or greater, a greater percentage (20% to 60%) of exercising asthmatic individuals experienced SO_2-induced bronchoconstriction. A clear concentration-response relationship has been demonstrated following exposures to SO_2 at concentrations between 0.2 and 1.0 ppm, in terms of both increasing severity of effect and proportion of asthmatic individuals affected.

The results of multiple epidemiologic studies show associations between short-term exposures (generally 24-hour averages) to ambient SO_2 and respiratory morbidity. These studies were conducted in areas where the mean ambient 24-hour average SO_2 concentration ranged from 1 to 30 ppb, with maximum values ranging from 12 to 75 ppb. Several multicity studies as well as single-city studies have found an association between 24-hour average SO_2 concentrations and respiratory symptoms in children, particularly those with asthma.[152–154] Limited epidemiologic evidence suggests that atopic children and adults are at increased risk for SO_2-induced respiratory symptoms.[155] Generally consistent associations also have been observed between ambient SO_2 concentrations and emergency department visits and hospitalizations for all respiratory causes, particularly among children and older adults (≥65 years), and for asthma.[156–160]

The observed associations of asthma symptoms with 24-hour average SO_2 exposures in epidemiologic studies are generally coherent with increases in symptoms reported in asthmatic subjects in controlled human exposure studies after 5- to 10-minute exposures; it is possible that these associations are determined in large part by peak exposures within a 24-hour period. In other words, the effects of SO_2 on respiratory symptoms and lung function observed in human experimental studies using peak exposures provide some biologic plausibility for the increased emergency department visits and hospital admissions observed in epidemiologic studies.

Only some of the published epidemiologic studies have assessed potential confounding by co-pollutants using multivariable regression models. In these studies, the effect of SO_2 on respiratory health outcomes appeared to be generally robust and independent of the effects of gaseous co-pollutants, including NO_2 and O_3, but this was not always the case for measures of particulate pollution.[158,161] A review by the EPA concluded that the observed effects of SO_2 on respiratory end points likely occur independent of the effects of other ambient air pollutants.

Several studies have assessed the effects of decreases in SO_2 concentrations on respiratory symptoms due to air quality regulations. In eastern Germany, a marked decline in ambient SO_2 concentrations (90% across the decade of the 1990s) was associated with a decrease in the prevalence of respiratory symptoms.[162] During the study period, however, decreases in other ambient air pollutants, including approximately 60% lower PM concentrations, also occurred. In a similar study of the effect of a 1990 regulation requiring use of low-sulfur fuel for power generation and on-road vehicles in Hong Kong, large reductions in ambient SO_2 concentrations of up to 80% were associated with reduced respiratory symptoms; in this study, reductions in ambient PM were less than 20%.[163] Although the improved respiratory symptoms observed in both of these intervention studies may be partially attributable to declining concentrations of air pollutants other than SO_2, the results nevertheless

provide support for a causal relationship between SO_2 and respiratory health.

Nitrogen Dioxide

The term *oxides of nitrogen* (NO_x) includes all forms of oxidized nitrogen compounds, including nitric oxide (NO), nitrogen dioxide (NO_2), and all other oxidized nitrogen-containing compounds formed from NO and NO_2. NO_x is emitted by combustion sources mainly as NO with smaller quantities of NO_2. Motor vehicle traffic and electric utilities are the two largest NO_x sources in the United States. Nitrogen oxide is the primary NO_x species emitted from most combustion sources, but is rapidly converted to NO_2; thus, NO_2 is the focus of most health effects studies. Nitrogen dioxide is another of the criteria pollutants regulated by the EPA to protect public health. It is an oxidant gas like O_3, but less potent. Although high concentrations sometimes found in silos are well known to cause the acute and sometimes lethal pulmonary edema of "silo-filler's disease,"[164] the much lower levels of NO_2 in outdoor air had not been definitively linked to adverse health effects in epidemiologic studies until the last decade. When it became apparent that indoor concentrations of NO_2 often exceeded outdoor concentrations, particularly in homes equipped with gas stoves, this discovery enabled epidemiologic study of this pollutant because indoor air is relatively free of the other pollutants normally associated with NO_2 in outdoor air. Research interest focused on the possibility that exposure to NO_2 in indoor air might increase the occurrence of respiratory infections, in part because of animal studies that exposure increased risk of experimental infections.[165]

Controlled human exposure studies provide evidence for increased airway responsiveness to both nonspecific and specific challenges in asthmatic subjects after short-term exposure to NO_2. The results of several older studies suggested that short-term (30- to 60-minute) exposures to NO_2 at concentrations in the range of 0.1 to 0.3 ppm may cause increased airway responsiveness to nonspecific bronchoconstrictor agents such as methacholine and histamine.[166] More recent studies involving allergen challenge in asthmatics suggest that NO_2 may enhance both allergen-induced bronchoconstriction and inflammatory responses after exposures as low as 0.26 ppm NO_2 for 30 minutes during rest.[167,168]

New evidence from a number of epidemiologic studies supports an association between ambient NO_2 and respiratory morbidity, especially among persons with asthma. In particular, a study that evaluated the effect of an intervention that reduced indoor exposure to NO_2 from gas heaters provided evidence of improvement in respiratory symptoms in asthmatic children.[169] Studies using community ambient monitors to assign exposures to NO_2 also found associations between ambient NO_2 and respiratory symptoms in asthmatic children.[152,153] Positive associations were observed in cities where the 24-hour average ambient concentrations were within the range of typical large U.S. urban areas. The results of multipollutant models generally showed that the NO_2 associations were robust to adjustment for co-pollutants including O_3, particles, and carbon monoxide.

Multiple epidemiologic studies also showed positive associations between short-term ambient NO_2 concentrations and emergency department visits and hospital admissions for respiratory causes, especially asthma.[161,170–172] These associations are particularly consistent for children and older adults (65+ years) when all respiratory diseases are the outcome, and for children and adults of all ages when asthma is the outcome.

In addition to the epidemiologic evidence that short-term exposure to ambient NO_2 can cause respiratory morbidity, long-term exposure to NO_2 has been associated with decreased rate of growth of lung function. Results from the longitudinal Children's Health Study indicated that decrements in lung function growth were substantial for boys and girls who lived in southern California communities with relatively high annual average ambient NO_2.[128] The mean annual NO_2 concentrations in the communities ranged from approximately 5 to 40 ppb, well below the current EPA national ambient air quality standard of 53 ppb as an annual average. Similar associations have also been found for PM, inorganic (mostly nitric) acid vapor, and proximity to traffic (<500 m) in this cohort; the high correlation among traffic-related pollutants makes it difficult to determine the independent effect of NO_2 on lung function growth.[128,173]

Because short-term exposures to NO_2 can induce greater airway responsiveness among asthmatic subjects in human experimental studies and are associated with respiratory outcomes, especially asthma, in epidemiologic studies, there is coherent evidence to support a short-term averaging time for air quality standards to control this pollutant.

Ozone

Ozone (O_3) is a colorless, pungent, relatively water-insoluble gas that occurs with other photochemical oxidants and fine particles to form "smog." Tropospheric O_3, or ground-level O_3, is an environmental air pollutant and is distinct from the stratospheric O_3 that occurs at altitudes of greater than 10 km (6.2 miles) above the earth's surface. O_3 is generated by a series of sunlight-driven reactions involving NO_x and volatile organic compounds from predominantly mobile (i.e., motor vehicle), but sometimes stationary sources. The meteorologic conditions that tend to foster the generation of O_3 are typically present from late spring to early fall. Peak concentrations of O_3 typically occur in mid-afternoon, after both the morning rush hour and several hours of bright sunlight. Indoor sources of O_3 include office equipment with electric motors or ultraviolet light, such as photocopy machines, and electrostatic devices, such as air purifiers and ion generators.

While O_3 has long been associated with southern California smog, many other areas of North America also experience high concentrations of this pollutant, especially Houston, Mexico City, and cities in the eastern

United States and Canada during the summer months. In these areas, there are many days each year when the current EPA national ambient air quality standard for O_3 is exceeded.

Ozone is a potent oxidant and is capable of reacting with a variety of extracellular and intracellular molecules. When these molecules include unsaturated lipids, free radicals and toxic intermediate products are generated that can lead to cellular damage or cell death.[174] Direct cytotoxicity is a major mechanism of O_3-induced tissue injury; secondary damage from the inflammatory response likely also plays a role.

Dosimetric studies indicate that much of the inhaled O_3 is deposited in the upper and proximal lower airways.[175] However, because of its relative water insolubility, a considerable fraction does penetrate to the distal airways and alveoli. At the tissue level, the dose is highest at these sites.[176] Increased inspiratory flow, which occurs with exercise, may overcome the upper airway "scrubbing mechanisms" and cause greater deposition of O_3 in the distal lung.[177]

Most of the research on the health effects of O_3 has focused on short-term exposure. In controlled human exposure studies, O_3 inhalation by healthy subjects causes mean decrements in FEV_1 and FVC that correlate with concentration, exposure duration, and minute ventilation.[178–180] These decrements in lung function are primarily a result of decreased inspiratory capacity rather than airway obstruction. The mechanism of the decreased inspiratory capacity appears to be neurally mediated involuntary inhibition of inspiratory effort involving stimulation of C fibers in the lungs.[181] Somewhat surprisingly, older subjects and those who are cigarette smokers demonstrate lower O_3-induced decrements in pulmonary function than healthy subjects.[182] The acute decrements in pulmonary function induced by O_3 usually resolve within 24 hours.

Respiratory symptoms appear to be associated with these mean decrements in pulmonary function. There is a correlation between the decline in FEV_1 and the probability of developing lower respiratory tract symptoms (e.g., substernal chest discomfort, cough, wheeze, and dyspnea).[180] Another adverse effect of short-term exposure to O_3 is enhanced airway responsiveness to nonspecific stimuli such as methacholine and histamine.[180] This effect may persist longer than the acute decrements in lung function and may occur even in individuals who do not experience a decline in their FEV_1.

Ozone exposure may induce adverse respiratory consequences through a variety of mechanisms. Nasal inflammatory changes, injury to type I alveolar cells, ciliated airway epithelial cell injury, infiltration of the airway mucosa by neutrophils, and increased bronchoalveolar lavage fluid neutrophils and inflammatory mediators have been observed after O_3 exposure.[183–185] Airway inflammation has been demonstrated after exposure to ambient concentrations with exercise.[186]

The effects of *chronic* O_3 exposure in humans have not been adequately defined. It has been hypothesized that chronic exposure would lead to emphysematous or fibrotic parenchymal changes; however, to date, animal toxicologic studies have failed to substantiate the induction of diffuse disease after long-term exposure to ambient concentrations. However, a recent study showed that O_3 exposure of neonatal rhesus monkeys led to abnormal development of conducting airways, especially with coexposure to house dust mites.[187] In addition, some epidemiologic studies, but not all, suggest that long-term residence of children in a high ambient O_3 environment can lead to remodeling of the small airways.[128,188]

Multiple epidemiologic studies show that high ambient O_3 concentrations are associated with an increased rate of asthma attacks and increased respiratory-related hospital admissions/emergency department visits for respiratory disease.[189] The biologic plausibility of these findings is supported by the results of controlled human exposure studies showing that O_3 increases nonspecific airway responsiveness, asthmatic subjects have a greater inflammatory response to exposure, and specifically sensitized asthmatic subjects have enhanced bronchoconstrictor responses to inhaled allergen.[190,191] In addition to the exacerbation of preexisting asthma, some evidence exists that exposure to O_3 could induce new cases of asthma; for example, children playing outdoor sports in polluted areas of the Los Angeles basin have a three- to fourfold increased risk of asthma.[192]

A newly documented effect of ambient O_3 is its association with greater mortality; this has been reported in both Europe and the United States.[193,194] Although this effect was first reported for respirable PM, both O_3 and fine PM are capable of generating oxidative stress and local inflammation in the deep lung. Similar to what has been observed in PM mortality studies, it appears that elderly people with preexisting heart and lung disease represent the group at greatest risk for O_3-related death. If excess oxidative stress is a critical step in a pathway that leads to early mortality in individuals with heart and lung disease, it is not surprising that exposure to both ambient O_3 and PM is associated with increased risk. Of additional concern, recent studies have suggested that young adults living in southern California have increased oxidative stress and cytogenetic damage compared to those living in northern California, perhaps related to differential exposure to O_3.[195,196]

In summary, tens of millions of persons in the United States are exposed to levels of O_3 above the current U.S. national ambient air quality standard. This exposure is capable of inducing both acute decrements in lung function and respiratory symptoms. Although these effects are transient, acute respiratory tract injury and inflammation can also be induced by short-term exposure to ambient concentrations of O_3. Exacerbations of asthma and increased risk of death of the elderly appear to be the most important health effects of short-term exposure. The long-term consequences of O_3-induced acute injury and inflammation are not well understood, but there is epidemiologic evidence consistent with airway remodeling.

KEY POINTS

- Although the hazard of air pollution for human health has been recognized for less than a century, great progress has been made in defining the sources, properties, and distribution of pollutants. More recently, the importance of indoor air pollution has become clear.
- Epidemiologic studies, taken together with controlled human exposure studies, animal studies, and in vitro studies, have delineated many of the serious respiratory health effects of air pollution. Significant questions remain, however, about the impact of multiple pollutants acting together, the effect of pollution on susceptible populations, and the minimum level at which the risk of health effects increases substantively. Further research is needed to define these important questions.
- Great progress has been made in clearing the air in the United States and other developed countries. But levels of indoor and outdoor pollutants remain higher than is desirable for human health. In developing countries, the problem is compounded by biomass smoke, which may very well be the world's leading cause of obstructive lung disease.
- Further research that addresses the important remaining questions in air pollution, especially the minimum threshold above which health effects begin to occur, will provide further impetus to refine regulation to protect public health.

CHAPTER 68

ACUTE PULMONARY RESPONSES TO TOXIC EXPOSURES

Paul D. Blanc, MD, MSPH

INTRODUCTION

PATHOGENESIS OF IRRITANT LUNG INJURY

GENERAL MANAGEMENT PRINCIPLES

CHRONIC SEQUELAE AND RESIDUAL EFFECTS

SPECIFIC EXPOSURES

Chlorine, Chloramines, Hydrochloric Acid, and Related Chemicals

Oxides of Nitrogen, Ozone, Sulfur Dioxide, and Acid Aerosols

Military and Crowd Control Agents

Cadmium, Mercury, and Other Toxic Metals

Metal Fume Fever, Polymer Fume Fever, Organic Dust Toxic Syndrome, and Other Inhalation Fevers

Fluorocarbon Aerosol Spray Pneumonitis

Hydrocarbon Pneumonitis and "Fire-Eater's Lung"

Paraquat

Smoke Inhalation

Pharmacologic Syndromes

Other Inhalant Exposures

INTRODUCTION

This chapter focuses on the acute effects on the lung after exposure to toxic substances. As used in this chapter, "acute" subsumes short-term exposures (minutes to hours), with the initial onset of pulmonary responses within a similarly rapid time period. Generally, the relevant toxicant exposures are of high intensity, far in excess of recommended safety limits for the workplace or the environment. The lung is the target organ for toxicity in the acute pulmonary responses addressed in this chapter. Importantly, *target organ* does not equate with *route of exposure*. For many acute exposures, inhalation is the route of delivery for toxins leading to the lung injury. However, in some instances, the route of delivery for the toxin may be by inhalation, yet the primary target organ for the toxic insult is not the lung (e.g., solvent inhalation that causes central nervous system depression). Inhalation exposures leading to nonpulmonary illnesses are not addressed here. In contrast, paraquat-induced lung injury and hydrocarbon aspiration, examples of ingested toxins with severe acute target organ effects on the lung, are discussed in this chapter.

Moreover, this chapter does not address brief exposures inducing acute responses mediated by anamnestic (i.e., allergic or other immune mediated) mechanisms. These responses require prior exposures that already have led to sensitization, such as occupational asthma (see Chapter 64) or hypersensitivity pneumonitis (see Chapter 66). There are also a number of toxicants causing unusual pulmonary syndromes after subacute (days to months) as opposed to acute exposure. Some of these syndromes have emerged in recent years associated with new technologies or novel toxicants, such as popcorn workers' lung and other flavor industry workers' disease linked to the chemical diacetyl,[1,2] flock workers' lung caused by very short synthetic textile fibers,[3,4] and ardystil lung, a dye chemical–induced organizing pneumonia.[5,6] Although beyond the scope of this chapter, some of these syndromes are discussed elsewhere (see Section L, "Infiltrative and Interstitial Lung Diseases," and elsewhere in Section M, "Environmental and Occupational Disorders").

PATHOGENESIS OF IRRITANT LUNG INJURY

Acute lung toxicity results from a variety of exposures but, nonetheless, is manifest by a narrow repertoire of injury. Irritant toxic substances can be encountered in

various physical states relevant to their inhalational properties. Such states include gases, vapors (i.e., the gaseous form of a substance that is a liquid or a solid at normal temperatures), fumes (i.e., an aerosol of solid material, often metals, of small particle size suspended in a gaseous medium [most <1.0 μm and many <0.1 μm] that has condensed from a vaporized state), and aerosols (i.e., liquid droplets or fine particulates dispersed in a gaseous medium; smoke is a subset of aerosol resulting from incomplete combustion). These exposures include heterogeneous toxic agents that are capable of causing extensive cell injury throughout the upper and lower respiratory tract. The primary location of respiratory tract injury and the onset of clinical symptoms are partly dependent on the solubility of the gas, vapor, fume, or aerosol involved, and in the case of fumes or aerosols, particle or droplet physical characteristics. Other factors that determine the injury pattern following exposure include amount of the toxic substance inhaled; duration of exposure to the inhalant; concentration of the inhalant in the ambient air; other physical properties (such as pH or chemical reactivity); and a variety of host factors, such as age, use of respiratory protection, and comorbid illness. Overwhelming exposures to any irritant inhalant, however, can cause extensive damage throughout the respiratory tract.

Ammonia[7] and sulfur dioxide[8] are examples of substances that are highly soluble in water. Such highly soluble substances cause immediate irritation of the conjunctival mucosa and upper airways. In contrast, oxides of nitrogen,[9] ozone,[10] and phosgene[11] have relatively low water solubility. For this reason, exposure to one of these agents may *not* be characterized by immediate symptoms of mucous membrane irritation. This may lead to more prolonged exposure and delay in seeking medical attention. Both more and less soluble irritant exposures can lead to distal lung injury, but in the case of highly soluble materials, a history of severe upper respiratory symptoms should precede the presentation of distal airway and alveolar damage.

Irritants reaching the lower respiratory tract, either because of their inherent physical characteristics or because of exposures that overwhelm the absorptive capacity of the upper airway, can injure both the lung epithelium and its endothelium. Pathophysiologically, irritant injury at this level leads to a nonspecific pattern of diffuse alveolar damage similar to that seen from a variety of different causes (see Chapters 55 and 60). The pathologic changes in fatal cases of irritant lung injury include focal and confluent areas of edema with protein-rich fluid in the alveolar spaces, hyaline membrane formation, and denudation of the alveolar epithelium.[12,13] In addition, mucous membranes of the bronchial and bronchiolar walls may be destroyed or denuded. A component of pulmonary hemorrhage may occur in irritant lung injury but typically is not a major clinical manifestation. Its presence should raise suspicion of other syndromes.[14]

On the cellular level, respiratory tract injury may be mediated through the deposition or formation of an acid, alkali, free radical, or other reactive chemical species. In most cases, the precise cellular mechanisms of injury from irritant inhalants have not been fully delineated. This is true even for relatively common irritants such as chlorine or even the chemical warfare agent phosgene, substances for which a great deal of human and experimental animal data exist.[15,16]

Acute irritant injury is the predominant, but not the only, pathophysiologic mechanism underlying acute toxic lung syndromes. In contrast to the anatomic distribution commonly seen in water-soluble irritant chemical–related injury, it may be difficult to delineate a descending, hierarchical pattern from upper airway to lower lung injury following exposure to a diverse group of agents. Many of these exposures lead to acute lung injury via a nonimmunologic mechanism (clinically, acute respiratory distress syndrome; pathologically, diffuse alveolar damage). Some of the diverse agents causing these syndromes are detailed subsequently in this chapter. Other toxin exposures produce various other syndromes, such as heavy metal pneumonitis,[17] hydrocarbon aspiration,[18] or paraquat lung injury.[19,20] The inhalation fever syndromes mark the principal exception to this in that the pathophysiology of this group of self-limited acute lung syndromes appears to be cytokine mediated, without obvious lung injury.[21]

GENERAL MANAGEMENT PRINCIPLES

Symptoms and signs of acute inhalation injury can be delayed in onset. Following removal from exposure while safeguarding the rescuing personnel, the next most important management decisions include protection of the airway (i.e., preemptive intubation may be required to prevent precipitous airway obstruction from progressive airway edema) and treatment of hypoxemia. The nasopharynx and larynx may manifest injuries earliest because they are exposed to the highest concentrations of inhaled water-soluble toxicants. Within a few hours after exposure, progressive airway edema, mucopurulent membrane production, and bronchorrhea may develop. Bronchoconstriction, peribronchial edema, and bronchial mucosal slough may result in the development of atelectasis. In the distal airways and alveoli, epithelial and endothelial injury leads to permeability-induced edema. This can manifest injury ranging from mild interstitial edema to diffuse alveolar damage. Pulmonary edema may be rapid following high-concentration toxicant exposure or may be delayed up to 24 to 48 hours. Diffuse alveolar damage after severe acute toxic lung injury should be managed consistent with the basic management of acute lung injury due to other causes (see Chapters 55, 89, and 90). This extends to the role of protective ventilation strategies.[22] Concomitant airway injury with acute bronchospasm often warrants treatment with bronchodilators because of the airway obstruction.

A beneficial role for corticosteroids in the acute phase of irritant and other chemically mediated forms of acute injury to the lungs has not been established by controlled trials in humans.[23,24] Experimental data suggest that if there is a beneficial effect of anti-inflammatory treatment

following toxic inhalation exposure, it is likely to be as an adjunct to bronchodilators for the management of airway obstruction. In a rat model, systemic corticosteroid treatment following chlorine inhalation showed a significant beneficial effect in terms of airway resistance and nonspecific airway responsiveness but not in a morphologic measure of injury. In a pig model, it was found that benefits were similar between inhaled and systemic corticosteroids.[25,26] Despite the lack of controlled evidence of efficacy, anecdotal reports of benefits from systemic corticosteroid use continue to appear.[23,27]

Prophylactic antibiotic drugs have not proved to be efficacious in toxic lung injury; antibiotics should be reserved for those patients with clinical evidence of infection, applying the recommended approach in fire smoke–related acute lung injury.[28] To date, convincing data do not support the use of other pharmacologic agents, such as antioxidants, in the generic treatment of toxic chemical lung injury.[23]

There are certain exposure-specific management issues that do occasionally arise. In paraquat-induced lung injury, for example, oxygen toxicity is a particular issue because of its specific mechanism of action, that is, high concentrations of oxygen may lead to more severe lung injury.[19] In paraquat as well, immunosuppressive therapy has been of particular interest and has yielded some promising data but remains to be adequately supported in randomized, controlled studies.[20] In the case of certain metal toxins, chelation may have a therapeutic role, as is addressed later in relation to the specific exposures involved. Inhalation fever is self-limited, so the principal clinical management issue is to exclude other exposures with less benign outcomes.[21]

CHRONIC SEQUELAE AND RESIDUAL EFFECTS

Among persons surviving symptomatic exposure to acute irritants, persistent structural and functional effects may occur. Long-term consequences to the upper airways (nose, pharynx, and larynx) can be sequelae of acute inhalational exposures; upper airway complaints including chronic rhinitis (*reactive upper airway dysfunction syndrome* [RUDS]), anosmia, and vocal cord dysfunction have been reported.[29–32]

Follow-up studies of more homogeneous populations evaluated after inhalation injury (with only a minority experiencing severe injury) suggest that airflow obstruction and nonspecific airway hyperresponsiveness are the most common persistent abnormalities of the conducting airways after irritant injury. Even so, epidemiologic data suggest that these outcomes occur only in a minority of those exposed.[33–35] The term *reactive airway dysfunction syndrome* (RADS) has been applied to the persistence of airway reactivity after acute exposure to respiratory irritants.[36–39] The more general term *irritant-induced asthma* has also been used to describe this condition.[40,41] Insofar as this syndrome represents a form of work-related asthma, it is addressed in Chapter 64.

Chronic injury to the lower airways and lung parenchyma are unusual sequelae of acute inhalational exposure. Long-term follow-up evaluation after recovery from acute respiratory distress syndrome due to heterogeneous causes (predominantly associated with sepsis) suggests that residual deficits in lung volumes, airflow, and gas exchange may persist long after recovery.[42] Bronchiolitis obliterans (BO),[43–50] bronchiectasis,[7,49,51–54] bronchiolitis obliterans with organizing pneumonia (BOOP),[55,56] and pneumomediastinum[57–59a] may all occur, but are rare complications. Irritants, in particular nitrogen oxide and related exposures, have long been known to cause BO.[60] Yet even with nitrogen dioxide, BO is an infrequent event; for example, only 1 case was found in a series of 20 moderate to severe exposures.[44] Pathologically, irritant-induced BO usually is characterized by intrabronchial granulation tissue (to which the term *proliferative bronchiolitis obliterans* is applied), as opposed to constrictive (obliterative) BO.[12,13] The latter appears to be the pathologic correlate of popcorn worker's lung[2] and has been reported in one case of BO following exposure in the World Trade Center disaster.[61] In addition to residual obstructive ventilatory deficits, restrictive deficits may also occur following severe irritant inhalation injury.[51,62] There is also some indication that an isolated reduction in residual volume may be noted in the follow-up of such cases.[63,64] Finally, nonspecific respiratory complaints after acute inhalation events can be a somatic manifestation of a psychological process.[65,66]

SPECIFIC EXPOSURES

Chlorine, Chloramines, Hydrochloric Acid, and Related Chemicals

Among the toxic agents causing pulmonary responses (Table 68-1), **chlorine** is a common and potent irritant inhalant accounting for substantial human morbidity.[15,67–69] Common forms of exposure include industrial leaks,[70] environmental releases occurring primarily during transport,[71,72] water purification,[73] swimming pool–related events,[27,74] household cleaning product misadventures,[75] and even homemade chemical bombs.[76] In the form of a yellow-green acrid gas, industrial and environmental releases typically present clear-cut exposure histories. Because the gas is heavier than air, higher contamination can be expected in low-lying areas (hence, its use in trench warfare in World War I).[77] However, other environmental conditions may supervene. Examples include one well-documented case of the gas rising along the heated outside wall of a factory where rooftop workers were exposed.[70] In another case, chlorine initially collected in a basement but then was sucked up into the central heating system of a dormitory.[78]

The history of exposure to chlorine may be less straightforward when inhalation occurs after de novo generation of gas from chlorine-containing liquids or powders. The most common *liquid* formulation associated with chlorine gas release is hypochlorite bleach, whereas the active chlorine component of dry *powdered*

TABLE 68-1. Selected Toxic Agents Causing Pulmonary Responses after Acute Exposure

Agent	Common Exposure Scenarios	References
Acid aerosols	Plating; microelectronics; other manufacturing	99, 114–118
Acrolein	Structural or wildland fires; other combustion	244, 248
Ammonia	Industrial refrigeration leaks; fertilizers	7, 270, 274
Brevetoxin	Aerosolization of "red tide" toxin	263, 264
Bromine	Water treatment; chemical manufacturing	46, 275–279
Cadmium fume	Flame cutting of soldered or sheet metal materials	153–156
Chloramines and nitrogen trichloride	Bleach + ammonia mix; chlorination + ammonia	79–81
Chlorine gas	Gas leak; water treatment; bleach + acid mix	15, 68–72
Chlorine dioxide	Pulp paper bleaching	105, 106
Crowd control agents (tear gas)	Military and police training and operations	144–146
Dimethyl sulfate	Industrial chemical yielding sulfuric acid	112, 113
Fluorocarbon polymers	Overheating polymers	120, 178, 184
Fluorocarbon sprays	Waterproofing and related aerosol sprays	214–218
Hydrocarbons	Aspiration of low-viscosity materials, "fire-eating"	18, 224, 228–231
Hydrogen sulfide	Sewers and manure pits; fossil fuel and geothermal production	282, 286–289
Mercury vapor	Gold extraction, heating cinnabar	158–164
Methyl bromide	Pesticide fumigant	280, 281
Methyl isocyanate	Pesticide manufacturing	289, 291
Methyl isothiocyanate	Breakdown product of metam sodium fumigant	292, 293
Mustard gas	Chemical warfare agent	51, 125–129
Nickel carbonyl	Nickel processing, metal reclamation	165–168
Nitrogen dioxide	Silage; combustion; explosives; welding; nitric acid mixes	9, 40, 94–97
Organic dusts/aerosols	Contaminated dust or bioaerosol generation	21, 200, 201
Organophosphates	Pesticide application; chemical warfare	137–139
Ozone	Bleaching; water treatment; plasma welding	102, 106
Paraquat	Herbicide skin contamination or ingestion	19, 234, 241
Phosgene	Chlorinated solvent breakdown by-product	11, 16, 132
Phosphine	Fumigation with aluminum or zinc phosphide, microelectronics	204–206
Sulfur dioxide	Refrigeration; cement manufacture; mining; pulp paper mills	8, 107–110
Tributyltin (bis[tributyltin] oxide)	Paint additive for mold inhibition	176
Vanadium	Ore processing; fossil fuel by-product, catalyst use	172, 175
Zinc chloride	Smoke bombs ("white smoke")	180, 192, 195
Zinc oxide fume	Welding galvanized steel; brass casting	137, 159, 168

bleaching cleansers is typically a chlorinated phosphate. In either liquid or powdered bleaches, the liberation of chlorine gas is pH dependent, occurring on contact with acids in common household products containing muriatic (hydrochloric), phosphoric, or hydrofluoric acid.[75] In contrast, mixing chlorine-containing products with ammonia leads to release of **chloramines** (monochloramine [NH_2Cl] and dichloramine [$NHCl_2$]) and related chemicals, especially nitrogen trichloride (NCl_3), chemicals whose irritant effects are attributed to in situ pulmonary reactions releasing chlorine, hypochlorous acid, and ammonia.[75,79,80] In chlorinated swimming pools, inadvertent mixing with nitrogen donors also occurs, with potential irritant effects attributed to nitrogen trichloride in particular.[79,81]

Irritant effects after inhalation of **hypochlorite** aerosols in confined spaces without a history of combining products (not an uncommon scenario when cleaning bathrooms) also can be associated with irritant effects. Similarly, in certain industrial operations, hydrochloric (hydrogen chloride in water) or hypochlorous acid aerosols are also respiratory irritants. Other sources of chlorine exposure occur in specific industrial processes that use a large number of inorganic chlorine derivatives. Worthy of particular mention are chlorine dioxide (used in pulp paper processing),[82] chlorinated silanes (gases used in microelectronics),[83] reactive metal halides (e.g., titanium or antimony chlorides),[17] and thionyl chloride (which breaks down to yield hydrogen chloride and sulfur dioxide).[46,84]

For chlorine and related chemicals, the acute respiratory response corresponds to the effective dose delivered to the lungs. All of these compounds appear to share a final common toxic pathway. As noted in the general discussion of acute toxic inhalations, water solubility is an important determinant of the dose reaching the lower airways. For chlorine, chlorine dioxide, chloramines, and nitrogen trichloride, lower solubility favors deeper penetration with a more effective delivered dose compared with an equivalent inhalation of acid aerosols.

However, exposure to any of these compounds is associated with some degree of immediate mucous membrane and upper airway irritation. In fact, the absence of acute irritant effects is not clinically consistent with chlorine gas or related exposures.

Chlorine inhalation may manifest any of the full spectrum of respiratory tract irritant effects, from minor mucosal responses to upper airway responses to diffuse alveolar damage.[27,70–77,85] Persistent airway hyperresponsiveness after irritant exposure has been associated particularly with chlorine gas and chlorine-containing products, although this may reflect the frequency of such exposures rather than a propensity for chlorine to have this effect.[15,40,41] There is also limited evidence that persons with underlying airway hyperreactivity may be more responsive to chlorine.[86]

Use of inhaled bronchodilators and steroids may be indicated for both acute and residual bronchospasm following chlorine inhalation. Although several case reports and series have touted the potential benefits of nebulized sodium bicarbonate inhalation in the acute treatment of chlorine or chloramine inhalation, the efficacy of this intervention has never been assessed in a controlled trial.[80,87–90] One small controlled trial administered inhaled bicarbonate 3 months or more after exposure in irritant-induced asthma.[91]

Oxides of Nitrogen, Ozone, Sulfur Dioxide, and Acid Aerosols

These inhalants are major air pollutants; the effects of low-level exposure are discussed in detail in Chapter 67. When they are inhaled in high concentrations, these irritants cause acute lung injury. Because of lower solubility, longer exposure with a greater predilection for lung injury may occur with ozone[10] and, even more commonly, nitrogen dioxide.[92] Nonetheless, with sulfur dioxide and acid aerosols, sufficient intensity of exposure leads to diffuse alveolar damage.

High-intensity exposure to **oxides of nitrogen** occurs through decomposition of organic matter as well as through other sources. Examples of exposure scenarios include nitrogen dioxide–induced lung injury among farmers (also known as silo filler's disease),[44,93,94] use of internal combustion engines in enclosed spaces (with large outbreaks associated with ice resurfacing equipment used in indoor skating rinks),[9,95–97] thermal degradation of polymers (e.g., in structural fires),[28] toxic gas produced by the detonation of explosives,[48,98] the release of gas through reactions of nitric acid breakdown in air or in reaction with metals or organic materials,[99–101] welding by-products, particularly when "gas-shielded" techniques are employed (manual inert gas welding or tungsten inert welding),[102] and the release of compressed nitrogen dioxide gas.[103] Historically, the detonation of explosives has been one of the most important sources of exposure to nitrogen oxides.[98] Nitric oxide, an inhalant used therapeutically, breaks down to nitrogen dioxide in the presence of oxygen and, thus, must be monitored with appropriate delivery devices.[104]

High-intensity occupational **ozone** exposure is unusual, but it can occur with welding conditions similar to those associated with oxides of nitrogen.[102] More recently, ozone in water treatment and in pulp paper bleaching also has emerged as a health issue; in the latter industry, there is often concomitant exposure to chlorine dioxide characterized by intermittent "gassings."[105,106]

Important sources of high-level **sulfur dioxide** exposure include mining and ore refining,[8] Portland cement manufacturing,[107] sulfur treatment of fruit,[108] and industrial releases.[109] Historically, sulfur dioxide has been and continues to be important in sulfite process pulp paper processing, where acute gas releases are superimposed on chronic lower-level exposure as with other irritant exposures in the paper industry.[105,106,110] In the past, sulfur dioxide was a common refrigerant.[111]

In ambient air pollution, **sulfuric acid** is an acid aerosol of primary concern, but this can be encountered in higher levels occupationally. Sulfuric acid exposure occurs both through direct use and through the breakdown of a highly toxic industrial chemical, dimethyl sulfate.[112,113] A number of other inorganic and organic acid vapors and aerosols are also important potential causes of acute lung injury, including chromic,[114] acetic,[115] formic,[116] and hydrofluoric acids.[101,117,118]

Hydrofluoric acid (hydrogen fluoride) inhalation, in addition to nonspecific irritant effects, can induce clinically significant hypocalcemia.[119] Exposures occur in manufacturing of both microelectronics and phosphate fertilizers, in household use of hydrofluoric acid rust removal agents (the mixture of which with hypochlorite bleach can evolve both chlorine and hydrogen fluoride), and in pyrolysis of fluorinated polymers.[120] Hydrogen fluoride is a chronic exposure problem in the aluminum smelting industry.[121] Hydrogen fluoride is also released as a breakdown product of sulfur hexafluoride, an electrical insulating liquid chemical used in equipment.[122]

Military and Crowd Control Agents

Sulfur Mustard

Unfortunately, chemical warfare agent exposures are not of mere historical interest.[77,123,124] Of the major World War I chemical weapons, only sulfur mustard (mustard gas) has been used "militarily" since World War II. Classified as a vesicant because of blistering induced by skin contact, mustard gas inhalation causes severe respiratory injury. Based largely on the Iranian experience of their Iraqi war veterans, sulfur mustard survivors can exhibit residual tracheobronchitis, asthma, bronchiectasis, bronchotracheomalacia, BO, and fibrosis.[51,124–129] Nitrogen mustards were sulfur mustard derivatives originally developed for military purposes but later applied medically; nonetheless, occupationally related acute lung injury has been reported through industrial release.[130]

Phosgene

Another World War I toxic gas, phosgene, is currently encountered as a chemical industry process chemical

and as a thermal breakdown product or ultraviolet photoreactant of chlorinated solvents (e.g., methylene chloride).[11,131] An occult cause of exposure can be inadvertent phosgene production from welding metals "degreased" with solvents.[102] Phosgene is the prototypic deeply penetrating inhalant exhibiting a delayed onset of symptoms (12–24 hr after exposure).[22,132,133]

Chloropicrin

Chloropicrin, another World War I gas, is a low-threshold irritant currently encountered in chemical manufacturing and as a component of fumigants.[134–136]

Neurotoxins

The modern chemical warfare armamentarium is dominated by systemic toxins developed from organophosphate pesticides; the nerve agent "VX" is prototypical.[137,138] These highly lethal neurotoxins have important respiratory effects, including manifestations of both muscarinic receptor stimulation (bronchorrhea and bronchospasm) and nicotinic receptor depolarization blockade (respiratory muscle paralysis); treatment is based on reversing enzyme inhibition and countering the effects of acetyl cholinesterase excess.[139]

Although the lung is typically the portal of entry for biologic warfare agents, this topic is beyond the scope of this chapter; infectious processes are covered elsewhere (e.g., see Chapter 69 for mediastinal involvement in anthrax).

Chloroacetopenone (Mace), Other Tear Gas Agents, and Zinc Chloride

Crowd control agents ("tear gases"), as opposed to the war gases, are intended to incapacitate persons via immediate mucous membrane irritation.[140] The agents in greatest use worldwide are chloroacetophenone ("mace"), and orthochlorobenzamalonitrile.[141,142] In addition to their mucous membrane effects, case reports have implicated these agents in lower respiratory injury and even persistent effects following high-intensity exposures (e.g., in enclosed buildings).[143–146] Unlike tear gas, exposure to smoke bomb releases (sometimes referred to as "white smoke") can cause severe lower respiratory injury; through a pyrotechnic reaction between hexachloroethane and zinc oxide, the potent respiratory irritant zinc chloride fume is released.[147,148] Military, police, and others exposed, often during ill-conceived training exercises, are at risk.[147–152]

Cadmium, Mercury, and Other Toxic Metals

Inhalation of certain metal fumes or metal vapors can cause an acute pneumonitis.[17] The two metals most important clinically are **cadmium** and **mercury**. In both instances, the most important factor in pulmonary insult is acute inhalation at a relatively high exposure level.

Cadmium

Exposure typically occurs through welding, brazing (high-temperature soldering) or flame-cutting metal or working with molten metal under conditions of inadequate ventilation.[153–156] In welding, brazing, and flame-cutting, the usual source of cadmium is the welding rod, brazing solder, or a metal coating, rather than the base metal itself.[102] In areas of the world where jewelry-making is carried out at a cottage industry level, cadmium use in silver-working can present a particular exposure risk.[157]

Mercury

High levels of the relatively volatile metal can be generated effectively from many nonenclosed operations, most notably through heated metal reclamation processes (e.g., home refining of mercury-gold amalgams or even reclaiming of mercury from electronic equipment).[158–162] Exposure has also occurred through burning mercury sulfide (Chinese red cinnabar) and mercuric oxide for medicinal purposes.[163,164]

Nickel Carbonyl

Nickel carbonyl is an organic metal derivative and potent pulmonary toxin, with exposure occurring through nickel refining, manufacturing processes in which it is used as a catalyst or intermediate, and metal recycling or reclaiming operations.[165–167] Inorganic nickel, although a sensitizing substance, is not associated with pneumonitis.

Other Metals

Other metals, including antimony, manganese, and beryllium, are sometimes cited as causes of acute lung injury consistent with metal pneumonitis, but there are few reports in the last 50 years providing documentation of such disorders.[7] A recent case report implicated copper dust inhalation with acute lung injury.[168]

Dangerous exposures to cadmium, mercury, and nickel carbonyl occur in part because these agents are not immediately irritating, analogous to the delayed symptoms after phosgene or nitrogen oxide gas inhalation. Patients typically present in respiratory distress 12 to 24 hours after exposure. Indeed, the exposure history often remains occult unless aggressively pursued. Metal pneumonitis from these materials also can include fever as a clinical manifestation of the toxic syndrome. However, the term *metal fume fever* should not be used in this context.[169]

The toxic mechanism in heavy metal pneumonitis is presumed to be inhibition of enzymatic and other critical cellular functions. Chelation treatment has not been shown to be effective in heavy metal pneumonitis due to cadmium or mercury, although chelation is often initiated in the case of mercury injury.[163,164] The agent dithiocarb (diethyldithiocarbamate) has been used as a chelating antidote for nickel carbonyl pneumonitis,

based on supportive animal data.[170,171] Disulfiram has been suggested as a potential alternative treatment, although experimental data to support this practice are weak.[167,171]

Two other metal compounds are well-documented bronchial irritants in humans. **Vanadium** (typically as a metal oxide), which is encountered in metal processing and, in lower concentrations, as a fossil fuel by-product, causes acute bronchitis.[172] Among boilermakers, vanadium-rich fuel oil ash is suspected to be a key exposure related to acute respiratory symptoms.[173] In a single case report, high-intensity exposure to ash from an oil-burning furnace was associated with diffuse alveolar damage; although vanadium was detectable in the residue, the toxic mechanism in this case was unclear.[174] In another case report, vanadium (as vanadyl pyrophosphate) was linked to pneumonitis.[175] **Tributyltin** (bis[tributyltin] oxide), an organotin compound employed as a mildew and mold retardant, is also an acute airway irritant.[176]

Metal Fume Fever, Polymer Fume Fever, Organic Dust Toxic Syndrome, and Other Inhalation Fevers

There are a number of febrile flulike pulmonary syndromes reflecting similar clinical responses to a diverse group of acute inhalational exposures.[21,177] Their hallmark is chills, fever, malaise, and myalgia with onset 4 to 8 hours after intense inhalation of fumes or organic dusts.[21,169,178] Common respiratory complaints include cough or mild dyspnea, but findings of chest radiographic opacities or hypoxemia are inconsistent with this disorder. Peripheral leukocytosis usually accompanies the syndrome; bronchoalveolar lavage shows a marked influx of neutrophils.[179–181] These syndromes all are self-limited, resolving clinically within 12 to 48 hours. Inhalation fevers share a common feature of tachyphylaxis, with a blunted response to daily repeated inhalation (and hence the name "Monday morning fever" among both brass founders and cotton mill workers).[21,182,183]

Signs or symptoms of pneumonitis should suggest alternative, less benign diagnoses, such as cadmium pneumonitis,[154,155] hypersensitivity pneumonitis (see Chapter 62), active infection (in the case of water-source aerosols), or inhalation of more toxic temperature-dependent fluoropolymer pyrolysis by-products (which include hydrogen fluoride and carbonyl fluoride).[129,184,185] Toxic pneumonitis due to fluorocarbon-containing aerosol sprays is an exposure scenario distinct from fluoropolymer pyrolysis by-product–caused polymer fume fever or acute lung injury and are dealt with separately (see later).

Metal fume fever is associated with **zinc oxide** inhalation from welding galvanized metal or brass working.[186] There is only limited clinical evidence that other metals (magnesium and copper) cause a similar response,[169,187] and experimental data further discount magnesium as a potential cause of fume fever.[188]

Polymer fume fever is associated with thermal breakdown products of fluoropolymers (e.g., Teflon and related materials).[178,189–191] The pathophysiologic mechanisms underlying the metal and polymer fume fever syndromes have not been established, but research suggests that pulmonary cytokines may play a key role.[192–195]

Organic dust toxic syndrome (ODTS) is associated with inhalation of materials contaminated with thermophilic bacteria and fungal spores, including wood chips,[196] straw,[197] silage,[198] grains and flour,[199] and textile raw materials.[183] The increasing industrialization of agricultural processes, especially the use of animal confinement techniques, is an additional source of exposure leading to ODTS, although these same settings can produce irritant gases such as hydrogen sulfide and ammonia.[200,201] ODTS has gone by various names, including pulmonary mycotoxicosis,[202] silo unloader's syndrome,[198] and mill fever.[203] One of the best documented historical outbreaks of ODTS occurred among individuals who work with stained (contaminated) cotton mattresses.[183] Inhalation of aerosols from contaminated water sources produces a self-limited febrile syndrome similar to ODTS. Some of these outbreaks are attributable to inhalation of *Legionella* species without actual infection (i.e., without clinical evidence of pneumonia) and are referred to as "Pontiac fever."[204–206] Water sources associated with contaminated aerosols causing inhalation fever syndromes can include saunas or hot tubs,[207,208] commercial (industrial) humidifying systems,[209,210] and metal machining cooling fluids.[211] Going along with these heterogeneous exposure scenarios, a variety of different names have been used for these syndromes, include humidifier fever,[210] sump bay fever,[212] and bath water fever.[207] As with ODTS, many of the same occupational and environmental conditions can lead to or be concomitant with cases of hypersensitivity pneumonitis and, more specific to waterborne aerosols, active respiratory infection. In addition to its self-limited nature, a key characteristic differentiating an outbreak of inhalation fever from other syndromes is its relatively high attack rate over a fairly short time period. As with metal fume fever and polymer fume fever, cytokines are presumed to be key mediators of the ODTS and water-borne aerosol-related inhalation fevers, with endotoxin and related factors being key exposure variables.[21,213]

Fluorocarbon Aerosol Spray Pneumonitis

Acute lung injury following inhalation exposure to commercial fluorocarbon-containing aerosol products is an important emerging syndrome first reported in the early 1990s.[214] This syndrome is distinct both from fluoropolymer fume fever as previously discussed and from exposure to irritant by-products from higher-temperature thermal breakdown of such polymers. A key feature of fluorocarbon aerosol pneumonitis is the onset of symptoms within several hours after using a spray product containing fluorocarbon polymers. Exposure can occur in an occupational setting (e.g., construction), but

consumer exposures from over-the-counter products is a common scenario. These exposures can be relatively brief with varying degrees of ventilation; importantly, exposure need not be in an enclosed space. Victims are usually naive to previous exposure; there is nothing in the condition to suggest a hypersensitivity mechanism. Application of multiple types of fluorocarbon-containing products have been linked to outbreaks; although waterproofing leather and fabric sprays have dominated the reports, other products include floor stain protector, rust-proofing spray, grout sealer, and ski wax.[214–221] The clinical presentations manifest a range of severity consistent with varying degrees of nonspecific acute lung injury; management is based on standard support care. The application of various descriptive labels based on the exposure scenario can obscure the consistent pattern of the syndrome.[217,222]

Hydrocarbon Pneumonitis and "Fire-Eater's" Lung

Hydrocarbon pneumonitis occurs with oral ingestion of hydrocarbons and associated aspiration. This is a prominent issue in the pediatric age group, accounting for many hospital admissions each year. The common hydrocarbons involved are mineral spirits, mineral seal oil (common in furniture polish), lamp oil, kerosene (paraffin), turpentine (pine oil), gasoline, and lighter fluid.[18,223–225] Even though these substances have systemic toxic effects such as central nervous system depression, life-threatening complications of ingestion are predominantly the result of concomitant hydrocarbon aspiration and subsequent pulmonary compromise, making the lung the target organ of concern in hydrocarbon ingestion. Pneumatocele is a recognized complication of hydrocarbon pneumonitis.[226] In contradistinction to aspiration hydrocarbon pneumonitis, the toxicity of hydrocarbon (solvent) vapor inhalation manifests primarily in either central nervous system or cardiac effects. Major pulmonary target organ damage associated with acute hydrocarbon exposure by inhalation is unusual but has been reported.[227]

"Fire-eater's lung" is an important variant of hydrocarbon pneumonitis.[228,229] Rather than children, this syndrome typically involves adolescents or young adults who are exposed through mishap during flame-blowing performances using a variety of different flammable materials. The substances used overlap with some of the reported pediatric exposures (kerosene, gasoline) but can also include other hydrocarbons such as jet fuel and, in France, an aromatic hydrocarbon enriched petroleum-distillate called "kerdan."[230,231] There has also been a case of citronella oil aspiration in a fire-eater.[228] As with hydrocarbon pneumonitis in children, fire-eater's lung can also be complicated by pneumatocele.[232] Although the term "acute lipoid pneumonia" has been used to refer to the "fire-eater's lung" syndrome, this is a misnomer.[233]

In both childhood and adult pneumonitis, hydrocarbon aspiration occurs at the time of initial ingestion event or subsequently with vomiting. Low viscosity of an ingested hydrocarbon is considered a major factor promoting aspiration (presumably for mechanical reasons), for example, with mineral seal oil.[18,224] Although theoretical consideration has been given to potential effects on surfactant as being mediators of hydrocarbon aspiration toxicity, the chemical pneumonitis of the syndrome appears to be nonspecific.

Paraquat

Paraquat is a widely used herbicide and a potent toxin. Ingestion rather than inhalation is the typical route of exposure associated with human toxicity. Systemic reactions following skin exposure have occurred almost exclusively owing to substantive direct exposure to the skin (soaking of the skin with paraquat) or when the skin integrity has been breached (e.g., preexisting skin lesions or burn). The theoretical risk of smoking contaminated materials has never been established clinically.

Most paraquat deaths result from suicidal intent.[19,234,235] Paraquat ingestion is a relatively uncommon method of suicide in the United States, but its incidence is greater in a number of other countries, perhaps related to patterns of crop utilization and ease of access.[234,236] Although paraquat ingestion leads to acute gastrointestinal tract necrosis and multiorgan failure, the lung is the target organ for toxicity among those surviving the immediate postingestion period. Diquat, a related dipyridyl herbicide, does not cause the syndrome of lung toxicity associated with paraquat.[237]

The pulmonary toxicity of paraquat, in contrast to its gastrointestinal effects, does not reflect caustic irritant injury. The major lung effect of paraquat toxicity is the development of pulmonary edema (usually observed 24–48 hr after ingestion). The pulmonary edema may evolve to a condition resembling acute respiratory distress syndrome (associated with histopathologic findings similar to those of diffuse alveolar damage), which may progress to induce an accelerated, chemically induced pulmonary fibrosis. After stabilization following acute multiorgan paraquat toxic effects, disease progression is marked by rapidly worsening respiratory distress, hypoxemia, and a restrictive ventilatory defect, with decreased lung compliance and diffusing capacity, ending in death from ventilatory failure within days to weeks.[19,234] Survivors may demonstrate modest and slow improvement in lung function.[238]

The mechanism of paraquat toxicity is attributed to the generation of superoxide radicals that may be partly iron dependent.[239] Consistent with an oxidant mechanism, supplemental oxygen and radiation therapy may worsen the outcome.[19,234,240] There are no known antidotes for paraquat poisoning, and enhanced elimination (hemoperfusion) has not demonstrated a clear benefit.[19,234] Plasma paraquat levels can be determined and may have a role in prognosticating survival.[241] Data suggest a possible benefit from immunosuppression, but this awaits confirmation through controlled clinical trials.[20] Death results from multiorgan failure and usually occurs within 1 to 2 weeks, but may be observed up to 6 weeks after ingestion.

Smoke Inhalation

The generic term *smoke inhalation* includes potential exposure to a wide array of substances because of the complex chemistry of heat decomposition and pyrolysis.[24,28] Although cytotoxic anoxia from carbon monoxide, cyanide, and oxidants represents a major manifestation of toxic insult from acute smoke inhalation, this *nonpulmonary target organ* effect is not covered here.[242–244] However, there are a number of chemical irritants produced as pyrolysis by-products that do have significant potential target organ pulmonary toxicity. In contrast to thermal injury to the respiratory tract, which is typically limited to upper airways, with laryngeal edema the major potential medical management problem,[24,245,246] smoke inhalation from fires can affect the entire respiratory tract through irritant injury.

In certain cases, irritant chemicals from fires result from liberation of preformed substances, but most commonly, the toxins of concern are formed de novo. These irritants are produced by the thermal degradation of both naturally occurring and synthetic polymers. The predominant by-products of heat breakdown are determined by the nature of the polymers consumed, but the precise mixture of agents released in any specific event may be difficult to predict, varying in particular according to temperature and oxygen availability.[78,247]

Generally, the chemical monomer precursor is not a significant polymer breakdown product, although residual monomers can be evolved under certain circumstances. For example, hydrogen chloride rather than vinyl chloride is released when polyvinyl chloride is burned. Many of the specific chemical irritants that can be released as common thermal breakdown by-products are addressed elsewhere in this chapter. These include the following: hydrochloric acid (hydrogen chloride), hydrofluoric acid (hydrogen fluoride), and other acids; ammonia; phosgene; and oxides of nitrogen. The zinc chloride "smoke" of smoke bombs (in contrast to the heterogeneous character of "natural smoke") is also discussed separately.

Aldehydes merit specific attention, however, because smoke from fires may represent the most common source of high-intensity irritant inhalant injury caused by this group of chemicals. These chemicals include formaldehyde, acetaldehyde, and acrolein. Of these aldehydes, **acrolein** (CH_2=CHCHO), although the most severe irritant, is least familiar to most health care providers. Acrolein, a highly reactive chemical, is formed as an important pyrolysis product of both synthetic (e.g., acrylic) and natural polymers.[248]

The general considerations concerning irritant exposure discussed previously, including air concentration and water solubility, come into play in smoke inhalation. These factors are further complicated by the potential interactive effects of multiple simultaneous exposures as well as the modifying impact of physical cofactors such as airborne respirable particulates (e.g., soot) that may serve as adsorbent carriers facilitating deep lung penetration. In practice, detailed exposure data delineating the irritant contents of a specific smoke exposure are rarely available. Information that may help to elucidate exposure conditions include identity of the products involved (e.g., specific synthetic polymers, if known), history of inhalation within an enclosed or confined space, evidence of thermal injury, and carboxyhemoglobin and methemoglobin levels as markers of inhalation severity based on other concomitant exposures (carbon monoxide and oxidants).[242–244]

Firefighters (both urban and wildland) and nonoccupationally exposed victims of irritant smoke inhalation have proved important groups in which to study acute inhalational syndromes. Large-scale conflagrations (e.g., urban "wildland" fires) can expose substantial numbers of people to irritant combustion by-products, as can smoke drift from intentional burning of agricultural residue. Studies of such populations have demonstrated acute and persistent airflow obstruction and increased nonspecific airway hyperresponsiveness after smoke inhalation.[249–257] Bronchiectasis and BO have both been associated with combustion by-product exposure.[46,49] The acute respiratory effects and potential sequelae of exposure to the plume generated by the destruction of the World Trade Center appear to relate to other factors such as alkaline (high-pH) dust from concrete, gypsum, and glass fibers, rather than to standard smoke particulate.[32,51,258,259]

Pharmacologic Syndromes

Certain natural and synthetic chemical exposures exert acute target organ lung effects mediated by specific mechanisms consistent with known pharmacologic actions. These chemicals are site-specific for key cellular functions leading to adverse respiratory effects. As noted previously, the most potent chemical warfare agents act through acetyl cholinesterase inhibition, with profound impacts on respiratory function.[137,138] Similar, albeit less potent, agents have widespread use as agricultural chemicals. Both **organophosphate** and **carbamate pesticides** lead to respiratory compromise as a principal toxic effect. For example, in one case series, a considerable number of poisonings from these pesticides led to respiratory failure, accompanied by a high case-fatality rate; in contrast, all the patients without concomitant respiratory failure survived.[260]

Inhaled **capsaicin**, of interest as a research tool to study *substance P*–mediated effects, is associated with cough in occupational settings (e.g., in chili pepper processing).[261] When used as a "personal defense spray," respiratory irritation has been reported, although ocular problems are more common.[262] Another naturally occurring toxin with a primary respiratory effect is **brevetoxin**. This toxin, produced by dinoflagellates, is associated with "red tides." Environmental inhalation exposure from airborne aerosols of **red tide** (due to wind and surf action) causes cough, sneeze, and wheeze.[263,264] The toxin appears to act by stimulating sodium channels in the lung. Respiratory irritation may also be a manifestation of *Pfiesteria* dinoflagellate toxin inhalation (although potential neurotoxicologic effects have been of more concern).[265,266]

Other Inhalant Exposures

Ammonia

Anhydrous **ammonia** is a gas at room temperature and ambient pressure, although ammonia more commonly is encountered in aqueous form (e.g., in cleaning solutions). In addition to incidents in the chemical industry and in hazardous transportation, commercial refrigeration systems and farming (fertilizer) represent important sources of potential exposure to ammonia gas.[7,267–273] Anhydrous ammonia release has also occurred from illicit methamphetamine laboratory operations, although such exposures are often in the context of conflagrations with concomitant thermal burns and other coexposures.[274] Ammonia has prominent irritant warning properties (such as burning eyes). It is linked with lung injury chiefly in settings of overwhelming exposure or where immediate escape has not been possible. Asthma and bronchiectasis both have been documented after ammonia exposure.[7,271] Acute ammonia exposure has also been reported to have residual upper airway effects, including decreased olfactory acuity.[29] Death may result from laryngeal edema and airway obstruction, acute pulmonary edema, or complications of the pneumonic process (e.g., bacterial superinfection).

Bromine and Methyl Bromide

Bromine is an irritant halogen. It usually is handled as a liquid rather than as a gas, but it vaporizes readily. Sources of bromine exposure other than environmental releases include chemical synthesis and water purification.[50,275–278] Bromine is a more potent irritant than chlorine and approximately a hundred times more irritating than ammonia.[279] **Methyl bromide** is a major industrial fumigant with far-greater potential for public exposure. Methyl bromide is also a potent respiratory irritant, but central nervous system effects may account for more important target organ toxicity in typical exposures.[280,281]

Hydrogen Sulfide

Hydrogen sulfide is a common by-product of petroleum extraction and refining as well as a potential hazard from the breakdown of organic materials (hence, its common name, "sewer gas").[282] Significant release can also occur through geothermal and volcanic sources.[283] Hydrogen sulfide is a respiratory irritant, but it is an even more potent cytotoxic asphyxiant, impairing cytochrome oxidase and cellular respiration. Therefore, in cases of severe hydrogen sulfide exposure, rapid cardiovascular collapse and death often overshadow any pulmonary organ effects, with irritant symptoms of importance only in lower intensity exposures.[282,284–288]

Methyl Isocyanate and Methyl Isothiocyanate

Methyl isocyanate (MIC) use is restricted to a narrow industrial application in the synthesis of pesticides. The mass fatalities at Bhopal, India, make MIC an important toxin for historical reasons. The toxicity of MIC was the result of its severe irritant properties leading to pulmonary edema.[289–291] No cyanide-mediated mechanism was involved. **Methyl isothiocyanate**, a breakdown product of the soil fumigant metam sodium, is an irritant chemically related to MIC that was also involved in a mass exposure episode, although less severe than the MIC release at Bhopal, and has also been associated with respiratory symptoms following agricultural application.[292,293] Urethane exposures do not involve MIC and do not have its toxicity; the isocyanates associated with urethane, such as toluene diisocyanate (TDI), diphenylmethane diisocyanate (MDI), and hexamethylene diisocyanate (HDI), are pulmonary irritants but are primarily of concern because of the sensitization they induce (see Chapter 64).

Miscellaneous Exposures

A number of other occupational and environmental agents result in acute pulmonary syndromes. Examples of such exposures include **diethylaminoethanol** and **cyclohexylamine** (both anticorrosive boiler additives),[294,295] **amitrole** and **glyphosphate** (both common herbicides),[296,297] **sodium azide** (used in a variety of chemical applications but important as a potential inhalant through automobile airbag deployment),[298] **diazomethane**, which is explosive but also highly toxic to the lung with a delayed onset similar to that of nitrogen dioxide,[299,300] **diborane** (an irritant gas used in manufacturing microelectronic equipment),[301,302] **barium** (inhalation can cause bronchospasm and respiratory muscle weakness in addition to life-threatening hypokalemia),[303] and **hydrogen selenide** (an irritant gas used in several industrial processes as well as being a potential metal processing by-product).[304,305]

Phosphine is an important agricultural fumigant with pulmonary and systemic toxicity that is generated on site as a gas given off by aluminum or zinc phosphide (e.g., in particular grain storage facilities or railway grain transport cars, where bystander exposure can occur); phosphine also has industrial applications, particularly in the production of microelectronics.[306–308a] **Acetic anhydride** (used in making epoxy and other resins) has also been associated with acute lung injury.[309] A distinctly different pattern of injury is associated with a related epoxy chemical, **trimellitic anhydride**, which causes severe pulmonary hemorrhage after subacute exposure.[16] **Osmium tetroxide** is a very potent respiratory irritant with terrorist weapon potential; fortunately, to date experience with human inhalation exposure has been limited.[310] **Carbon dioxide**, although a bulk asphyxiant and not a respiratory irritant, does cause shortness of breath and induces tachypnea; exposure can occur through natural geologic sources and through dry ice sublimation in an enclosed space.[311,312,312a]

Baby (talcum) powder aspiration is an inhalational pediatric acute pneumonitis occurring within hours of heavy exposure; infant inhalation of nontalcum powders has also led to pneumonitis.[313–315] Naturally occurring sources of exposure can also be associated with acute

and subacute lung responses, although these syndromes are poorly characterized.

Epidemiologically, *Stachybotrys chartarum* (*atra*) mold growth indoors in water-damaged residential structures was initially linked to a cluster of cases of pulmonary hemorrhage in infants, although the association was later retracted in a follow-up review by the U.S. Centers for Disease Control and Prevention.[316,317] The potential link between *Stachybotrys* and other human, predominantly nonpulmonary pathologies is even more questionable.[318] Other case reports have occasionally linked other molds or mold by-products with lung injury (as opposed to self-limited ODTS, discussed previously).[319] **Lycoperdonosis** is a potentially severe, acute pulmonary syndrome following intentional inhalation (sometimes as a natural medicinal treatment) of puffball mushroom (*Lycoperdon*) spores.[320,321,321a] The pathophysiology of the syndrome is not understood, but its high attack rate with heavy exposure suggests a toxic rather than an allergic or infective mechanism. Although toxic mushrooms with predominant muscarinic effects can cause bronchorrhea and bronchospasm, this would be anticipated to occur in the context of generalized cholinergic excess, similar to the anticholinesterase pesticides discussed previously.[322]

KEY POINTS

- Short-term inhalation exposures to toxic substances may have important effects on the lung as the target organ for damage.
- A number of substances cause acute respiratory tract toxicity, but the repertoire of pulmonary pathologic responses to such injury is fairly limited.
- Although modified by the solubility and other physical properties of the toxic agent, to a large degree, injury depends on the intensity and duration of exposure.
- Extensive injury can lead to acute pulmonary edema and diffuse alveolar damage.
- Specific exposures of importance include chlorine, oxides of nitrogen, sulfur dioxide, acid aerosols, toxic metal fumes, and pyrolysis by-products.
- Aside from acute irritant or toxic lung insult leading to airway injury and diffuse alveolar damage, other patterns of acute responses include the inhalation fevers (which are self-limited and appear to be cytokine mediated) and certain target-specific effects, such as those elicited by cholinesterase inhibition.
- Exposure by ingestion of some substances (e.g., hydrocarbons and paraquat) can cause important acute pulmonary target organ toxicity.
- Useful resources for information about specific toxins: National Library of Medicine's **TOXNET** (http://toxnet.nlm.nih.gov/) is a Web-based collection of resources covering toxicology, chemical safety, environmental health, and related areas. The **Household Products Database** (http://householdproducts.nlm.nih.gov/) is a consumer guide that provides information on the potential health effects of chemicals contained in more than 7000 common household products used inside and around the home. **Tox Town** (http://toxtown.nlm.nih.gov) is an interactive guide to commonly encountered toxic substances, public health, and the environment. **TOXMAP** (http://toxmap.nlm.nih.gov) is an interactive mapping site that helps users explore the geographic distribution of certain chemical releases, their relative amounts, and their trends over time. **Haz-Map** (http://hazmap.nlm.nih.gov) is an occupational health database designed for health and safety professionals and for consumers seeking information about the health effects of exposure to chemicals and biologicals at work. **WISER** (Wireless Information System for Emergency Responders) (http://wiser.nlm.nih.gov) is a system designed to assist first responders in hazardous material incidents.

CHAPTER 69

BIOTERRORISM

Christian Sandrock, MD, MPH, FCCP

INTRODUCTION

BIOTERRORISM: A HISTORICAL PERSPECTIVE

BASICS OF BIOTERRORISM

CDC CATEGORY A AGENTS

Anthrax
Smallpox
Plague
Tularemia
Botulism
Viral Hemorrhagic Fevers

SELECT CDC CATEGORY B AGENTS

Direct Pulmonary Agents
Nonpulmonary Agents (Gastrointestinal and Toxin)

RECOGNITION AND DETECTION OF A BIOTERRORISM EVENT

INFECTION CONTROL

PUBLIC HEALTH AND CRITICAL CARE RESPONSE

INTRODUCTION

Bioterrorism, once limited to military-directed biowarfare, has developed considerable prominence over the last decade due to increasing world threats and the anthrax outbreak in the United States in 2001. Clinicians and public health officials have become more aware of these rare diseases as local, state, and national directed programs increase detection, therapeutic options, and response to these agents. The agents of bioterrorism have some select features and characteristics that will allow clinicians and public health officials to appropriately detect and respond to one or multiple cases of febrile respiratory illnesses and respiratory failure.

Early recognition of bioterrorism agents can be difficult since the early prodromal phase of most agents is similar and often indistinguishable from other sources of febrile respiratory illnesses. Febrile respiratory illnesses and respiratory failure can signify a natural outbreak (such as severe acute respiratory syndrome [SARS], plague, tularemia, or a novel strain of influenza) or a bioterrorism event.[1,2] Most cases of febrile respiratory illnesses admitted to intensive care units (ICUs) are caused by community-acquired pneumonia, and up to 11% of these community-acquired pneumonia cases subsequently develop respiratory failure and acute respiratory distress syndrome (ARDS).[3,4] Although most cases of community-acquired pneumonia are recognizable, the rare and contagious causes (e.g., plague) can have a larger impact on the health care and public health systems.[2,5] Thus, early recognition of these rare infections becomes important for two reasons. Firstly, early infection control and public health preparedness strategies can be implemented to reduce spread in both the public and health care arena, particularly in the early phases of disease when patients are most contagious and likely to undergo aerosol-generating procedures by health care workers. Second, early detection of an intentional release of these agents is a bioterrorism event, and public health and law enforcement authorities can provide immediate investigation and support. Therefore, early suspicion of a bioterrorism event, along with early protective measures and public health contact, will reduce the likelihood of transmission to health care workers, visitors, patients, and ultimately the community.

Bioterrorism involves the deliberate release of viruses, bacteria, or their by-products (e.g., toxin) to cause morbidity and mortality in humans, animals, or plants.[6,7] All bioterrorism agents are naturally occurring organisms or toxins that can cause sporadic disease under natural circumstances, but on occasion, medical manipulation has been attempted to increase resistance to antibiotics or increase organism virulence.[7] This chapter provides an overview of the major agents of bioterrorism along with clues for detection, steps for public health response, and infection control interventions.

BIOTERRORISM: A HISTORICAL PERSPECTIVE

Bioterrorism has been around for centuries, from ancient Mesopotamia to current times.[7,8] The initial goal was to either incapacitate the enemy through death or stir great panic or fear into the population, leading to surrender. For example, in the 14th century, the Tartars would catapult plague-infected corpses into Kaffa, thereby leading to disease spread and the ultimate defeat of the city (and also starting the second wave of the Black Death in Europe).[9] In the New World, smallpox-infected blankets were distributed to native tribes from the West Indies to the Great Plains, with disastrous results. However, bioterrorism took form in the last 100 years with extensive biowarfare units in World War I and II.[7,8] Most notably, Unit 731 of the Japanese army in World War II used anthrax, plague, cholera, and typhoid on Chinese prisoners with great mortality, but transition to the battlefield was less successful.[7–9] The Cold War period saw both the United States and the former Soviet Union develop bioweapon stockpiles that have since been dismantled. However, over the past 25 years, an increase in individual-directed bioterrorism has occurred, culminating in the anthrax outbreak in 2001 that utilized the postal service for distribution, with 18 resulting cases.[7,8,10]

BASICS OF BIOTERRORISM

The route of transmission of bioterrorism agents can be by air (e.g., aerosol generation), food source (e.g., botulism), or water supply (e.g., gastroenteritis agents). Delivery can mimic naturally occurring disease, especially if the food or water supply to the public has been targeted. However, under aerosol generation, rapid increases in new cases are seen in low-risk populations, as seen with the anthrax cases in 2001.[11]

As most bioterrorism agents are infectious diseases, presentation of disease is usually covert, with health care workers seeing the initial cases as incubation periods vary and cases present over time. Particularly with contagious agents such as plague, smallpox, and viral hemorrhagic fevers, secondary infections will propagate the event to last weeks to months, stretching the capacity of the health care system.[2,7] Chemical and explosive forms of terrorism, however, are often overt and immediately known, with first responders in the field evaluating the initial cases and subsequent cases rarely occurring following the initial event. Therefore, subtle epidemiologic clues (such as an increase in pneumonia or a specific rash) may be the initial trigger to the clinician that a bioterrorism event has occurred.[12]

The Centers for Disease Control and Prevention (CDC) separated bioterrorism agents into three broad categories (A, B, and C) in 1999 based on ease of spread and severity of illness.[7,8,13,14] *Category A agents* are considered the highest risk to the public and national security for the following reasons: (1) easy person-to-person spread with many of the agents, (2) high mortality in those infected, (3) major public health impact causing panic and social disruption, and (4) requirement for specific and specialized public health emergency response (e.g., public prophylaxis or protective equipment)[7,8,13,14] (Table 69-1). *Category B agents* are moderately easy to spread and will result in moderate morbidity but low mortality in those infected. Less specific public health response is required (Table 69-2).[7] *Category C agents* are considered future or potential threats since they are easily available and can have a high mortality but have not been documented or engineered successfully (Table 69-3).[14] Although all of these agents can potentially cause serious disease, the category A agents, along with select category B agents, will be seen by clinicians and have the greatest impact on the public and health care system. These agents also present initially with a nonspecific prodromal phase with a few epidemiologic clues, thereby separating them from other less threatening causes of a febrile respiratory illness. Tables 69-4 to 69-8 list

TABLE 69-1. Centers for Disease Control and Prevention Category A Agents of Bioterrorism

Definition: Category A agents have the potential to be easily disseminated, have higher contagiousness, have high morbidity and mortality, and require increased public health preparedness

Anthrax (*Bacillus anthracis*)

Smallpox (variola major)

Plague (*Yersinia pestis*)

Tularemia (*Francisella tularensis*)

Botulism (*Clostridium botulinum* toxin)

Viral hemorrhagic fevers (filoviruses [e.g., Ebola, Marburg] and arenaviruses [e.g., Lassa, Machupo])

TABLE 69-2. Centers for Disease Control and Prevention Category B Agents of Bioterrorism

Definition: Category B agents are moderately easy to disseminate, carry a high morbidity but low mortality, and require public health laboratory and surveillance enhancements

PULMONARY AGENTS

Glanders (*Burkholderia mallei*)

Melioidosis (*Burkholderia pseudomallei*)

Psittacosis (*Chlamydophila psittaci*)

Q fever (*Coxiella burnetii*)

Ricin toxin from *Ricinus communis* (castor beans)

NONPULMONARY AGENTS

Brucellosis (*Brucella* species)

Epsilon toxin of *Clostridium perfringens*

Food safety threats (e.g., *Salmonella* species, *Escherichia coli* O157:H7, *Shigella*)

Staphylococcal enterotoxin B

TABLE 69-3. Centers for Disease Control and Prevention Category C Agents of Bioterrorism

Definition: Category C agents have the future potential for engineering for easy dissemination or high mortality

Influenza (novel strain)

Nipah virus

Typhus disease (*Rickettsia prowazekii*)

Viral encephalitis (alphaviruses [e.g., Venezuelan equine encephalitis, eastern equine encephalitis, western equine encephalitis])

Water safety threats (e.g., *Vibrio cholerae, Cryptosporidium parvum*)

FIGURE 69-1 ■ Anthrax lesion on the skin of the forearm caused by the bacterium *Bacillus anthracis.* The cutaneous ulceration has begun to turn black, hence the origin of the name "anthrax," after the Greek word for coal. (Courtesy of the Centers for Disease Control and Prevention/#2033 (James H. Steele). Available at http://phil.cdc.gov/phil/details.asp [accessed January 3, 2009].)

the unique features associated with category A agents: clinical syndromes, preferred diagnostic methods, radiologic features, treatment, and infection control and respiratory protection.

CDC CATEGORY A AGENTS

Anthrax

General

Anthrax is caused by a sporulating gram-positive rod, *Bacillus anthracis.* Its ecology has three distinct stages, a soil stage, animal infection, and human infection.[15,16] Anthrax is part of the normal soil flora, so local multiplication occurs if soil conditions are favorable. Otherwise, anthrax will persist for long periods of time in a spore form, resistant to decontamination and environmental influences. From the soil, disease spreads to herbivores, such as cattle, as they come into contact with highly infectious soil through grazing.[15,16]

Human disease largely occurs through contact with animal products, such as animal skins, where the bacillus form converts back to the spore form. In 2001, however, 22 cases of anthrax occurred in the United States as an act of bioterrorism through the postal system, placing anthrax on the forefront of bioterrorism.[10] Besides this outbreak in 2001, anthrax remains relatively rare in the United States, with most endemic and epizootic cases occurring in the Middle East. Most cases in the United States occur through handling of animal products, such as the 2006 cases associated with African animal hide drum skins.[16] The threat of anthrax as a bioterrorism and zoonotic agent still remains.

Disease occurs when the spore form is introduced subcutaneously or via inhalation, becomes the vegetative (bacillus) form, and starts replication.[15,16] Endotoxin secretion, along with a thick capsule that avoids phagocytosis, leads to local spread, edema, hemorrhage, and tissue necrosis. The anthax capsule, edema factor toxin, and lethal factor toxin act in concert to drive disease.[15,16]

Clinical Presentation

Three clinical disease syndromes occur with anthrax: cutaneous, gastrointestinal, and inhalational.[15–17] *Cutaneous anthrax* is the most common form worldwide, and has an incubation period of 7 to 14 days after inoculation of spores into the subcutaneous space. This is followed by a small, painless papule that can be pruritic. The papule enlarges and develops a central vesicle, followed by erosion into a painless black eschar (Fig. 69-1). Edema surrounds the tissues, and regional lymphadenopathy also may occur along with systemic symptoms of fever and malaise. The hands, arms, face, and neck are the most common areas affected.

With *inhalational anthrax,* the spores that reach the distal airways are brought into the mediastinal lymph nodes, where replication occurs followed by onset of disease.[15] The incubation period averages 1 to 7 days, followed by clinical symptoms of a nonspecific febrile illness, often mimicking influenza. However, within 24 hours, disease rapidly progresses with the development of respiratory failure, hemorrhagic mediastinitis, necrotizing pneumonia, shock, multiorgan failure and death (Table 69-4).[17] The development of shock and multiorgan failure can occur rapidly, and along with the hemorrhagic mediastinitis, is the clinical hallmark of anthrax.

Gastrointestinal anthrax is rare and occurs after the consumption of undercooked meats of infected animals, usually in family clusters. Bowel edema occurs, followed by mesenteric lymphadenitis and necrosis, with rapid progression to shock and death.[17]

The mortality for cutaneous anthrax remains low at less than 1% in treated patients (20% in untreated), while inhalational anthrax can carry a mortality of 89%.[15–17] The inhalational cases from 2001 in the United States had a lower mortality of 45%.[10]

TABLE 69-4. Unique Clinical Syndromes Associated with the CDC Category A Agents of Bioterrorism

Agent	Unique Clinical Finding/Syndrome
Anthrax	Hemorrhagic mediastinitis
Smallpox	Poxlike rash with systemic inflammatory response syndrome leading to septic shock
Plague	Sudden acute respiratory failure and sepsis
Tularemia	Patchy alveolar pneumonia with sepsis
Botulism	Descending flaccid paralysis
Viral hemorrhagic fevers (e.g., Eloba)	Sepsis with bleeding diathesis

TABLE 69-5. Preferred Diagnostic Methods for CDC Category A Agents

Agent	Laboratory Diagnostic Method
Anthrax	Culture of organism from blood or body fluid. Serology for uncultured cases. BSL 3 required at state and regional public health laboratory.
Smallpox*	EM or PCR of pox lesion. Viral isolation from skin/fluid. BSL 4 laboratory (CDC only).
Plague	Culture of organism from blood or sputum. Serology for uncultured cases. BSL 3+ at state or regional public health laboratory.
Tularemia	Serology or tissue histology. Difficult to culture. Performed at local, state, and regional public health laboratories.
Botulism	Isolation of toxin from blood or stool. Toxin identification (A–E) performed at state or regional public health laboratories.
Viral hemorrhagic fevers (e.g., Ebola)*	Serology or viral culture from blood/body fluid. BSL 4 at state or regional public health laboratory.

*Culture and/or species identification is performed at the CDC only.
BSL, bio-safety laboratory; CDC, Centers for Disease Control and Prevention; EM, electron microscopy; PCR, polymerase chain reaction.

TABLE 69-6. Radiologic Features of CDC Category A Agents of Bioterrorism

Agent	Radiologic Pulmonary Findings
Anthrax	Widening of mediastinum. May also have patchy alveolar opacities, pleural effusion, and lobar pneumonia but less likely.
Smallpox	Patchy alveolar opacities.
Plague	Diffuse, patchy, alveolar opacities.
Tularemia	Diffuse, patchy, alveolar opacities.
Botulism	Normal to lower lung volumes.
Viral hemorrhagic fevers (e.g., Ebola)	Diffuse alveolar opacities with areas of dense consolidation. Widened mediastinum and pleural effusions also reported.

Diagnosis

The diagnosis of anthrax is best performed by culture of the blood, sputum, pleural fluid, cerebrospinal fluid, or skin[16,18] (Table 69-5). Clinicians should notify the laboratory of suspected anthrax since spore formation during culture can occur, leading to spread to laboratory workers if not properly handled. Additionally, any suspect case of anthrax should involve the public health laboratories for confirmation and strain typing. Polymerase chain reaction (PCR) and enzyme-linked immunosorbent assay (ELISA)–based rapid assays exist and have a good sensitivity and specificity.[16,18]

The radiologic findings associated with anthrax include a widened mediastinum consistent with hemorrhagic mediastinitis, the hallmark of anthrax[15,16] (Table 69-6). However, in 2001, other findings including patchy alveolar opacities, lobar consolidation, and pleural effusions were also reported.[16] In each of these cases, a widened mediastinum was present on chest radiograph, with follow-up confirmation performed by computed tomography scan.

Treatment, Prophylaxis, and Prognosis

Treatment includes supportive therapy and antibiotics[17,18] (Table 69-7). Intensive care management with early and appropriate volume resuscitation along with lung-protective low-tidal-volume ventilation should be used if indicated.[2] Antibacterial treatment includes ciprofloxacin, doxycycline, and, if susceptible, penicillin.[17-19] In 2001, rifampin, clindamycin, or vancomycin in combination with ciprofloxacin was used.[17-19] The isolate in 2001 was resistant to penicillin. Appropriate pleural space drainage or the use of a central nervous ventriculoperitoneal shunt may also be used in individual cases. Corticosteroids were used to reduce edema and hemorrhage in some cases, but there is very limited data on their efficacy.[17] A live virus vaccine, which is toxigenic and uncapsulated, has been used in veterinary medicine to control disease in animals, but use in humans has been more limited due to a frequent dosing regimen, side effects, and efficacy concerns, and it is currently reserved for military personnel.[16,18] Exposure to aerosolized spores requires prophylaxis with either ciprofloxacin or doxycycline in adults, and amoxicillin as a second-line agent in children and pregnant women.[16,18]

Infection Control

Anthrax is not contagious as the vegetative bacillus form of disease exists during clinical infection[7,16] (Table 69-8). Contact with infected animals and animal products increases the likelihood of disease spread, so limiting contact or wearing appropriate personal protective equipment (PPE), particularly in endemic areas, is indicated.

TABLE 69-7. Treatment of Select CDC Category A Agents

Agent	Primary Treatment	Secondary Treatment
Anthrax	Ciprofloxacin 15 mg/kg IV twice daily	Clindamycin 900 mg IV three times daily
Plague	Gentamicin 5 mg/kg IV/IM daily	Ciprofloxacin 15 mg/kg IV twice daily
	Streptomycin 1 g IM daily	Chloramphenicol 15 mg/kg IV four times daily
Smallpox	Supportive care	Cidofovir*
	Vaccinia Immune Globulin 0.6 mg/kg IV/IM*	
Tularemia	Gentamicin 5 mg/kg IV/IM daily	Doxycycline 100 mg IV twice daily
	Streptomycin 1 g IM daily	Ciprofloxacin 15 mg/kg IV twice daily
		Chloramphenicol 15 mg/kg IV four times daily
Viral hemorrhagic fevers	Supportive care	Experimental with immune globulin from donors
	Ribiviron for Lassa fever	
Botulism	Trivalent antitoxin (A, B, E)	None
	Supportive care	

*Obtained through the CDC only (see http://www.bt.cdc.gov/agent/smallpox/vaccination/vig.asp).
CDC, Centers for Disease Control and Prevention; IM, intramuscularly; IV, intravenously.

TABLE 69-8. Infection Control and Respiratory Protection for CDC Category A Agents

Agent	Isolation	Baseline Protection	Protection in Higher Risk Procedures
Viral hemorrhagic fever	Airborne and contact	N95 mask	N95 mask or PAPR
Smallpox	Airborne and contact	N95 mask	N95 mask or PAPR
Botulism	None	None	Surgical
Plague*	Droplet and contact	N95 mask	N95 mask or PAPR
Tularemia	None	None	Surgical
Anthrax	None	None	Surgical

*Isolation can be stopped after 48 hours of appropriate antibacterial therapy.
PAPR, powered air-purifying respirator.

Smallpox

General

Variola virus is the causative agent of smallpox and is a member of the Poxviridae family.[20] Smallpox was eradicated worldwide in 1977 but now has regained interest as a potential bioterrorism agent.[20,21] Smallpox was endemic worldwide and at one point accounted for over 10% of all deaths worldwide until the last endemic case in Somalia in 1977.

It occurs in two forms, variola major and variola minor.[20,21] Variola major is the most common form of smallpox, has more severe disease with an extensive rash and fever, and carries a higher mortality (around 20% in the unvaccinated). Variola minor is less common and less severe, with mortality historically under 1%. Variola minor has a genetic sequence very similar to that of variola minor, with gene expression differences likely causing the variable mortality between the major and minor forms.

Smallpox is very contagious, with approximately half of all unvaccinated household contacts contracting disease.[20,21] However, after global eradication by 1977, routine vaccination for smallpox ceased worldwide.[22] However, due to an increasing unvaccinated population along with its contagiousness and ability to be transmitted by aerosol, smallpox is a CDC category A bioterrorism agent. Only two stockpiles of the virus remain (at the CDC and the Russian State Research Center) for continued research.[23,24]

Clinical Presentation

Smallpox infection occurs when the viral particles enter the respiratory tract, replicate locally, and then are carried to regional lymph nodes.[20,21] Subsequent viremia occurs with spread to lymphoid organs, followed by further viral amplification and the progression of symptoms. Variola major occurs in five main clinical categories: ordinary, modified, flat, hemorrhagic, and variola sine eruptione.[20,21]

Ordinary-type infection accounted for more than 70% of cases. After an incubation period of 10 to 14 days, disease onset (preeruptive phase) occurs with high fever, severe headache, and malaise. The preeruptive phase can last 2 to 4 days and is followed by the eruptive phase, which is characterized by rash. The lesions first appear as small erythematous macules on the mucous membranes, tongue, and face (herald spots).[20,21,25] Spread then occurs in a centrifugal fashion, with macules

FIGURE 69-2 ■ The maculopapular lesions on this patient's arm were caused by the smallpox virus, variola major. These lesions were in their pustular phase of development. (Courtesy of the Centers for Disease Control and Prevention/#10495 (Dr. John Noble Jr.). Available at http://phil.cdc.gov/phil/details.asp [accessed January 3, 2009].)

evolving into papules, then vesicles, and finally the classic pustules (pox) (Fig. 69-2) by day 5 to 7 of the rash (see Table 69-4). Fever usually resolves during the eruptive phase but may occur after the pustules develop. Crusting and healing begin by day 14 of the rash.

The *modified type* of variola major is similar to the ordinary type except for a more rapid but less severe rash, as this type was common in vaccinated individuals.[20,21,25] The *flat type* had pustules that remained flat and confluent and often occurred in children.

The *hemorrhagic type* was rare but very severe, with the lesions and mucous membranes becoming hemorrhagic.[20,21,25] This type was more common in pregnant women and rapidly led to multiorgan failure within a few days.

Patients with *variola sine eruptione* would have a fever but no rash; this type was often found in prior vaccinated individuals as well.

Diagnosis

Diagnosis is largely clinical, with the acute onset of fever followed by the characteristic rash of deep-seated vesicles or pustules[20,26] (see Table 69-5). For laboratory diagnosis, virus isolation from a skin lesion with reverse transcriptase–PCR confirmation is used, and is only performed at the CDC or World Health Organization laboratory.[20,26]

Radiologic findings in smallpox are limited largely to diffuse alveolar opacities from an inflammatory response associated with the primary infection[20,27] (see Table 69-6). Lobar opacities are seen and mostly associated with secondary bacterial pneumonia.

Treatment, Prophylaxis, and Prognosis

Treatment is largely supportive, with some evidence that cidofivir has activity in animal models[20,27,28] (see Table 69-7). Aggressive ICU support, including volume resuscitation, vasopressor support, and low-tidal-volume ventilation should be used for severe cases.[1] Vaccination early in disease may also reduce the severity of illness and is the mainstay for reducing spread and controlling disease in the community.[22] Vaccination can be administered within 4 days of exposure to a known case to provide protection.

Mortality from the ordinary type was around 20% from multiorgan failure and hypotension, with the flat and hemorrhagic types carrying a higher mortality and the modified and sine eruptione types carrying a much lower mortality. Complications include secondary bacterial skin infections and pneumonia, along with encephalitis, orchitis, and extensive scarring of the skin and corneas.[20,21]

Infection Control

Spread is through contact with infected lesions or respiratory secretions and thus full PPE, including gown, gloves, and face shield, is required.[28] CDC guidelines recommend airborne isolation with use of an N95 particulate respirator or a powered air-purifying respirator (PAPR) for respiratory protection, and all health care workers handling any smallpox patient must receive the vaccination[28] (see Table 69-8). Any suspected case of smallpox should involve public health officials immediately.

Plague

General

Yersinia pestis is the etiologic agent of plague and has caused a number of pandemics throughout human history.[9] Plague is a zoonosis, primarily affecting rodents, with humans and other animals (domestic cats) being accidental hosts.[29,30] The natural ecosystem of *Y. pestis* depends largely on the flea and rodent interaction, with seasonal variability noted based on environmental conditions. Infected fleas bite their rodent hosts, inoculating the rodent. Mortality in these animals remains lower than in other nonrodent mammals, and disease is passed from infected rodent to flea and the life cycle continues. Transmission to humans occurs by rodent-infected flea bites, infected animal scratches or bites, exposure to infected humans, and bioterrorism.[29,30] Transmission by infected flea bites is the most common mode, with squirrel, rabbit, domestic cats, and prairie dogs being the most common animals of transmission. Large rodent or other animal die-offs, particularly in more susceptible species, may herald a large epidemic in nature.[29,30] Plague is found worldwide, and in the United States endemic disease is found largely in the western states.

Clinical Presentation

Three clinical syndromes are associated with plague: bubonic plague (80% to 90% of cases), septicemic plague (10% of cases), and pneumonic plague (very rare).[29,30] After an incubation period of 2 to 7 days, symptoms usually occur and differ depending on clinical syndromes.

FIGURE 69-3 ■ An axillary bubo and edema exhibited by a plague patient. (Courtesy of the Centers for Disease Control and Prevention/#2061 (Margaret Parsons, Dr. Karl F. Meyer). Available at http://phil.cdc.gov/phil/details.asp [accessed January 3, 2009].)

In *bubonic plague,* a sudden onset of fevers, chills, and headache is followed by pain and swelling in the regional lymph nodes proximal to the site of the bite or scratch.[29,30] This lymph node (bubo) is characterized by intense tenderness with erythema and edema but without fluctuation (Fig. 69-3). Without treatment, disease disseminates, leading to complications such as pneumonia, meningitis, sepsis, and multiorgan failure. The development of a secondary pneumonia becomes extremely concerning as these patients are highly contagious.

Septicemic plague occurs with acute fever followed by sepsis without the presence of a bubo.[29,30] Additional symptoms such as nausea, vomiting, and diarrhea also complicate septicemic plague. Rapid sepsis, disseminated intravascular coagulation, and multiorgan failure develop quickly.

In *pneumonic plague,* most cases are secondary from bubonic or septicemic plague, but a primary pneumonic plague can occur after exposure to infected humans, animals, or aerosols in an intentional bioterror attack.[29,30] Due to the high contagiousness of plague, disease can spread rapidly with primary pneumonia as seen with past outbreaks in human history, subsequently creating a sustained pandemic. Initial cases in primary pneumonic plague have a very short incubation period of hours to a few days, followed by sudden onset of fever, cough, rapid onset of respiratory failure and ARDS, and death (see Table 69-4).

Diagnosis

The clinical diagnosis for plague can be difficult, but exposure to animals in an endemic area may be the first clue[29–31] (see Table 69-5). During intentional dissemination, multiple cases of severe, rapidly progressive pneumonia may be the first clue. Laboratory diagnosis is primarily by culture of the sputum or blood as *Y. pestis* grows well on most laboratory media. Serology and rapid diagnostic testing by ELISA or PCR is also available but is used primarily in field testing.[29–31]

A sudden and diffuse alveolar filling process is seen on chest radiographs consistent with acute lung injury[29,30] (see Table 69-6). Additional mediastinal lymphadenopathy may be present, as may be pleural effusion in later stage cases. Lobar opacities are less common.

Treatment, Prophylaxis, and Prognosis

The primary agent for antibacterial therapy has long been considered streptomycin, but based on its limited availability, gentamicin or doxycycline is preferred[29,30] (see Table 69-7). Most isolates are fully susceptible to gentamicin and doxycycline, as well as ciprofloxacin, which has been used in a more limited manner.[32] Chloramphenicol is preferred for cases of meningitis due to its ability to cross the blood-brain barrier. As most cases of primary pneumonia lead to multiorgan failure and acute lung injury, volume resuscitation, vasopressor support, and low-tidal-volume ventilation are indicated.[2] There is no evidence of corticosteroid benefit. Postexposure prophylaxis includes ciprofloxacin and doxycycline orally, with trimethoprim-sulfamethoxazole (if susceptible) or gentamicin for children and pregnant individuals.[32]

Infection Control

Due to the high rate of transmission of plague via aerosols, all patients should be on strict airborne isolation until at least 48 hours of antibiotics have been given[30] (see Table 69-8). Infection control measures include airborne isolation, including negative-pressure isolation. Appropriate PPE, including an N95 mask or PAPR, should be worn.

Tularemia

General

Tularemia is caused by the gram-negative bacterium *Francisella tularensis* and is a zoonotic disease, with humans as accidental hosts.[33] *Francisella tularensis* is found throughout the northern hemisphere and in a wide variety of wild and domesticated species. The organism persists in nature since it is passed transovarially in ticks, with disease coming after bites from infected vectors (ticks, flies, mosquitoes). Human infections occur by vector contact (ticks and flies), handling infected animals, improperly prepared animal meat, animal scratches and bites, drinking contaminated water, or aerosolization of the organism from the environment or in bioterrorism.[33–35] However, human-to-human transmission does not occur, largely since the organism is intracellular during infection and thus harder to spread from person to person.

Clinical Presentation

Approximately six distinct clinical syndromes occur with tularemia: ulceroglandular, glandular, typhoidal, pneumonic, oropharyneal, and oculoglandular.[36,37]

FIGURE 69-4 ■ Tularemia lesion on the dorsal skin of the right hand caused by the bacterium *Francisella tularensis.* (Courtesy of the Centers for Disease Control and Prevention/#2032 (Dr. Brachman). Available at http://phil.cdc.gov/phil/details.asp [accessed January 3, 2009].)

Ulceroglandular disease accounts for approximately 60% to 70% of cases.[36,37] Abrupt onset of fevers, chills, headache, and malaise occurs after an incubation period of 2 to 10 days. Most patients will have a single papuloulcerative lesion with a central eschar and associated tender lymphadenopathy (Fig. 69-4). In *glandular disease,* enlargement of lymph nodes occurs without the characteristic lesion (about 15% of cases).[36,37]

Pneumonic tularemia occurs with primary inhalation or hematogenous spread from typhoidal tularemia, and this is believed to be the main clinical presentation in a bioterrorism event with tularemia.[34] The incubation period tends to be shorter in these cases, with the rapid onset of pneumonia developing. Respiratory failure and ARDS develop rapidly (see Table 69-4).

Typhoidal tularemia is rare and can occur with or without pneumonia, as patients present with a febrile illness followed by sepsis without the glandular disease.[37] *Oropharyngeal tularemia* occurs rarely when undercooked infected meat or water is ingested and is associated with fever, pharyngitis, and cervical lymphadenopathy.[37]

Oculoglandular tularemia occurs with direct innoculatioin from contaminated fingers or accidental exposure. Besides conjunctival swelling and erythema, regional lymphadenopathy may be present.

Diagnosis

Francisella tularensis is very difficult to grow on culture media (requires cysteine), and since it is largely an intracellular organism, diagnosis is difficult[38,39] (see Table 69-5). Clinical suspicion must be high, particularly if the risk factors of vector exposure, animal exposure, or multiple community cases suggesting aerosolization occur. Therefore, serology by ELISA or histologic examination showing gram-negative intracellular organisms is the most likely method.[38,39] If serology is performed, a single elevated titer may not be specific and thus acute and convalescent titers are more predictive.[38,39]

Radiographic studies show patchy opacities bilaterally, lobar disease, and hilar adenopathy[40] (see Table 69-6). Pleural effusions and a miliary pattern can also occur, although this is less common. Hilar and mediastinal adenopathy may occur.

Treatment, Prophylaxis, and Prognosis

Similar to plague, aminoglycosides are the first treatment[39,41] (see Table 69-7). Gentamicin is preferred, with doxycycline or ciprofloxacin used as second-line therapy. For meningitis, chloramphenicol is preferred. In cases of exposure, doxycycline or ciprofloxacin is the preferred treatment, with trimethoprim-sulfamethoxazole or amoxicillin for children and pregnant patients.[39,41] Specific ICU management of tularemia includes supportive care and low-tidal-volume ventilation for ARDS. The overall mortality for tularemia is around 4%, but is thought to be higher in aerosolized disease that causes pneumonia or typhoidal tularemia.[36,37]

Infection Control

Human-to-human transmission does not occur, so once the diagnosis is confirmed, respiratory isolation can be lifted[37,41] (see Table 69-8). Reporting tularemia to public health officials varies across North America, but pneumonic or typhoidal cases, particularly if thought to be secondary to a bioterrorism event, should be reported.

Botulism

General

Clostridium botulinum, a gram-positive, spore-forming, obligate anaerobe, is the bacterium that produces and excretes botulinum toxin.[42,43] This neurotoxin is responsible for the clinical disease known as botulism and is the only category A agent that is a toxin. Seven serotypes of botulinum toxin exist, A through G, and are produced by different strains of *C. botulinum.* All act on the presynaptic nerve terminal of the neuromuscular junction and the cholinergic autonomic synapses. Disruption of neurotransmission occurs, leading to the clinical findings. Serotypes A, B, and E predominate in clinical disease, although any serotype can cause disease.[42,43] Serotypes C and D are predominately found in animal populations. Botulinum toxin is extremely lethal, with the median lethal oral dose estimated to be 1 ng/kg, although two to three times this dose may be needed for inhalation.[42,43]

Disease presents from potentially four different sources: food-borne, wound, infant, and intentional.[42,43] Food-borne disease occurs in outbreaks and is often associated with home-canned foods, such as fruits, vegetables, and fermented fish. Wound botulism has been associated with intravenous and subcutaneous injection of black tar heroin, mostly of Mexican origin. Infant botulism occurs sporadically in some western states, likely from spore acquisition from soil or raw honey, with subsequent toxin production in the gastrointestinal

tract. Finally, intentional release during a bioterrorism event may occur, with oral ingestion or aerosolization of the toxin.

Clinical Presentation

Clinical disease begins with the acute onset of bilateral cranial neuropathies with rapidly descending weakness (see Table 69-4). Of note, no fever is present and the patient maintains normal mentation.[42,43] The cranial neuropathies are usually symmetrical and often begin with oculomotor dysfunction. However, asymmetrical cranial nerve dysfunction has been reported.[44] Diplopia, dysphagia, ptosis, and facial weakness are the most common.[42,43] In food-borne exposure, gastrointestinal symptoms, including nausea and vomiting, may also occur. In infant botulism, poor feeding and lethargy may also be noted. Both wound and food-borne sources for botulism usually have an onset of symptoms at 12 to 36 hours after exposure and rapidly progress over the next 12 hours. If botulism is not suspected and treatment does not occur rapidly, eventual weakness and paralysis of respiratory muscles ensues, requiring mechanical ventilatory support.[44] Once the muscles of respiration are involved, mechanical support is required from 1 to 3 months.[44]

Diagnosis

Early and prompt diagnosis is essential since early treatment can alter the progression of weakness. Thus, the clinical findings of cranial nerve palsies, particularly in the appropriate clinical setting (e.g., heroin use) should prompt consideration (see Table 69-5). Laboratory diagnosis is by toxin or organism isolation, either in the spore or vegetative form.[45] Isolation of toxin from blood or stool is most reliable, and in some cases environmental isolation may be necessary to make the diagnosis.[45] The growth of *C. botulinum* from a stool or wound sample with the corresponding clinical findings can also confirm the diagnosis. Electromyography will also support the diagnosis if toxin and organism isolation is unsuccessful. There are no specific radiologic changes seen with botulism. Low lung volumes on chest radiographs may be seen but are not specific to the disease process (see Table 69-6).

Treatment, Prophylaxis, and Prognosis

Treatment must be started promptly and is directed at toxin neutralization[42,43,46] (see Table 69-7). An equine trivalent antitoxin (against serotypes A, B, and E) is available from state public health departments and the CDC and has been shown to decrease mortality in food-borne outbreaks as well as lessen the likelihood of respiratory failure in wound botulism.[46] Anaphylaxis and serum sickness have been reported. A human-derived antitoxin is available and is used in infant cases. Antibiotic administration is favored for wound botulism, with penicillin or clindamycin being the drugs of choice.[42,43] Since botulism results from exposure to the toxin, antibiotics are not recommended for food-borne and inhalational cases. In all cases of botulism without respiratory failure, routine monitoring of forced vital capacity is recommended, with early intubation if the vital capacity falls below 10 mL/kg (approximately 30% predicted). There is no direct prophylaxis for exposure, but in high-risk threats a vaccine directed against serotypes A and E is available and has been largely used in the military.[46] Death from botulism occurs from respiratory failure, so cases with prompt recognition and treatment have a low mortality.[44]

Infection Control

Since botulism is a toxin-based disease, infection control should follow universal precautions[42] (see Table 69-8). During an exposure to spores or toxin, decontamination should occur, although secondary infections in medical personnel have not been reported.

Viral Hemorrhagic Fevers

General

The hemorrhagic fever viruses include a wide number of geographically distributed viruses found worldwide, including Ebola and Marburg viruses and the viruses causing Rift Valley fever, Bolivian, Argentine, and Crimean-Congo hemorrhagic fevers, Lassa fever, yellow fever, and dengue fever.[47–49] Ebola and Marburg viruses are in the family Filoviridae, and Lassa virus as well as the viruses causing Bolivian (Machupo virus) and Argentine (Junin virus) hemorrhagic fever are in the family Arenaviridae. The Crimean-Congo and Rift Valley fever viruses belong to the Bunyaviridae family. Only the Filoviridae (Ebola and Marburg viruses) and Arenaviridae are listed as category A agents. The Filoviridae family serves as a classic template for viral hemorrhagic fevers and is largely discussed here.[47] Marburg virus has a single species, while Ebola virus has four different species that vary in virulence in humans.[48,49] Transmission appears to occur through contact with nonhuman primates and infected individuals. Settings for transmission have occurred in vaccine workers handling primate products, nonhuman primate food consumption, nosocomial transmission, and laboratory worker exposure. The use of hemorrhagic fever viruses in bioterrorism has also been postulated, largely based on their high contagiousness in aerosolized primate models.[48,49] The exact reservoir for these viruses was initially thought to be wild primates, but recently bats have been labeled as the reservoir, passing the infection on to nonhuman primates in the wild.

Clinical Presentation

The clinical manifestations of both Marburg and Ebola viruses are similar in presentation and pathophysiology, with morality being the only major difference between them.[49,50] The initial incubation period after exposure to either virus is 5 to 7 days, with clinical disease beginning

FIGURE 69-5 ■ Marburg virus rash. This posterior-oblique view of the back of a patient shows the measles-like maculopapular rash, which can appear on Marburg patients around the fifth day after the onset of symptoms, and usually may be found on the patient's chest, back, and stomach. This patient's skin blanched under pressure, which is a common characteristic of a Marburg virus rash. (Courtesy of the Centers for Disease Control and Prevention/#6571 (Dr. J. Lyle Conrad). Available at http://phil.cdc.gov/phil/details.asp [accessed January 3, 2009].)

with the onset of fever, chills, malaise, severe headache, nausea, vomiting, diarrhea, and abdominal pain.[49,50] Disease onset is abrupt, and over the next few days, symptoms worsen to include prostration, stupor, and hypotension. Shortly thereafter, impaired coagulation occurs with increased conjunctival and soft tissue bleeding. In some cases, more massive hemorrhage can occur in the gastrointestinal and urinary tracts, and in rare instances, alveolar hemorrhage can occur.[49,50] The onset of maculopapular rash on the arms and trunk also appears classic and may be a very distinctive sign (Fig. 69-5). Along with the bleeding and hypotension, multiorgan failure occurs eventually leading to death (see Table 69-4). Reports of outbreaks and cases have largely occurred in developing countries where critical care resources are more limited, thus experience with mechanical ventilation and the development of ARDS is not well documented.

Diagnosis

The diagnosis of viral hemorrhagic fevers becomes extremely important in order to initiate supportive care before the onset of shock, alert and involve the public health department, and institute infection control measures. However, diagnosis is difficult outside of the endemic area. Viral hemorrhagic fevers should be suspected in cases of an exposed laboratory worker or an acutely ill traveler from an endemic area (i.e., central Africa), or in the presence of some classic clinical findings with increasing cases within the community, suggesting a bioterrorism attack.[49] Outside of travel or laboratory exposure, the presence of a high fever, malaise and joint pain, conjunctival bleeding and bruising, confusion, and progression to shock and multiorgan failure should raise suspicion of a viral hemorrhagic fever, particularly if multiple cases are presenting in the community. Laboratory diagnosis includes antigen testing by ELISA or viral isolation by culture, but these tests are only performed by the CDC currently[49] (see Table 69-5).

Radiologic changes include a diffuse alveolar process consistent with acute lung injury[49,50] (see Table 69-6). As the disease progresses, the alveolar process can become dense as alveolar hemorrhage increases. Additional pleural effusions may also be present.

Treatment, Prophylaxis, and Prognosis

As no specific therapy is available, patient management includes supportive care, including a lung-protective strategy with low-tidal-volume ventilation if ARDS appears as part of the disease course[48–50] (see Table 69-7). With the arenavirus group (Lassa, Junin, and Machupo viruses) and the Bunyaviridae (Crimean-Congo hemorrhagic fever and Rift Valley fever viruses), ribavirin is recommended.[48–50] In a few cases in a Zaire outbreak in 1995, whole blood with immunoglobulin G antibodies against Ebola virus may have improved outcome, although analysis showed these patients were likely to survive anyhow.[47] If exposure occurs to a health care worker, there is no specific postexposure prophylaxis, and infection control and occupational health personnel should be involved, with potential quarantine measures for exposed individuals. Case fatality rates have reached 80% to 90% in the recent outbreak of Marburg virus in Angola, but Ebola virus case fatality rates appear lower at 50%.[47,49–51]

Infection Control

Although transmission appears to spread by droplet route, airborne precautions are recommended, with respiratory protection with an N95 mask or PAPR and placement of the patient in a respiratory isolation room[48–50] (see Table 69-8). Equipment should be dedicated to that individual, and all higher risk procedures should be done with adequate, full PPE. Any suspected case of viral hemorrhagic fever should immediately involve the public health officials and infection control department, as public health interventions and outbreak investigation will be paramount to reduce spread of disease within the community and to investigate any potential bioterrorism attack.

SELECT CDC CATEGORY B AGENTS

Direct Pulmonary Agents

Glanders (Burkholderia mallei)

The disease glanders is caused by the gram-negative bacterium *Burkholderia mallei.*[52] Glanders is primarily a disease of horses, and humans become secondarily infected through broken skin or droplet inhalation. Naturally occurring human infection is rare, but occupational cases (horse veterinarians) do occur sporadically.

In bioterrorism, aerosolization is the likely method. Glanders can occur as an acute or chronic skin infection, but with aerosolization, rapid pneumonia and/or sepsis will present.[52] Diagnosis is by culture, but since *B. mallei* is an uncommon organism, laboratories may misclassify it. Treatment includes supportive care as well as systemic antibiotics such as imipenem or a third-generation cephalosporin.[52] Ciprofloxacin is also an option. Since this is a rare disease, transmission to humans has not been documented, but universal precautions with droplet isolation for respiratory cases are recommended. Any suspect case should involve immediate contact with the public health department.

Melioidosis (Burkholderia pseudomallei)

Similar to glanders, melioidosis is caused by the gram-negative bacterium *Burkholderia pseudomallei.*[52,53] Unlike glanders, this bacterium has a natural reservoir in the soil and contaminated water and is spread through direct contact or inhalation. Thus, disease predominates during the rainy season. In bioterrorism, aerosolization will lead to a clinical picture of pneumonia or melioidosis sepsis.[52,53] With melioidosis, the incubation period can be highly variable, with some cases not presenting for extended periods while others may remain asymptomatic.[52–54] Most symptomatic cases will develop sepsis with multiple metastatic foci and eventually multiorgan failure. Diagnosis is by culture, which occurs readily by routine methods. Treatment involves imipenem or a third-generation cephalosporin, followed by a 20-week treatment with doxycycline and trimethoprim-sulfamethoxazole for metastatic foci eradication.[52,53]

Psittacosis (Chlamydophila psittaci)

Psittacosis is caused by an intracellular bacterium routinely associated with birds such as parrots, cockatiels, and canaries. *Chlamydophila psittaci* presents nonspecifically, and most cases often go undiagnosed.[55,56] As a category B bioterrorism agent, *C. psittaci* can cause morbidity with very low mortality. Intentional aerosolization would lead to multiple cases of nonspecific "atypical pneumonia" with cough, fever, and headache.[55,56] Diagnosis is difficult and relies on serology due to the difficulty in isolating the organism. Treatment is with doxycycline, a macrolide, or ciprofloxacin. Mortality is low at 1% in treated cases.[55,56] Universal precautions are required for patient care, although an N95 mask and coveralls are recommended for environmental decontamination.

Q Fever (Coxiella burnetii)

Q fever is a zoonotic disease caused by *Coxiella burnetii.* Cattle, sheep, and goats are the primary reservoirs of *C. burnetii,* and this disease is found worldwide.[57] *Coxiella burnetii* usually does not cause clinical disease in animals, but organisms are found in milk, urine, feces, amniotic fluids, and placenta. The organisms are resistant to heat and drying, and often cause infection by inhalation of environmental dust contaminated by dried placental material, birth fluids, and excrement. Incubation time is 1 to 2 weeks, after which only about one half of all infected persons develop a clinical illness.[57] The clinical illness is characterized by high fevers (often greater than 40° C/104° F), severe headache, myalgia, sore throat, nonproductive cough, nausea, vomiting, diarrhea, abdominal pain, and chest pain.[57,58] Fever usually lasts for 1 to 2 weeks. Thirty percent to 50% of patients with a symptomatic infection will develop pneumonia.

One percent to 2% of people with acute Q fever die of the disease.[57,58] A small percentage of those infected will develop chronic Q fever (infection that persists for more than 6 months). Complications of chronic Q fever include endocarditis. As many as 65% of persons with chronic Q fever will die of the disease. Making the diagnosis of Q fever requires serologic testing, most commonly using the indirect immunofluorescence assay.[57,58] Doxycycline 100 mg twice daily for 15 to 21 days is the treatment of choice for acute Q fever.[57,58] Quinolone antibiotics may be an effective alternative.

Ricin Toxin

Ricin is a potent biologic toxin (toxic protein) derived from part of the waste when castor beans (*Ricinus communis*) are processed during manufacture of castor oil.[59] Ricin acts as a toxin by the inhibition of protein synthesis; 0.2 mg (1/5000th of a gram) is thought to be the lethal dose. Symptoms begin within 4 to 12 hours after exposure. Systemic effects of ricin poisoning will depend upon route of exposure and exposure dosage. Signs and symptoms from oral ingestions would include vomiting and profuse diarrhea; fever, myalgia and arthralgia, hallucinations, and seizures may occur.[59] Hypovolemic shock and multiorgan failure may occur, and would represent the likely cause of death.[59]

After an inhalational exposure, the symptoms could include cough, respiratory distress, and bronchoconstriction. Influenza-like symptoms (fever, myalgia, and arthralgia) may occur, as well as hypotension, respiratory failure, and multiorgan failure.[59] Few symptoms and signs exist to separate this from other causes of respiratory failure, though excessive diaphoresis has been reported and would be unusual in other causes. No specific treatment or antitoxin exists. Treatment consists of decontamination and supportive therapy.[59]

Nonpulmonary Agents (Gastrointestinal and Toxin)

Brucellosis (Brucella Species)

Brucellosis is caused by a number of species within the genus *Brucella.* Disease is naturally common in livestock workers, particularly in areas of poor sanitation, where *Brucella* is found in the natural reservoir of domesticated animals.[60] *Brucella* is a category B agent due to its low mortality and prolonged incubation period.[61] After exposure through ingestion of contaminated food or intentional aerosolization, symptoms would develop after a

few weeks to months. Initially fevers would persist irregularly over weeks to months, followed by arthalgias, gastrointestinal symptoms, and possibly endocarditis.[60] Diagnosis is an epidemiologic link with isolation of the organism by blood culture. However, growth is slow, so all cultures should be kept for 4 weeks if the diagnosis is suspected. Treatment is with doxycycline for up to 6 weeks, with trimethoprim-sulfamethoxazole for children.[60] There are unique infection control precautions.

Epsilon Toxin of Clostridium perfringens

The *Clostridium* species produce a vast amount of toxins, and epsilon toxin is produced by *Clostridium perfringens* types B and D.[62] The toxin acts directly on the cell membrane, producing pores that cause nonselective permeability. *Clostridium perfringens* uses the toxin to gain access into the bloodstream from the gut. However, in bioterrorism, intentional release via ingestion or inhalation of the toxin without bacteria is most likely.[63] Rapid ingestion or inhalation would cause diffuse tissue edema that would manifest as central nervous system dysfunction (weakness, ataxia, confusion), pulmonary edema (shortness of breath, cough, bronchospasm, respiratory failure), nausea, vomiting, tachycardia, and hypotension.[62] Diagnosis requires clinical suspicion consistent with a bioterrorism attack, and toxin can be detected by PCR. Treatment is supportive, with penicillin if *C. perfringens* is released at the same time.[62]

Food Safety Threats (e.g., Salmonella Species, Escherichia coli O157:H7, Shigella)

Enteropathogenic gram-negative bacteria, such as *Escherichia coli, Salmonella,* and *Shigella,* constitute a large group of agents that make up food supply threats.[64] Public health officials are very familiar with these bacteria from numerous episodes of food contamination yearly, leading to localized outbreaks and large product recalls. In an intentional release, these agents will produce widespread gastrointestinal symptoms leading to significant morbidity but with low mortality. After an incubation period of 3 to 7 days, abdominal cramping, nausea, vomiting, and diarrhea occur. The diarrhea may be voluminous and bloody.[64] Diagnosis is by stool culture of the agents, and an aggressive public health investigation usually yields the initial agent, as bioterrorism will resemble a point-source outbreak.[65] Treatment is intravenous hydration as needed and, with some agents (*Salmonella, Shigella*), antibacterial therapy with ciprofloxacin.[65]

Staphylococcal Enterotoxin B

Staphylococcal enterotoxin B is a toxin produced by *Staphylococcus aureus* and commonly associated with food poisoning. Symptoms of food poisoning include vomiting and diarrhea several hours after ingesting food.[66] Naturally occurring, it is rarely lethal. The clinical presentation would depend on the route of administration. Oral administration (poisoning of food or water supplies) would present as vomiting and diarrhea.[66] If inhaled, respiratory failure with neurotoxic effects may be seen.[66]

RECOGNITION AND DETECTION OF A BIOTERRORISM EVENT

The recognition of a bioterrorism event versus a naturally occurring infection is paramount and relies on a high suspicion on behalf of the clinician. However, this recognition is difficult in the early stages of disease when many of the category A agents present with nonspecific symptoms.[67] In addition, these agents have their highest contagiousness during this initial period before more specific clinical or diagnostic features arise, increasing the likelihood of spread to health care workers and the community. Therefore, a systematic approach is advocated initially in all febrile respiratory illnesses, with suspicion and public health contact occurring when specific clinical findings or epidemiologic features are detected that lead the clinician to suspect a bioterrorism or emerging infectious disease event.[1,68]

Figure 69-6 outlines an approach to early isolation, testing, and involvement of institutional infection control and public health in cases of acute febrile illness. Upon admission, cases of acute febrile illness and respiratory failure should undergo initial diagnostic testing, including pretreatment Gram stain, respiratory culture, and urine antigen testing for *Legionella.* If an etiologic agent is identified on initial screening and clinical findings (i.e., gram-positive diplococci with a lobar pneumonia on radiograph), targeted treatment is performed with appropriate isolation based on the pathogen. However, if an agent is not easily identified in a patient with acute febrile illness, patients should be placed in isolation and further diagnostic testing should be performed. Additionally, if multiple simultaneous cases with similar symptoms or a case with an uncommon epidemiologic link (e.g., food source) is determined, patient isolation and contact with public health should occur. If certain clinical features subsequently arise, then specific diagnostic testing should be performed and public health authorities alerted. If no clear etiology is detected, then further evaluation is warranted with more invasive and expansive testing. Although bronchoscopy generates aerosols and can increase transmission risk, it should not be avoided in these cases as isolation and etiology becomes important from a public health perspective. Contact with both the public health authorities and institutional infection control is paramount throughout the process and should occur as early as possible when clinical suspicion of bioterrorism arises or when diagnostic tests do not yield results.

Once a bioterrorism agent is suspected, confirmation is performed by the public health authorities. Initial cases must meet a case definition for the suspected agent (see www.cdc.gov/bioterrorism/casedef.asp) before further evaluation occurs. In order to meet the case definition, at least one critical and distinguishing feature must be met along with other clinical and laboratory

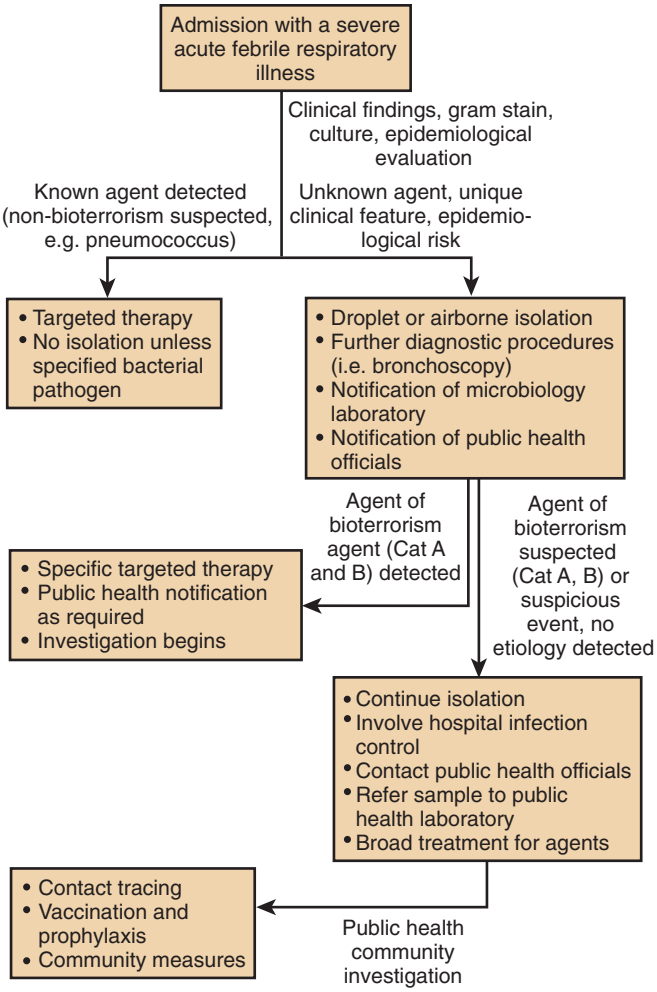

FIGURE 69-6 ■ General response to a febrile respiratory illness with respiratory failure.

features. After this stage, confirmatory diagnostic testing proceeds with selected methods that are usually performed at trained state or federal laboratories.

INFECTION CONTROL

Involvement of institutional infection control, microbiology, and public health should be started as early as possible. Ideally, notification should occur when one of four conditions is met: (1) a clinical or epidemiologic feature suggestive of bioterrorism (see Table 69-4), (2) an unexpected clinical link or increase in number of cases (e.g., pneumonia with respiratory failure), (3) if an extensive workup of a febrile respiratory illnesses has no direct results and an infectious disease is suspected, or (4) transmission of disease to health care workers occurs. Hospital-based infection control will assist in isolation and health care worker protection, and the hospital-based microbiology laboratory should be notified of suspected pathogens, allowing for worker protection and targeted testing of samples.[1,68] Finally, public health involvement will allow a broader bacterial, viral, and fungal testing, including subtyping and resistance testing. If the agent is a novel or emerging pathogen, as seen with SARS or avian influenza, early public health involvement will allow for rapid laboratory testing, epidemiologic investigation, case definition, and community prevention.

TABLE 69-9. Respiratory Care Procedures That Carry a Higher Risk for Disease Transmission in Patients with a CDC Category A Agent

Nebulization of medication
Endotrachial intubation
Nasotracheal suctioning
Noninvasive positive-pressure ventilation
Bag-valve-mask ventilation
Bronchoscopy
Humidified oxygen delivery
Non-rebreather mask without expiratory filter

The basic infection control requirements are outlined in Table 69-8. Anthrax and botulism are the only category A agents that are not contagious and do not require respiratory protection. If the number of cases exceeds the health care capacity for isolation, patient cohorting and accessory isolation measures can be used. Finally, higher risk procedures should be limited in these cases (Table 69-9). Aerosol-generating procedures are most common in ICU patients, and reducing unnecessary risky procedures will reduce patient and health care worker risk. However, these procedures should not be avoided if needed. Appropriate PPE should be worn by health care workers at all times, and if worn properly, disease transmission risk is low.[69]

PUBLIC HEALTH AND CRITICAL CARE RESPONSE

Acts of terrorism, such as conventional explosive devices or chemical attacks, result in a single point of mass casualties with an immediate critical area response. In contrast, as some of the category A agents are spread by contact and respiratory transmission, increasing cases will be seen after the initial outbreak. As these cases progress, the cumulative number of cases with severe respiratory illness will increase, putting stress on the critical care system and leading to a sustained need for emergency mass critical care (EMCC) from weeks to months. Sustained EMCC can lead to depletion of critical care resources, such as mechanical ventilation, specially trained staff, antibiotics and antivirals, and ICU bed capacity.[5] Thus, the unique issues associated with sustained EMCC have led to critical issues and advancements in planning and response to a bioterrorism or emerging infectious diseases outbreak.[70,71]

Recent consensus statements have recommended special critical care preparedness to include ICU capacity expansion, critical care resource storage, and the

coordination of critical care across communities to a regional and statewide level.[70,71] Capacity for critical care should be approximately three times normal ICU capacity, with all critically ill patients to be located in acute care hospitals (less severely ill patients will be diverted to alternate sites within the community). Each hospital should have enough supplies for 10 days per critically ill patient along with plans to have expanded care by non–critical care specialists in the case of a shortage.[72] ICU admission should be limited to the most severely ill (e.g., no observation). Most importantly, the identification of a triage mechanism is recommended for the allocation of scarce resources in sustained EMCC, with the most identified critical resource being mechanical ventilation and medical oxygen supply.[73] This triage mechanism would shift critical care from optimal care of the individual to optimal care for the population and would identify critically ill patients who may not get specific scarce resources during a period of limited supply in an outbreak. It would include inclusion and exclusion criteria for ICU admission along with a triage scoring mechanism for patient assessment. Recent publications have suggested the use of the Sequential Organ Failure Assessment (SOFA) score due to its use in sequential assessments and its ease of administration (less laboratory and data requirements). Additional triage scoring systems may be warranted in future outbreaks as disease and outbreak conditions change.

KEY POINTS

- Bioterrorism and emerging infectious diseases present unique and differing diagnostic and treatment options.
- Aggressive supportive care is the mainstay for all critically ill patients infected with a bioterrorism agent.
- Generally, many of the CDC category A agents present with a nonspecific prodrome that then develops into severe disease with specific epidemiologic hallmarks.
- The category B agents are very diverse but carry a lower morbidity and mortality, with a number of agents having few to no pulmonary manifestations.
- Early recognition relies on the astute clinician, with early involvement of public health and institutional infection control to reduce further spread to health care workers and the community.
- During an outbreak of a category A agent, mass critical care for a sustained period may be required, leading to depletion of critical patient care resources.

INTRODUCTION

Nearly 30 million people live at altitudes greater than 2500 m, primarily in the Rocky Mountains of North America, the Andes Mountains of South America, the Ethiopian Highlands of East Africa, and the Himalaya Mountains of south central Asia. These people have developed the ability to live and reproduce at elevations as high as 5000 m but, in some cases, develop chronic medical problems attributable to their high-altitude residence. In addition to long-term residents, many lowlanders venture to high altitude for work and recreation. These more acute exposures also pose the hazards of acute altitude illnesses or altitude-related exacerbations of preexisting diseases. With growing awareness of such risks, persons are seeking advice on traveling to these regions. It is, therefore, imperative that the counseling physician be able to provide guidance about minimizing risks and managing problems should they occur.

The purpose of this chapter is to review the normal adaptive processes that occur in response to high altitude, specifically the compensatory changes that occur in the transport of oxygen from the air to the tissues in the setting of decreased barometric pressure. We discuss acute and chronic adaptation and explore factors determining the limits of adaptation and performance at high altitude. We also review the consequences of maladaptation—the acute and chronic illnesses of high altitude—and discuss strategies for managing these situations. Finally, we present an approach to the traveler with underlying medical problems who is planning a trip to high altitude.

ADAPTATION TO HIGH ALTITUDE

Under normal conditions, the P_{O_2} diminishes as oxygen moves from air to the tissues. Ventilation, regional matching of ventilation and blood flow, diffusion of oxygen from the air to the blood, transport within the circulation, diffusion of oxygen from the blood into the tissue, and metabolism in the mitochondria are all links in this oxygen transport chain. As altitude increases, the barometric pressure declines (Table 70-1) and, as a result, the P_{O_2} at every step in this chain is lower than it would be at sea level. Compensatory processes occur at each step in the chain at different rates to raise the P_{O_2} and maintain adequate oxygen delivery and, thereby, facilitate tolerance of the hypoxic environment. As far back as Paul Bert, in the latter half of the 19th century, researchers have investigated the full spectrum of these adaptive responses. Hornbein and Schoene[1] and West et al.[2] have compiled extensive reviews of this vast literature, while West[3] has described the historic

TABLE 70-1. U.S. Standard Atmosphere: Altitude, Barometric Pressure, and Inspired Partial Pressure of Oxygen*

Altitude (meters)	Altitude (feet)	Barometric Pressure (mm Hg)	Inspired P_{O_2} (mm Hg)
0	0	760	159
1,000	3,280	674	141
2,000	6,560	596	125
3,000	9,840	526	110
4,000	13,120	463	97
5,000	16,400	405	85
6,000	19,680	354	79
8,000	26,240	268	56
8,848	29,028	253	43

*Values except 8,848 m are taken for mid-latitude (45°N). There is greater variation at higher altitudes.

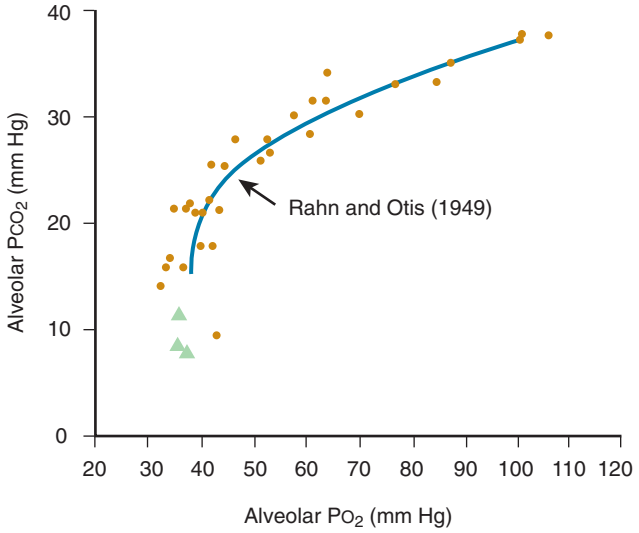

FIGURE 70-1 ■ Oxygen–carbon dioxide diagram demonstrating the alveolar gas composition in acclimatized subjects at high altitude. *Solid circles* represent data collected by Rahn and Otis (Rahn H, Otis B: Man's respiratory response during and after acclimatization to high altitude. Am J Physiol 157:445–449, 1949), while the *triangles* are measurements from three altitudes on Mt. Everest. At extreme altitudes, marked hyperventilation maintains alveolar P_{O_2} at approximately 35 mm Hg. (Redrawn from West JB, Hackett PH, Maret KH, et al: Pulmonary gas exchange on the summit of Mt. Everest. J Appl Physiol 55:678–687, 1983.)

achievements in the field. A summary of the key features of the adaptive responses to high altitude is provided in the following sections.

Pulmonary Adaptation

Control of Ventilation

Acute Response. Upon acute hypoxic exposure, alveolar ventilation increases. This response, referred to as the hypoxic ventilatory response (HVR), minimizes the drop in alveolar P_{O_2} (Fig. 70-1). There is interindividual variability in this response, which subsequently plays an important role in adaptation, maladaptation, and performance at high altitude. Large increases in ventilation are generally not seen until the arterial P_{O_2} falls below 60 mm Hg and, at any given altitude, ventilation continues to increase over weeks, in a process called ventilatory acclimatization. At extreme elevations, the increase in minute ventilation can be dramatic. Data obtained from a single individual on the summit of Mt. Everest (8848 m, barometric pressure ~253 mm Hg; see Fig. 70-1) revealed an alveolar P_{CO_2} of 7.5 mm Hg. As a result, despite an inspired P_{O_2} of only 43 mm Hg, the individual maintained an alveolar P_{O_2} of 34 mm Hg.

HVR is mediated in large part by peripheral chemoreceptors in the carotid body. Neural discharge from the whole carotid sinus nerve is related hyperbolically to decreasing arterial P_{O_2},[4] and surgical ablation of carotid body input (e.g., carotid endarterectomy or bilateral carotid body resection for intractable dyspnea) results in loss of the ventilatory response to acute hypoxia.[5]

The ventilatory response to a relatively constant hypoxic stimulus varies over time (Fig. 70-2). With initial exposure and the subsequent acute rise in minute ventilation, the arterial P_{CO_2} at the medullary and peripheral chemosensors decreases and depresses the ventilatory response.[6] Subsequently, over days, ventilation increases and continues to rise for months.[7] The classic explanation for this steady increase was that renal compensation for the respiratory alkalosis permitted full realization of the hypoxic stimulus to ventilation. However, measurement of blood pH reveals that hypocapnic alkalemia persists as ventilation increases, suggesting that other mechanisms beyond renal compensation, which is completed within 3 to 4 days, must be responsible for this change. It was proposed that a relative acidosis in the cerebrospinal fluid (CSF) and at medullary chemosensors trigger the increased ventilation, but lumbar CSF remains alkaline during high-altitude (3100 m) sojourns of up to 3 weeks, while during deacclimatization, hyperventilation persists even when arterial P_{CO_2} and blood and CSF pH have returned toward normal.[8] The pH of interstitial and intracellular fluid in the brain has also failed to show changes that could account for the increase in ventilation.[9] These results suggest that some mediator(s), other than hydrogen ion, sustain the hyperventilation during a high-altitude sojourn. One possible mediator may be erythropoietin (EPO) signaling in the brain via EPO receptors.[10] Another factor that promotes progressive hyperventilation is an increase over time in carotid body sensitivity to hypoxia.[11]

Intermittent Hypoxic Exposure. The sustained increase in ventilation described in the previous section generally pertains to exposures lasting days to weeks.

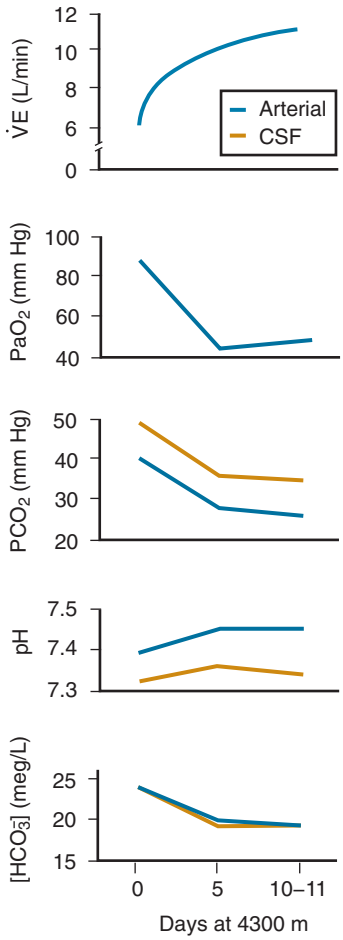

FIGURE 70-2 ■ Ventilatory acclimatization during a 10- to 11-day sojourn to 4300 m. Ventilation continues to increase as cerebrospinal fluid (CSF) acid-base alterations parallel plasma changes. HCO_3, bicarbonate; Pa_{O_2}, arterial oxygen tension; P_{CO_2}, carbon dioxide tension; $\dot{V}_E$, minute volume of ventilation. (Redrawn from Forster HV, Dempsey JA, Chosy LW: Incomplete compensation of CSF [H+] in man during acclimatization to high altitude [4300m]. J Appl Physiol 38:1067–1072, 1975.)

Shorter, intermittent exposures also affect ventilatory responses to both oxygen and carbon dioxide.[12] Studies have focused on the "dose" and frequency of the hypoxic stimulus necessary to induce a physiologic response. For example, 8 hours of exposure to isocapnic and poikilocapnic hypoxia (end-tidal P_{O_2} = 55 mm Hg) increases the chemosensitivity to carbon dioxide compared to controls,[13] while exposure to a simulated 4500-m altitude for 1 hr/day was associated with increased HVR, ventilatory equivalents ($\dot{V}_E/\dot{V}_{O_2}$), and arterial oxygen saturation (Sa_{O_2}) during postexposure hypoxia.[14]

Chronic Ventilatory Adaptation. Long-term high-altitude residents have lower minute ventilation and higher arterial P_{CO_2} than acclimatized lowlanders at the same elevation and have blunted ventilatory responses to acute hypoxia.[15] The blunted response occurs in conjunction with hypertrophy of the carotid bodies and may be an adaptive phenomenon in which the disadvantage of the lower arterial P_{O_2} is offset by the decreased energy expenditure associated with lower ventilation.

Pulmonary Function and Mechanics

On ascent, several changes occur in lung function. Vital capacity decreases in the first 24 hours and remains depressed over time at high altitude.[16] Proposed mechanisms for this observation include increased interstitial fluid volume, resulting in airway narrowing, air trapping, and delayed emptying of some lung units,[16] pulmonary vascular engorgement,[17] and decreased respiratory muscle strength.[18] Peak expiratory flow rates are increased and airway resistance is reduced.[19] The lower airway resistance is presumably due to decreased air density, which counteracts any airway narrowing that might occur due to hypoxia and hypocapnia.

In high-altitude residents, vital capacity is increased compared to non-native residents,[20] with the magnitude of the increase dependent on the length of stay at high altitude. Those born and raised at high altitude develop larger vital capacities than those who move to high altitude later in life.[21]

Gas Exchange

Ventilation and Perfusion Matching. The increase in ventilation during acute hypoxia is matched by increased cardiac output and pulmonary perfusion. Additionally, alveolar hypoxia triggers hypoxic pulmonary vasoconstriction (HPV), which increases pulmonary vascular resistance. These changes cause redistribution of blood flow to areas of the lung that are usually less well perfused at sea level and may, thereby, improve ventilation-perfusion matching ($\dot{V}_A/\dot{Q}$) and optimize gas exchange.

Diffusion. Several factors limit diffusion of oxygen from the alveolus to the blood at high altitude. Decreasing barometric pressure lowers the alveolar P_{O_2}, which, in turn, decreases the pressure gradient for diffusion such that, at altitudes above 2500 m, even the estimated pulmonary transit time at rest of 0.75 second may not be adequate for end-capillary equilibration of oxygen to occur; diffusion limitation is exacerbated during exercise due to the shortened transit time of blood across the pulmonary capillary and the fall in mixed venous P_{O_2}. Because the low arterial P_{O_2} lies on the steep portion of the oxygen-hemoglobin dissociation curve, a small decrease in P_{O_2} will result in a proportionately greater drop in pulmonary capillary oxygen content than occurs at sea level. West and Wagner[22] modeled these factors for the summit of Mt. Everest (barometric pressure ~250 mm Hg) and found that alveolar-capillary equilibration of oxygen is far from complete (Fig. 70-3).

With long-term residence at high altitude, the diffusing capacity of the lung increases, although the mechanism remains unclear. When compared to sojourners, high-altitude residents have a lower alveolar-arterial P_{O_2} difference, increased diffusing capacity, and, despite having lower minute ventilation, a higher arterial P_{O_2} at rest and during exercise.[23,24]

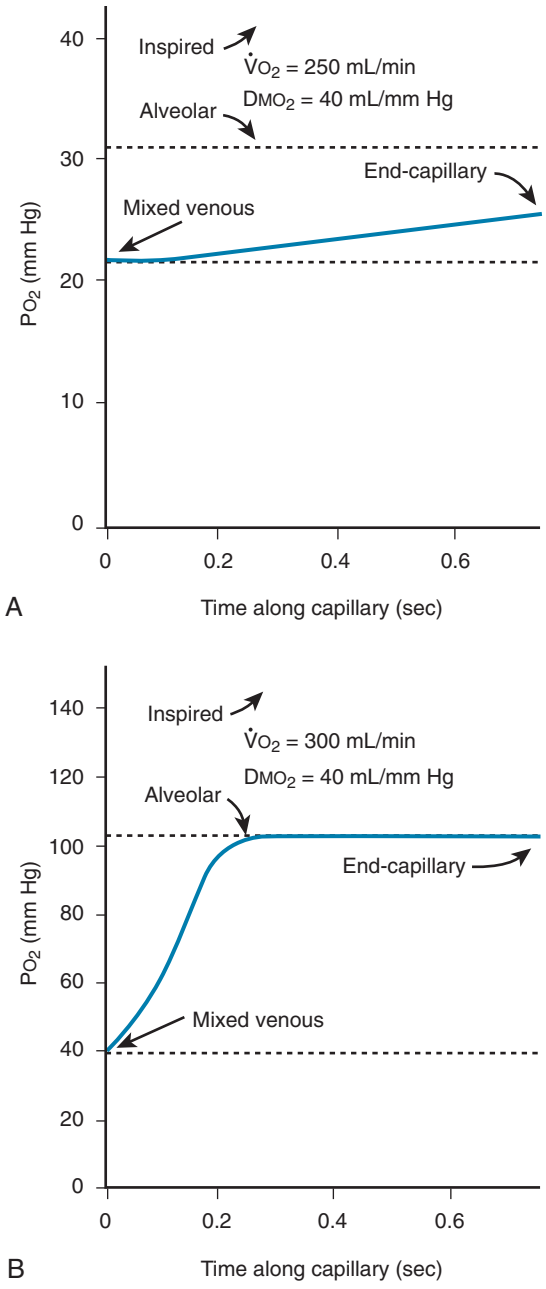

FIGURE 70-3 ■ Comparison of the calculated time course of oxygen tension (P_{O_2}) in the pulmonary capillary of a climber at rest on the summit of Mt. Everest (**A;** barometric pressure = 250 m, inspired P_{O_2} = 43 mm Hg) to sea-level values (**B;** barometric pressure = 760 mm Hg, inspired P_{O_2} =150 mm Hg). At sea level, there is adequate time for equilibration of alveolar and end-capillary oxygen, whereas at extreme altitude, even at rest, when transit time for the red blood cell is presumably similar to that at sea level, full equilibration is not realized, resulting in end-capillary blood that is not fully saturated. DMO_2, diffusion capacity of the alveolar capillary membrane; $\dot{V}O_2$, oxygen consumption. (Redrawn from West JB, Wagner PD: Predicted gas exchange on the summit of Mt. Everest. Respir Physiol 42:1–16, 1980.)

Cardiovascular Adaptation

Cardiac Response

With acute hypoxia and decreased arterial oxygen content, cardiac output increases in an effort to maintain oxygen delivery, such that for any given work rate, cardiac output is higher than at sea level. After about 1 week, the relationship between cardiac output and work rate returns to that seen at sea level. The increase in cardiac output is driven largely by an increase in heart rate rather than a change in stroke volume. Stroke volume declines upon initial exposure to high altitude and remains lower than sea level values despite acclimatization. This is not due to depressed myocardial function, as studies reveal evidence of preserved cardiac contractility in hypoxia,[25] and, instead, is likely due to diminished preload from a reduction in plasma volume. Systemic blood pressure is elevated in sojourners upon acute exposure to high altitude, likely due to increased sympathetic activity,[26] but decreases over time. In fact, in as little as 1 to 2 years after moving to high altitude, many people have lower systemic pressure, likely secondary to a vasodilatory effect of hypoxia on systemic arterial smooth muscle.

Hemodynamic Response

At high altitude, the low alveolar P_{O_2} triggers vasoconstriction in the pulmonary vasculature, a response known as *hypoxic pulmonary vasoconstriction.* Pulmonary artery pressure increases minimally until the alveolar P_{O_2} drops below 70 mm Hg, at which point a more marked rise ensues (Fig. 70-4). There is, however, substantial interindividual variability in this response,[27] part of which may be explained by the differences in iron stores between individuals.[27a]

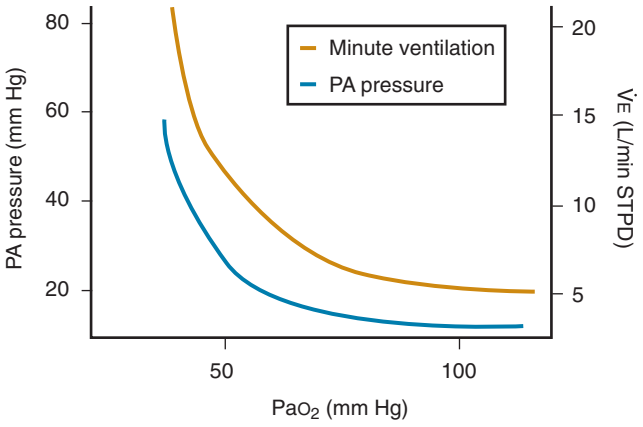

FIGURE 70-4 ■ Relationship of arterial oxygen tension (Pa_{O_2}) to minute ventilation ($\dot{V}_E$) and pulmonary arterial pressure (PA). Although there is variability among individuals, both the ventilatory and the pulmonary vascular response do not increase until Pa_{O_2} falls below 70 mm Hg. (Redrawn from Reeves JT, Wagner WW Jr, McMurtry F, et al: Physiological effects of high altitude on the pulmonary circulation. *In* Robertshaw D [ed]: International Review of Physiology: Environmental Physiology III. Baltimore: University Park Press, 1979, pp 289–310.)

Chronic hypoxic exposure results in even greater increases in pulmonary vascular resistance and pulmonary hypertension due to pulmonary vasoconstriction, hyperviscosity from polycythemia, and extensive vascular remodeling due to smooth muscle hypertrophy and collagen hyperproliferation. The precise time course of these changes is not clear. Groves et al.[28] exposed individuals to progressively lower inspired oxygen tensions during a simulated ascent of Mt. Everest (Operation Everest II) over a 40-day period and found that upon breathing a fractional concentration of oxygen in inspired gas (FIO_2) of 1.0, pulmonary artery pressures did not return to their sea-level baseline. This result suggests that some vascular remodeling had occurred in just a few weeks. Depending on the severity of changes, particularly the degree of intimal fibrosis, reversal of pulmonary hypertension may require months or years at low altitude.

Hematologic Adaptation

Erythropoietic Response

Hemoglobin concentration increases within 1 to 2 days of ascent and continues to rise for a number of weeks. The initial rise is due to hemoconcentration from the diuresis that occurs upon initial ascent; further changes are due to increased red blood cell production, which occurs as a result of hypoxia-mediated release of erythropoietin by the kidneys. Serum erythropoietin levels increase within 24 to 48 hours of ascent to high altitude, and then decline over 3 weeks as acclimatization progresses.[29] Both red blood cell volume and total blood volume increase. The erythropoietic response ceases on descent and the hematocrit returns to sea-level values in approximately 3 weeks.

Although the hematocrit generally increases with altitude, there is interindividual variability in the responses of both sojourners[30] and highlanders.[31] Similar variability is seen between different highland populations; Andean natives demonstrate greater erythropoiesis than either Himalayan or Ethiopian highlanders.[32] Whether the greater erythropoiesis in Andean natives is secondary to environmental exposures, such as high levels of cobalt in and around mining regions,[33] or to an up-regulation of the erythropoietic response to the renal sensing of hypoxia[34] is not clear.

While increasing hemoglobin concentration can augment arterial oxygen content, it may also impair oxygen delivery because, as the hematocrit approaches 60%, viscosity increases sufficiently to impair cardiac output.

Oxygen-Hemoglobin Affinity

Oxygen transport by blood is also influenced by the oxygen affinity of hemoglobin, as defined by the shape and position of the oxygen-hemoglobin dissociation curve. An important feature of the oxygen-hemoglobin relationship is the manner in which the dissociation curve steepens as the arterial PO_2 falls below 60 mm Hg. As a result, with ascent to high altitude, the arterial PO_2 falls into a range in which the oxygen content of hemoglobin drops precipitously with only small decreases in PO_2.

To mitigate the potentially large impact on oxygen delivery, adaptations occur in the oxygen-hemoglobin relationship. For example, with initial exposure to high altitude and the resultant respiratory alkalosis, the dissociation curve shifts to the left. This shift enhances oxygen loading in the lungs and increases arterial oxygen content but comes at the expense of potentially decreased oxygen off-loading in the tissues. Over time, the curve shifts back to the right in response to increased 2,3-diphosphoglycerate (2,3-DPG) concentrations and renal compensation for the respiratory alkalosis and improves oxygen off-loading in the tissues.

Coagulation

Studies at high altitude do not show consistent patterns of change in hemostasis, with conflicting results regarding the effect of high altitude on platelet counts, bleeding times, and markers of thrombin and fibrin formation.[35,36] Changes such as increased fibrinogen levels and prolonged clot lysis times have been noted in patients with high-altitude pulmonary edema (HAPE),[37] and taken as evidence that thrombosis and platelet aggregation may contribute to this disease. However, Bartsch et al.[38] performed careful longitudinal studies while subjects were developing HAPE and concluded that platelet and coagulation changes were epiphenomena and had no causative role. There may be a link between underlying coagulopathy and thromboembolic risk at altitude,[39] but more work is necessary on this question.

Tissue Adaptation

At the final stage of oxygen delivery, oxygen moves from plasma to the site of oxidative phosphorylation in the mitochondria. While driving pressures of only 1 to 2 mm Hg are necessary for diffusion from cytoplasm to the mitochondria, driving pressures of 10 mm Hg may be needed for movement from capillary plasma to the cytoplasm. At sufficiently high altitudes, the capillary PO_2 may fall to levels at which diffusion into the mitochondria is impaired. Morphologic and biochemical responses occur to overcome this problem. In general, evidence points to reduced diffusion distance from blood to mitochondria in muscle due to diminished fiber size, increased myoglobin concentration, and changes in the levels or activity of enzymes involved in oxidative metabolism. Finally, recent evidence indicates that cytoglobins, heme proteins expressed in many cells that have oxygen binding and transport characteristics similar to myoglobin, may be up-regulated in hypoxia and play a role in adaptive responses.[40]

Central Nervous System Adaptation

Cerebral Blood Flow

On acute exposure, hypoxia triggers an increase in cerebral blood flow that is, in part, offset by hypocapnic-

mediated cerebral vasoconstriction; the net result is a modest increase in cerebral blood flow,[41] which appears to be equally distributed between white and gray matter.[42] The acute cerebrovascular response may be biphasic in nature, with an initial decrease in cerebral blood flow due to acute hypocapnia followed by a subsequent increase triggered by arterial hypoxemia.[43] After 4 to 5 days, cerebral blood flow decreases but is still 13% greater than the sea-level value.[41] This increase in cerebral blood flow helps maintain oxygen delivery when arterial oxygen content is at its lowest until other adaptive mechanisms take effect and raise arterial oxygen content.

Cerebral Function

As one ascends, motor, sensory, and complex cognitive abilities are progressively impaired. New tasks are learned with difficulty at 3048 m, and simulated altitudes of 6100 m result in a decrement in sensory, perceptual, and motor performance. Short-term memory is impaired in climbers ascending without supplemental oxygen to 8500 m or higher.[44] Even acute, modest decreases in Sa_{O_2} to 85% impair mental concentration and fine motor coordination; a further decrease to 75% results in poor judgment, irritability, and decreased muscle function.

It is difficult to predict which individuals will experience neurologic dysfunction at high altitude, but combined data from a field study on Mt. Everest and a chamber study simulating an ascent of Mt. Everest (Operation Everest II) demonstrated that individuals with a high HVR and higher Sa_{O_2} had more pronounced neuropsychometric dysfunction.[45] One explanation for these findings is that those with a more brisk HVR might have greater hypocapnic cerebral vasoconstriction and, consequently, lower cerebral oxygen delivery.

A recent study in which brain magnetic resonance imaging (MRI) was performed on climbers who had ascended to summits between 5895 and 8848 m[46] demonstrated evidence of subcortical lesions suggestive of small infarctions. The study did not correlate these findings with symptoms or signs of neurologic dysfunction and did not include follow-up studies to determine if these lesions resolved, but the results raise the question as to whether high-altitude exposure causes permanent cerebral injury and whether the observed dysfunction at high altitude persists over time. Existing evidence suggests that the transient deterioration in learning, memory, and expression of verbal material returns to baseline within 1 year but that fine motor coordination problems may persist for longer periods of time.[45,47]

Cellular Adaptive Mechanisms

As with cytoglobin up-regulation in peripheral tissues, intracerebral expression of neuroglobin, another protein related to hemoglobin and myoglobin, is increased during hypoxic stress and may play a role in limiting neuronal injury.[48]

Fluid Homeostasis and Renal Function

Upon ascent to high altitude, diuresis and natriuresis occur and, as with the hypoxic ventilatory response, these peripheral chemoreceptor-mediated responses vary almost 10-fold between individuals over the first 24 to 48 hours at altitude.[49] Following acclimatization, further gains in elevation may lead to additional diuresis and natriuresis.[50] The mechanism underlying this observed diuresis and natriuresis is not clear, but it does not appear to result from changes in renin, angiotensin, aldosterone, or atrial natriuretic peptide levels. Acute hypoxia causes a two- to threefold increase in urinary protein excretion, with even higher levels seen in persons who develop high-altitude illness.

CHANGES IN COMMON SEA-LEVEL ACTIVITIES AT HIGH ALTITUDE

Sleep

Difficulty sleeping is a common problem at high altitude. In studies examining pharmacologic prophylaxis of acute mountain sickness (AMS), for example, over 70% of people receiving placebo reported poor quality sleep.[51] There is also objective evidence of impairment, increased arousals, sleep architecture changes, and an increased incidence of periodic breathing.[52] In addition, the most severe hypoxemia experienced by both sojourners and natives occurs during sleep, as steep, transient drops in oxygen saturation often accompany apneic periods.

The mechanisms underlying periodic breathing at high altitude have been reviewed elsewhere.[53] The consensus is that sleep eliminates most cortical influences on respiration, leaving hypoxemia via carotid chemoreceptors as the prominent drive. The effect of hypoxia-induced changes in P_{CO_2} on hypoxic drive may set up oscillations of ventilation in a poorly damped system. At moderate altitudes (<3000 m), this periodic breathing diminishes over several days as ventilatory acclimatization proceeds, but at higher altitudes periodic breathing persists for long periods of time.[54]

Periodic breathing during sleep at high altitude can be eliminated by breathing supplemental oxygen (Fig. 70-5) and can be reduced through the use of respiratory stimulants such as acetazolamide.[55] A review of trials of acetazolamide in AMS prophylaxis demonstrated that sleep was also improved in the acetazolamide groups compared to the placebo groups.[51,56] More recently, the benzodiazepine temazepam has also been shown to reduce the incidence of periodic breathing and improve measures of sleep quality without a negative effect on next-day reaction times or maintenance of wakefulness.[54] γ-Aminobutyric acid receptor agonists, including zolpidem and zaleplon, can also improve sleep quality and sleep architecture, but there is no evidence that either agent decreases periodic breathing.[57]

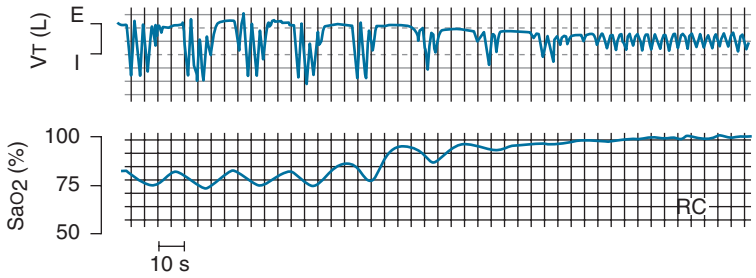

FIGURE 70-5 ■ Periodic breathing in a lowlander at 5400 m during sleep while breathing ambient air (*left half of tracings*) and oxygen (*right half of tracings*). *Upper panel* is tidal volume (V_T, inspiration downward), and *lower panel* is arterial oxygen saturation (Sa_{O_2}, %). (Redrawn from Lahiri S, Maret K, Sherpa MG: Dependence of high-altitude sleep apnea on ventilatory sensitivity to hypoxia. Respir Physiol 52:281–301, 1983.)

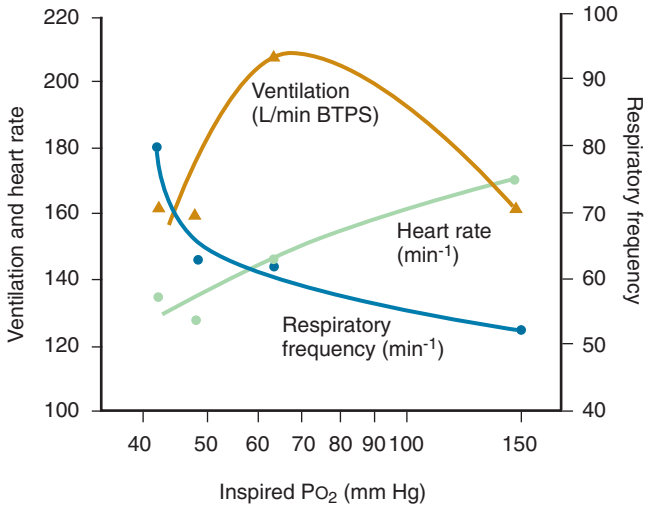

FIGURE 70-6 ■ Maximum minute ventilation ($\dot{V}_{E_{max}}$), respiratory frequency, and heart rate versus inspired P_{O_2}. At 6300 m, $\dot{V}_{E_{max}}$ is increased because of the stimulation to ventilation from hypoxia as well as a decreased density of the inspired air, whereas at over 8000 m, $\dot{V}_{E_{max}}$ is decreased, probably as a result of a diminished metabolic demand from low work rates. Frequency continues to increase. Maximum heart rate decreases with increasing altitude. (Redrawn from West JB, Boyer SJ, Graber DJ, et al: Maximal exercise at extreme altitudes on Mount Everest. J Appl Physiol 55:688–702, 1983.)

Exercise

Exercise at high altitude is different in many important respects from exercise at sea level.

Maximal Work

With acute and prolonged hypoxic exposures, maximal oxygen consumption ($\dot{V}_{O_2}$ max) and work capacity are decreased relative to sea-level values.[58,59] $\dot{V}_{O_2}$ max decreases about 10% per 1000 m of altitude gain, such that at approximately 0.5 atm, $\dot{V}_{O_2}$ max is about half of its sea-level value, and at 0.33 atm (as at the summit of Mt. Everest), $\dot{V}_{O_2}$ max is about 23% of that at sea level. Because maximum oxygen uptake is decreased at altitude, maximum minute ventilation and heart rate at peak exercise are also reduced compared to their sea-level values (Fig. 70-6).[58,59]

Ventilation

Because of the decrease in air density and the lower concentration of oxygen molecules, greater minute ventilation is required to achieve the same oxygen uptake at high altitude. As a result, the ventilatory response to exercise is augmented at altitude compared to sea level.[58,60] For example, the ventilation for a given metabolic rate (the ventilatory equivalent, $\dot{V}_E/\dot{V}_{O_2}$) in sojourners to 6300 m is almost four times as great as at sea level. The increase is a function of both the altitude attained and the strength of the individual's HVR.[60] The increase in ventilation comes at a price, however. The oxygen cost of breathing during exercise at extreme altitude may be as high as 40% of the overall metabolic rate at high levels of exercise and may result in allocation of cardiac output to respiratory muscles that could otherwise be dedicated to muscles of locomotion. Subjects also often experience extreme dyspnea that may affect the intensity and duration of exercise. Rest leads to rapid resolution of dyspnea in normal individuals, however.

Gas Exchange

Unlike at sea level, where arterial oxygen saturation remains constant with increasing work loads in most normal individuals, it decreases with increasing workloads following either short-duration[61] (Fig. 70-7) or long-duration high-altitude exposures.[58] Alveolar hypoxia decreases the driving gradient for diffusion, while pulmonary capillary transit time is shortened as a result of the increase in cardiac output, thereby creating a true diffusion limitation (see Fig. 70-3). $\dot{V}_A/\dot{Q}$ mismatching may also contribute to the observed gas exchange abnormalities[61]; nonuniform hypoxic pulmonary vascular response may lead to interstitial pulmonary fluid accumulation that, in turn, creates $\dot{V}_A/\dot{Q}$ heterogeneity and impairs gas exchange.

Cardiovascular Response

For any given submaximal work rate, cardiac output and heart rate are higher during exercise at altitude compared to sea level. Because maximum exercise capacity is reduced, peak heart rate and cardiac output are reduced relative to sea-level values. With acclimatization, cardiac output at submaximal workloads returns to sea-level values while heart rate remain elevated. Because maximum exercise capacity is not restored to sea-level

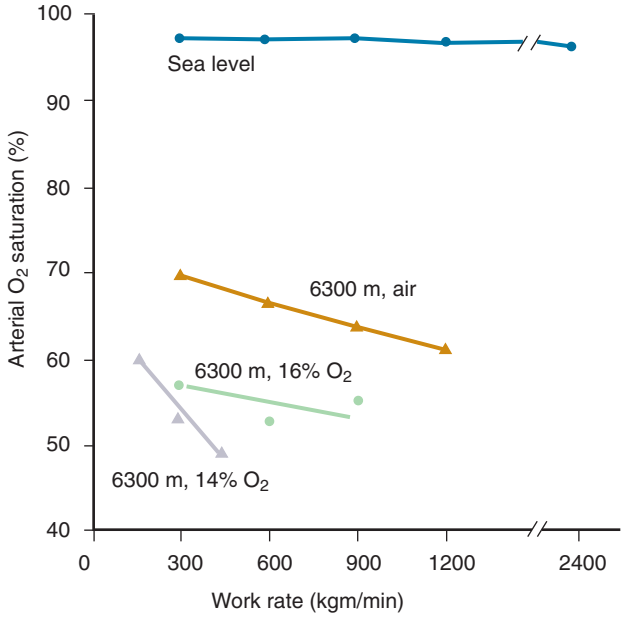

FIGURE 70-7 ■ Arterial oxygen saturation (%) does not decrease with exercise at sea level but drops progressively with higher workloads at greater altitudes due to a diffusion limitation of oxygen transfer across the alveolar-capillary interface. (Redrawn from West JB, Boyer SJ, Graber DJ, et al: Maximal exercise at extreme altitudes on Mount Everest. J Appl Physiol 55:688–702, 1983.)

values over time, maximum cardiac output, heart rate, and stroke volume all remain decreased following prolonged exposure.[25]

Pulmonary artery pressures reach high levels during exercise at high altitudes.[28] Whether these high pressures limit exercise capacity at altitude is not clear. On the one hand, because cardiac output is maintained at levels appropriate for the work rates attained, the increase in pulmonary vascular resistance in healthy sojourners to high altitude would not appear to limit exercise. However, in a recent field study of acclimatized individuals,[62] administration of the phosphodiesterase inhibitor sildenafil prior to a maximum exercise test at 5245 m improved pulmonary artery systolic pressure and maximum exercise capacity compared to placebo, but others have not confirmed this.[63,63a] Thus, it remains unresolved whether the rise in pulmonary artery pressures contributes to limiting exercise capacity at high altitude.

Exercise Performance at High Altitude

The effect of altitude on exercise performance varies based on the type of activity and the duration of stay at high altitude. Performance for running events of less than 2 minutes' duration at less than 3000 m altitude is not impaired and may even be slightly improved because of decreased air density. Performances in events of longer duration are predictably diminished and cannot be restored to sea-level capacity with prolonged stay at high altitude. Some improvements do occur with time, but overall performance does not return to sea-level values. Finally, as noted earlier, maximum oxygen consumption, peak heart rate, and peak minute ventilation are reduced at high altitude. Regardless of the duration of stay or the intensity of training, these values do not return to sea-level values.

Training at High Altitude

There is considerable interest in whether living and training at high altitude improves performance at lower elevations. In the past, many elite endurance athletes relocated to and trained at moderate altitudes of 2000 to 2500 m, but, unfortunately, the beneficial effects on performance after return to sea level were generally not realized, as athletes could not attain the same maximum speeds and power output during training at altitude that they needed to reach during their sea-level races. More recently, interest has been raised in using intermittent hypoxic exposure as an alternative means to apply the benefits of high-altitude acclimatization to sea-level performance. Beidleman et al.,[64] for example, found that intermittent exposure to 4300 m for 3 weeks improved ergometrics and strength in trained cyclists. In their landmark study, Levine and Stray-Gundersen[65] studied four well-matched groups of athletes: (1) those who lived low and trained low (1350 m), (2) those who lived low and trained high (3000 m), (3) those who lived high and trained high, and (4) those who lived high and trained low. The group that lived high and trained low seemed to have gained the benefit of hypoxic conditioning while not losing the intensity of training sessions. This advantage was presumably due to the modestly elevated hemoglobin from the altitude exposure, although there was individual variability in the erythropoietic response.[66]

Because of the limited access to high altitude for many athletes, recent interest has focused on "bringing the mountain to the athlete"[67] by having the athlete spend time each day in an oxygen-depleted tent that can be set up in the home or training center. The key question that has emerged from this practice and the studies noted previously, however, is what "dose" of hypoxic exposure is necessary to see a benefit in sea-level performance. A recent review of studies on the topic concluded that athletes needed to reside at 2000 to 2500 m for more than 4 weeks for greater than 22 hr/day in order to derive physiologic benefits from the live high–train low model.[67]

MALADAPTATION

The physiologic adaptations described previously give individuals the ability to tolerate high-altitude exposure. Whereas a person who makes a sudden ascent from sea level to the summit of Mt. Everest (8848 m) by helicopter, for example, would become unconscious within minutes and die soon thereafter, a climber using an appropriately slow ascent rate can complete the climb without obvious effects because the body adapts to the hypoxic environment. Regardless of the ultimate altitude achieved,[11] individuals who ascend too rapidly to altitudes above 2500 m may display maladaptive responses

and develop one of three forms of acute altitude illness: acute mountain sickness (AMS), high-altitude pulmonary edema (HAPE), and high-altitude cerebral edema (HACE). Because the risk of such illnesses decreases as individuals spend more time at altitude, long-term residents are not susceptible to these problems. However, several forms of chronic altitude illness, chronic mountain sickness, and right heart failure can affect these populations and represent important public health concerns.

Problems of Lowlanders on Ascent to High Altitude

Susceptibility to Altitude Illness

The incidence and severity of acute altitude illness depend on several factors, including the rate of ascent, the length of stay, and individual susceptibility. A trip to and from high altitude on the same day poses much less risk than an overnight stay because hypoxia is accentuated during sleep and because of more prolonged exposure associated with the overnight stay. Susceptibility to altitude illness varies considerably between individuals, but for a single individual the symptoms are often reproducible given the same rate of ascent and other circumstances. Whereas men and women are equally susceptible to AMS,[68,69] younger adults[68] and the obese[69,70] may be slightly more vulnerable to AMS. Recent trips to high altitude,[71] and residence at moderate altitude (>1900 m),[72] have a protective effect. Of note, being in good physical condition does not exert any protective effect.[73] There are insufficient data regarding whether preexisting illnesses increase susceptibility.

At present, there are no means to predict who will get sick upon ascent to high altitude. Variables such as HVR[74] and arterial oxygen saturation during hypoxic exposure[75] have been proposed as useful predictors for developing AMS, but have not been validated in further studies, and genetic differences such as the ACE gene polymorphism have no prognostic value.[76,76a] HAPE-susceptible individuals have been shown to have intense HPV and exaggerated pulmonary vascular responses to resting hypoxia and normoxic exercise[27,77] but this relationship has not been validated in prospective studies. In the end, the only useful predictive tool remains the patient's prior experience at high altitude, particularly when the ascent rate and altitude of the prior and planned sojourns are similar.

Acute Mountain Sickness

AMS is the most common form of acute altitude illness, affecting 22% to 50% of travelers to altitudes between 1850 and 4240 m.[68,69]

Clinical Presentation. AMS is marked by the presence of headache plus one or more other symptoms, including lassitude, insomnia, anorexia, nausea, dizziness, and, in severe cases, vomiting. Symptoms do not start immediately upon ascent but, instead, come on over many hours following arrival at altitudes above 2400 m (8000 feet), although the elevation at which symptoms begin varies between individuals. Affected persons frequently have difficulty sleeping and wake up the following morning with a severe headache. Although many people complain of a sense of oppression in the chest, there is rarely any respiratory distress or tachypnea so long as the patient is at rest.

On physical examination, many individuals manifest tachycardia, although a relative bradycardia has been documented in some case series.[78] Patients often appear slightly cyanotic with a dull, heavy look in their eyes. Localized crackles are present in 25% to 35% of the cases.[78] Decreased urine output in spite of adequate hydration and evidence of fluid retention may also be present.[68]

The symptoms and signs of AMS are nonspecific, and other items must be considered in the differential diagnosis, including dehydration, hypothermia, exhaustion, alcohol hangover, carbon monoxide poisoning, and respiratory or cerebral infections. The diagnosis is based solely on the clinical history, and there are no confirmatory laboratory tests. In order to say the person has AMS and not the more severe HACE, the patient must have normal neurologic and mental status examinations.

Natural Course of Untreated AMS. In a study of Indian soldiers[78] airlifted to 3300 to 5500 m, incapacitating illness lasted 2 to 5 days but full recovery often took longer; 38% recovered fully within 3 days, 40% were still ill after 1 week, and 13% had symptoms after 1 month. In tourists sleeping at a lower altitude (2700 m), symptoms lasted an average of 15 hours (range, 6 to 94 hours).[79] Most individuals tolerate or treat their own symptoms as the illness resolves over 1 to 3 days, but some persons with AMS seek medical help or are forced to descend. A small percentage of those with AMS (2% to 8%) proceed to develop HACE or HAPE, especially if ascent is continued in spite of illness.

Pathophysiology. Current concepts of pathophysiology emphasize the cerebral etiology of AMS. In very severe illness, elevated intracranial pressure and cerebral edema have been noted on neurologic imaging[80] and brain biopsy.[78] Brain MRI studies have demonstrated swelling in the white matter and none in the gray matter in patients with HACE,[80] a finding that suggests the edema is vasogenic in origin and initially confined to the white matter. Patients with AMS appear to have slightly increased brain volume (0.8% vs. 0.4%) and decreased intracerebral CSF volume by MRI versus those without symptoms.[81] Subsequent studies revealed conflicting data, with some reporting no evidence of changes consistent with cerebral edema[82] and others showing evidence of mild increases in brain volumes and evidence of cytotoxic edema in subjects with mild to moderate AMS.[83] It has been suggested that development of AMS may depend to some extent on the ability to shift CSF out of the cranium, and those individuals with smaller total CSF volumes may be at a disadvantage. This argument, referred to as the "tight-fit" hypothesis, might explain the possible difference in susceptibility between younger and older persons, as age-related increases in volume of sulci in the latter group may provide more room to accommodate mild brain swelling.[84]

Although the available evidence suggests cerebral edema plays a role in severe AMS, it remains unclear whether this causes milder forms of the disease. There is only one study of intracranial pressure in subjects with early AMS, and it failed to demonstrate an increase in CSF pressure.[84] Because headaches occur in early AMS at a time when edema and significant increases in intracranial pressure are unlikely, alternative explanations should be considered. The classic explanation that the headache and other symptoms of AMS are due to cerebral vasodilation alone seems unlikely, as attempts to link AMS symptom severity with middle cerebral artery blood flow velocity have shown no correlation.[85] Limited evidence that sumatriptan, a 5-hydroxytryptamine$_1$ receptor agonist, can prevent AMS[86] or treat high-altitude headaches[87] suggests that abnormal cerebrovascular reactivity or neuropeptide responses play a role in AMS pathophysiology. Another explanation is that hypoxia-induced changes in the blood-brain barrier alter permeability to plasma compounds with potential neurotoxicity or irritation. Studies in animals and cell cultures have established hypoxic-mediated increased permeability of the blood-brain barrier to large molecules, but this has not been observed in humans.[83] The mechanism underlying these blood-brain barrier changes is unclear, but factors such as oxygen free radical species and vascular endothelial growth factor have been proposed as possible explanations.[88,89]

The findings in severe AMS of possible cerebral edema, peripheral edema, and proteinuria also suggest there may be a defect in salt and water homeostasis, and an increase in capillary permeability. AMS-susceptible individuals have elevated aldosterone and antidiuretic hormone levels when compared with controls, while persons acclimatizing well exhibit diuresis, net water loss, and low antidiuretic hormone values.[90] A recent study confirmed the findings regarding antidiuretic hormone but found no difference in aldosterone levels between healthy controls and those with AMS.[91] These alterations in hormone levels cannot be attributed to a generalized increase in systemic capillary permeability or endothelial cell dysfunction, as subjects with and without AMS demonstrate no differences in the global transvascular escape of labeled protein.[92]

Hypoventilation may also contribute to the development of AMS. Acetazolamide and theophylline, two medications with respiratory stimulant properties, prevent the disorder,[56,93] while a brisk increase in ventilation on ascent to altitude has been associated with a lower incidence of AMS.[74] At the same time, however, prospective studies have not demonstrated a correlation between HVR measured prior to ascent and the development of AMS at high altitude.[94] Bartsch et al.[94] demonstrated that, as subjects developed AMS, they developed relative hypoventilation compared to well-adapting subjects, suggesting that HVR is blunted in response to AMS, rather than serving as its cause.

Prevention. A number of pharmacologic and nonpharmacologic measures prevent or ameliorate AMS. Because overly rapid ascent to too high an elevation is the leading risk factor for altitude illness, gradual ascent, with rest days for acclimatization, is considered the single best way to prevent all forms of altitude illness. Based on consensus opinion, it is recommended[81] that, above 3000 m, individuals should not increase their sleeping elevation by more than 300 to 500 m per night and should take an acclimatization day and sleep at the same elevation a second night every 3 to 4 days or after any large gain in elevation. This particular regimen has never been tested in a controlled study, but other studies[94a,94b] have established that graded ascent is associated with lower incidence of altitude illness. Strict adherence to the recommended ascent profile may be difficult due to differences in topography and travel schedules. Travelers should also avoid overexertion and refrain from heavy alcohol consumption or narcotic medication use, particularly before bedtime, in order to avoid hypoventilation, which can exacerbate the hypoxemia of high altitude. These strategies have never been subjected to rigorous study but represent commonsense measures in light of the physiologic changes at altitude.

Pharmacologic means can also be used to prevent AMS. The most commonly used medication for this purpose is acetazolamide.[56,68] Its principal action is renal carbonic anhydrase inhibition, which causes a bicarbonate diuresis and a metabolic acidosis, which, in turn, stimulates ventilation, increases alveolar P_{O_2} and enhances oxygen off-loading in the tissues. In effect, the drug speeds natural acclimatization by accelerating the pace of ventilatory adaptation by several days. Actions of acetazolamide on carbonic anhydrase elsewhere in the body, such as the peripheral and central chemoreceptors, may also contribute to its preventive role.[95]

Although there has been recent debate about the proper dosing regimen for AMS prophylaxis, a growing body of clinical evidence supports the use of either 125 mg or 250 mg twice a day (Table 70-2). Acetazolamide is well tolerated, with the most common side effect being paresthesias involving the hands, feet, and lips. Nausea and drowsiness occasionally occur, and carbonated beverages taste flat, probably secondary to the inhibition of hydration of carbon dioxide on the palate. Acetazolamide has a sulfonamide moiety and shares the cautions common to all sulfa drugs. The likelihood of a cross reaction is low (~7% to 10%),[96] but case reports describe fatal anaphylactic reactions in people with documented sulfa allergy who received acetazolamide.[97]

For patients who do not tolerate or cannot take acetazolamide, dexamethasone is an effective alternative for AMS prophylaxis.[98] Studies comparing dexamethasone and acetazolamide have revealed approximately equal effectiveness of the two drugs in preventing AMS.[99] Dexamethasone does not speed the acclimatization process and may be associated with reappearance of symptoms if it is abruptly discontinued. Suggested doses are listed in Table 70-2.

As noted earlier, theophylline can prevent AMS but, given the narrow therapeutic window of the medication, it should not be used for this purpose. Several studies demonstrate that gingko biloba can prevent AMS,[100,101] but given that there are also several negative trials[102,102a,103] and concerns about variability in gingko preparations from manufacturer to manufacturer,[102] this medication should not be used for AMS prophylaxis.

TABLE 70-2. Dosing and Use of Altitude Illness Medications in Normals and Patients with Underlying Disease

Medication	Dose in Normal Individuals	Liver Disease	Chronic Kidney Disease	Other Major Dosing Issues
Acetazolamide	*AMS Prevention:* 125 or 250 mg bid *AMS Treatment:* 250 mg bid	Use is contraindicated.	Avoid use in patients with GFR < 10 mL/min, metabolic acidosis, hypokalemia, hypercalcemia, and hyperphosphatemia or recurrent nephrolithiasis.	Avoid in patients on chronically high doses of aspirin or with ventilatory limitation (FEV_1 < 25% predicted). Caution in patients with documented sulfa allergy. Avoid concurrent use of topiramate.
Dexamethasone	*AMS Prevention:* 4 mg bid or 2 mg qid *HACE Treatment:* 8 mg once followed by 4 mg q6h	No contraindication; no dose adjustments necessary.	No contraindication; no dose adjustments necessary.	Expect elevated blood glucose values when used in diabetic patients. Avoid in patients at risk for peptic ulcer disease or upper GI bleeding. Caution in patients at risk for amebiasis or strongyloidiasis.
Nifedipine	*HAPE Prevention:* 20–30 mg of sustained-release version q12h *HAPE Treatment:* 20–30 mg of sustained-release version q12h	Reduced dose required (10 mg bid).	No contraindication; no dose adjustments necessary.	Caution in patients taking medications metabolized by CYP isozyme 3A4 and 1A2 pathways. Caution during concurrent use with other antihypertensive medications.
Tadalafil	*HAPE Prevention:* 10 mg bid *HAPE Treatment:* Unknown	*Child's Class A and B:* maximum 10 mg daily. *Child's Class C:* Do not use tadalafil.	Dose adjustments necessary if GFR < 50 mL/min: if GFR 30–50 mL/min, use 5-mg dose, maximum 10 mg in 48 hr; if GFR < 30 mL/min, no more than 5 mg.	Increased risk of gastroesophageal reflux. Caution in patients taking medications metabolized by CYP isozyme 3A4 pathway. Avoid concurrent use of nitrates or α-blockers.
Sildenafil	*HAPE Prevention:* 50 mg q8h *HAPE Treatment:* Unknown	Dose reductions recommended. Starting dose 25 mg tid. Avoid use in patients at risk for variceal bleeding.	Dose adjustments necessary if GFR < 30 mL/min.	Increased risk of gastroesophageal reflux. Caution in patients taking medications metabolized by CYP isozyme 3A4 pathway. Avoid concurrent use of nitrates or α-blockers.
Salmeterol	*HAPE Prevention:* 125 μg bid *HAPE Treatment:* Unknown	Insufficient data.	No contraindication; no dose adjustments necessary.	Avoid concurrent use of β-blockers, monoamine oxidase inhibitors, or tricyclic antidepressants. Possible adverse effects in coronary artery disease patients prone to arrhythmia.

AMS, acute mountain sickness; bid, twice daily; CYP, cytochrome P-450; FEV_1, forced expiratory volume in 1 second; GFR, glomerular filtration rate; GI, gastrointestinal; HACE, high-altitude cerebral edema; HAPE, high-altitude pulmonary edema; qid, four times daily; tid, three times daily.

In most cases, pharmacologic prophylaxis is not necessary; a slow ascent profile is usually sufficient to prevent AMS. Pharmacologic prophylaxis may be reserved for people with known susceptibility to AMS who are returning to altitudes at which they have been sick in the past, people flying into high-altitude destinations (e.g., La Paz, Bolivia), or people whose work mandates a rapid ascent (e.g., rescue teams). In other circumstances, it is reasonable to delay use of acetazolamide until the symptoms of AMS first develop, at which time it can be taken in the usual dosage until symptoms improve.

Treatment. In general, descent leads to resolution of all forms of altitude illness. Patients with mild illness may not require descent, however, and often recover by remaining at the same elevation and resting for a period of time. In more severe illness, descent is indicated and should continue until symptoms resolve. How much descent is required varies depending on the severity of the case; less severe illness may resolve with descent of only 300 m, while more severe illness may require further drops in altitude. At times, field conditions may be such that descent is infeasible and alternative treatments are necessary. Severely ill patients can be placed

on supplemental oxygen if gas tanks or an oxygen concentrator is available, or "low altitude" can be brought to the patient through the use of lightweight portable hyperbaric chambers. These chambers can be pressurized to 2 psi and effect a descent of approximately 1500 m. By means of a foot pump, sufficient gas flow is maintained to keep the carbon dioxide concentration low and the oxygen concentration close to 21%.[104] Studies demonstrate that the chamber is as effective as administering supplemental oxygen with an F_{IO_2} of 0.26 to 0.30, although the therapy is difficult to implement with claustrophobic individuals or those who are vomiting. As with oxygen therapy, relief of symptoms is generally immediate, but long treatment times are needed in severe illness and to ensure sustained improvement upon removal from the chamber.[104]

Acetazolamide can ameliorate symptoms of AMS and improve arterial oxygenation,[105] while aspirin,[78] ibuprofen,[106] and acetaminophen[106] have been shown to be treat the headache associated with AMS. Prochlorperazine is useful for treating nausea and vomiting and, unlike some other antiemetics, may actually increase HVR rather than depress ventilation.[107] Even if it is not being used for AMS prophylaxis, dexamethasone should be part of the high-altitude traveler's medical kit, especially in remote areas of the mountains, as rapid treatment of evolving symptoms with dexamethasone may keep patients ambulatory, allowing them to descend on their own without need for an expensive evacuation.

High-Altitude Cerebral Edema

HACE is a potentially fatal form of acute altitude illness defined by the onset of mental status changes and/or ataxia in a person with AMS, or by the presence of both neurologic signs in a person without AMS who has recently ascended to altitude.

In addition to ataxia and altered level of consciousness, many people develop an incapacitating headache, persistent nausea and vomiting, and debilitating lassitude. Affected individuals may also develop one of many neurologic symptoms and signs, including papilledema, visual changes, cranial nerve palsies, bladder dysfunction, abnormal reflexes, paresthesias, pareses, aphasia, clonus, hallucinations, seizures, and behavioral changes.[68] If the disease is not recognized and treated promptly, coma and death may ensue.

The incidence of HACE is difficult to assess because the boundary of progression from AMS may be hard to define and the symptoms and signs may be similar to those of cerebral hypoxia secondary to *severe* hypoxemia from pulmonary edema. Incidences of 0.53% to 1.25% have been reported.[78,108] At higher altitudes, HACE may affect 2% to 8% of those experiencing AMS and is more common in those with HAPE.[68,78] The differential diagnosis includes all other causes of encephalopathy, such as carbon monoxide poisoning, hypertensive crisis, severe cerebral hypoxia secondary to HAPE, meningitis, hypoglycemia, moderate to severe hypothermia, and migrainous encephalopathy. Because HACE is generally a problem of global neurologic dysfunction marked by gradual onset over a period of hours, the sudden onset and/or presence of focal neurologic deficits, high fevers, or neck stiffness should prompt consideration of alternative diagnoses. Diagnosis in the field is based on the clinical history and clinical examination. Heel-to-toe walking along a straight line is an effective test for the presence of ataxia. Where advanced diagnostic modalities are available, MRI reveals a pattern of reversible increased T2-weighted signal in the corpus callosum, and in particular the splenium, which may help differentiate HACE from other conditions.[80]

Pathology reports reveal gross cerebral edema in persons who die from HACE.[109] Findings included swelling and flattening of the cerebral gyri, compression of the sulci, herniation of cerebellar tonsils and unci, small petechial hemorrhages, and venous and sinus thromboses. Brain MRI performed in patients with nonfatal HACE also reveals evidence of hemosiderin deposition, a finding consistent with the presence of microhemorrhages.[110]

The definitive treatment for HACE is descent, although recovery is not as rapid as in AMS and HAPE, and descent of more than 1000 m may be necessary. Oxygen or hyperbaric therapy may be lifesaving temporizing measures if descent is not possible. In the only study of therapy, severe neurologic symptoms and signs responded to furosemide and betamethasone, although the drugs were not studied separately or in a prospective manner.[78] Dexamethasone is now routinely used in HACE management (see Table 70-2). Mannitol and glycerol have been suggested for treatment but are difficult to use safely in the field due to lack of adequate monitoring of serum osmolality and volume status, and should only be used in a hospital or clinic setting.

High-Altitude Pulmonary Edema

HAPE is the most common cause of death from high-altitude illness. It was previously misdiagnosed as pneumonia, bronchitis, or congestive heart failure until reports by Hultgren and colleagues[77] and Houston,[111] revealed it to be a distinct form of noncardiogenic pulmonary edema.

Clinical Presentation. HAPE typically occurs within 2 to 4 days of ascent to altitudes above 2400 m (8000 feet), most commonly beginning on the second night. In the early stages of the disease, individuals develop worsening exercise performance and require increasing amounts of time to recover from exertion. Individuals also complain of fatigue, weakness, and a persistent dry cough; symptoms of AMS may also be present. As the disease worsens, individuals become short of breath with minimal exertion. Dyspnea at rest, audible chest congestion, and production of pink frothy sputum are late findings in severe disease. Even in the absence of concurrent HACE, severe hypoxemia may produce mental changes, ataxia, and altered levels of consciousness.

On physical examination, the patient often appears better than one would expect based on blood gases and radiographic findings. Vital sign abnormalities may include low-grade temperatures to 38.5° C, as well as

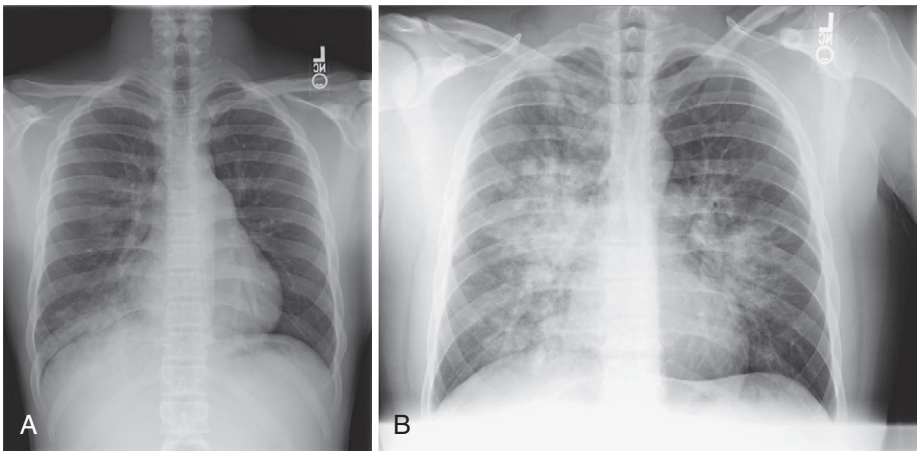

FIGURE 70-8 ■ **A,** Typical roentgenograph of high-altitude pulmonary edema in a 15-year-old boy. Note that the edema is unilateral, right sided, and predominantly in the right middle lobe. **B,** Severe high-altitude pulmonary edema in a 27-year-old man. Note the normal heart size and the presence of bilateral opacities in this case. (Both images courtesy of Peter Hackett.)

tachycardia and tachypnea. Crackles are initially heard in the right mid-lung fields and then more diffusely as the disease worsens. Generalized pallor and nail bed cyanosis may also occur. Radiographs and computed tomography scans show patchy, alveolar opacities, which may be limited to one area (the right lung field predominating initially) or generalized, depending on illness severity (Fig. 70-8). Arterial blood gases reveal severe hypoxemia. In a study at 4559 m, for example, individuals with HAPE had a mean Pa_{O_2} of 23 ± 3 mm Hg and an average saturation of 48 ± 8% versus 40 ± 5 mm Hg and 78 ± 7 % for healthy controls.[112] Pulmonary artery pressure is high, but pulmonary wedge pressure is normal and heart size is not increased.[77,113]

Pathologic Findings. A total of 22 autopsies have been reported in persons dying of HAPE.[78,114] A red cell–rich proteinaceous exudate with hyaline membranes is characteristic. All had some areas of pneumonitis with neutrophil accumulation but no evidence of bacterial accumulation. Pulmonary veins were not dilated. Most reports mention capillary and arteriolar thrombi and fibrin deposits, as well as hemorrhage and infarcts.

Bronchoalveolar lavage samples obtained within the first 24 hours of ascent to 4559 m demonstrated increased amounts of red blood cells and protein but an absence of inflammatory mediators and neutrophils,[115] while samples obtained later in the disease process show even more protein, neutrophilia, and evidence of inflammation marked by such inflammatory mediators as leukotriene B_4 thromboxane B_2,[116] and interleukin-1, -6, and -8 and tumor necrosis factor-α.[117]

Possible Mechanisms. HAPE is a form of noncardiogenic pulmonary edema. Left ventricular function and pulmonary capillary wedge pressure remain normal. Although the mechanisms underlying HAPE remain incompletely understood, it appears that elevated pulmonary artery pressures play a central role in the process, as multiple investigations have shown that affected individuals have markedly elevated pulmonary artery pressures when compared to healthy controls.[77,113]

HAPE-susceptible individuals have exaggerated HPV, which likely accounts for the elevated pulmonary artery pressures; multiple studies demonstrate that HAPE-susceptible individuals have abnormally high pulmonary artery pressure responses during hypoxic breathing and normoxic and hypoxic exercise as well as on ascent to high altitude before the onset of edema.[27,118] Lower HVR[119,120] and slightly lower lung volumes[120] may also contribute to increased pulmonary artery pressure by increasing alveolar hypoxia and reducing the number of recruitable vessels. Finally, evidence suggests that increased sympathetic tone[121] and alterations in vasoactive mediator (endothelin, nitric oxide) production by pulmonary endothelial cells[122,123] may also lead to stronger hypoxic pulmonary vasoconstriction.

Given the central importance of elevated pulmonary artery pressures in the pathogenesis of HAPE, the question is how these elevated pressures cause fluid accumulation when patients with severe pulmonary hypertension at sea level do not typically have pulmonary edema. Hultgren[124] has suggested that edema results from uneven hypoxic vasoconstriction, resulting in overperfusion of the microvasculature in areas of the lung where arteriolar vasoconstriction failed to protect downstream vessels. Uneven perfusion is suggested clinically by the typical patchy roentgenographic appearance (see Fig. 70-8) and by MRI studies in persons breathing hypoxic gas mixtures,[125,126] which demonstrate greater heterogeneous regional perfusion in HAPE-susceptible subjects.

The leak in overperfusion edema may be due to *capillary stress failure* in which high shear forces cause biomechanical stress and injury in the precapillary arterioles and capillaries.[127] The mechanism(s) by which high pressures and shear stress lead to a high permeability–type leak may involve a continuum of pressure-related phenomena by which pericellular and transcellular movement of plasma and even red cells occurs into the lung interstitium and subsequently into the alveolar space. At lower levels of pressure elevation,

stretch on collagen and other supporting extracellular matrix elements may induce dynamic and quickly reversible changes in barrier permeability[128] that, with greater duration and further pressure elevation, may lead to capillary rupture and alveolar hemorrhage, as seen in severe cases of HAPE.

Although the data largely establish a hydrostatic basis for HAPE, interest in the role of inflammation was raised when bronchoalveolar lavage studies on patients with HAPE demonstrated increased cellularity and the presence of chemotactic (leukotriene B_4) and vasoactive (thromboxane B_2) mediators compared to controls.[116] Swenson et al.[115] clarified the role of inflammation by performing bronchoalveolar lavage in HAPE-susceptible individuals and normal controls within the first 24 hours of arrival at 4559 m, well earlier than the lavage samples were obtained in the other studies. The lavage fluid demonstrated high protein and red blood cell content, the levels of which correlated with pulmonary artery pressures measured by echocardiography (Fig. 70-9), but no evidence of cytokine expression or neutrophil recruitment in the earliest phase of the disease. These findings solidified the notion that HAPE starts as a result of high intravascular pressure and not due to an inflammatory process.

While inflammation is not the primary factor in most cases, it may still play a role in certain situations. Respiratory viral infections have been shown to predispose to HAPE in children,[129] and anecdotal reports of viral infections preceding HAPE exist for adults. This suggests that viral infections may trigger inflammation, which makes the microvascular endothelium more vulnerable to increased pressures. Indeed, increased interstitial fluid accumulation has been documented during hypoxic exposure after priming by endotoxin or virus in animals.[130] This potential role for upper respiratory tract infections and subsequent inflammation may explain why HAPE has been seen at surprisingly low altitudes (1500 to 2400 m).[131]

Changes in fluid transport dynamics in the lung may also contribute to HAPE. Water and sodium transport by type I and II alveolar epithelial cells is important in normal lung fluid balance, and investigations in cell culture and animal models demonstrate that hypoxia decreases alveolar transepithelial sodium transport[132] and alveolar fluid clearance.[133] Subsequent studies in humans have examined transepithelial potential differences across the nasal mucosa as a model of alveolar epithelial function and demonstrate lower transepithelial nasal potentials in normoxia in HAPE-susceptible individuals versus nonsusceptible controls.[134] The reduced nasal potential difference was attributed to decreased sodium transport by the epithelial sodium channel. A more recent study confirmed the difference in nasal potential between HAPE-susceptible individuals and controls in normoxia, but it could not attribute these differences to alterations in epithelial sodium channel activity.[135] Transalveolar sodium transport can be increased by β_2-receptor stimulation, and a field study has reported successful prevention of HAPE with inhalation of salmeterol, a long-acting β_2-agonist.[134] However, given the multiple actions of this drug, including increased ventilatory response to hypoxia and tightening of cell-to-cell contacts, the contribution of enhanced alveolar fluid clearance to the study's positive outcome remains uncertain.[136]

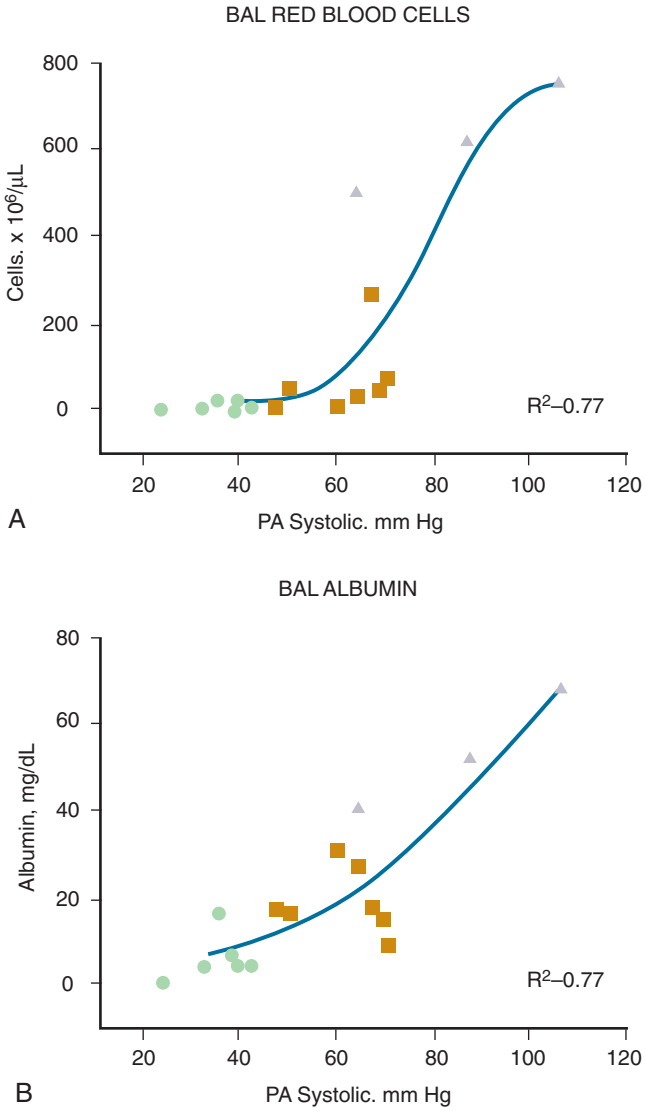

FIGURE 70-9 ■ The relationship between pulmonary artery pressure measured by echocardiography and the amount of red blood cells and albumin in bronchoalveolar lavage (BAL) fluid of normal and HAPE-susceptible (*triangles*) individuals at sea level and 4559 m. The *circles* in the lower left of both panels show values for red blood cells and albumin in normal subjects at low altitude (490 m) and the *squares* show values in the same subjects at altitude (4559 m). Correlation coefficients are provided for the best-fit curves of the data at high altitude. (From Swenson ER, Maggiorini M, Mongovin S, et al: Pathogenesis of high-altitude pulmonary edema: Inflammation is not an etiologic factor. JAMA 287:2228–2235, 2002.)

Allemann et al.[137] documented an increased incidence of patent foramen ovale (PFO) in HAPE-susceptible individuals at low and high altitude compared to healthy controls and argued that its presence may increase the risk of HAPE. It is not clear, however, whether the PFO actually causes HAPE or is a sequela of prior marked

rises in pulmonary artery pressure during sojourns to high altitude or during normoxic exercise, a feature of pulmonary vascular responses seen in HAPE-susceptible individuals.[138] Shunting through a PFO might act to lower pulmonary artery pressure by reducing total pulmonary blood flow, but the consequent greater arterial hypoxemia might increase pulmonary vascular resistance because the vasovasorum of the pulmonary arteries is fed by the bronchial arteries, and isolated bronchial arterial hypoxemia has been shown to increase HPV.[139]

Finally, it has been proposed that HAPE is a form of neurogenic pulmonary edema, as the presence of red blood cells, the spectrum of serum proteins in HAPE lavage fluid, and the absence of architectural damage are all features seen in this other form of noncardiogenic pulmonary edema.[140] Sympathetically mediated pulmonary venous constriction is thought to play a large role in neurogenic pulmonary edema,[141] while, as noted earlier, increased sympathetic activity may play a role in HAPE[121] and α-adrenergic blockade has been shown to decrease pulmonary artery pressure in HAPE.[142] What is lacking in HAPE, however, is the severe neurologic injury typically seen in neurogenic pulmonary edema. Although some HAPE patients have concurrent AMS or HACE, this is usually far less severe injury than the profound central nervous system alterations (e.g., subarachnoid hemorrhage) in most cases of neurogenic pulmonary edema. HAPE and neurogenic pulmonary edema are likely distinct processes that share features of a common final pathway to edema formation.

Prevention. The nonpharmacologic preventive measures previously described for AMS also apply to HAPE, with slow ascent being the most important strategy. Because unrecognizable subclinical pulmonary edema might be converted to clinical edema by exercise, avoidance of overexertion, especially when fatigued, may help prevent HAPE. Nifedipine has been shown to be effective in preventing HAPE in subjects with a past history of the illness.[143] Because the incidence of HAPE is low, prophylactic nifedipine should be reserved for known susceptible individuals. A single study established that high-dose inhaled salmeterol may be considered for prophylaxis,[134] although very high doses (2.5 times those used in asthma management) were used in the study and may be associated with side effects that affect patient tolerance. Salmeterol should not be used as monotherapy for prevention of HAPE and should only be considered as an add-on to other agents. More recently, the phosphodiesterase inhibitor tadalafil as well as dexamethasone, have also been shown to prevent disease in known susceptible individuals.[144] None of these medications, however, has been compared with nifedipine in head-to-head studies. Recommended doses for these medications are provided in Table 70-2.

Treatment. Proper treatment depends on the severity of the illness and the immediate setting. For patients developing HAPE in remote locations with limited access to care, the first priority is descent to lower elevation. The patient's level of exertion should be limited during descent as exertion may increase pulmonary artery pressure and worsen the pulmonary edema. If HAPE is diagnosed early, recovery is rapid with descents of only 500 to 1000 m, and the victim may be able to reascend cautiously 2 or 3 days later. If descent is infeasible due to weather or other factors, supplemental oxygen or a portable hyperbaric chamber should be an urgent priority.[145] If neither option is available, positive-pressure mask ventilation may improve oxygenation, although the effect on outcomes has not been established.[146] Keeping the patient warm may also be important, because cold stress elevates pulmonary artery pressure.[147]

Given the reduced margin for error in remote settings, the use of a pulmonary vasodilator such as nifedipine is warranted regardless of whether supplemental oxygen is available. The data supporting this practice are limited, however, and the recommendation is based largely on extensive clinical experience. A single study[148] demonstrated that nifedipine can be used to manage HAPE in the absence of descent or supplemental oxygen, but this study included a small number of patients and lacked a control group. Other pulmonary vasodilators such as tadalafil and sildenafil have not been studied for HAPE treatment, but reports in the literature indicate clinicians are using them for this purpose, often in conjunction with calcium channel blocker therapy.[149] Given the absence of data supporting benefit and the risk of provoking systemic hypotension, concurrent use of two pulmonary vasodilators should be avoided.

With access to hospitals or clinics, treatment with bed rest and oxygen may be sufficient and evacuation to lower elevations may be unnecessary. In well-selected patients with mild disease and adequate support (family, friends) to monitor their clinical course, it may even be feasible to send them home or to their hotel with supplemental oxygen rather than admitting them to the hospital.[150] Complete resolution of the edema may require 24 to 72 hours of oxygen therapy if treated near the altitude of onset, whereas removing the patient to a lower altitude results in more rapid improvement. Pulmonary vasodilators can be added in patients who worsen or fail to improve with conservative measures. There are no data regarding whether nifedipine is superior to phosphodiesterase inhibitors for this purpose, although there is more clinical experience with the less expensive nifedipine. A single case series documented the use of continuous positive airway pressure (CPAP) to relieve dyspnea in patients with HAPE,[131] but there are no controlled data to suggest this improves outcomes. Because fevers as high as 38.5°C have been described in HAPE, a finding of elevated temperature should not prompt administration of antibiotics unless the clinical picture is consistent with pneumonia. Patients who do not improve on an appropriate regimen should undergo investigations to identify other causes of hypoxemia and lung infiltrates.

Problems of High-Altitude Residents

Chronic Mountain Sickness

First described in Andean dwellers by Monge[151] in 1928 and often referred to as Monge's disease, chronic moun-

tain sickness (CMS) is the more commonly described form of chronic altitude illness. It occurs in persons born and living at high altitude as well as in lowlanders who move to high altitudes and stay for prolonged periods of time (>1 year). Excessive erythrocytosis, defined as a hematocrit above 60% to 70% or more than 2 standard deviations above the average value for healthy residents at a given high altitude, is an essential characteristic of the syndrome.

There are geographic and ethnic differences in the prevalence of CMS. It is rarely found in natives of the Tibetan plateau but is frequently encountered in the Andes, in the North American Rockies, and in other mountainous regions where lowlanders have moved, such as with Han Chinese who have been relocated to Tibet.[152,153] The reason for these regional differences is only speculative, but it is thought possibly to be secondary to more advantageous adaptations that the Tibetans have undergone because of the much greater duration of their existence on the Tibetan plateau compared with that of the Andeans. Especially relevant may be that Tibetans have much less HPV and lower hematocrits, as compared with other high-altitude populations. These may potentially be markers of more successful adaptation over a much longer period of time.

Clinical Presentation. Symptoms of CMS are similar to those found in persons suffering polycythemia at low altitude: headache, dizziness, lethargy, impaired memory and mentation, and poor sleep. Subsequent investigations reveal cyanosis, plethoric appearance, and elevated hematocrit and hemoglobin. The diagnosis can only be established by eliminating all other causes of polycythemia. Indeed, much confusion in the literature regarding incidence and other aspects of CMS may be due to inadequate validation of the diagnosis. Monge,[151] for example, noted a high frequency of bronchial complications in patients with CMS, whereas Kryger et al.[153] found evidence of lung disease in 50% of those with CMS in Leadville, Colorado. Indeed, when viewed as a syndrome, it is possible that many cases represent an interaction between some underlying chronic lung disease, high altitude, and, perhaps, heavy metal toxicity.[33]

Pathophysiology. Blunted HVR and relative hypoventilation are the likely initiating factors in CMS. Hypoventilation causes greater alveolar hypoxia and arterial hypoxemia, which, in turn, triggers more HPV and greater pulmonary hypertension, while the low arterial P_{O_2} leads to increased erythropoietin secretion and more red blood cell production.[153-155] At the same time, polycythemia may blunt ventilatory responses,[156,157] so cause and effect are not clear. Hypoxia itself may also contribute to the ventilatory depression, as evidenced by an increase in ventilation in some natives with CMS when given supplemental oxygen.

While the excessive polycythemia of CMS is likely due to greater hypoxemia, the actual hematocrit is often higher than expected for the measured Sa_{O_2},[158] suggesting that affected individuals may have exaggerated hematopoietic responses to a given hypoxic stimulus.[154] Severe nocturnal desaturation may also contribute to the development of polycythemia, as investigations in the Rocky Mountains revealed greater hypoxemia during sleep in patients with CMS compared to healthy controls.[159]

More recently, Jefferson et al.[33] found that a majority of subjects with CMS and excessive erythrocytosis in an Andean mining community had detectable serum concentrations of cobalt, a heavy metal known to independently stimulate renal erythropoietin production. This may help explain the higher incidence of CMS in high-altitude regions where mining is common.

Treatment. The key to treating CMS is to decrease the red cell mass. Improving oxygenation and thereby reducing the hypoxic stimulus for red blood cell production is the most physiologic approach to achieving this goal. Although relocation to a lower altitude is the definitive treatment for CMS, this approach is not feasible for many patients and other treatments are often employed. Phlebotomy has long been used, but despite the common practice and prompt subjective improvement, long-term benefits have not been well documented. Low-flow oxygen during sleep is probably effective, especially for those with marked sleep desaturation. By virtue of their ability to increase alveolar P_{O_2}, respiratory stimulants, including medroxyprogesterone[160] and acetazolamide,[161] are effective in decreasing hematocrit and treating CMS. Daily use of angiotensin-converting enzyme inhibitors can suppress erythropoietin secretion and decrease the need for phlebotomy.[162]

High-Altitude Pulmonary Hypertension

An alternative form of altitude-related disease in long-term residents has now been described in areas outside the Andes Mountains. Referred to as high-altitude pulmonary hypertension, it is marked by pulmonary hypertension and cor pulmonale without polycythemia. A recent consensus panel[163] defined the disease to be present if a resident at altitudes above 2500 m has a mean pulmonary artery pressure greater than 30 mm Hg or a systolic pulmonary artery pressure greater than 50 mm Hg, right ventricular hypertrophy, right heart failure, and moderate hypoxemia and lacks excessive erythrocytosis (hemoglobin < 21 g/dL in men and <19 g/dL in women). There is considerable overlap between this disease and subacute mountain sickness, a syndrome of pulmonary hypertension and right heart failure seen in lowlanders after weeks to months at high altitude,[164] with the major difference being the time spent at high altitude by the affected individual. There is also some debate as to whether this truly represents a separate entity from CMS or is simply a variant of the same disease.[155]

Affected individuals present with dyspnea, cough, cyanosis, peripheral edema, and physical examination findings consistent with right heart failure. Right-axis deviation, right ventricular hypertrophy, and P-pulmonale may be present on the electrocardiogram, while chest imaging reveals right ventricular and right atrial enlargement and prominence of the pulmonary arteries.[163] The pulmonary hemodynamics are similar to those seen in patients with CMS.[155] The optimal treatment for the disorder is relocation to lower elevation, but, as in CMS, descent may not be feasible and pharmacologic

options may be necessary. Unfortunately, aside from a small placebo-controlled trial that demonstrated that a 3-month course of the phosphodiesterase inhibitor sildenafil lowered pulmonary artery pressure by a modest amount (~6 to 7 mm Hg) and improved 6-minute walk distance,[165] larger studies of this and other pulmonary vasodilators are lacking and no formal treatment protocols exist at this time.

Reentry Pulmonary Edema

Some persons living for years at high altitude, who then descend to lower altitudes, develop HAPE on reascent. The phenomenon has been most often observed in Peru, where high-altitude residents can return from sea level to high altitude quite rapidly. Cases have also been reported in Leadville, Colorado, but reports are conspicuously absent from Nepal and Tibet, possibly because rapid return to high altitude is often less readily available. Authors have suggested that the incidence of HAPE on reascent may be higher than during initial ascent by sojourners,[166] but data on true incidence are lacking; children and adolescents may be more susceptible than adults.[166] It has been postulated that the increased muscularization of pulmonary arterioles that develops with chronic high-altitude exposure generates an inordinately high pulmonary artery pressure on reascent, causing the edema. Aside from a study by Marticorena and Hultgren[167] that demonstrated that treatment with bed rest alone may be sufficient in mild to moderate cases, no treatment trials have been conducted for reentry HAPE, and the disorder should be managed the same as HAPE in unacclimatized lowlanders.

PREEXISTING ILLNESS AND HIGH ALTITUDE

Given the prevalence of many common diseases, such as hypertension and chronic obstructive pulmonary disease (COPD), in the general population, it is likely that many high-altitude travelers have some underlying medical condition. This situation raises two important questions: (1) will the underlying disease predispose these individuals to high-altitude illness; and (2) will the added stress of hypoxia at high altitude worsen control of their underlying problems? To date, few studies have examined what happens to people with respiratory and other diseases when they visit high-altitude destinations, and even fewer data are available about how to treat them before and after their exposure. Several major categories of respiratory diseases are discussed in this section, while other major disease categories, including heart disease,[168] renal disease,[169] and diabetes,[170] are reviewed elsewhere.

Respiratory Diseases

High-altitude exposure poses several challenges to patients with lung disease that have been reviewed extensively elsewhere.[171] Several major forms of lung disease are considered here in brief.

COPD and Interstitial Lung Disease

A drop in barometric pressure and subsequent fall in inspired P_{O_2} place patients with severe COPD and interstitial lung disease at risk for arterial desaturation, particularly with exertion. During the pretravel evaluation, patients with moderate to severe COPD[172] and interstitial lung disease[173] should be tested to determine their predicted arterial P_{O_2} at high altitude. Those patients in whom the predicted value falls below 50 mm Hg, the same threshold used for determining supplemental oxygen needs on commercial air flight, should be provided a prescription for home oxygen, which they can arrange to fill at their destination (e.g., a ski resort town). An alternative strategy in patients with less severe disease would be to have them monitor their own pulse oximetry using a portable handheld device and fill a prewritten home oxygen prescription if their saturation falls below thresholds stipulated by their physician. COPD patients should travel with their controller medications and a supply of rescue medications in the event of an exacerbation. The sleeping elevation should be restricted to elevations below 3000 m because no studies have examined COPD or interstitial lung disease patients above this altitude.

Asthma

Changes in air temperature, humidity, and density may alter lung mechanics and airflow obstruction in patients with asthma, but field data demonstrate that mild, well-controlled asthmatic patients have decreased bronchial responsiveness at elevations as high as 5000 m and should tolerate travel up to these elevations.[171,174] Patients must have their asthma under good control prior to any trip to high altitude and should travel with both their controller medications and an adequate supply of rescue inhalers and prednisone for use in the event of an exacerbation.

Pulmonary Vascular Disease

Low alveolar oxygen tensions provoke HPV and increase pulmonary artery pressure. This response may provoke either acute right heart failure or HAPE in patients with primary or secondary pulmonary hypertension. No systematic studies have examined this issue, but several case reports and case series document the occurrence of HAPE in patients with pulmonary hypertension secondary to anatomic or nonanatomic causes.[171] Patients with known or suspected pulmonary hypertension should undergo echocardiography to measure pulmonary artery pressures. Travel to high altitude should be avoided in patients with moderate to severe disease, although the threshold used to proscribe travel is not clear. The available evidence suggests that mean pressures of about 40 mm Hg are sufficient to trigger HAPE, but a wide range of pressures have been documented in

case reports of this phenomenon at high altitude.[171] Patients with less severe disease should use nifedipine and should be encouraged to monitor their pulse oximetry either by using a handheld device or by periodically visiting a local clinic. Patients with congenital absence of a pulmonary artery should also avoid high-altitude travel, as these individuals are known to be susceptible to HAPE.[175]

Sleep Apnea

The limited available data suggest that the number of obstructive apneas is markedly decreased at high altitude. In a study of normal individuals with low baseline apnea-hypopnea indices, the obstructive sleep apnea (OSA) index fell from 5.5 ± 6.9 to 0.1 ± 0.3 events/hr at 5050 m,[176] while in a study of adult men with moderate OSA at baseline, the obstructive respiratory disturbance index fell from 25.5 ± 14.4 to 0.5 ± 0.5 events/hr at 2750 m.[177] The mechanism behind the decreased number of obstructive events is unclear but may relate to changes in air density, increased respiratory drives, and increased upper airway tone.[177]

In both studies, however, the decrease in obstructive events was offset by an increase in the incidence of central apneas. Whether these central events have the same impact as obstructive events on sleep quality and subsequent daytime performance is not known. Furthermore, to the extent that obstructive events persist at high altitude, one would expect greater arterial desaturation than at sea level. As a result, it would be prudent for people with severe OSA to travel to high altitude with their CPAP machine, provided reliable access to power sources can be arranged. Patients should be aware that machines lacking pressure-compensating features may not deliver the set pressure at high altitude, and higher pressures may be needed for adequate relief of symptoms. Recommendations for adjusting the set pressure have been made elsewhere.[178] Acetazolamide may also be considered for the purpose of decreasing the incidence of central apneas.

Thromboembolic Disease

Many case reports document arterial or venous thromboembolic events at high altitude, but a careful review of the cases reveals that most events occurred in people with underlying coagulopathy.[171] These findings fit with a recent study in which the most marked rises in thrombin-antithrombin complexes during hypobaric hypoxic exposure were seen in those with the factor V Leiden mutation or oral contraceptive use.[39] In the absence of clear data regarding thromboembolism risk at high altitude, people should simply continue their sea-level regimen upon travel to high altitude. There is no indication to start anticoagulation in those not previously on such medication. Efforts should be made to maintain mobility and good hydration throughout the trip. The international normalized ratio (INR) may change with trips to and from altitude,[179] and patients on warfarin should consider obtaining follow-up INR values upon returning from a long sojourn or periodically during prolonged stays at a new altitude.

Altitude-Illness Medications and Underlying Medical Diseases

As noted earlier, acetazolamide, dexamethasone, nifedipine, and the phosphodiesterase inhibitors play a large role in the prevention and treatment of high-altitude illness. The efficacy and safety of these medications in preventing and treating altitude illness has largely been established on the basis of studies in healthy individuals with no underlying medical disease. However, given the increasing numbers of people traveling to high altitude, it is possible that many of those using these medications for management of altitude illness will have underlying medical problems or will be using other medications that cause adverse drug interactions. Practical guidelines for the selection and dosing of the altitude illness medications in such patient populations have been reviewed elsewhere[180] and are summarized in Table 70-2.

KEY POINTS

- Important adaptive responses occur at every step of the oxygen transport chain that maintains oxygen delivery in the setting of lower ambient oxygen levels, but the magnitude of these changes varies among individuals and affects individual tolerance of this environment.
- Various aspects of sleep, including respiratory patterns, sleep architecture, and subjective impressions of sleep quality, are altered and contribute to poor sleep at high altitude. The number of obstructive apneas decreases at altitude, but this change is matched by an increase in the number of central events.
- Maximum exercise capacity is reduced at high altitude and does not recover to sea-level baseline values even with prolonged time and acclimatization at high altitude.
- An overly rapid ascent to too high an elevation is the primary reason people develop acute altitude illness, while undertaking a gradual ascent is the best nonpharmacologic means for preventing high-altitude illness.

KEY POINTS—CONT'D

- Acute mountain sickness is the most common form of acute altitude illness and is marked by the onset of headache plus one or more other symptoms, including light-headedness, gastrointestinal upset, fatigue, and poor sleep several hours following ascent to high altitude.
- High-altitude cerebral edema is an uncommon but potentially fatal form of altitude illness that is marked by the presence of ataxia and/or signs of global encephalopathy in patients with preceding symptoms of acute mountain sickness.
- High-altitude pulmonary edema is a noncardiogenic pulmonary edema that occurs primarily as a result of excessive rises in pulmonary artery pressure following acute ascent to high altitude.
- Long-term high-altitude residents are generally not susceptible to acute forms of high-altitude illness but are at risk for two forms of chronic altitude illness (chronic mountain sickness and high-altitude pulmonary hypertension) for which the optimal form of treatment is relocation to lower elevation.
- High-altitude travelers with underlying medical problems should be evaluated prior to their sojourn to determine whether their underlying problem may be adversely affected by high altitude or may increase the risk of acute altitude illness.
- The choice of medications for the prevention and treatment of high-altitude illness may need to be altered in patients with underlying medical problems or who are taking certain medications.

INTRODUCTION

Increased Pressure

Humans are exposed to increased pressure when submerged underwater and when subjected to elevated pressures in closed pressure vessels. Underwater exposure is experienced by divers, who are subject to increasing pressure directly proportional to depth (Table 71-1). Pressure vessels include hyperbaric chambers used for treatment of medical and diving-related diseases, pressurized tunnels and caissons used for underwater construction, and underwater habitats. As depth and pressure increase, the diver breathes gas of increased density using breathing equipment that provides oxygen and allows for elimination of carbon dioxide.

Relation to Altitude

Exposure to altitudes above 18,000 feet (0.5 atmosphere absolute [ATA]) may result in free gas formation in tissues due to supersaturation of inert gases dissolved at atmospheric pressure.[1] Divers with increased inert gas in their tissues from diving can develop free gas in these tissues when going to altitude after diving even though they follow established protocols for ascent from depth to the surface. Flying after diving is a common occurrence among sport divers, who may fly in commercial aircraft (about 8000 feet equivalent altitude) shortly after diving.

Water Immersion

Increases in intrathoracic blood volume occur with water immersion.[2] Intrathoracic pressure at end-expiration increases from −5 cm H_2O while standing in air to −2 cm H_2O during immersion,[3] and abdominal pressure increases from −6 cm H_2O in air to +12 cm H_2O during immersion.[4] This increased hydrostatic pressure prevents blood from pooling in the peripheral veins. The increase in transdiaphragmatic pressure and the absence of venous blood pooling increase venous return during

TABLE 71-1. Pressure Equivalents for Altitude and Depth

	Feet	ATA	mm Hg	psi
Altitude above sea level	12,000	0.636	483	9.3
	8,000	0.742	564	10.9
	4,000	0.863	656	12.7
Sea level	0	1	760	14.7
Depth in sea water	33	2	1,520	29.4
	66	3	2,280	44.1
	99	4	3,040	58.8
	132	5	3,800	73.5

ATA, atmospheres absolute; psi, pounds/square inch.

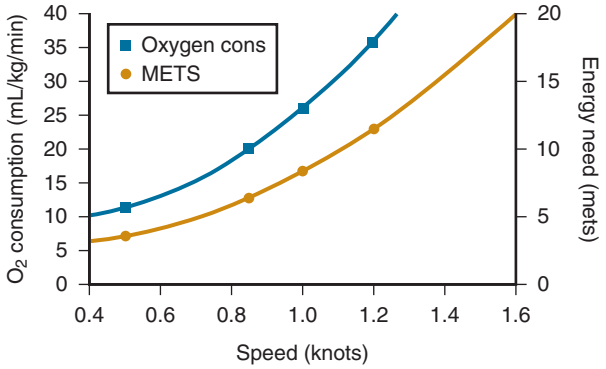

FIGURE 71-1 ■ Oxygen consumption and metabolic equivalents (METS) are shown for underwater swimming. (Data from Navy Department: U.S. Navy Diving Manual, Vol 1, Rev 3: Air Diving [Publication No. NAVSEA 0994-LP-001-9110]. Washington, DC: U.S. Navy Department, 1996.)

immersion. The magnitude of the increase in the intrathoracic blood volume during head-out immersion has been estimated to be 700 mL.[2] The central blood shifts result in an increase in cardiac output[5] and an increase in central venous pressure. The increase in intrathoracic blood volume causes a diuresis due to release of natriuretic hormones and suppression of antidiuretic hormone.

Breath-hold divers can develop sudden unconsciousness during ascent from long apneic dives.[6] This phenomenon is called *shallow water blackout* and is due to a progressive reduction in arterial P_{O_2} as the breath-hold diver ascends with decreasing ambient pressure and arterial P_{O_2} that is further reduced due to metabolic needs.

Thermal Exposure

Most diving is done in water with temperature below the skin temperature (30°C), and the diver loses heat throughout the dive. Therefore, hypothermia is a constant hazard in diving and occurs rapidly in the absence of protective garments even in relatively warm water (e.g., 22° to 23°C). Heat loss is inhibited in divers doing moderate work in water above 30°C, and hyperthermia can develop.

Cold stress evokes thermogenic responses, reflected by changes in oxygen consumption ($\dot{V}_{O_2}$). A rise in $\dot{V}_{O_2}$ upon exposure to cold water generates additional body heat in order to minimize core temperature change. A slower rise in $\dot{V}_{O_2}$ can occur in divers wearing thermal protection.

Peripheral vasoconstriction occurs in response to the stress of cold water diving. The magnitude of the vasoconstriction is dependent on body core temperature, which, in turn, is affected by the amount of thermal protection and the water temperature. Divers face heat loss even in tropical waters, which have temperatures ranging from 29° to 31°C.

Energy Needs for Diving

A scuba diver swimming underwater at a speed of 1.0 knot (about 100 feet/min) consumes about 25 mL of oxygen/kg per minute (Fig. 71-1).[7,8] This is a high workload and is uncommon in sport scuba diving. A diver with a maximum $\dot{V}_{O_2}$ of 40 mL/kg per minute would tolerate swimming at 1.3 knots for a few minutes but would become extremely tachypneic to compensate for lactate production. For a diver with a maximum $\dot{V}_{O_2}$ of 40 mL/kg per minute, sustainable swimming speed, working at 60% to 65% of maximum capacity, would be about 100 feet/min, whereas the diver with a maximum $\dot{V}_{O_2}$ of 25 mL/kg per minute would only be able to sustain a swimming speed of about 70 feet/min. Safety considerations suggest that the sport diver should be able to tolerate a sustained workload of about 24 mL/kg per minute (60% of maximum).[7,8] Scuba divers who maintain this level of physical conditioning can be expected to respond appropriately to most diving workloads. Poorly conditioned divers can experience severe dyspnea under even mildly stressful conditions that exceed their anaerobic threshold.

EQUIPMENT

Open-Circuit Scuba

The most commonly used breathing equipment in diving is the open-circuit scuba (self-contained underwater breathing apparatus). This equipment (Fig. 71-2) consists of a metal cylinder containing compressed air connected to a pressure regulator that lowers pressure first to about 150 psi over ambient pressure and then to ambient pressure with a demand-type regulator with a mouthpiece in the diver's mouth. This device delivers ambient-pressure air only when inhalation is initiated and allows flow that matches the minute volume of the diver. A typical scuba cylinder can supply approximately 2100 L of air at the surface (1 ATA). This volume is reduced in direct proportion to ambient pressure. For example, at a depth of 66 feet of seawater (fsw) or 3 ATA pressure, the effective volume of air is decreased to 700 L. With a minute

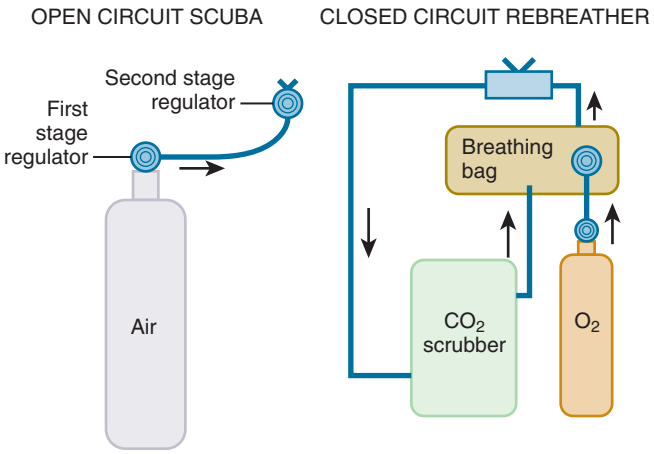

FIGURE 71-2 ■ The schematics show two types of self-contained diving systems. The open-circuit scuba is the system commonly used for recreational diving. Air is exhaled into the surrounding water. Rebreather systems allow exhaled breathing gas to be recycled through a carbon dioxide scrubber, mixed with additional breathing gas, and returned to the diver through a breathing bag. Breathing gas is replenished via a demand valve. This system can be used with 100% oxygen or oxygen-enriched air mixtures. Other forms of rebreather systems contain separate oxygen and inert gas supplies, and mixing is controlled with a small computer to maintain a constant oxygen partial pressure.

ventilation of 20 L/min, this air supply would last 105 minutes at the surface but only 35 minutes at 66 fsw. Open-circuit scuba is usually limited to depths above 200 feet because of limited air supply, nitrogen narcosis, and oxygen toxicity.

Closed-Circuit Scuba

The self-contained rebreather uses a carbon dioxide absorbent to remove exhaled carbon dioxide and replenishes only the oxygen used. Inert gas is conserved by recycling the exhaled gas through the carbon dioxide absorbent and then adding oxygen before the gas is rebreathed (see Fig. 71-2). Little gas is released into the surrounding water, oxygen can be carried in volumes adequate for several hours of exposure, and gas consumption is independent of depth. Although use of closed-circuit scuba in the past was confined to commercial and military divers, such rebreather systems now are becoming popular among recreational divers.

Surface-Supplied Equipment

Commercial diving often employs this form of equipment. The diver breathes compressed air or other gas mixtures pumped from the surface to the helmet, and the excess flows out through the bottom of the helmet. The modern diving helmet is attached at the collar to a diving suit so that air flows from the helmet into the suit to maintain an air layer for thermal protection. Modern systems contain a demand mask built into the helmet.

DISORDERS RELATED TO DIVING: NOMENCLATURE

Golding and coworkers[9] described a scheme for categorizing decompression-related disorders that has become the standard nomenclature. They described disorders related to supersaturation of inert gases in tissues with subsequent bubble formation as *decompression sickness* (DCS). They described a systemic form of DCS that involves the central nervous system, the lungs, and the circulation ("serious," type II) and a nonsystemic (peripheral) form that involves the skin, bones, and joints ("minor," type I). *Arterial gas embolism* is named separately based on different pathophysiologic mechanisms.

Francis and Smith[10] suggested the term *decompression illness* for these two disorders because they can be clinically difficult to separate and they require the same therapy; however, in this chapter, we use a pathophysiologic classification of the pressure disorders whenever possible.

PRESSURE EFFECTS: BOYLE'S LAW

Relation of Gas Volume to Depth

Boyle's law states that, if the temperature of a fixed mass of an ideal gas is kept constant, volume and pressure are inversely related. This relationship is described by the equation $P \cdot V = K$, where P is absolute pressure, V is volume, and K is a constant. Consequently, when the pressure is doubled, the volume is reduced to one half of the original volume. Because the gas volume is proportional to the absolute pressure, the volume change from 33 to 66 fsw (from 2 to 3 ATA) is less than the change from the surface to 33 fsw (from 1 to 2 ATA). Changes of depth in shallow water cause greater volume changes than equivalent changes of depth in deeper water. Rapid volume expansion resulting from depth changes in shallow water can cause tissue injury.

Barotrauma

With increased pressure, volume in the lungs, middle ear, paranasal sinuses, and gastrointestinal tract are reduced. Displacement of tissues into the diminishing volume of these spaces may cause tissue injury and may cause dysfunction of the organ involved. Middle ear barotrauma is the most common diving-related disorder encountered in divers.[11] Barotrauma can affect a paranasal sinus with an occluded orifice, a small residual air pocket left between a tooth filling and the base of the tooth, or the air space within a diving mask. All can produce tissue injury due to displacement of tissues into the diminishing air space. Although lung barotrauma on descent is possible by breath-hold diving to a depth that reduces the lung volume below the residual volume,[4] in practice this has not been observed because of the increased intrapulmonary blood volume and compression of the thorax.

Pulmonary Barotrauma and Arterial Gas Embolism

When a diver subjected to increasing pressure breathes from an air supply at depth, the breathing gas is pressurized to the ambient pressure so that pressure gradients from breathing supply to the airways are not altered as the diver descends. Ascent to the surface after breathing compressed air from depths as shallow as 4 feet can cause pulmonary barotrauma. Studies by Behnke[12] and by Polak and Adams[13] reported the features of lung barotrauma. Fatalities were identified in which an ascending diver with no evidence of pulmonary disease sustained pulmonary barotrauma due to inadequate exhalation during ascent. In some cases, obstruction of a single bronchus was thought to cause overexpansion of a lung segment. Later studies[14] provided further insight into mechanisms and prevention of pulmonary barotrauma.

Pathophysiology. Under experimental conditions, transpulmonary pressures (i.e., the difference between intratracheal and intrapleural pressures) of 95 to 110 cm H_2O are sufficient to disrupt pulmonary parenchyma and allow gases into the interstitium.[14] Extra-alveolar gas will migrate through perivascular sheaths of the pulmonary vasculature to cause mediastinal emphysema and pneumothorax.[14] Gas can also dissect into the retroperitoneum and into the subcutaneous tissues of the neck. When intrathoracic pressure drops after the pulmonary barotrauma, extra-alveolar gas can pass into ruptured blood vessels, travel to the left side of the heart, and enter the arterial circulation as gaseous emboli. The dissemination of gas bubbles throughout the arterial circulation causes injury to other organ systems and to skeletal muscle, which is evident by a rise in serum creatine kinase level.[15]

Pulmonary barotrauma can occur in divers who would not be considered at risk for lung overpressure. Tetzlaff and colleagues[16] suggested that prospective pulmonary function testing could be used as a means of separating individuals with a history of asthma who can dive safely from those who might be at risk for pulmonary barotrauma. They identified reduced midexpiratory flow at 25% of vital capacity in pulmonary barotrauma patients. The authors also performed computed tomography (CT) of the chest and found 13 lung abnormalities among the 15 patients with pulmonary barotrauma. Both studies suggest that occult lung disease and asthma may contribute to unexplained cerebral air embolism. However, other authors have disagreed with these interpretations.[17] Epidemiologic studies have not demonstrated a significant relationship between asthma and an increased risk for pulmonary barotrauma. In a retrospective study of submarine candidates undergoing submarine escape training, Benton and associates[18] identified a small forced vital capacity as a risk factor for pulmonary barotrauma.

Clinical Manifestations of Arterial Air Embolism. The brain is commonly involved. Loss of consciousness, hemiplegia, stupor, and confusion occur within minutes after the diver surfaces. Also frequently seen are seizures, vertigo, visual disturbances, sensory changes, headache, and circulatory collapse.[19] In a study of pulmonary barotrauma resulting from submarine escape training, Elliott and associates[19] found that most individuals fully recover if they are promptly recompressed.

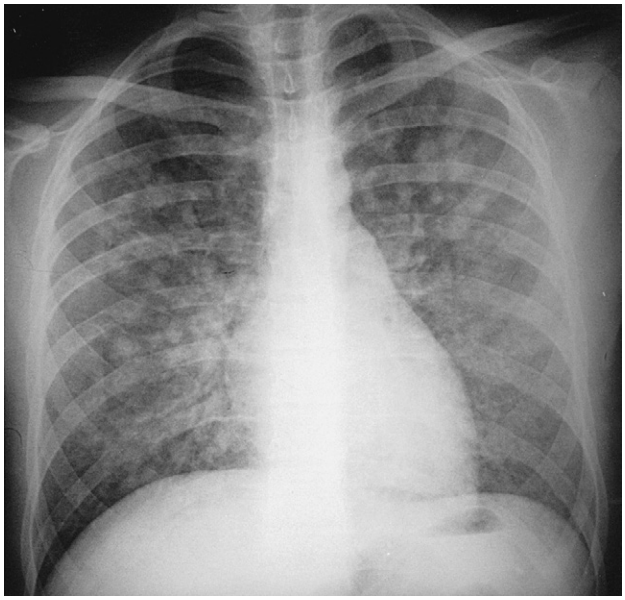

FIGURE 71-3 ■ Chest radiograph from a diver showing pulmonary barotrauma and near drowning. The diffuse pulmonary edema pattern is suggestive of water aspiration.

Victims of arterial gas embolism frequently suffer near drowning episodes when they lose consciousness in the water. Chest radiographs (Fig. 71-3) may show a diffuse lung edema pattern. About 5% of patients immediately develop apnea, unconsciousness, and cardiac arrest. This catastrophic course results from filling of the heart and great vessels with air. Many of these individuals are unresponsive to cardiopulmonary resuscitation and advanced life support measures.[20] Harker and coworkers[21] reported the pulmonary findings of 31 patients with cerebral air embolism from diving: 25% demonstrated pneumomediastinum; 10%, subcutaneous emphysema; 6%, pneumocardium; 3%, pneumoperitoneum; and 3%, pneumothorax. Fifty-two percent had pulmonary infiltrates indicating associated drowning.

Extra-alveolar gas can enter the mediastinum and the subcutaneous spaces of the neck and can enter the pleural space. Mediastinal emphysema is generally associated with mild substernal pain or no symptoms. The pain is described as either a dull ache or tightness and may be exacerbated by inspiration, coughing, or swallowing. The pain may radiate to any portion of the upper torso. Unless massive, this condition is not usually associated with respiratory symptoms. On physical examination, a crunching sound synchronous with cardiac action may be auscultated (Hamman's sign). The chest radiograph confirms the diagnosis. No treatment is usually necessary.

Air dissecting cephalad from the mediastinum causes subcutaneous emphysema in the neck. Swelling and crepitus in the root of the neck and supraclavicular fossa, sore throat, hoarseness, and dysphagia may result.

Radiographs may be helpful in detecting subtle cases, but CT scans are more sensitive and can be useful to confirm the diagnosis of barotrauma in doubtful cases. Brain MRI done within a few days of injury will show scattered grey and white matter lesions.[21a] When extra-alveolar gas ruptures into the pleural space, a pneumothorax results. Laboratory evaluation may show an elevated hematocrit level and elevation of several serum enzyme levels.[22] Treatment for arterial gas embolism requires recompression in a hyperbaric chamber (see later).

Middle Ear Barotrauma

Middle ear barotrauma occurs when the eustachian tube is blocked during descent and the middle ear space cannot equilibrate with the increasing ambient pressure. The tympanic membrane is displaced inward and may rupture. The middle ear may fill with blood from engorged mucous membranes. Infection and hearing loss are complications. Symptoms during descent include pain in the affected ear that increases with depth. Relief of pain without proper ventilation of the middle ear usually indicates that the tympanic membrane has ruptured. Cold water entering the middle ear when the tympanic membrane ruptures may cause vertigo due to unilateral vestibular stimulation. Late complications include bacterial otitis media, serous otitis media, and chronic tympanic membrane perforation.[11] In rare cases of middle ear barotrauma, the facial nerve is injured by the increased pressure and a temporary facial paralysis results.[23] A modified Valsalva maneuver is commonly used to equilibrate middle ear pressure. Because middle ear barotrauma causes edema and hemorrhage into the middle ear, equalization is usually impossible to achieve until healing is complete. The presence of middle ear barotrauma usually prohibits diving until it is resolved.

Alternobaric Vertigo. Vertigo occurs on ascent when the reduction of middle ear pressure is not uniform in both ears. The pressure imbalance causes differential stimulation of the labyrinths, resulting in vertigo. The sensation of vertigo may persist for 1 to 2 hours after diving and gradually disappears without therapy. Symptoms are similar to labyrinthitis and can include nausea, vomiting, and generalized malaise. Some subjects may be particularly susceptible to alternobaric vertigo if they have had previous injury or infection of the labyrinths. In susceptible individuals, use of moderate doses of antihistamines or decongestants may prevent symptoms. The disorder must be differentiated from vestibular DCS, which is usually associated with deeper, prolonged diving or saturation diving.

Inner Ear Barotrauma

Inner ear barotrauma occurs on descent in divers who perform a forceful Valsalva maneuver to equalize middle ear pressure. If the eustachian tube is blocked, middle ear pressure becomes progressively more negative relative to ambient pressure.[11,24] When a Valsalva maneuver is performed, intrathoracic pressure, central venous pressure, spinal fluid pressure, and inner ear pressure rise above ambient pressure, thereby increasing the gradient between the inner ear perilymph and the middle ear. If the pressure between the inner ear and middle ear becomes large enough, the round or oval window will rupture, and perilymph will leak from the inner ear to the middle ear. Symptoms include vertigo, nausea, vomiting, tinnitus, and loss of hearing on the affected side. Severity may vary, and some divers will complain of hearing loss, tinnitus, or vertigo only after diving.

Treatment varies from conservative therapy to surgical repair of the round or oval window. Vertigo and nausea can be treated with benzodiazepine medications. Tinnitus and reduced hearing may become chronic, particularly if no treatment is provided. Divers who exhibit clinical evidence of inner ear barotrauma with intact round and oval windows may have a pressure injury to the organ of Corti and the vestibular system.[25] Klingmann and colleagues found an increased prevalence of a patent foramen ovale (PFO) in divers with inner ear barotrauma.[26]

Sinus Barotrauma

When a sinus orifice is occluded, pressure within the sinus becomes negative with respect to ambient pressure, and mucosal blood vessels become engorged and eventually rupture. Pain over the affected sinus during descent and epistaxis on ascent are usual symptoms. Headache following a dive may indicate sphenoid sinus barotrauma. The disorder is usually self-limiting; treatment includes decongestants and maneuvers to drain the affected sinus. Persistence of blood in the sinus may result in bacterial sinusitis. Prevention is accomplished by avoiding diving with congestion of the nasopharynx and prudent use of decongestants. If a maxillary sinus orifice is occluded, the maxillary branch of the trigeminal nerve may be compressed during ascent and result in infraorbital paresthesias that usually resolve in 2 to 3 hours.

Less Common Forms of Barotrauma

Facial barotrauma (mask squeeze) occurs in the distribution of the diving mask. Facial edema, ecchymoses, and conjunctival hemorrhages are noted after diving. Retroorbital hematoma has been described as a complication.[27] The disorder is self-limiting; no treatment is needed.

Tooth barotrauma occurs on descent when air pockets under fillings or in areas of decay become compressed. Severe toothache results. Rarely, an air pocket under a filling expands on ascent and ejects the filling from the tooth. Careful dental work prevents this disorder.[28]

Gastrointestinal barotrauma occurs when air enters the stomach during diving due to faulty breathing apparatus or by air swallowing. On ascent, the expanding air will distend the stomach or intestine. Gastric distention can occlude the esophageal-gastric junction and prevent eructation. Distention of the stomach may cause stomach rupture and pneumoperitoneum.[29] The diver experiences abdominal pain, which increases during ascent. Treatment requires surgical repair of the ruptured viscus.

Divers with previous gastric surgery may be prone to gastric air trapping.[30]

DISSOLVED INERT GAS EFFECTS: HENRY'S LAW

Gas Solubility

Pressure determines the amount of gas that is dissolved in tissues and fluids of the body. A person subjected to increased ambient pressure takes up gases into the tissues of the body according to an exponential kinetics process. At equilibrium, the partial pressure of the gas and the solubility of the gas in the specific tissue (Table 71-2) determine dissolved gas content of tissues. Inert gases (nitrogen, helium) are limiting factors in diving because, as the diver ascends with increased dissolved gas in the tissues, these gases are able to supersaturate quickly and form a gas phase. Oxygen and carbon dioxide do not become supersaturated in most diving exposures.

Inert Gas Kinetics

Gases dissolve in tissues, fats, and water according to Henry's law: $Q = c \cdot P$, where c, a solubility coefficient, and P, the partial pressure of the gas, determine the quantity (Q) of dissolved inert gas. Solubility coefficients for water and lipid are provided in Table 71-2. Although Henry's law determines the amount of gas in the tissue, there is a finite time required for equilibrium to be achieved. Factors that affect the rate of entry include blood flow to the tissue and the rate of diffusion of gases into the tissue. Tissue gas concentration follows an asymptotic curve in which the tissue gas concentration approaches the maximum concentration for the given pressure after time has elapsed. These curves represent different body compartments that have different gas exchange characteristics.[31] Similar kinetics control the washout of inert gas from tissues when ambient pressure is reduced.

The majority of diving is of short duration (i.e., minutes to hours) and shallow exposure (i.e., in depths shallower that 200 feet). Such diving exposures allow only a few tissue compartments to reach equilibrium based on Henry's law, while most are not fully saturated. Divers can return to the surface from these short-duration dives by following a schedule of ascent based on depth and time.[31] Decompression tables have been incorporated into submersible wrist-mounted computers, which provide instantaneous information on decompression during diving.

When diving exposure is long enough, all tissues reach equilibrium at the new ambient pressure and are fully saturated with inert gas. Bond[32] demonstrated that divers could spend prolonged periods (weeks) under pressure, with all tissues saturated at the increased pressure, without serious physiologic changes. Working dives conducted with Bond's techniques have been performed at depths over 1000 feet in open sea for periods up to 3 to 4 weeks.

TABLE 71-2. Characteristics of Inert Gases*

Gas	Molecular Weight	Lipid Solubility†	Water Solubility	Narcotic Potential‡
Helium	4	0.015	0.009	0.23
Neon	20	0.019	0.009	0.28
Hydrogen	2	0.036	0.018	0.55
Nitrogen	28	0.067	0.013	1.00
Argon	40	0.140	0.026	2.32

*Solubility of the various gases in lipid is related to their narcotic potential. Helium is the least and argon the most narcotic gas in the list.
†Expressed as gas volume/solute volume at 1 bar.
‡Values relative to nitrogen.

Inert Gas Supersaturation in Tissues

When the diver ascends after breathing pressurized gas, tissues can become supersaturated with gas. When the degree of supersaturation becomes excessive, dissolved gas will leave solution and form free gas. Boycott and colleagues[33] first demonstrated that symptoms could be prevented by keeping the degree of supersaturation below a certain level. They suggested a 2 : 1 ratio of initial to final tissue partial pressure after ascent. Their concept of a critical pressure ratio is the basis for most decompression tables used to prevent DCS.

Boycott and colleagues[33] assumed that the body could be considered as a set of tissue compartments with different rates of gas uptake and elimination. Although these tissues do not represent discrete anatomic structures, they provide a convenient means to understand the kinetics of inert gas exchange. In most decompression tables, stops during ascent are selected to avoid excess supersaturation in tissues with specific gas-exchange rates (Fig. 71-4). Decompression procedures are well defined for air and other mixtures of nitrogen and oxygen; helium and oxygen; nitrogen, helium, and oxygen (trimix); hydrogen and oxygen; and a few rare earth gases such as argon and neon used in experimental exposures.

Decompression Sickness

Excess supersaturation causes dissolved gases to change phase to the gaseous form in blood and tissues.[34] Expansion of gases in blood and tissues on ascent results in damage and dysfunction of tissues and organs and venous gas embolism to the lungs. Sudden decompression following a long, deep dive can be fatal. DCS is the disorder caused by damage to organs and tissues as a result of free gas production and growth.

In the 19th century, Bert[35] described the pathophysiology of DCS. Several investigators in the early 20th century concluded from autopsies on divers and caisson workers that DCS is caused by free gas in the blood and tissues.[36] Based on free gas volume and location, they

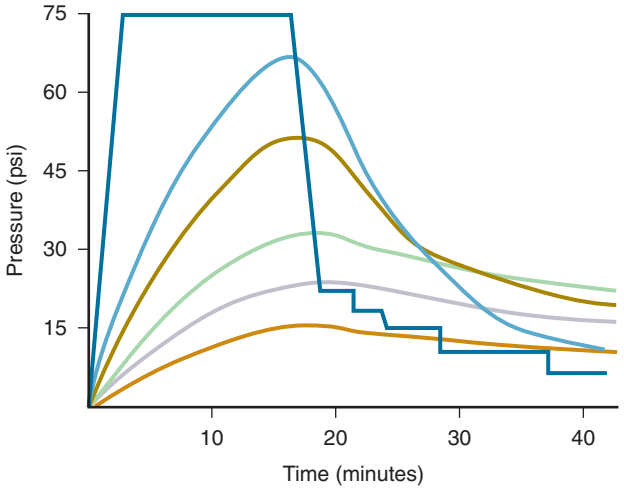

FIGURE 71-4 ■ Theoretical nitrogen gas concentrations are expressed in units of pressure for an exposure of 75 psi (5.1 ATA) following the depth-time profile indicated by the *dark blue line.* Curves are shown for five theoretical tissue compartments with different rates of gas exchange. Tissue gas concentration increases during exposure to pressure. When pressure is reduced, gas concentration in tissues begins to fall. Stops during return to baseline allow tissue concentration to fall to a safe level of supersaturation before reducing pressure further. (Data from Boycott AE, Damant GCC, Haldane J: The prevention of compressed air illness. J Hyg [Cambridge] 8:342–443, 1908.)

were able to explain the variety and severity of the symptoms. Paralysis resulted from free gas in the spinal cord, cerebral dysfunction was thought to result from free gas in the brain, and dyspnea was associated with free gas in the pulmonary circulation. Muscle and joint pain may be due to free gas in ligaments, fascia, periosteum, marrow, or nerve sheaths.

Hallenbeck and colleagues[37] described effects of free gas in blood and tissues that were not caused by mechanical obstruction. Subsequent studies identified clotting and platelet activation by bubbles, intravascular coagulation, plasma leakage from the intravascular space, hemoconcentration, and hypovolemia[38] as manifestations of bubble surface effects. Hematologic abnormalities are infrequent in mild cases.[39] Venous gas emboli are commonly present before overt symptoms of DCS appear.[40]

Free gas and tissue injury result in activation of the inflammatory cascade.[41] The inflammatory response causes fluid to leak into the interstitial tissues of the systemic and pulmonary vascular beds.[42] In severe cases, pulmonary edema, hypovolemia with significant plasma loss, and hemoconcentration will result.

Factors Affecting Risk of Decompression Sickness

The use of Doppler ultrasound for intravascular bubble detection has provided insight into the presence of bubbles following diving.[43] Many divers demonstrate venous gas emboli but no manifestations of DCS. The concept of a threshold or dose-response effect has been postulated, wherein a clinical disorder requires a certain volume of free gas whereas lesser amounts are asymptomatic.[44] However, the presence of venous bubbles in asymptomatic divers and aviators is associated with increased risk of developing symptoms of DCS after diving or altitude exposure.[45,46] Exercise and temperature during decompression have recently been shown to be risk factors for DCS. Repeated diving exposures over several months appears to lower DCS.[46a]

Patent Foramen Ovale. Moon and coworkers[47] reported 30 patients with a history of DCS who were studied with bubble contrast echocardiography for identification of a PFO. Sixty-one percent of 18 patients with serious DCS had shunting, whereas a 25% prevalence was seen in normal volunteers. Wilmshurst and associates[48] identified a single patient with paradoxical gas embolism through an atrial septal defect and suggested that the atrial septal defect augmented symptoms of DCS in this patient. Moon and coworkers[49] evaluated 90 divers with previous DCS who were studied using bubble contrast echocardiography and color flow Doppler to detect right-to-left shunting through a PFO. Fifty-nine of 90 had experienced serious decompression symptoms, whereas 31 had experienced pain only or mild symptoms.

Cerebral gas embolism is usually thought to be due to lung barotrauma. However, in the presence of a PFO, cerebral gas embolism can be caused by venous bubbles transiting the PFO.[50] Germonpré and associates[51] found that divers with cerebral DCS have a high incidence of large PFO compared to control subjects. The presence of a PFO may be associated with a two- to fourfold increase in the risk of DCS.[52] The high prevalence of PFO in the population and the very low incidence of DCS suggest that a PFO can only play a minor role in the pathophysiology of DCS. In some divers, an intrapulmonary shunt can allow venous bubbles to enter the left heart.[52a] There is no current need to close a PFO as a prophylactic measure.[53]

Age. Attempts to determine the impact of age on susceptibility to DCS have aroused much debate. A 10-year study by the U.S. Air Force on flight exposures ranging from 1500 to 30,000 feet show a threefold increase in susceptibility when comparing aviators 18 to 21 years of age with aviators 42 years of age and older.[54] The study suggests a trend toward increased DCS susceptibility in individuals over age 42. Carturan and colleagues[55] examined the effects of age and physical condition on venous bubble formation in sport divers. They found a correlation between bubble formation, increased age, and decreased physical condition. However, both of these studies have significant methodologic problems. Klingmann and coworkers reported an increased incidence of DCS in novice divers compared to more experienced divers.[56]

Clinical Manifestations

Sport and military divers have similar rates of type I and type II DCS (Table 71-3), whereas commercial divers have the highest incidence of DCS. Musculoskeletal DCS (type I) is the most common form. In the late 1990s, the incidence of DCS was about 2 in 10,000 dives for the sport diver.[57]

TABLE 71-3. Frequency and Incidence of Decompression Sickness (DCS) in Sport, Military, and Commercial Air Diving Populations

Source	Military	Sport	Commercial	All
Total dives*	648,488	2,577,680	43,063	3,269,231
Frequency				
Total DCS*	172	878	152	1,202
Type II DCS*	86	649	9	744
Incidence DCS†	2.65	3.41	35.3	3.68
Incidence DCS II†	1.33	2.52	2.09	2.28

*Values are number of events. Type II DCS is systemic, serious DCS.
†Incidence per 10,000 dives; DCS II, DCS type II.

TABLE 71-4. Frequency of Decompression Sickness (DCS) Symptoms in 100 Cases

Symptom	Percentage of All DCS Symptoms
Skin itch	4
Headache	11
Fatigue/malaise	13
Bone/joint pain	54
Spinal/back pain	11
Spinal/neurologic	22
Respiratory	21

Data from Navy Department: U.S. Navy Diving Manual, Vol 1, Rev 3: Air Diving (Publication No. NAVSEA 0994-LP-001-9110). Washington, DC: U.S. Navy Department, 1996.

Symptoms of DCS can mimic a variety of other disorders (Table 71-4). Free gas entering the venous system will cause varying degrees of pulmonary vascular obstruction. A classic syndrome ("chokes") manifested by chest pain, dyspnea, and cough is described.[58] DCS is often associated with free gas in the blood and local tissue injury that activates an inflammatory process,[41] with damage to vascular endothelium, microvascular occlusion, and focal regions of tissue ischemia. A common manifestation of DCS in divers is spinal cord dysfunction, usually at levels below the diaphragm.[59] Symptoms include paresthesias, muscle weakness, paralysis of the lower extremities, bowel or bladder incontinence, urinary retention, and sexual impotence. Hawes and Massey[60] reviewed the neurologic manifestations of DCS. In cases of sudden ascent from deep depth ("blowup"), a massive DCS syndrome will occur with both cerebral and spinal neurologic symptoms, unconsciousness, hypovolemic shock, pulmonary edema, and a high mortality rate. A rare but important symptom of systemic (type II) decompression sickness is sudden acute neurologic hearing loss and vestibular dysfunction. DCS of this type usually occurs from deep, prolonged diving exposures and, if untreated, can result in permanent deafness.[61] Presence of a PFO (see earlier) can contribute to cerebral gas embolism in DCS.

The musculoskeletal form of DCS is manifested by pain in the extremities and joints.[62] Symptoms of local joint pain are often confused with pain from injuries, and the diagnosis of DCS may be missed. In some populations, a high incidence of osteonecrosis is found in divers who have experienced musculoskeletal DCS in the distant past or who have experienced deep, prolonged exposures in caisson work,[62] as well as in diving instructors[63] and in workers in commercial diving operations. An erythematous or purpuric skin rash (cutis marmorata) may also be a manifestation of DCS. A systematic method for diagnosing DCS is described by Grover and colleagues.[64]

Treatment

The clinical manifestations of arterial gas embolism and DCS often overlap, and treatment goals for both disorders include recompression and other adjunctive measures. The initial treatment of DCS and arterial gas embolism should always be a return to pressure by recompression in a hyperbaric chamber and administration of oxygen at increased ambient pressure (hyperbaric oxygen). Fluid replacement and antiplatelet agents are also a part of the initial treatment. Once stabilized with pressure and oxygen, the patient must be decompressed slowly to permit the inert gas to be carried away from tissues by the circulatory system and then to be exhaled by the lungs. With early treatment, DCS and air embolism generally have an excellent prognosis for recovery. When delay occurs, or when the injury is severe, permanent injury to the brain or spinal cord may result.

Hyperbaric Therapy. Treatment of DCS and arterial gas embolism should be instituted with recompression as soon as possible after the injury. A history and physical evaluation, including a neurologic examination and cognitive assessment, should be obtained before treatment when possible. Therapy is provided in a hyperbaric chamber by a trained medical team. Return to depth underwater is generally not a satisfactory method of recompression for DCS or air embolism. However, this treatment has been used in remote areas with a support team properly equipped and trained in open water

treatment. Hyperbaric therapy can be briefly delayed for further diagnostic studies only if the findings from such studies could influence the choice of therapy. The usual practice is to follow the standard protocols for pressure treatment outlined in the *U.S. Navy Diving Manual*[8] that involve a pressure exposure equivalent to a 60-foot depth in seawater (60 fsw) using intermittent oxygen therapy.

Most practitioners use a hyperbaric treatment protocol lasting about 6 hours (see Table 6 in *U.S. Navy Diving Manual*[8]) for treatment of types I and II DCS. Recompression therapy for cutis marmorata resulting from DCS has been recommended by some, but most cases, when not associated with other evidence of DCS, resolve spontaneously. Itching and erythema of the skin may also be noted following hyperbaric chamber exposures, but these skin findings alone do not require recompression therapy.

When a diver ascends from extreme depths with significant missed decompression, the practitioner may choose to use recompression tables that pressurize the diver to a "depth of relief," to use alternate gas mixtures (i.e., helium and oxygen), or to hold the diver for over 24 hours at a single depth to stabilize the medical status (saturation treatment).[65] For surface-supplied air and scuba divers, the principal treatment gases are oxygen and air. For treatment depths greater than 60 fsw (18 meters of seawater [msw]), enriched nitrogen-oxygen (nitrox) or helium-oxygen (heliox) may also be used. Helium-oxygen mixtures are sometimes used for treatments deeper than 200 fsw (60 msw).

Repeated hyperbaric oxygen treatments can be given, although end points for repetitive therapy are not well defined. Treatments can be administered until no further change of symptoms is found or for a fixed number of exposures (e.g., five). However, controlled trials to determine efficacy of repetitive treatments are not available. Treatment of arterial gas embolism follows similar protocols. Recompression to 60 fsw and oxygen therapy are usually successful.[66] Recompression to 165 fsw depth equivalent (5 ATA) is recommended if symptoms persist after recompression to 60 fsw.[8]

Supplemental Oxygen and Fluids. Early administration of supplemental oxygen on the surface is thought to be beneficial for treating both DCS and arterial gas embolism.[67] The recommended inspired concentration of oxygen is 100%. Intravenous fluid administration also may be a useful initial treatment. Central nervous system injury may be exacerbated by hyperglycemia, and glucose-containing intravenous solutions should be administered cautiously. Measurement of hematocrit and urine specific gravity is useful to guide fluid replacement therapy.

Diagnostic Testing

Chest radiography can be used to diagnose pneumothorax, pneumomediastinum associated with pulmonary overpressure accidents, and the pulmonary abnormalities associated with aspiration or capillary leakage associated with chokes. Chest or abdominal CT can also be used to diagnose pneumothorax, pneumomediastinum, or pneumoperitoneum. In most cases, it is not necessary to postpone recompression treatment in order to obtain radiographic studies. If pneumothorax is suspected, a chest radiograph can be helpful in making the decision to insert a chest tube. Neurologic and psychological testing may be useful in determining response to treatment when brain injury is present. Electronystagmography and audiography may be useful in distinguishing inner ear DCS from inner ear barotrauma. Inner ear DCS requires recompression, whereas inner ear barotrauma is managed with bed rest, avoidance of straining, and possibly surgical intervention. The circumstances causing the two syndromes are distinct (see earlier) and are helpful in the differential diagnosis; however, in the event the distinction cannot be made, recompression therapy may be of benefit. Central nervous system injury can be diagnosed by magnetic resonance imaging (MRI) and correlated with clinical findings.[68] MRI images of the brain in divers with no history of decompression-related disorders are also found to be abnormal in some studies[69]; the significance of MRI findings in these individuals is unclear. DCS case reviews provide some guidance on use of MRI in patients with DCS.[70]

Emergency Treatment

Because divers may be injured in areas remote from medical care, treatment measures should be instituted during transit to a hyperbaric chamber facility. Emergency treatment before transfer of an injured diver should include 100% oxygen by mask, aspirin 325 to 975 mg by mouth, and Ringer's lactate (or normal saline) intravenously. One study of oxygen, aspirin, intravenous fluids, and hydrocortisone 1 to 2 g intravenously during transit to a hyperbaric chamber found that two thirds of the cases had a favorable outcome[71]; however, it remains unproven whether emergency treatment alters long-term outcome. A favorable response to urgent care should not prolong transfer to the closest facility capable of providing recompression therapy.

INERT GAS NARCOSIS

Inert gas narcosis (nitrogen narcosis) results from breathing air at depths greater than 100 fsw.[72] Symptoms include loss of fine motor control and high-order mental skills, inappropriate response to emotional stress, hostility, and unconsciousness. Symptoms increase with depth from 100 feet. At 300 to 400 feet, unconsciousness may occur owing to the anesthetic effect of nitrogen at this pressure. In diving deeper than 200 feet, helium replaces nitrogen as the inert gas to prevent narcosis. Fatigue, heavy work, and hypothermia can augment the narcotic effect of nitrogen. Symptoms disappear immediately on ascending to a shallow depth. Often there is amnesia for the events that occurred below.[72] Nitrogen effects on nervous function are thought to have the same mechanism of action as anesthetic gases. Narcotic potential varies among the inert gases (see Table 71-2).

OXYGEN TOXICITY

Oxygen toxicity in divers primarily affects the central nervous system. Pulmonary oxygen toxicity is rare in diving, but may be of some concern in prolonged hyperbaric oxygen treatments. Acute toxicity to the brain usually occurs when oxygen partial pressure exceeds 1.4 ATA, although cases have been noted with P_{O_2} as low as 1.2 ATA. Higher partial pressures can be tolerated for brief periods. The affected diver may experience auditory or visual hallucinations, and commonly suffers a grand mal seizure. When underwater, a seizure can leads to drowning. Use of enriched oxygen mixtures by sport divers has increased the incidence of acute oxygen toxicity in this population. A detailed discussion of oxygen toxicity can be found in standard textbooks on diving.[73]

MEDICAL QUALIFICATIONS FOR DIVING

Military divers have the most stringent requirements, whereas recreational divers have the most relaxed requirements. Commercial divers, caisson and tunnel workers, and hyperbaric chamber workers all have unique standards. Disorders that limit cardiovascular or pulmonary function during exercise, physical deconditioning, metabolic disorders that limit exercise capacity, and certain physical handicaps can compromise diving safety.

Exercise Requirements

Workloads in diving vary based on the type of diving (see previous discussion). A diver swimming underwater at a speed of 1.0 knot consumes about 24 mL of oxygen per kilogram per minute.[74] Safety considerations suggest that divers should tolerate a sustained workload of about 24 mL/kg per minute to ensure safety under adverse diving conditions. Divers who do not achieve this level of fitness should avoid exposures that may require high levels of physical exertion.

Disorders Causing Sudden Unconsciousness

Seizure disorders are considered to be a contraindication to diving because a diver sustaining a seizure underwater is at risk for drowning and may compromise the safety of others who attempt a rescue. It has been recommended that a diving candidate with a history of a seizure disorder should be seizure free without antiseizure medications for 4 years before being considered for diving.[75] This recommendation, however, is not supported by clinical studies, although isolated cases of underwater seizures in epileptic divers have been recounted. Insulin-dependent diabetes mellitus is considered a contraindication to commercial and military diving due to the risk of hypoglycemia; however, special training for diabetic recreational divers has allowed safe diving for insulin-dependent sport divers.[76]

Pulmonary Disorders

Asthma has been a subject of controversy in diving because of possible air trapping and pulmonary overinflation during ascent. However, an increased risk for pulmonary barotrauma has not been supported by clinical observation.[77] Criteria for safe diving by patients with a history of asthma include evidence that midexpiratory flow is not reduced after exercise by greater than 50%. A more detailed discussion of issues related to asthma and diving has been published.[78] Clinical and operational experience suggests that patients with a history of spontaneous pneumothorax may be at risk for lung collapse and development of a progressively worsening tension pneumothorax during diving. Treatment requires immediate decompression of the pleural space through an intercostal needle or chest tube and may be difficult in remote diving sites.

Cardiac Disorders

Patients with coronary disease may develop angina pectoris, myocardial infarction, or sudden death while diving. Caruso and associates[79] found that the highest incidence of diving-related death from cardiovascular disease in divers occurs in the age range from 60 to 70 years (Fig. 71-5). Mebane and colleagues[80] reported the mortality experience from the Diving Alert Network. Of 33 cases of sudden death while diving, 31 were attributed to coronary disease, one was related to a cerebral vascular accident, and one was related to aortic stenosis. Screening of diving candidates for coronary disease is particularly important in the sport diving community, in which candidates at increased risk for

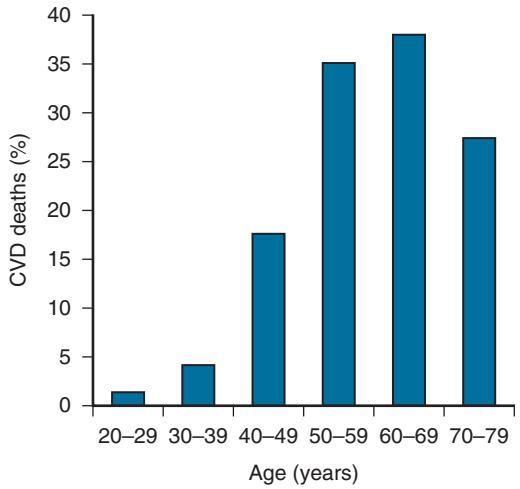

FIGURE 71-5 ■ Incidence of cardiovascular-related diving deaths as a percentage of all deaths in different age groups of recreational divers. (Data from Caruso JL, Bove AA, Uguccioni DM, et al: Recreational diving deaths associated with cardiovascular disease [abstract]. Undersea Hyperb Med 28:76, 2001.)

coronary disease due to age and chronic illness may present for training.

Diving candidates with atrial septal defects risk paradoxical embolism of gas bubbles that form in the venous circulation during decompression.[74] The presence of an atrial septal defect is considered to be a contraindication to diving. PFO effects on diving are discussed in an earlier section. A ventricular septal defect does not appear to produce a risk for paradoxical embolization of bubbles. Patients with a right-to-left shunt and arterial hypoxemia will normally have severely limited exercise capacity and should not dive. A detailed treatment of this topic can be found elsewhere.[74]

Diving-Induced Arrhythmias

Reflex bradycardia from diving has been described by a number of investigators.[81] This arrhythmia is thought to be related to facial immersion and cooling, and is found in diving mammals[82] as well as humans. The autonomic adjustments to apneic diving in marine mammals appear to be an oxygen-conserving reflex, but this effect does not appear to be significant in humans in spite of a well-developed reflex in many free divers. Ackerman and colleagues[83] described a series of drowning cases associated with a familial inherited long QT syndrome. The syndrome was confirmed by genetic testing. Although their cases were related to swimming, the same risk is likely to occur in divers with the long QT syndrome.

DROWNING

Drowning is reported as the leading cause of death in the approximately 100 to 150 scuba fatalities in the United States each year[84]; however, arterial gas embolism may be the precipitating factor or even the cause of death in many of these accidents.[85] In the United States, drowning of males is approximately five times more common than of females. As with fatal automobile accidents, the single most important factor in drowning incidents involving adults is alcohol, contributing to deaths in 30% to 70% of cases.[86] With scuba-related drowning incidents, the most common factor is entanglement or the diver running out of air at depth or in a cave. Although the terms *drowning* and *near drowning* have been used in the past to describe victims who respectively either died or survived (at least temporarily), it is simpler and preferable to use the term *drowning* for all individuals who suffer from submersion incidents.[87,88]

There is strong evidence that intentional hyperventilation before breath-hold diving is associated with drowning episodes.[6] Hyperventilation reduces the arterial P_{CO_2}, so the breath-hold breakpoint is prolonged sufficiently for hypoxemia to occur before the individual is forced to breathe. The hypoxemia in turn causes the individual to lose consciousness, and the submersion incident then occurs. This is termed *shallow water blackout*.

Hypothermia leading to drowning has been reported frequently; however, in diving fatalities this is an unusual occurrence due to the almost universal use of thermal protection by divers. Hypothermia reduces a person's ability to function until the point of unconsciousness or helplessness is reached. At that time, the victim's head falls into the water, resulting in drowning. Maximum breath-hold times of normally clothed individuals drop dramatically in cold water, further compromising their ability to survive in rough water where they may be intermittently submerged. However, in rare circumstances, hypothermia can have a protective effect on the drowning victim (see later).

Hypothermia is one of many conditions that can precipitate drowning by causing unconsciousness. In the case of scuba diving incidents, contamination of the diver's air supply with carbon monoxide produces rapid unconsciousness, and oxygen-induced seizures (see earlier) have been implicated as the cause of death in divers using oxygen-enriched air as a breathing mixture.

Pathophysiology

Approximately 10% to 15% of drowning victims may not aspirate fluid during immersion.[89] To account for the lack of aspiration in these individuals, it has been hypothesized that reflex laryngospasm occurs and persists until reflex ventilatory activity ceases. However, experimental data to support this hypothesis are lacking. In drowning victims who do not aspirate, the period of hypoxemia generally is as long as the immersion incident itself. If ventilation can be reestablished before the development of injury secondary to hypoxemia, recovery typically is rapid and uneventful. A review of early "dry" drowning studies does not support the dry drowning hypothesis.[90] It is much more likely that dry drowning actually represents arrhythmic death.

Unlike the victim without aspiration, the individual who aspirates remains hypoxemic, even after being removed from the fluid medium and even after ventilation is reestablished. As a result, in the latter group the period of hypoxemia is longer, and secondary damage to other organ systems is more likely to occur.[91] The continuing hypoxemia is most frequently due to direct lung injury from the aspirated fluid, which causes areas of low ventilation-perfusion ratio to develop. With saltwater aspiration, it is believed that hyperosmotic fluid causes transudation of fluid into alveoli, and the aspiration of debris (sand, diatoms, algae, etc.) causes a reactive exudate. As a result, alveoli become filled and are not ventilated. In freshwater aspiration, it is believed surfactant is washed out of the lungs, causing areas of focal alveolar collapse, leading to areas of shunt and low ventilation-perfusion ratio, and hypoxemia. These abnormalities persist until the lung damage resolves or until surfactant can be regenerated.

Victims often swallow large amounts of fluid during the drowning episode, so further decreases in ventilatory function may occur as a result of elevation of the diaphragm from gastric distention. Vomiting and aspiration of gastric contents may further complicate the drowning episode. Hypoxemia and decreased alveolar ventilation ($\dot{V}_{A_2}$) produce a number of consequences. Elevations of arterial P_{CO_2} and decreases in pH occur quickly.

Metabolic acidosis can be severe because the victim often struggles during the drowning episode. Finally, cardiovascular collapse may occur, resulting in cardiac arrest. If hypoxemia and decreased cardiac output persist long enough, anoxic cerebral damage can ensue.[92,93] Although electrolyte disturbances are usually not a significant problem in drowning, the exception to this situation appears to be drowning victims in the Dead Sea, where electrolyte concentrations are greater than those in normal seawater. Victims of drowning in that unique environment have major electrolyte abnormalities, which may be responsible for fatal arrhythmias in that group, whereas the marked hypertonicity of the fluid may explain the severe lung injury that these victims may receive.[94,95] The remaining specific consequence of drowning is aspiration pneumonia. The pathogens and the clinical picture of pneumonia associated with drowning have been reviewed extensively.[96]

Because cardiac arrest is secondary to hypoxemia in drowning, it takes a significant amount of time to occur. If the water in which the victim is immersed is cold enough, if the surface area–to-mass ratio of the victim is large enough, and if the victim swallows enough water, core temperature may decrease sufficiently that oxygen demands are markedly decreased. However, it is unclear whether this mechanism is adequate to explain the degree of cooling and the amount of cerebral protection that appears to occur in some incidents.

Clinical Presentation

The clinical presentation of drowning victims is highly variable. The patient who is unconscious and reported to be without vital signs at the site of the accident may be hemodynamically stable and neurologically intact in the emergency room, whereas the victim initially thought to be hemodynamically stable at the scene might deteriorate significantly before arrival at the hospital.

Cardiovascular System

Victims of significant drowning may suffer cardiac arrest and respond to resuscitative measures. Whether this represents premature cardiopulmonary resuscitation by inexperienced rescuers or a response to therapy is not certain. However, it is not uncommon for a victim to be brought to the emergency room still requiring cardiopulmonary resuscitation. If the patient "responds" to cardiopulmonary resuscitation at the scene of the rescue with a stable rhythm or if the patient never suffers a cardiac arrest, supraventricular tachycardias are commonly seen. If the patient presents with a viable rhythm, it will most likely be supraventricular tachycardia secondary to hypoxemia and acidosis.[92] Usually, however, the patient is hemodynamically intact (i.e., adequate blood pressure and pulse with a presumably adequate cardiac output). Some patients may have a primary cardiac arrest that may mimic a drowning episode. This is known to occur in patients with coronary ischemia and in patients with the long QT syndrome. The spectrum and frequency of cardiac channel defects in swimming-triggered arrhythmia syndromes may be greater than previously suspected.[97,98] Pathologic diagnoses may be further complicated by terminal aspiration secondary to agonal breathing after cardiac arrest, and thus postmortem analyses that depend upon aspiration may be misleading.[99,100]

TABLE 71-5. Average Blood Gas Measurements in Hospitalized Near-Drowning Victims Breathing Room Air upon Admission

	pH	$Paco_2$ (mm Hg)	Pao_2 (mm Hg)	Base Excess (mEq)
Fresh water	7.26	38	66	−9
Seawater	7.37	36	56	−5
All	7.30	37	62	−7

Data from Modell JH, Davis JH, Giammona ST, et al: Blood gas and electrolyte changes in human near-drowning victims. JAMA 203:337–343, 1968.

Pulmonary System

Patients with water aspiration may present with few or no respiratory complaints or with severe pulmonary edema.[101] The latter is probably due to direct lung injury and is not usually cardiac in origin. Patients who have aspirated any significant quantity of water frequently have a widened alveolar-arterial oxygen gradient and anything from mild to severe hypoxemia. Arterial P_{CO_2} can be low or elevated depending on alveolar ventilation (Table 71-5). Chest radiographs can show patchy infiltrates, which are most common in the periphery or in the medial basal regions, or frank pulmonary edema (see Fig. 71-4).[102] The pulmonary edema is a form of the acute respiratory distress syndrome.[102] The clinical course cannot be predicted with certainty by the radiographic picture of lung injury. Victims with clear-cut pulmonary difficulties may show minimal radiographic abnormalities, and those with minimal clinical injury may have severely abnormal radiographic pictures.

An interesting form of pulmonary edema found in divers was described by Wilmshurst and colleagues[103] and by Hampson and Dunford.[104] This is manifest as severe dyspnea while diving, associated with arterial hypoxemia, lung congestion, and a normal cardiovascular system. The syndrome may be related to negative-pressure pulmonary edema, a phenomenon well described in the anesthesia literature.[105] Chenaitia et al. reported a case of Takotsubo cardiomyopathy with similar symptoms.[105a]

Neurologic Status

The neurologic status of patients can also be quite varied. To compare results among different groups, a classification scheme has been suggested to describe these patients.[106] In this classification system, patients are placed into category A, B, or C based on their initial neurologic status. Category A patients are awake,

category B patients are blunted, and category C patients are comatose. Within category C, patients are further classified as C1, C2, or C3, depending on their best motor response. The C1 comatose patient has a decorticate response, the C2 patient has a decerebrate response, and the C3 patient has no motor response at all.

Treatment

Restoration of normal neurologic function, although unusual, has been described even after prolonged drowning-induced cardiac arrest.[107,108] As cardiac arrest in this setting is invariably due to hypoxemia and acidosis, the first goal must be to establish a reliable airway and to supply as high an inspired oxygen concentration as possible. Until the results of arterial blood gas determinations are available, 100% oxygen should be provided. Endotracheal intubation is the preferred method for establishing an airway. This approach needs to take into account the possibility of a concomitant unstable neck injury if there is associated trauma,[109] and the risk of aspiration. However, without signs or a history of trauma, the risks of an unstable cervical spine injury are very low.[110] At present there are insufficient data to warrant the routine use of the Heimlich maneuver in near drowning victims.[111]

Patients with cardiac arrest due to drowning can have a profound metabolic acidosis. The doses of bicarbonate required to reverse such acidosis may be far larger than the doses recommended for patients suffering cardiac arrest from primary heart disease.[112] If bicarbonate is to be given, arterial blood gas determinations are necessary to guide precise bicarbonate dosing. Concurrently, a nasogastric tube should be inserted to decompress the stomach, and body temperature readings should be obtained to rule out hypothermia. In the presence of a significantly lowered body temperature, aggressive rewarming measures should be instituted.

Once an adequate airway has been obtained and spontaneous cardiac activity achieved, an adequate arterial P_{O_2} must be established to ensure adequate oxygen delivery to the tissues. Generally, in the drowning victim, hemodynamic stability is relatively easy to achieve. Occasional patients will have marked decreases in blood pressure and cardiac output. The initial therapy for hypotension of most etiologies is a trial of fluids, but for a drowning victim with pulmonary edema, this may not be appropriate. As a result, this group of patients may require invasive hemodynamic monitoring. With knowledge of pulmonary artery wedge pressure and cardiac output, more rational decisions concerning the need for fluids or pressors can then be made. Isolated measurement of the central venous pressure is generally not an accurate method of judging intravascular volume status in the presence of noncardiac pulmonary edema. In the case of immersion pulmonary edema in a diver, the cause of hypoxemia is not water aspiration, and therapy should include diuretics to reduce lung congestion.[104]

Positive end-expiratory pressure is extremely effective in reversing the abnormal ventilation-perfusion relationships leading to hypoxemia. Usually only modest amounts of pressure are necessary to achieve adequate oxygenation, and the improvement in pulmonary function can be quite dramatic. Positive end-expiratory pressure apparently does not alter the course of the underlying pulmonary injury but rather allows for adequate oxygenation while the lung is recovering. It also allows this recovery to take place at a level of inspired oxygen that is not in itself toxic to the lung.[113] Usually the pulmonary injury resolves over a period of 48 to 72 hours, and ventilatory support in most circumstances is relatively brief, unless infection develops. Consequently, in patients who are able to tolerate it, nasal continuous or bilevel positive airway pressure may be a reasonable method for short-term ventilatory support. However, the risk of aspiration is not inconsequential with this treatment.[114] At present there are insufficient data to warrant the use of inverse-ratio ventilation in cases of drowning.[115] It may be prudent to manage some drowning victims with high-flow oxygen delivery systems for relatively brief periods before resorting to more invasive methods of providing adequate oxygenation.

The use of antibiotics in the drowning victim who aspirates ocean water or swimming pool water is generally necessary only for those individuals who become febrile, develop new pulmonary infiltrates, or develop purulent secretions.[116] Prophylactic antibiotics do not improve mortality or decrease morbidity.[92] Because most pulmonary infections in the near drowning victim appear to be hospital acquired, prophylactic antibiotics seem only to select for more resistant organisms.[117] In addition to clinical experience, experimental evidence also suggests that the use of prophylactic antibiotics is not indicated. If the victim aspirates heavily contaminated water with a known or suspected organism (as in the case of aspiration in a hot tub), the use of prophylactic antibiotics may be appropriate. A rare complication of drowning is the aspiration of sand or gravel.[118] Although bronchoscopy for the routine management of the drowning victim is probably not warranted, consideration for this procedure should be made when unexpected difficulties with mechanical ventilation occur.

Routine use of adrenocorticosteroids to treat the lung injury associated with near drowning is unwarranted. Experimental evidence with this form of aspiration as well as others strongly suggests that steroids do not improve the long-term outcome or short-term morbidity.[119] Artificial and animal-derived surfactants,[120] extracorporeal membrane oxygenation,[121] cardiopulmonary bypass,[122] and hypothermia[123] have also been used to treat the pulmonary injury associated with drowning. Any victim who has more than minimal respiratory symptoms, an abnormal chest radiograph, or abnormal arterial blood gas measurements should be observed, because pulmonary damage may not be clinically manifest for several hours after the incident.[124] Nearly all patients who will demonstrate significant problems of gas exchange will do so by 4 to 8 hours after the incident; therefore, consideration for discharge from the emergency department may be appropriate in people who can be observed in this fashion.[125] Indeed, current evidence suggests many victims can safely be

sent home by lifeguards after a water rescue.[126] In the setting of a diving accident, an unconscious victim may have sustained an air embolism as well. Whenever doubt exists, both conditions should be treated simultaneously.

Prognosis

The prognosis for the drowning victim depends mainly on the duration of immersion, the length of the anoxic period, and the degree of damage secondary to the anoxic episode. Patients who arrive at the hospital neurologically intact have an excellent prognosis and should survive neurologically unimpaired. Additionally, the occurrence of an apparent (i.e., undocumented) cardiac arrest does not in itself suggest a poor outcome; however, cardiac arrest that persists through the period of initial first aid and transport to the hospital is a poor prognostic sign. The presence of spontaneous respirations on presentation to the emergency department following cardiac arrest in the field is a good prognostic sign.[127] The duration of immersion correlates with the degree of damage secondary to the anoxic episode and therefore with the outcome. No prognostic test has proven to be a reliable basis for treatment decisions, and predictions concerning outcome cannot be made in the presence of severe hypothermia.

Conclusion

Diving and work in compressed air have produced occupational exposure to hazardous environments for over 100 years. In the past 50 years, diving has become a recreation participated in by millions of individuals throughout the world. Besides the medical support for commercial diving and the unique training needed by physicians who support military diving, any physician may encounter a recreational diver seeking consultation about an illness related to a diving exposure, or medical clearance for diving. Therefore, knowledge of the basic physiology and pathophysiology is important in understanding the patient's illness or evaluation requirements. Occasionally a physician may be confronted with treatment for an acute medical emergency related to diving exposure, such as DCS, arterial gas embolism, or drowning. This chapter provides a basic introduction and a basis for initiating treatment, seeking consultation, or furthering education in this interesting area of environmental medicine.

KEY POINTS

- Middle ear barotrauma is the most prevalent diving injury, while pulmonary barotrauma, although uncommon, is the most severe form of barotrauma injury due to the accompanying cerebral arterial gas embolism.
- Decompression sickness results from dissolution of dissolved inert gas and results in free gas formation in blood and tissues following inadequate decompression from exposure to increased pressure.
- Clinical manifestations of acute decompression sickness include disorders of the brain and spinal cord, musculoskeletal pain, chest pain, dyspnea, and skin rash occurring up to 24 hours following an exposure to increased pressure.
- Treatment of decompression sickness and arterial gas embolism should be instituted with recompression in a hyperbaric chamber as soon as possible after the injury.
- Assessment for fitness for diving includes consideration of the type of diving (recreational, commercial, military), and a number of chronic disorders that can be aggravated by the diving environment.
- Although drowning without aspiration is theoretically possible, the majority of drownings are associated with aspiration of water into the lungs and an accompanying hypoxemia.
- Goals of therapy for a drowning victim include reversing hypoxemia with positive-pressure ventilation and oxygen, treating metabolic acidosis, managing accompanying cardiac arrhythmias, and use of antibiotics when indicated.

Tricyclic Antidepressant Overdose
Hydantoin
Dantrolene
Conclusion

INTRODUCTION

Adverse drug reactions have been the object of intense scrutiny since the early 1990s and have been recognized as a top safety priority by health care quality improvement organizations across the United States.[1] A groundbreaking report published in 1999 by the Institute of Medicine only intensified this attention by suggesting that medical errors, including medication errors, may be responsible for 98,000 patient deaths per year in the United States.[2] Specifically, medication errors and preventable adverse drug events may injure 1.5 million people and cost billions of dollars annually. Nonpreventable adverse drug reactions may occur in 2% to 5% of hospitalized patients.[3] Table 72-1 lists the classification of drug reactions.

We know relatively little about the pharmacokinetic properties of drugs in individual patients. Some metabolites last only a fraction of a second and are not measurable. Many drug-related injuries are not reproducible in animals and therefore cannot be studied in depth. Moreover, if a drug administered in the therapeutic dose range caused an adverse reaction in most of the patients who received it, the drug would not be usable. Thus, the very success of many drugs and the fact that only a small percentage of the population reacts adversely to drugs have also limited understanding of pulmonary toxicities. In spite of significant research in pharmacogenetics and drug metabolism, and except for a few instances, pulmonary complications often seem to occur in idiosyncratic fashion, likely determined by the patient's susceptibility profile, the chemical properties of the drug, and other environmental factors. Nevertheless, drug-induced pulmonary disease can be a significant problem. Analysis of a case series of open-lung biopsies in immunocompromised hosts with diffuse pulmonary disease disclosed that 21% of patients had disease that was likely to have been caused by a chemotherapeutic drug. Regulatory agencies have discouraged reports of adverse drug reactions that are neither unexpected nor serious except in the case of drugs recently approved for use. As such, the actual frequency of such adverse events remains unclear. It is estimated that less than 5% of all adverse drug-induced pulmonary diseases and overall less than 1% of serious and unexpected events are formally reported to the Food and Drug Administration (FDA).[1] The number of drugs associated with pulmonary toxicity is steadily increasing.[4] By 2009, more than 350 drugs have been identified to cause adverse pulmonary reactions. These reports are of various nature and quality, ranging from clear toxicities established in large series to isolated case reports of unequal interest. Some of these medications are listed in Table 72-2. To minimize mortality and significant morbidity, it is incumbent upon the clinician to keep in mind at least the more common drugs that may induce pulmonary disease.[5–9]

MECHANISMS OF DRUG-INDUCED PULMONARY INJURY

Four mechanisms of drug injury to the lungs are recognized: (1) oxidant injury, such as during chronic nitrofurantoin ingestion; (2) direct cytotoxic effects (and these effects may be aggravated by oxidant injuries); (3) deposition of phospholipids within cells, such as produced by cationic amphophilic drugs such as amiodarone; and (4) immune-mediated injury through drug-induced systemic lupus erythematosus (SLE).[7,10–14] Although extensive investigation has been undertaken to look for other forms of immune system–mediated injury, only the SLE induced by drugs has been proven.

Oxidant-mediated injury is believed to play a significant role in several of the drug-induced pulmonary diseases, namely, the chronic fibrosis related to nitrofurantoin, and possibly many of the chemotherapeutic drug–induced pulmonary injuries.[15] In vitro, nitrofurantoin is capable of generating toxic oxygen-derived substances such as hydrogen peroxide, hydroxyl radical, superoxide, and singlet oxygen. These oxygen radicals generate singlet electron transfers that disrupt critical cell functions. Nitrofurantoin may produce pulmonary fibrosis by accelerating the generation of oxygen radicals within lung cells and by overwhelming the normal antioxidant protective mechanisms. This in turn incites inflammatory and fibrotic reactions.

It is postulated that chemotherapeutic drug injury represents a direct toxic reaction. Considerable research has been done on bleomycin-induced lung injury. Bleomycin does not have a major effect on the bone marrow or on immunocompetency. The exact mechanism of bleomycin lung injury is not fully known. However, epithelial cells in the lung and skin contain lower levels of a specific inactivating enzyme against bleomycin than do epithelial cells in other organs. Thus, the drug is allowed to accumulate within these cell and induce deoxyribonucleic acid (DNA) fragmentation.[11] Because bleomycin toxicity appears to be related to dosage and age, the toxicity probably is related to the levels of inactivating enzyme in certain individuals. Bleomycin apparently overwhelms this enzyme with a large total dose. It is also likely that there is a relative deficiency of the enzyme in individuals over 70 years of age. Some individuals of any age may be relatively deficient in this enzyme and hence especially sensitive to bleomycin lung toxicity.

The first cells to be affected by bleomycin are the type I alveolar epithelial cells. Repair of injured type I cells

TABLE 72-2. Classification of Drug-Induced and Related Pulmonary Diseases by Type of Medication

CHEMOTHERAPEUTIC
Cytotoxic
- Azathioprine
- *Bleomycin
- Busulfan
- Chlorambucil
- Cyclophosphamide
- Etoposide
- Interleukin-2
- Melphalan
- *Mitomycin C
- Nitrosoureas
- Procarbazine
- Tumor necrosis factor
- Vinblastine
- Zinostatin

Noncytotoxic
- *Bleomycin
- *Cytosine arabinoside
- *Gemcitabine
- *Methotrexate
- *Procarbazine

ANTIBIOTIC
- *Amphotericin B
- Nitrofurantoin
  - *Acute
  - Chronic
- Sulfasalazine

ANTI-INFLAMMATORY
- *Acetylsalicylic acid
- Gold
- Interferons
- Leukotriene antagonists
- Methotrexate
- Nonsteroidal anti-inflammatory agents
- *Penicillamine

ANALGESIC
- *Heroin
- *Methadone
- *Naloxone
- *Placidyl
- *Propoxyphene
- *Salicylates

CARDIOVASCULAR
- *Amiodarone
- Angiotensin-converting enzyme inhibitors
- Anticoagulants
- *β-Blockers
- Dipyridamole
- Flecainide
- *Protamine
- Tocainide

INHALANT
- Aspirated oil
- *Oxygen

INTRAVENOUS
- *Blood products
- *Ethanolamide maolate (sodium morrhuate)
- Ethiodized oil (lymphangiogram)
- Talc

MISCELLANEOUS
- Appetite suppressants
- Bromocriptine
- *Complement-mediated leukostasis
- Dantrolene
- *Hydrochlorothiazide
- Methysergide
- Radiation
- Systemic lupus erythematosus (drug-induced)
- *Tocolytic agents
- *Tricyclics
- L-Tryptophan

*Typically present as acute or subacute respiratory insufficiency.

is accomplished by type II cells, which proliferate and differentiate into type I cells to restore the normal air-blood barrier. The vulnerability of the type II cell to bleomycin depends on the state of its cell cycle. If it is in the resting G_0 phase, the cell appears resistant to bleomycin injury, whereas if the cell is proliferating or differentiating, atypical exaggerated metaplasia occurs. Consequently, with net loss of type I alveolar epithelial cells, a fibroblastic reparative process is initiated. Bleomycin can also stimulate fibroblasts directly to increase collagen synthesis. Type I cells are particularly vulnerable to injury by bleomycin, but in the steady state, the type II cell is generally considered to be injury resistant. By dosing bleomycin repeatedly, the likelihood increases that type II cells will be exposed during their vulnerable proliferative period.

Additional information indicates that bleomycin injures lung cells through the generation of reactive oxidants.[16] Antioxidant defenses may be of value in the amelioration of bleomycin-induced lung toxicity.[17] Accordingly, breathing supplementary oxygen potentiates bleomycin-induced oxidant injury. However, not all of the reactions to chemotherapeutic drugs are as dose and age related as bleomycin, nor does oxygen potentiate the toxicity of most drugs.

Amiodarone has brought to light another potential mechanism of drug-induced lung injury. Amiodarone has been demonstrated to produce phospholipidosis in alveolar macrophages and type II cells. In amiodarone pulmonary toxicity, there is a marked accumulation of abnormal alveolar macrophages containing lamellar inclusions, which in turn contain a variety of phospholipids.[12] It is not known whether this phospholipidosis is directly related to the accompanying interstitial pneumonitis. There are more than two dozen cationic amphophilic drugs known to induce a phospholipid storage disorder in cells, particularly in the lungs. It is believed that these drugs impair phospholipid catabolism. The process is reversible with discontinuation of the agent.

Drug-induced SLE is another established mechanisms of drug-induced pulmonary disease.[13] There are two groups of drugs associated with drug-induced SLE. The first group commonly elicits antinuclear antibody formation in a large percentage of the persons taking the drug, but only a small percentage of these persons develop clinical symptoms of SLE. The second group is made up of numerous drugs that have been reported to induce antinuclear antibodies only rarely, but virtually all persons afflicted develop SLE.

In drug-induced SLE, the antibodies are primarily directed against histones. In contrast, during idiopathic SLE, the antinuclear antibodies are heterogeneous and consist of antibodies recognizing native DNA, histones, and nonhistone ribonuclear proteins, as well as antibod-

ies formed against extranuclear host components such as clotting factors.[13] Exactly how drugs incite antibodies to nuclear protein is not clear, because these agents are in themselves nonimmunogenic. A current hypothesis proposes that the drug acts as an adjuvant or immunostimulant to augment responses to "self" antigens. Autoimmunity then develops from the clonal expansion of cell-reacting lymphocytes, which are ordinarily held in check by a balance of helper and suppressor influences.

CHEMOTHERAPEUTIC AGENTS

Chemotherapeutic agent are extensively used in solid and hematologic malignancies, but also are increasingly employed for their immunosuppressive properties in the management of various inflammatory disorders. Because of the severity of diseases in which they are employed, higher risk for potential adverse lung reactions are typically tolerated, hence pulmonary complications of chemotherapy are not uncommon in the clinical setting. It is, however, a diagnostic challenge for the clinician who has to determine the responsibility of the chemotherapeutic agent usually on the basis of a diagnosis of exclusion and decide to discontinue it, with the risk of depriving his or her patient of a potentially beneficial therapy. Oncology patients are prone to a number of pulmonary complications irrespectively of their chemotherapy regimen, including opportunistic infections, atypical presentations of common lung infections, radiation-induced lung injury, cardiogenic or noncardiogenic pulmonary edema, and, of course, metastatic lung involvement. The various presentations of drug-induced pulmonary disease must be rapidly differentiated from these other etiologies whose clinical presentations, including fever and diffuse radiographic abnormalities, may be extremely similar to chemotherapy-induced pulmonary reactions. Furthermore, virtually all histopathologic patterns have been described in the context of chemotherapy-induced lung disease, including usual interstitial pneumonia, nonspecific interstitial pneumonia, desquamative interstitial pneumonia, lymphocytic interstitial pneumonia, bronchiolitis obliterans with or without organizing pneumonia, and diffuse alveolar hemorrhage. Less commonly, non-necrotizing granulomatosis (methotrexate), alveolar proteinosis (busulfan), and pulmonary veno-occlusive disease (nitrosoureas) have also been reported. In addition, combination regimens are generally the rule, making it sometimes difficult to incriminate one agent over the other. Chemotherapy-associated pulmonary reactions have become a major problem, particularly in relation to therapeutic regimens containing bleomycin, methotrexate, cyclophosphamide, and a host of newer agents (Table 72-3).

Consistent criteria for drug-induced lung disease have not been officially established. Uncertainty that a given respiratory complication is linked to a particular drug is generally present. Furthermore, confirmation with rechallenge is to be avoided since it is often neither practical nor generally ethical. Hence, the diagnosis of cytotoxic lung damage rests upon an appropriate history of drug exposure, histologic evidence of lung injury, and, most importantly, the exclusion of other causes of the lung damage. Pulmonary manifestations are rarely specific enough to clearly point toward a drug effect. There is no single diagnostic test or tissue biopsy that can definitively confirm the diagnosis of chemotherapy-associated lung disease. Thus, a careful and thorough evaluation to eliminate the possibilities of other conditions producing these effects, particularly infection, is warranted. Clinicians caring for these patients must be aware of myriad chemotherapeutic agents that can injure the lungs. It is estimated that 10% to 20% of patients undergoing some type of chemotherapy will develop respiratory symptoms directly related to their treat-

TABLE 72-3. Pharmacologic Action of Selected Chemotherapeutic Agents with Associated Pulmonary Toxicities

ANTIBIOTIC-DERIVED AGENTS
Bleomycin
Mitomycin C

ALKYLATING AGENTS
Busulfan
Cyclophosphamide
Chlorambucil

Tumor necrosis factor-α

OTHER MISCELLANEOUS CHEMOTHERAPY AGENTS
Procarbazine
Zinostatin
Vinblastine

ment.[5,9] Thus, the clinician should maintain a high index of suspicion, and carefully screen for other competing causes of pulmonary injury that may affect these immune-compromised patients.

The clinical presentation of many chemotherapy drug effects is quite similar, with the exception that some present more acutely, whereas others tend to be more insidious in their onset. In general, nonproductive cough, dyspnea, and often fever begin weeks to years after the agent is first administered. Occasionally, symptoms may presently acutely as in the case of hypersensitivity reactions, or in a delayed fashion occurring years after discontinuation of the drug, perhaps reactivated by radiotherapy, a process called "radiation recall." Fever is common with most chemotherapeutic drug–induced pulmonary injury, but it may not be consistently present. Chills are usually absent and weight loss is often present. The chest radiograph in cases of chemotherapy-induced lung disease may be unremarkable for days or weeks before showing typical changes of a diffuse interstitial infiltrative pattern. Alternatively, there may be a diffuse mixed alveolar-interstitial pattern, which may occasionally be useful in recognizing early drug effects (Fig. 72-1). Auscultation of the lungs will frequently reveal crackles, which are also nonspecific. In some instances, small pleural effusions may be present during adverse drug reactions, but these are not consistently present. Clubbing has not been reported in any chemotherapeutic pulmonary toxicity.

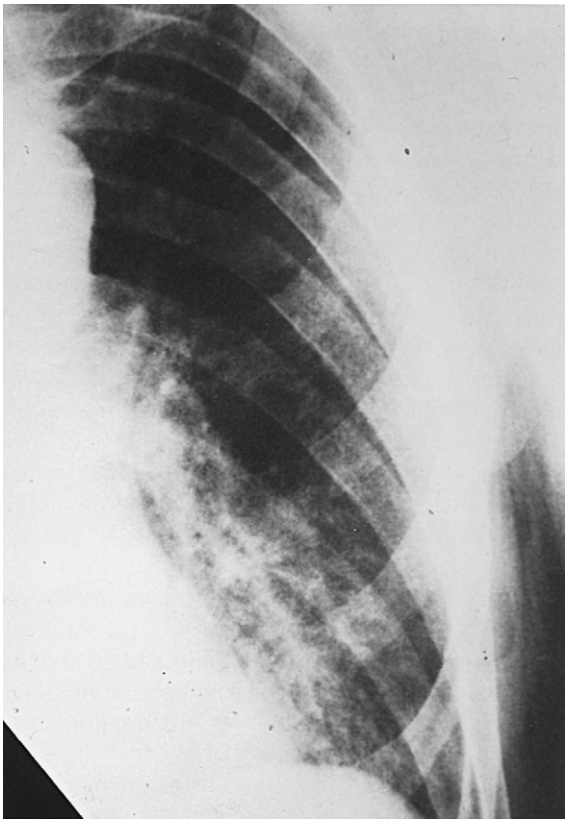

FIGURE 72-1 ■ A close-up chest roentgenogram showing an alveolar interstitial pattern that is characteristic but not diagnostic of cytotoxic lung disease.

The results of lung function studies are abnormal in almost all patients with cytotoxic drug–induced lung disease when compared with pretreatment testing. The carbon monoxide diffusing capacity may decrease before reduced volumes are detected. In addition, this decrease in carbon monoxide diffusing capacity may precede the onset of symptoms and radiographic changes by days or weeks.[5] In several prospective investigations, diffusing capacity has been used to detect early onset of pulmonary reactions, at which time the agents are discontinued to minimize progression into overt clinical disease.[18] Bronchoalveolar lavage may be another means of assessing early lung damage from these drugs; however, the results are often variable. In general, the greatest utility of bronchoalveolar lavage is to exclude infection.

Some reactions related to chemotherapeutic agents have been associated with cytologic atypia in affected pulmonary tissues. The histologic finding of markedly atypical type II pneumocytes, with relative fewer type I cells, has been reported. These type II pneumocytes may appear "bizarre"; however, the nuclear-to-cytoplasmic ratio remains normal, and there is no increase in mitotic activity in these cells.[7] Therefore, these changes should not be interpreted as a harbinger of malignancy. The simple presence of cytologic atypia cannot by itself definitely establish chemotherapy-associated lung injury. For instance, cytologic atypia may be present in occasional busulfan-treated patients without radiographic, clinical, or pathologic evidence of lung injury. In addition, cellular atypia can also be observed in the setting of a severe viral infection. In addition, tissue examination in chemotherapy-associated lung injury may demonstrate an inflammatory cell infiltrate in the interstitium as well as deposition of collagen in the septal walls. Lung remodeling can progress to severe fibrosis, resulting in respiratory insufficiency.

Antibiotic-Derived Agents

Bleomycin

Bleomycin is an antibiotics chemotherapeutic agent that was isolated in 1966 from *Streptomyces verticillus*. Its pulmonary toxicity was recognized early and has since been one of the main factors limiting its use in the clinical setting. It is by far the best understood type of drug-induced toxicity and represents in many aspects the prototype of "chemotherapy lung." The incidence of bleomycin lung toxicity ranges anywhere from zero to 46%, and pulmonary function testing and chest radiographs reveal that 20% of patients treated with bleomycin develop overt pulmonary disease, and as many as 3% die from pulmonary consequences of bleomycin therapy.[5,19]

The mechanisms by which bleomycin exerts its antineoplastic effects are diverse. Direct cytotoxic effect, prevention of neoangiogenesis by the tumor, stimulation of the production of various cytokines, and free radical generation via formation of a complex between ferrous

iron and oxygen are likely the most important.[20,20a,20b,20c] The latter effect may explain worsened bleomycin toxicity with high fraction of inspired oxygen. This is often a problem during anesthesia and in the postoperative recovery period.[21,22] This sensitivity to supplemental oxygen may persist for months and, perhaps, years after discontinuation of the drug. Several other contributing factors have been described. Perhaps one of the most consistent features of bleomycin-induced lung disease is the concept of cumulative toxicity. The incidence of pulmonary toxicity is significantly greater in those who have received a cumulative dose of over 450 units, with a 10% death rate in those having received a total dose greater than 550 units of bleomycin. However, doses as little as 50 units may occasionally suffice, especially when other synergic factors are present. Rapid rates of delivery by the intravenous route may also play a role, and slower infusion rates as well as intramuscular injections have been suggested.

Bleomycin is metabolized primarily by the kidneys. Hence, renal failure predisposes to impaired metabolism of the drug and increased toxicity. It is also inactivated by an enzyme, bleomycin hydrolase, present in most tissues except for the lungs and skin. This may explain the scleroderma-like skin changes occasionally observed with bleomycin. Radiotherapy is itself a common cause of pulmonary complications and is also thought to promote the generation of free radicals, toxic to both the tumor cells and surrounding tissues. The concomitant use of bleomycin and radiotherapy may be synergistic. In addition, as stated earlier, treatment with bleomycin may reactivate prior radiation-induced lung disease, a process called radiation recall. Pulmonary toxicity is also increased in patients over 70 years of age and in those with preexisting lung disease. There is good evidence that pediatric patients may also be at increased risk, with 70% of children treated with bleomycin for rhabdomyosarcoma developing pulmonary toxicity in one study.[23] Impaired or immature ability to process free radicals and inadequate kidney function may explain these differences. Finally, bleomycin toxicity may be synergistically increased by several other chemotherapeutic agents, including cyclophosphamide.

Although of uncertain value, determination of pretreatment carbon monoxide diffusing capacity and its frequent monitoring have been suggested in an attempt to predict subsequent clinical deterioration. Progressive fall in the carbon monoxide diffusing capacity should prompt withdrawal of further bleomycin administration.[24] Vital capacity and pulmonary capillary blood flow may be better predictors of lung toxicity.[25] In addition, the enhanced sensitivity of computed tomography scanning may also be useful in establishing an early diagnosis of bleomycin pneumonitis. In one series of 100 patients receiving bleomycin, thoracic computed tomography scans were abnormal in 38%, whereas the chest radiographs were abnormal in only 15%.[26] Serial imaging studies are not recommended in the absence of specific symptoms.

One study demonstrated that, if the patient survives the acute injury from bleomycin, pulmonary findings might improve substantially over time.[27] However, if significant fibrosis is present, the process may progress insidiously despite the administration of corticosteroids. Histological, end-stage bleomycin pneumonitis may be indistinguishable from idiopathic usual interstitial pneumonitis.

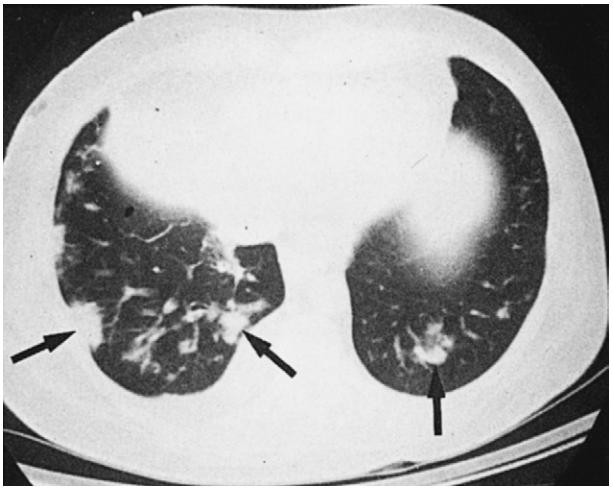

FIGURE 72-2 ■ A computed tomography scan of bleomycin pneumonitis showing a nodular pattern (*arrows*). The histologic features of this form of bleomycin-induced lung injury are typical of bronchiolitis obliterans with organizing pneumonitis.

Other forms of bleomycin-induced lung disease have been described, albeit less common. Hypersensitivity reactions are possible with an association of fever and peripheral blood or bronchoalveolar lavage eosinophilia.[5,18] Discontinuation of bleomycin and initiating corticosteroids usually brings about rapid reversal of this hypersensitivity variant of bleomycin pneumonitis.

An additional rare, but clinically important, presentation of bleomycin pneumonitis can occur: the clinical presentation of nodular pulmonary lesions mimicking tumor metastasis (Fig. 72-2).[28,29] These reactions to bleomycin have been described in the setting of lymphoma or seminoma, requiring surgical biopsy to differentiate bleomycin-associated lung injury from recurrence of the primary malignancy. These nodular lesions from bleomycin often exhibit the histologic pattern of bronchiolitis obliterans with organizing pneumonia.[7] Similar reactions have been described in association with other chemotherapeutic agents, including methotrexate, cyclophosphamide, chlorambucil, mitomycin, and interferon, and also with nonchemotherapeutic agents such as amiodarone, gold, and nitrofurantoin, and even in cases of radiation toxicity.[7] Pneumothorax and pneumomediastinum have also been described.

In suspected cases of bleomycin lung toxicity, discontinuation of the drug is warranted. Administration of corticosteroids is often recommended, but the evidence for this remains anecdotal at best. It would seem prudent to pay particular attention to avoid high fractions of inspired oxygen and concomitant radiotherapy and to monitor the kidney function carefully during the duration of treatment.

Mitomycin C

Mitomycin C is another antibiotic chemotherapeutic agent associated with pulmonary toxicity, which shares features similar to those induced by bleomycin. It has been employed in the management of bladder tumors, lung cancer, anal canal cancer, metastatic breast carcinoma, metastatic liver tumors, and esophageal malignancies. One series estimated the incidence of mitomycin-induced pneumonitis to be approximately 8%, with two additional series suggesting the incidence ranged from 12% to as high as 39%.[30,31] Similar to bleomycin-induced lung toxicity, the cumulative dose appears associated with the incidence of pulmonary manifestations in a linear fashion, with pulmonary fibrosis unlikely at doses less than 30 mg/m^2. Again, high fraction of inspired oxygen and radiotherapy may exacerbate this phenomenon. Concomitant administration of other chemotherapeutic agents such as bleomycin, doxorubicin, or cyclophosphamide may synergistically enhance pulmonary toxicity.

The symptomatology, radiographic abnormalities, and histologic findings of mitomycin-induced pneumonitis are similar to those of other alkylating drug toxicities. However, it has been suggested that the carbon monoxide diffusing capacity may not fall prior the onset of clinical symptoms, making it an unreliable predictor of overt lung disease.[31] In addition, a favorable response to corticosteroid therapy has also been quite dramatic in many of these patients, possibly greater than in other forms of chemotherapy-associated lung injury.

In addition to mitomycin-induced pneumonitis, there are reports of an unusual reaction to mitomycin C consisting of microangiopathic hemolytic anemia with associated noncardiogenic pulmonary edema and renal failure, in particular when associated with 5-fluorouracil.[32] This may be associated with pulmonary hypertension. Most of these patients developed side effects between 6 and 12 months after beginning mitomycin C chemotherapy. Up to one half of these patients evolve into the acute respiratory distress syndrome, with mortality as high as 95% in some series. The mortality in patients with mitomycin C–associated hemolytic uremic syndrome who do not develop acute respiratory distress syndrome is still in the range of 50%. In some instances, this unusual drug reaction appears to be precipitated by blood transfusions. Microangiopathic changes are present in the lungs and kidneys with intimal hyperplasia of the arterioles, along with prominent nuclear atypia of the capillary cells and capillary fibrin thrombi. Treatment is essentially supportive, with initiation of plasma exchange with or without dialysis and corticosteroids when deemed appropriate.

Other Antibiotic Chemotherapeutic Agents

A variety of other antibiotic chemotherapeutic agents have been associated with respiratory complications, although the very nature of combined chemotherapeutic regimens makes it difficult to definitely attribute the responsibility of one drug over another. Doxorubicin is an anthracycline agent notorious for causing cumulative cardiotoxicity with possible cardiogenic pulmonary edema. Rare cases of interstitial pneumonias have also been described, usually in combination with other drugs, typically with mitomycin C. Organizing pneumonia has rarely been reported. Infusion reactions with dyspnea may be observed in 5% to 10% of patients treated with pegylated liposomal doxorubicin. Epirubicin is a similar compound with fewer side effects. Pulmonary complications are rare but may occur in conjunction with other chemotherapeutic agents. Mitoxantrone is an anthracedione inhibitor of topoisomerase II essentially used in the treatment of multiple sclerosis. Rare cases of subacute interstitial pneumonias have been described. Cases of reactivation of prior radiation pneumonitis have also been observed with actinomycin D.[23]

Alkylating Agents

Busulfan

Busulfan has been used for the management of chronic myeloproliferative disorders. It was discovered in 1961 and found to be responsible for significant pulmonary toxicity shortly after. The average duration from the initiation of therapy to the onset of respiratory symptoms is roughly 3.5 years, ranging between 8 months and as late as 10 years. However, busulfan pulmonary toxicity can occur as soon as 6 weeks following initiation of therapy. The incidence of busulfan pulmonary toxicity is estimated to be 6%, with a reported range of 2.5% to 43%.[33] Busulfan-induced lung toxicity distinguishes itself from other forms of chemotherapy-induced lung disease in many ways. The mortality rate is extremely high, in the range of 80%.[23] No effective therapy has been identified, and discontinuation of the drug with or without initiation of corticosteroid therapy, although recommended, is of unclear value. No obvious aggravating factors have been identified, except perhaps the concomitant administration of other chemotherapeutic agents or radiotherapy. Age and cumulative dose do not seem to play any important role.

Dyspnea, fever, and cough begin in a more insidious fashion with busulfan than with many other chemotherapy lung toxicities. Such symptoms have even been reported to begin months after busulfan therapy has been discontinued. The chest radiograph in busulfan toxicity reveals a combined alveolar and interstitial process to a greater degree than in other chemotherapy reactions. This is likely due to a high degree of desquamation of injured epithelial cells into the alveolar spaces. This alveolar debris may be so extensive as to suggest alveolar proteinosis in some patients receiving busulfan. This form of alveolar proteinosis is more refractory to therapeutic lavage than is idiopathic alveolar proteinosis.

Cyclophosphamide

Cyclophosphamide is widely included in combination chemotherapy for hematologic malignancies and solid

tumors, including breast cancer. The incidence of pulmonary toxicity is estimated at around 1%, although accumulating evidence suggests that it may be largely underestimated. A case series from a large tertiary referral center only identified six patients over 20 years in whom cyclophosphamide was the only factor contributing toward pulmonary injury.[34] Clinical features of cyclophosphamide-associated pulmonary toxicity include fever, dyspnea, cough, gas-exchange abnormalities, parenchymal infiltrates, and pleural thickening. Two patterns of cyclophosphamide-induced lung toxicity have been described. First, an early-onset pneumonitis can occur within the first 1 to 6 months after institution of therapy. This form generally responds to withdrawal of cyclophosphamide. In contrast, a late-onset pneumonitis may develop after months or even years of therapy, and result in progressive lung fibrosis and bilateral pleural thickening. This late-onset variety unfortunately has minimal response to withdrawal of cyclophosphamide or to corticosteroid therapy.[34] The dose of cyclophosphamide and development of lung disease are not clearly related. Supplemental oxygen and radiotherapy may increase the likelihood of lung manifestations. Likewise, concomitant administration of other agents such as bleomycin, and perhaps carmustine, in preparation before bone marrow transplantation seem to accentuate the phenomenon. There have also been very rare reports of negative rechallenge with cyclophosphamide without subsequent recurrence of the pulmonary toxicity. For obvious reasons, this is generally not recommended.

Chlorambucil

This agent has been prescribed primarily for chronic lymphocytic disorders. The clinical presentation, chest radiographic abnormalities, and histologic features of chlorambucil-associated pneumonitis are remarkably similar to those described in other alkylating agent–induced pulmonary toxicities.[9] Cumulative doses in excess of 2 g seem to increase the risk significantly. The presentation is usually insidious, occurring 6 months to a year or more after the start of therapy. Surveillance of lung function, particularly diffusing capacity, may be of benefit in anticipating which patients will deteriorate and require discontinuation of the agent. Few data are available on the efficacy of corticosteroid therapy in chlorambucil-related lung toxicity.

Melphalan

Melphalan has been enlisted in the treatment of multiple myeloma. There have been relatively few well-documented cases of pulmonary toxicity associated with melphalan.[35] The course of melphalan-associated pulmonary injury varies from acute to more subacute in tempo. Patients present with insidious to abrupt onset of dyspnea, cough, and frequently fever. There are no particular clues for predicting which patients will develop side effects. The incidence of pulmonary side effects from melphalan must be generally low, in view of the fact that this agent has been widely employed in the long-term management of myeloma.

Ifosfamide

Ifosfamide is structurally related to cyclophosphamide and has been used in for the treatment of a variety of solid tumors, including lung, testicular, and breast cancer. Case reports of subacute interstitial pneumonias can be found in the literature, although the responsibility of ifosfamide remains unclear, as it was used in combination with other chemotherapeutic agents such as docetaxel. One case of fatal acute pneumonitis primarily due to ifosfamide has been reported. A case of methemoglobinemia has also been described, presumably secondary to the interaction between 4-thioifosfamide, a metabolite of ifosfamide, and glutathione and resultant oxidative stress.[36]

Other Alkylating Agents

Procarbazine is primarily used in the treatment of Hodgkin's lymphoma and glioblastoma multiforme. Rare cases of interstitial pneumonias have been reported, sometimes characterized by significant eosinophilia suggesting a hypersensitivity reaction. Progression to widespread and irreversible fibrosis seems rare.[37]

Oxaliplatin has been associated with laryngeal dysesthesia and was thought to be responsible for the development of diffuse alveolar damage, often in association with 5-fluorouracil. More typically, severe anaphylactic reactions during infusion of the drug can occur in about 1.3% of the cases. Eosinophilic pneumonia has also been rarely reported.[38,39]

Temozolomide is a second-generation alkylating agent now considered standard of care as an adjuvant therapy for glioblastoma in association with radiotherapy. It is also used in the treatment of metastatic melanoma. Few respiratory side effects have been described, mainly pharyngitis, sinusitis, cough, upper respiratory tract infection, and dyspnea. Pneumonitis was found to occur in up to 4.8% of patients in Phase II trials. One case of organizing pneumonia that resolved after discontinuation of treatment was described.[40]

Several cases of mild pneumonitis have been described with chlorozotocin, an alkylating agent used in the treatment of neuroendocrine tumors. All cases resolved with discontinuation of the drug and administration of corticosteroids.[41]

Antimetabolites

Methotrexate

Methotrexate is present in many combination regimens for malignancies, and also is used extensively for nonmalignant conditions, including psoriasis and rheumatoid arthritis. It interferes with the metabolism of folic acid, hence specifically targeting replicating cells and leading to a variety of well-described adverse effects, including bone marrow suppression, mucositis, alopecia, and

gastrointestinal manifestations. Pulmonary toxicity is thought to occur in about 10% of all patients treated, but is fortunately rarely fatal. Dyspnea, nonproductive cough, and fever usually commence a few days to several weeks after initiation of therapy. However, in rare cases, symptoms may be observed a few months or years after onset of therapy.[42] Methotrexate-associated pneumonitis is almost always reversible with or without the addition of corticosteroids. Eosinophilia is seen in at least half of the cases, and the disease is therefore believed to represent a hypersensitivity reaction.[5] The intriguing feature of this reaction is that the drug may be reinstituted following resolution of methotrexate pneumonitis without necessarily triggering a subsequent recurrence of symptoms or findings. In about one third of the patients, weakly formed granulomas are identified in lung biopsy, which is very unusual in other forms of chemotherapy-associated lung disease.[7] This in addition to the hilar lymphadenopathy occasionally present may mimic the typical manifestations of sarcoidosis. There is no cellular atypia, such as is seen in many other cytotoxic drug toxicities.

The chest radiograph tends to reveal a homogeneous infiltrate throughout all lung fields. Hilar adenopathy or pleural effusion occurs in at least 10% to 15% of patients with methotrexate lung toxicity. In distinct contrast to most of the other chemotherapy pulmonary toxicities, prospective investigations of patients receiving methotrexate have not demonstrated a diminished diffusing capacity that might predate subclinical toxicity. In addition, pulmonary toxicity in response to methotrexate does not appear to be dose related. There have been a few reports of fatal reactions occurring either from intrathecal methotrexate or from oral ingestion after previous intrathecal injections. Two other important manifestations associated with methotrexate should be mentioned. Opportunistic infections related to T-cell deficiency need to be excluded, in particular *Pneumocystis* pneumonia, which has been reported in a number of patients receiving methotrexate, either alone or in combination with corticosteroids.[43] Peculiar Epstein-Barr virus–related lymphomas that typically resolve after discontinuation of treatment have also been reported and may be directly related to an alteration in immune surveillance induced by methotrexate (as seen in posttransplantation lymphoproliferative disorders). The clinical presentation, chest radiography, and other clinical features can be quite similar to methotrexate lung.[43]

Azathioprine and 6-Mercaptopurine

There are over two dozen case reports of azathioprine-associated pneumonitis. However, the net overall incidence must be quite low, considering the widespread use of this agent for neoplastic as well as non-neoplastic conditions.[35] Nevertheless, the possibility of an azathioprine pneumonitis must be considered in any individual receiving this agent. Azathioprine is metabolized to 6-mercaptopurine, and there have been a handful of reports detailing cytotoxic interstitial pneumonitis in association with this metabolite.[6] However, most of these patients have also received other agents that potentially could be implicated in the lung injury described.

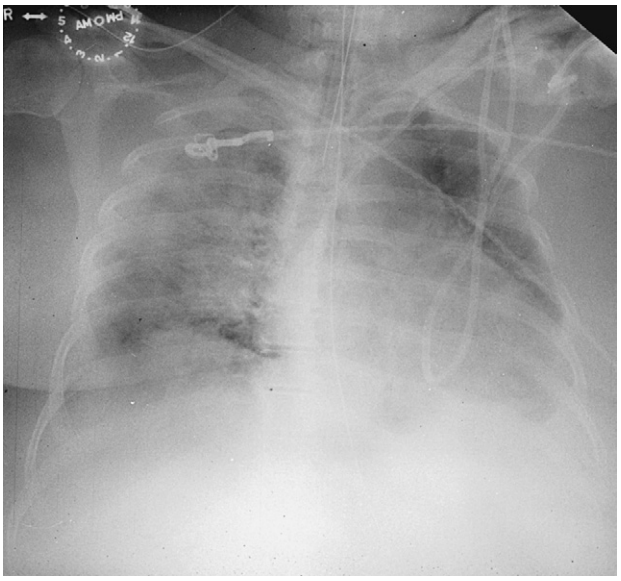

FIGURE 72-3 ■ A chest radiograph of a 44-year-old woman showing acute noncardiac pulmonary edema that resulted from cytosine arabinoside–induced pulmonary disease. Histologic examination typically demonstrates intense intra-alveolar proteinaceous material forming hyaline membranes, but little other reaction.

Cytosine Arabinoside

Cytosine arabinoside (ara-C) is a cytotoxic agent used to induce remission in acute leukemia and other hematologic malignancies prior to bone marrow transplantation. Intensive ara-C treatment regimens have been associated with rapidly fatal noncardiac pulmonary edema (Fig. 72-3).[6] Histologic examination of lung tissue during ara-C pulmonary toxicity reveals substantial accumulation of intra-alveolar proteinaceous material without the cellular atypia and mononuclear infiltration described with other cytotoxic drugs. In two large series, 13% to 28% of the patients with toxicity developed respiratory distress during the administration of the drug, and nearly one half developed symptoms within a month of completing drug administration. The mechanism underlying this reaction is unknown, and the associated mortality is high. Treatment for ara-C pulmonary toxicity is largely supportive, with mechanical ventilation, careful management of fluid status, and surveillance for superimposed infectious complications.

Gemcitabine

Gemcitabine is a pyrimidine analogue, with structure and activities similar to ara-C. It is highly active against non–small cell lung cancer, as well as breast, pancreatic, and ovarian cancers. It is usually well tolerated, with the most prevalent toxicity being bone marrow suppression,

FIGURE 72-4 ■ A computed tomography image of an individual with gemcitabine-induced lung disease. The pattern is a mixed alveolar and interstitial infiltration.

as well as nausea, rash, transaminase elevation, and edema in some cases. The evidence of pulmonary toxicity in association with gemcitabine has only recently emerged, and the incidence has probably been underestimated. Dyspnea has been reported in 10% of treated patients, with severe dyspnea reported in up to 5%.[44-46] Noncardiogenic pulmonary edema is thought to occur in 0.1% to 7% of all patients treated.[47] There are three major patterns of respiratory involvement in gemcitabine-related pulmonary toxicity. The first pattern is a nonspecific, self-limiting dyspnea occurring within hours to days of treatment. A second, relatively uncommon, pattern is that of an acute hypersensitivity reaction with bronchospasm. Lastly, a third pattern of severe respiratory involvement is occasionally seen. This is a severe idiosyncratic reaction with profound dyspnea and pulmonary infiltrates that may progress to life-threatening respiratory insufficiency within hours of infusion (Fig. 72-4). Most cases of gemcitabine-related pulmonary toxicity resolve with discontinuation of this drug. In cases of severe symptoms, discontinuation of the agent along with institution of corticosteroids, careful fluid management, and diuretic therapy may be warranted.[44] Cases of diffuse alveolar hemorrhage, pulmonary veno-occlusive diseases, and thrombotic microangiopathy have also been described.

Fludarabine

Fludarabine, another nucleoside analogue, is widely employed in the management of chronic lymphoproliferative disorders. The incidence of pulmonary toxicity related to fludarabine has been estimated to be approximately 8.6% in a series of 105 patients.[48-50] Affected individuals experience dyspnea as early as 3 days after the first round of chemotherapy, though later onset of pulmonary symptoms has also been reported. The chest radiograph reveals either interstitial or mixed alveolar-interstitial infiltrates. Nodular infiltrates have also been described. As is often the case with chemotherapeutic agents, particular attention should be given to the possibility of opportunistic infections. Most patients respond to discontinuation of the drug, and receive symptomatic and objective benefits from additional corticosteroid therapy.

Piritrexim

Piritrexim is an experimental oral inhibitor of the dihydrofolate reductase used in the treatment of parasitic infections, psoriasis, and transitional cell carcinoma. It is closely related to methotrexate, and pulmonary toxicity has been observed in up to 14% of patients.[51]

Nitrosoureas

Nitrosourea compounds have a role in the treatment of gliomas and other central nervous system tumors, as well as in conditioning protocols preceding autologous bone marrow stem cell transplantation. Pulmonary toxicity related to nitrosoureas is well recognized and represents one of the most common side effects of these agents.[52] In particular, bischloroethyl nitrosourea (BCNU, carmustine) has been described to induce both acute-onset pulmonary injury and delayed-onset pulmonary fibrosis, with a predilection for the upper lobes.[52] The incidence of pulmonary toxicity associated with the administration of BCNU varies from 1.5% to 20% and is dose related, with up to a 50% incidence of lung disease in those receiving a total dose of over 1500 mg/m^2. However, there have also been reports of pulmonary effects occurring with much lower doses. The duration of therapy before the onset of pulmonary toxicity for the acute variant of nitrosourea lung injury has generally ranged from 6 months to 3 years. There appears to be a synergistic effect with cyclophosphamide, with radiation therapy, and possibly with other chemotherapeutic agents. The outcome may be unpredictable and sometimes fatal. There have been fewer case reports of pulmonary toxicity with methylchloroethyl cyclohexyl nitrosourea (methyl-CCNU) and chloroethyl cyclohexyl nitrosourea (CCNU). Apparently, fever is less commonly associated with this form of pulmonary toxicity than with many other chemotherapeutic drugs. Therapy usually consists of withholding the offending agent, and institution of corticosteroids, which has variable and often only transient beneficial effects.[53]

A long-term complication of BCNU toxicity is upper lobe fibrosis that may appear many years after the completion of chemotherapy. O'Driscoll and colleagues followed 17 patients for up to 17 years, and 12 of the 17 (71%) developed delayed upper lobe fibrosis.[54] The fibrosis is insidious in onset and, once discovered, appears to be intractably progressive. Corticosteroid therapy has not proven to be effective in delayed BCNU upper lobe fibrosis. Another unusual reported complication that is almost exclusively associated with nitrosourea compounds is pneumothorax.[55] This may be related to the upper lobe fibrobullous changes present in patients with BCNU lung toxicity.

Cases of pulmonary fibrosis have also been reported with other nitrosourea agents, including lomustine (CCNU), semustine (methyl-CCNU), fotemustine (CENU)

and chlorozotocin (DCNU). Pneumothoraces have rarely been described with these agents.

Podophyllotoxins

Etoposide and Teniposide

Etoposide (VP-16), a topoisomerase II inhibitor, has been widely used in combination chemotherapy for non–small cell and small cell lung carcinoma. Despite its extensive use, only a few cases of etoposide-associated pulmonary toxicity have been reported.[56] Onset may occur shortly after the first round of chemotherapy. However, most of the associated cases present after prolonged treatment. Tissue examination reveals features of alveolar edema, diffuse alveolar damage, and atypical type II pneumocytes. Therapy consists of withdrawal of the agent and administration of corticosteroids, which provide variable improvement. In addition, etoposide may increase the intracellular levels of methotrexate, and combination of methotrexate and etoposide may synergistically increase the likelihood of adverse reactions.

Teniposide, another podophyllotoxin agent, is also associated with hypersensitivity reactions in 3.6% to 6.5% of the cases. This toxicity may present with dyspnea, bronchospasm, and hypertension.[51]

Paclitaxel

Paclitaxel is a highly potent chemotherapeutic agents used in the treatment of lung, breast, and ovarian carcinomas. Well-documented cases of pulmonary toxicity induced by paclitaxel can be found in the literature, but the frequency is unclear. Typical respiratory symptoms include cough, dyspnea, wheezing, and chest tightness that may occur within minutes of administration of the drug, suggesting a type I hypersensitivity reaction. Immunoglobulin E antibodies against paclitaxel itself or perhaps its vehicle, Cremophor EL, are thought to be responsible.[57] This reaction may occur in as many as 30% of patients, and premedication with corticosteroids is sometimes considered. Interstitial and reticulonodular infiltrates have been reported on chest radiographic studies.[58] Cases of transient pulmonary infiltrates and suspected interstitial pneumonitis have also been described. The true incidence of lung toxicity directly related to paclitaxel is not well understood. A prospective study of lung function in 33 patients receiving paclitaxel with carboplatin (an agent with little lung toxicity) in the setting of nonthoracic malignancy revealed an isolated decrease in diffusing capacity without other clinical or radiographic evidence of pulmonary toxicity.[59] In other studies, conducted on patients with lung carcinoma, significant early and late pulmonary toxicity has been noted in 10% and 68% of patients, respectively.[60] Attributing the toxicity directly to paclitaxel is confounded by the underlying thoracic neoplasm, as well as other cytotoxic agents used in these patients.[61] Nonetheless, clinicians should be aware of the potential of paclitaxel impairing pulmonary function.

Docetaxel

Docetaxel (Taxotere) is an additional taxane compound that has activity in the treatment of breast and non–small cell lung cancer. Occasional pulmonary toxicity based on a hypersensitivity reaction has been observed.[62] These patients have responded rapidly to corticosteroid therapy. Recently, a small case series has suggested that the combination of docetaxel and gemcitabine has a particular propensity to induce severe pulmonary toxicity.[63]

Novel and Emerging Agents

All-Trans Retinoic Acid

All-*trans* retinoic acid (ATRA) has been employed in acute promyelocytic leukemia, in which it promotes differentiation of myeloid precursors and stimulates the maturation of leukemic cells, thereby promoting remission. It has also been reported to reduce disseminated intravascular coagulation and hemorrhagic complications during promyelocytic leukemia. The main complication limiting its use is the development of the so-called retinoic acid syndrome, occurring in up to 25% of patients treated. This syndrome consists of diffuse edema, pleuropericardial effusions, and noncardiogenic pulmonary edema that may evolve into a generalized capillary leak syndrome. Hypotension and acute renal failure are commonly present. It may occur suddenly between days 2 and 21 of treatment. Its pathogenesis remain elusive, but it is thought to result from a massive release of cytokines from newly mature myeloid cells and adhesion of granulocytes to the pulmonary endothelium. Indeed, high leukocyte counts have been associated with an increased incidence of the syndrome in some, but not all, studies. In addition, multiple hemorrhagic complications have also been described. In one study, 9 of 35 patients with promyelocytic leukemia receiving ATRA developed respiratory distress.[64] Intravenous corticosteroid therapy seemed to be of benefit to these patients. Based upon these observations, an additional study has suggested that the incidence of ATRA-associated pulmonary complications may be reduced to roughly 10% through the use of preventative treatment with oral corticosteroids. The mortality associated with ATRA-induced pulmonary toxicity is estimated at around 9%. Tissue examinations of lungs affected by ATRA have revealed interstitial infiltration with maturing myeloid cells. However, the overall spectrum of the ATRA-associated pulmonary syndrome is continuing to evolve and includes the presence of myeloid cells and blasts in bronchoalveolar lavage fluid, nodular pulmonary infiltrates, pulmonary leukostasis, noncardiogenic pulmonary edema, acute respiratory distress syndrome, Sweet's syndrome, and diffuse alveolar hemorrhage.[65]

Tyrosine Kinase Inhibitors

Gefitinib (Iressa, ZD1839) is a selective tyrosine kinase inhibitor active on the epidermal growth factor receptor

(EGFR) used in patients with advanced non–small cell lung cancer who have failed to respond to platinum-based chemotherapy. Its use was recently restricted in the United States to patients already being treated with evidence of benefit, after the Phase III Iressa Survival Evaluation in Advanced Lung Cancer study showed no improvement in survival. Acute interstitial pneumonia has been associated with this drug, and the overall incidence of gefitinib-associated interstitial lung disease may be in the range of 1%, with a mortality rate approaching 30%.[28,66] A nested case-control study in an Asian population revealed an incidence of interstitial lung disease of 4.5 per 1000 person-weeks over a 12-week period.[67] Diffuse ground-glass opacities have been reported on computed tomography scan, with tissue examination demonstrating diffuse alveolar damage. Although some patients respond to withdrawal of the agent and institution of corticosteroid therapy, others progress to fulminant respiratory insufficiency. Hence, the clinician needs to remain mindful of this pulmonary complication of gefitinib therapy, and discontinue the agent if symptoms and radiographic abnormalities occur. In addition, erlotinib (Tarceva), another EGFR antagonist, has also been rarely associated with pulmonary toxicity, including fatalities. Recently, a limited number of cases showing pulmonary infiltration with eosinophilia, or other interstitial lung disease, have also been reported in association with imatinib mesylate (Gleevec, ST1571), an agent used in the treatment of chronic myelogenous leukemia and gastrointestinal stromal tumors.[68]

Irinotecan and Topotecan

Irinotecan, a semisynthetic camptothecin, has been employed for advanced colorectal cancer either alone or in combination with 5-fluorouracil, and in some lung cancer trials. Early studies of irinotecan in Japan documented a 1.8% incidence of pneumonitis.[69–71] In those studies, clinical features included dyspnea, fever, and reticulonodular pulmonary infiltrates. Empirical corticosteroids were recommended, but some patients progressed to fatal respiratory failure. In subsequent U.S. trials, cough and dyspnea were described in roughly 20% of treated patients.[72] However, many of these patients had intrathoracic malignancies. The reported incidence of serious pulmonary toxicity related to irinotecan was much lower in these subsequent trials (approximately 0.4%).[72] Radiotherapy and preexisting lung disease may increase the risk. Nonetheless, cases of serious irinotecan-associated interstitial pneumonitis have been reported in the United States. Patients with preexisting pulmonary disease may be at enhanced risk.

Topotecan is a similar agent and has rarely been reported to induce pulmonary toxicity, including cases of diffuse alveolar damage and constrictive bronchiolitis.

Monoclonal Antibodies

As our understanding of the pathogenesis of malignant processes continues to increase, the identification of specific target tumoral antigens had led to the development of specific immunotherapeutic tools, including monoclonal antibodies. Several new molecules have emerged as potentially beneficial adjunct agents in a variety of neoplastic processes.

Bevacizumab (Avastin) in a monoclonal antibody targeting the vascular endothelial growth factor, and designed to inhibit tumoral neoangiogenesis. It has been used in conjunction with conventional chemotherapeutic agents in the treatment of metastatic colon and nonsquamous non–small cell lung cancers. It is associated with hemorrhagic complications including fatal pulmonary hemorrhage thought to result from extensive tumor necrosis. As such, bevacizumab is contraindicated in patients with squamous cell histology and central nervous system metastases. Although it may seem counterintuitive, bevacizumab is though to increase the incidence of thromboembolic disease by twofold. This may be secondary to vascular injury with secondary exposure of the underlying endothelium with secondary activation of the coagulation cascade. Recently, cases of thrombotic microangiopathy with hypertension and acute renal failure have also been described. Cases of congestive heart failure have also been described, mostly in association with anthracycline agents, raising questions about this reported association.[73]

Cetuximab and panitumumab are two monoclonal antibodies directed against EGFR that are increasingly used in treatment of a number of neoplasms. They both have been associated with rare pulmonary toxicity. Interstitial lung disease has been reported in 0.4% of patients with cetuximab, and infusion reactions with bronchospasm and hoarseness may occur in 23% of the cases. Similar infusion reactions may occur with panitumumab and be severe in 1% of the cases.

Trastuzumab selectively binds the EGFR-2 (human epidermal growth factor receptor-2 [HER-2]) protein and is an adjuvant treatment of metastatic HER-2–positive breast cancer. As with other monoclonal antibodies, infusion reactions may present in 15% of the cases and are potentially associated with angioedema, fever, and bronchospasm. Trastuzumab reactions may also present as an acute or subacute interstitial pneumonia in approximately 0.5% of the cases, with a mortality rate estimated at 0.1%.

Rituximab is an anti-cd20 chimeric monoclonal antibody approved in 1997 for the treatment of non-Hodgkin's lymphoma. Its ever-increasing indications have led to an exponential increase in its use in a variety of diverse conditions from autoimmune inflammatory diseases to posttransplantation lymphoproliferative disorders. Pulmonary complications of rituximab appear fairly rare overall. A review of the literature in 2007 only identified 16 cases of interstitial lung disease assumed to be secondary to rituximab use. Specific patterns of lung injury have also been described in pathologic specimens, including diffuse alveolar hemorrhage and desquamative interstitial pneumonia, but the experience is often limited to isolated case reports.[74]

Immunomodulatory Agents

Interferons

Interferons have been used in a wide variety of malignant, infectious, and inflammatory disorders. Interferon alfa and interferon beta have been employed in the treatment of hairy cell leukemia, myeloma, T-cell lymphoma, chronic myelogenous leukemia, malignant pleural effusions, melanoma, renal cell carcinoma, and Kaposi's sarcoma. Interferon gamma has been included in investigative trials for mesothelioma, non–small cell lung carcinoma, and idiopathic pulmonary fibrosis.

Administration of interferons has been associated with a variety of pulmonary reactions. For instance, interferon alfa has been linked to severe exacerbation of bronchospasm in patients with preexisting asthma.[75] In addition, a granulomatous reaction indistinguishable from sarcoidosis has been described in relation to interferon therapy.[76] These toxicities usually respond to either reduction or withdrawal of the interferon treatment with or without the addition of corticosteroids. Noncaseating granulomas have been documented in the lung, lymph nodes, liver, and skin of affected patients.

Interferon-associated interstitial lung disease has also been reported.[77] Dyspnea and cough are observed and bilateral infiltrates are present on chest radiography. A CD8-predominant lymphocytic response is found in the bronchoalveolar lavage fluid, and a cellular interstitial pattern is present on histology. In some cases, interferon therapy has also been associated with bronchiolitis obliterans with organizing pneumonia.[78] Most affected patients respond to discontinuation of the interferon and administration of corticosteroids. Recently, interferon gamma has been used in idiopathic pulmonary fibrosis. A series has been reported in which four patients with advanced idiopathic pulmonary fibrosis developed acute hypoxemic respiratory failure during interferon gamma treatment.[79] This was not responsive to corticosteroids and was fatal in three cases. Interferon gamma is also associated with a high incidence of severe radiation pneumonitis when it is used in multimodality therapy for non–small cell lung carcinoma.

Rapamycin Analogs

Sirolimus was initially developed as an antifungal agent isolated from *Streptomyces hygroscopicus.* It is a macrolide antibiotic inhibitor of mTOR with antiproliferative and immunosuppressive properties essentially used to prevent rejection in solid-organ transplantation and as a coating agent in drug-eluting stents. It is currently under investigation for the treatment of lymphangioleiomyomatosis. Several patterns of drug toxicity have been described with sirolimus, including the subacute onset of interstitial pneumonitis (which usually resolves after discontinuation of therapy), bronchiolitis obliterans with organizing pneumonia, and diffuse alveolar hemorrhage. Rare cases of alveolar proteinosis and granulomatosis have also been reported. Typically, these pulmonary complications are reversible after discontinuation of therapy, but occasionally they represent a difficult diagnostic challenge in an immunosuppressed population prone to a variety of opportunistic infections.[80]

Everolimus is a similar inhibitor of the mTOR pathway that has been used as an immunosuppressive agent in solid-organ transplantation and is under investigation as an antineoplastic agent. Several types of pulmonary toxicity have been described, including bronchiolitis obliterans with organizing pneumonia and the subacute onset of interstitial pneumonitis.[81]

Temsirolimus is active against a variety of solid tumors, including endometrial cell carcinoma, breast cancer, and neuroendocrine tumors. It is FDA approved for the treatment of advanced renal cell carcinoma. In a retrospective review of 22 patients treated with temsirolimus, eight patients (36%) developed pulmonary complications. Half of these patients were symptomatic. On radiographic studies, two different patterns of involvement were identified consisting of ground-glass infiltrates or alveolar consolidation. Discontinuation of the drug is advised.[82]

Granulocyte-Macrophage and Granulocyte Colony-Stimulating Factors

Granulocyte-macrophage colony-stimulating factor and granulocyte colony-stimulating factor are widely applied in the treatment of bone marrow suppression following chemotherapy, thereby enhancing the immune response of treated patients. A number of case reports and small series have proposed that these biologic factors may potentiate pulmonary toxicity of other chemotherapeutic agents.[83] It has also been suggested that granulocyte-macrophage colony-stimulating factor may induce a recall phenomenon of toxicity from other drugs.

Other Chemotherapeutic Agents

Procarbazine

Procarbazine has found use in Hodgkin's disease and other lymphoproliferative disorders. Adverse pulmonary reactions related to procarbazine are fairly rare, with only a few cases of probable procarbazine pneumonitis being described.[35] These lung reactions may be cytotoxic in nature. In other patients, toxicity has been related to a rapid-onset hypersensitivity reaction associated with eosinophilia that declines after the drug has been discontinued.

Zinostatin

Zinostatin has been associated with occasional reports of pulmonary toxicity, usually only occurring in patients who have received the drug for prolonged periods of time.[35] Interestingly, this agent has been associated with the unique drug reaction of hypertrophy of the pulmonary vasculature, which may be associated with pulmonary hypertension.

Vinblastine

Vinblastine, a vinca plant alkaloid, is one of the oldest chemotherapeutic agents still in use. Vinblastine continues to be included in a wide variety of chemotherapeutic regimens for hematologic and solid malignancies. Traditionally, vinblastine was thought to have little if any pulmonary toxicity. However, reports have associated vinblastine with pulmonary complications when it is combined with other agents, particularly mitomycin C. This combination has been complicated by bronchospasm, interstitial pneumonitis, and a noncardiac pulmonary edema.[84,85]

Radiation

The acute effects of radiation can produce histologic changes mimicking cytotoxic lung responses and may occasionally involve areas of lung outside the port of radiation. The process is generally heralded by fever beginning 3 to 8 weeks after initiation of radiation therapy and may rapidly progress to a fatal outcome in spite of institution of corticosteroids. The disease may improve spontaneously but usually progresses to chronic radiation effects. Bronchoalveolar lavage fluid predominantly demonstrates lymphocytes in the involved lung as well as in the contralateral lung.[86] The chronic effects of radiation are well known. They begin 3 to 6 months or later after radiation therapy, and their primary effect is vascular. Recently, a form of radiation pneumonitis has been observed outside the treatment fields, usually in patients with breast cancer. Tissue examination has revealed bronchiolitis obliterans with organizing pneumonitis in these cases.[87]

ANTIMICROBIAL AGENTS

Nitrofurantoin

Acute Reaction

Nitrofurantoin pneumonitis may be one of the most common drug-induced pulmonary diseases.[88–90] Acute pulmonary reactions are probably underestimated. The incidence has been estimated to be anywhere from 1 in 550 to 1 in 5400 individuals.[90] The mechanism of the acute nitrofurantoin reaction is unknown. In spite of peripheral blood eosinophilia, eosinophils are not usually seen in the lung tissue.

The typical reaction begins a few hours to several days after initiation of therapy. It appears to be much more common in women, perhaps due to the increased use of this drug in women. Fever is present in the majority of cases, dyspnea is almost always present, and cough is present in about two thirds of cases. Other incidental findings include leukocytosis and eosinophilia in one third and an elevation in sedimentation rate in nearly one half of cases. The chest roentgenogram shows either an alveolar or an interstitial process or both. The reaction may be unilateral or asymmetrical and is generally most prominent at the bases. Pleural effusion has been found in one third of patients, most commonly unilaterally. Bronchospasm has been reported in a number of cases, but its incidence is unknown. It may occur in the absence of pulmonary parenchymal or pleural disease.[90]

The treatment consists of discontinuing the medication and providing supportive care. It is not known whether corticosteroids accelerate the resolution, and there is probably no indication for their use. There is also no role for rechallenge to confirm the diagnosis. Nitrofurantoin-induced SLE with pleuropulmonary disease and positive antinuclear antibody has also been reported. Little information is available on this form of lung disease.

Chronic Reaction

There is no clinical overlap between the acute and chronic pulmonary reaction to nitrofurantoin. Chronic reactions occur far less commonly than acute pulmonary reactions. In chronic reactions, fever and eosinophilia are much less common.[88,90,91] The onset of dyspnea and cough is usually insidious, beginning 6 months to many years after the chronic (either continuous or intermittent) use of nitrofurantoin. These reactions are more common in women.

The chest roentgenogram shows a diffuse interstitial process.[90,91] There is no associated bronchospasm or obstructive airway disease. Pulmonary function testing demonstrates a restrictive pattern. Bronchoalveolar lavage usually shows a lymphocytic reaction. Histologic analysis of lung tissue shows inflammatory cells and fibrosis. Clinically, radiologically, and histologically, this condition often mimics other forms of interstitial lung disease, including usual interstitial pneumonia, with the single exception that these patients have ingested nitrofurantoin chronically.

The literature varies as to the utility of corticosteroids. Our experience is that they are almost always required before significant resolution occurs. Others imply that the infiltrates resolve spontaneously on discontinuation of the medication.[91] Our policy is to observe the patient for 2 to 4 months after discontinuing nitrofurantoin and then repeating the chest roentgenogram and pulmonary function studies. If there is no improvement, a trial of corticosteroids is given.[92]

Sulfasalazine

Sulfasalazine is an antimicrobial drug that has been used for many years for the treatment of inflammatory bowel disease.[93] There appear to be two separate types of adverse pulmonary reactions: one is a pulmonary infiltrate and eosinophilia, and the other a bronchiolitis obliterans with organizing pneumonitis. The onset of symptoms of cough, dyspnea, and, in about half of cases, fever begins 1 to 8 months after initiation of continuous therapy. The dosage ranges from 1.5 to 8 g/day. The chest roentgenogram shows a variable pattern of lung infiltrates, ranging from upper lobe alveolar infiltrates to a diffuse interstitial process. Over half of the patients had significant blood eosinophilia, but none had migratory pulmonary infiltrates. The majority of the resolution

occurs within 1 week to 6 months after discontinuing the drug and, if necessary, adding corticosteroids. Sulfasalazine is metabolized to 5-aminosalicylic acid and sulfapyridine, both of which have been implicated in eosinophilic pneumonitis. In cases of suspected sulfasalazine-associated pulmonary disorders, it important to keep in mind that inflammatory bowel disease has been associated with a variety of pulmonary abnormalities independent of sulfasalazine use. Inflammatory bowel disease has been independently linked to airway inflammation, interstitial lung disease including bronchiolitis obliterans with organizing pneumonia, neutrophilic necrotic pulmonary nodules, and serositis. Most of these disorders respond to corticosteroid therapy.

Miscellaneous Antimicrobial Drugs

There are many scattered reports of unusual reactions to various antimicrobial drugs. In view of the wide use of these agents, the incidence is extremely small. Many of these reactions appear to be pulmonary infiltrates with eosinophilia. The polymyxin and aminoglycoside antibiotics are known to produce respiratory muscle weakness when they reach an excessive level in the blood.[94] Toxic levels in the blood occur in patients to whom these drugs are given by direct instillation into the peritoneal or pleural space, in persons with renal failure, or when the patient receiving them has been given a muscle-relaxing agent at the time of general anesthesia. These effects are reversible with physostigmine. The combined administration of granulocytes with amphotericin B may predispose some patients to transient deterioration in pulmonary function.[95]

ILLICIT DRUGS

Heroin

Although nitrofurantoin appears to be the most commonly reported prescribed drug with adverse pulmonary effects, heroin pulmonary edema may be the most common drug-induced pulmonary disease worldwide. Hospitals in all major cities of the United States receive hundreds of patients with heroin pulmonary edema. Heroin is diacetylmorphine and, because of its increased lipid solubility, it crosses the blood-brain barrier much more readily than morphine. There are several postulated mechanisms of heroin-induced noncardiac pulmonary edema. These include a direct toxic effect on the alveolar-capillary membrane, leading to an increased permeability and extravasation of fluid into the alveolar spaces; a neurogenic response to central nervous system injury; an allergic or hypersensitivity reaction; and an acute hypoxic effect on the alveolar-capillary membrane in association with secondary increased permeability. The hypoxemic theory is the one most commonly touted, but other causes of acute hypoxia, such as barbiturate overdosage with depression of the respiratory center, rarely result in noncardiac pulmonary edema.[56]

Heroin pulmonary edema can occur with the first intravenous use of the drug. It is believed that the effects of heroin are related to the dose. However, the exact dose is almost always unknown. Up to 40% of addicts hospitalized for acute drug overdose have acute pulmonary edema with severe hypoxemia and hypercapnia. The noncardiac pulmonary edema is indistinguishable at the outset from other forms of acute respiratory distress syndrome. The pulmonary capillary wedge pressure is usually within normal range. Typically, symptoms of dyspnea and somnolence begin within minutes of the intravenous "push," but reports of delayed onset of hours and even a few days have been published. The patient hypoventilates, producing hypoxemia and hypercapnia. The pupils are small. Auscultation of the lungs discloses crackles. The chest roentgenogram shows changes of noncardiac pulmonary edema. Acidosis can be metabolic as well as respiratory.

Up to one half of these patients vomit and aspirate, which leads to secondary bacterial infection. This should be suspected if the pulmonary infiltrates do not clear within 24 to 48 hours of treatment. Other pulmonary abnormalities include septic emboli from infected thrombophlebitis or tricuspid endocarditis. Treatment consists of assisted ventilation using positive end-expiratory pressure, oxygen, and intravenous naloxone to reverse the respiratory depression. This is usually sufficient treatment for the noncardiac pulmonary edema, which will reverse with time. Corticosteroids are unnecessary. Because up to half of these patients have aspirated and have bacterial infections, appropriate use of antimicrobial drugs is indicated.

Bronchiectasis and necrotizing bronchitis in chronic heroin abusers have been reported. These may be more sequelae of recurrent gastric aspiration than the effects of heroin, with or without pulmonary edema. Pulmonary function is abnormal in patients with pulmonary edema. Even after the roentgenographic clearance of the edema and the return of the lung volumes to normal, a reduction in the carbon monoxide diffusing capacity may persist. In chronic abusers of heroin and other illicit intravenous drugs, pulmonary function abnormalities are more likely to be related to talc granulomatosis (see later) than to sequelae of a single acute injury.

Methadone and Propoxyphene

Pulmonary sequelae similar to those associated with heroin have been reported with methadone and propoxyphene and likely have similar mechanisms. Treatment is the same as for heroin-induced sequelae. Addicts in drug rehabilitation programs have free access to methadone. They accumulate the drug illegally, dissolve it, and inject it. Noncardiac pulmonary edema has been reported in cases of both oral and intravenous overdose of methadone. Propoxyphene is a rapidly absorbed drug, and, even after oral ingestion, death can occur within 30 minutes from respiratory depression and arrest and noncardiac pulmonary edema. In some parts of the United States, propoxyphene is a commonly used drug in attempted suicide.

Methylphenidate

Methylphenidate may have more serious adverse side effects than either heroin or cocaine.[96,97] Methylphenidate can be abused either intravenously or orally. In one series of methylphenidate abuse, all 22 patients had chest pain and wheezing and most had abnormal pulmonary function tests and hemoptysis.[96] In another series, severe panlobular emphysema was found in seven patients who died as a result of the abnormalities.[97]

Cocaine

Cocaine use remains a major problem throughout the world, and there are increasing reports of adverse pulmonary effects from both intravenous and inhalation use of the drug. These are over and above the known cardiac effects of cocaine, which produces left ventricular failure with pulmonary congestion and edema. The principal long-term effects of cocaine are infection and aspiration, noncardiac pulmonary edema, particulate embolization, talcosis, diffuse alveolar damage, alveolar hemorrhage, intra-alveolar eosinophilic infiltration, lung mass with or without cavitation, and bronchiolitis obliterans with organizing pneumonia (Table 72-4).[98,99]

Talc Granulomatosis

Talc (magnesium silicate) is used as a filler in many medications intended for oral use. Addicts who abuse oral medications such as meperidine, methadone, propoxyphene, methylphenidate, amphetamines, and tripelennamine often crush the tablets, mix them with various solutions, and inject them intravenously. This results in the insidious onset of granulomatous interstitial fibrosis, granulomatous pulmonary arterial occlusion, or both.[98–100] This usually does not occur in heroin addicts, because heroin is mixed in soluble fillers such as quinine, lactose, or maltose. In large series of consecutive autopsies done on addicts, depending on the type of addiction, the incidence of talc granulomatosis ranges from 15% to 80%.

Dyspnea is the major symptom, cough occurs in some patients, and, in more advanced stages of pulmonary hypertension, symptoms of exercise-induced syncope and right-sided heart failure, and even sudden death, occur. The chest roentgenogram may be normal in up to half of patients with proven talc granulomatosis. Thus, a normal chest roentgenogram does not eliminate the possibility of this condition. Pulmonary function studies characteristically show a low diffusing capacity before any other abnormalities are evident, because of occlusion of pulmonary blood vessels. This may remain the only abnormality. Chest roentgenograms in these patients show diffuse micronodular densities varying in size between 1 and 3 mm, which may mimic alveolar microlithiasis. Therapy with corticosteroids provides little consistent improvement.

Histologically, the pulmonary tissue demonstrates granulomatous changes, with multinucleated giant cells, mononuclear inflammatory cells, lymphocytes, and fibrosis. Talc is detected by the presence of strongly birefringent crystals (using polarized light) within the granulomas. Bronchoalveolar lavage fluid shows an increased lymphocytosis, and intracellular and free talc have been identified in the bronchoalveolar lavage fluid. Talc retinopathy occurs in over half the patients. Talc emboli presenting as small, whitish, glistening foci near the macula within a small vessel are fairly characteristic.

CARDIOVASCULAR DRUGS

Angiotensin-Converting Enzyme Inhibitors

Angiotensin-converting enzyme (ACE) inhibitors are widely used for control of hypertension and in the management of congestive heart failure. Soon after their introduction, these agents were associated with nonproductive cough and more rarely with angioneurotic edema. Dry cough occurs in 5% to 20% of patients on ACE inhibitors, being reported with captopril, enalapril, lisinopril, and virtually all other ACE inhibitors. The mechanism of ACE inhibitor–induced cough likely involves accumulation of kinins and substance P, which are degraded by ACE and other endopeptidases. The cough generally is reported in the first few weeks after beginning therapy but may not be appreciated for a number of months. ACE cough is usually benign but can be quite annoying, and causes the discontinuation of these agents in half of the patients affected. Exacerbation of bronchospasm has been associated with ACE inhibitors only on very rare occasions. Fortunately, most patients can be switched to other classes of drugs. Rechallenge with a different ACE antagonist is not recommended as the cough will usually reoccur. Cough generally abates within 4 days of discontinuation of the agent, providing confirmation of the diagnosis. Of note, selective angiotensin receptor antagonists have much lower incidence of dry cough compared to ACE inhibitors and may represent a therapeutic option for many patients.

ACE inhibitors cause angioneurotic edema much less frequently; this condition is reported in 0.1% to 0.2% of patients receiving ACE inhibitors. This complication usually occurs within hours to, at most, 1 week after initiating therapy, and can be life-threatening. This reaction may be mediated by bradykinins but may also involve autoantibodies and complement system activa-

tion. Treatment involves airway protection, epinephrine, antihistamines, and corticosteroid administration. The ACE inhibitor must be discontinued and future use avoided in these patients.

Amiodarone

Amiodarone has significant benefit for ventricular and supraventricular dysrhythmias in patients who do not respond to most other antiarrhythmic agents. This drug is associated with a number of side effects, which include corneal microdeposits (in nearly 100% of the patients); peripheral neuropathy; liver dysfunction; thyroid dysfunction, including hypo- and hyperthyroidism; and bluish pigmentation of the skin. However, the most serious side effect is an interstitial pneumonitis, which occurs in up to 6% of patients and may be fatal.

The mechanism of amiodarone toxicity is unknown, but the toxicity is dose related and has distinctive histologic features. The histologic findings generally include foamy alveolar macrophages and type II pneumocytes containing lamellar inclusions. In one half of the patients on amiodarone who die of nonpulmonary causes, macrophages and type II pneumocytes contain a markedly increased amount of phospholipid.

The incidence of pulmonary toxicity from amiodarone varies widely but probably averages 4% to 6% of those patients on the drug.[12,101] The majority are men, but this may be related to increased use in men. Symptoms consist of insidious dyspnea, nonproductive cough, and occasionally a low-grade fever without chills, followed by subtle chest roentgenographic findings, which initially may be asymmetrical or even limited to the upper lobes. If the drug is continued, the process may diffusely involve the lungs with an interstitial or alveolar process. Pleural effusion is uncommon. Pleuritic chest pain occurs in about 10% of patients. Clubbing has not been reported. Crackles may be heard, but it is difficult to be certain whether these are due to pulmonary edema, because congestive heart failure is common in these patients. In about 20% of patients with amiodarone pneumonitis, the presentation will be acute, mimicking pneumonia.

Laboratory studies disclose a normal to mildly elevated leukocyte count, generally no eosinophilia, and an elevated sedimentation rate, with little or no reactivity to antinuclear antibody. Pulmonary function studies disclose a decrease in the total lung capacity and carbon monoxide diffusing capacity as well as hypoxemia. However, a decrease in the lung volumes and carbon monoxide diffusing capacity can occur as a result of congestive heart failure, and thus a change in these parameters is not diagnostic of impending clinical amiodarone pneumonitis. There are selected reports of using ^{67}Ga radionuclide lung scanning that may demonstrate its benefit in differentiating amiodarone pneumonitis from congestive heart failure.[102] There may be an increased predisposition to amiodarone pneumonitis if either pulmonary function or chest roentgenographic findings are abnormal before administration of the drug begins.

The majority of the patients who develop amiodarone pneumonitis have been taking the drug for at least a month, and some for a few years. Most are receiving at least 400 mg/day. However, there have been a number of reports of amiodarone pneumonitis occurring with as little as 200 mg/day. There are also reports of patients receiving 200 mg/day for months or even years and not developing amiodarone pneumonitis until the dose is boosted for purposes of better control of the arrhythmia. Generally, the systemic side effects from amiodarone, such as peripheral neuropathy and liver dysfunction, correlate with the serum levels, but this is not necessarily the case with the pulmonary toxicity. Perhaps the greater phospholipid turnover in the lung explains the greater chance for lung toxicity from amiodarone. The diagnosis of amiodarone pneumonitis is one of exclusion.

Normally, amiodarone pneumonitis is thought to be primarily an interstitial or alveolar process (or both) sometimes mimicking eosinophilic pneumonitis with peripheral infiltrates, but there are a number of reports of confluent lesions occurring as a result of amiodarone pneumonitis. Many of these lesions are bronchiolitis obliterans.[103,104] Computed tomography of the lung can further define these processes because amiodarone, being an iodinated compound, is radiopaque, and on a computed tomography scan the amiodarone pneumonitis lesions are denser than the surrounding soft tissue in the chest wall (Fig. 72-5). This latter finding may confirm the diagnosis.

Treatment consists of drug withdrawal and leads to a variety of responses. Some patients who were not treated with corticosteroids have died of pulmonary fibrosis and respiratory failure. Others have died in spite of being treated with corticosteroids. The majority respond to discontinuation of the drug and addition of corticosteroids, which are usually required for a period of at least

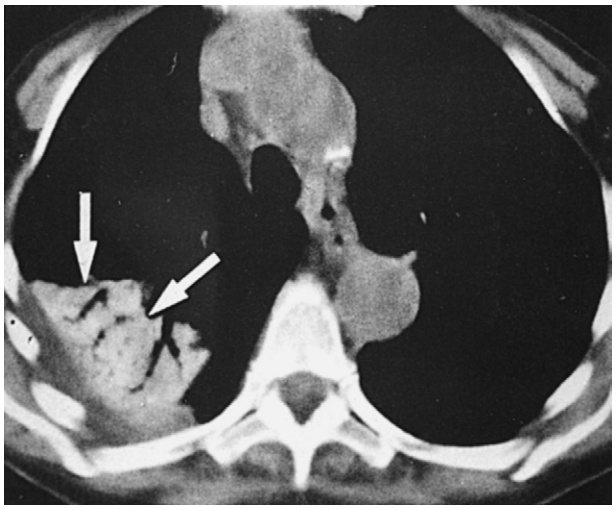

FIGURE 72-5 ■ A chest computed tomography (CT) scan showing confluent pulmonary masses (*arrows*) from amiodarone pneumonitis. Note that the masses are appreciably denser than the surrounding soft tissue in the chest wall in this CT scan obtained without contrast.

2 and perhaps 6 months or longer. There are many case reports of patients who continued on amiodarone because it was the only drug that controlled their ventricular dysrhythmia and who at the same time were given corticosteroids to suppress their pneumonic reaction.[105] For some patients, implantable automatic cardiac defibrillators provide a therapeutic option to chronic high-dose amiodarone therapy.

Initially, it was believed that tissue confirmation by biopsy was necessary to establish a diagnosis, although stopping the drug and adding corticosteroids may offer a presumptive diagnosis if the process clears. Bronchoalveolar lavage produces variable results.[12] The presence of foamy macrophages in lavage fluid or on biopsy only confirms exposure to the drug; their presence alone does not necessarily indicate amiodarone toxicity. Their absence does eliminate the diagnosis, however. Although not used frequently in recent years, a positive ^{67}Ga scan can be highly suggestive of an inflammatory pneumonitis rather than congestive heart failure. If the diagnosis has not been established, the clinician must decide whether to proceed with an open-lung biopsy to rule out other disease processes or to consider diminishing the dose or discontinuing the drug, or adding corticosteroids, or both. A lung biopsy usually reveals the foamy macrophages and epithelial cells, and variable inflammatory cell infiltration. In some cases, the tissue pattern of bronchiolitis obliterans with organizing pneumonia has been observed (Table 72-5). Reductions in sedimentation rate following discontinuation or reduction of amiodarone dosage may be of further value in establishing the diagnosis.

There are reports of postoperative acute respiratory distress syndrome in patients on amiodarone. Several of these patients have died as a result of the acute respiratory distress syndrome, which begins 18 to 72 hours after surgery. In one series, the acute respiratory distress syndrome occurred in 50% of the patients on or recently on amiodarone.[106] It has been postulated that the high fraction of inspired oxygen given during the operation and the postoperative period contributed to this complication.

Protamine

Protamine sulfate is used to reverse the anticoagulant effects of heparin following cardiovascular surgical procedures. Systemic hypotension is not uncommon following administration of this drug. However, there have been a number of cases of noncardiogenic pulmonary edema occurring within minutes to 1 or 2 hours after the administration of the drug.[107] It is frequently associated with an anaphylactic reaction and bronchospasm, an increase in pulmonary artery pressure with normal wedge pressure, and hypotension. In at least half of the patients there is a history of previous use of protamine, either in a similar situation or as protamine zinc insulin. Skin testing can confirm the sensitization. Therapy is supportive, including reintubation if the patient has been extubated, assisted ventilation with high inspired oxygen concentrations, administration of high-dose corticosteroids, and treatment of hypotension with an α-adrenergic agonist. In patients whose skin test is positive to protamine or who have a history of reaction to protamine, an alternative method of reversing the effects of heparin is to use intravenous hexadimethrine.

β-Adrenergic Antagonists

β-Adrenergic antagonists are among the most commonly prescribed drugs. β-Adrenergic receptors can be divided into excitatory β_1-receptors, located in the heart, and inhibitory β_2-receptors, located in the bronchi. The β-adrenergic blockers, or β-blockers, are competitive antagonists.

Propranolol was the first β-adrenergic antagonist introduced. It was quickly recognized that it had adverse effects on individuals with known obstructive lung disease. Studies have also demonstrated increased airway resistance in normal persons and in asymptomatic asthmatic patients who use propranolol.[108] Thus, this agent should be avoided in all patients with known obstructive lung disease, even those who are asymptomatic. The following β-adrenergic antagonists, presented in decreasing order of bronchoprovocation potential, are available for clinical use in the United States: propranolol, timolol, nadolol, metoprolol, atenolol, pindolol, and labetalol.[109]

Two features of β-adrenergic antagonists predict their potential for bronchoprovocation: their cardioselectivity and their intrinsic sympathomimetic activity. Generally, cardioselectivity is the more important of the two. If the drug is cardioselective, it has little effect on the inhibitory β-receptors located in the bronchial walls. Propranolol, timolol, and nadolol have essentially no cardioselectivity. Metoprolol has some cardioselectivity, and atenolol has considerable cardioselectivity, making atenolol the drug of choice in an individual with obstructive airway disease who needs a β-adrenergic antagonist. The other mechanism important in β-adrenergic antagonists is intrinsic sympathomimetic activity, with pindolol having strong intrinsic sympathomimetic activity. Labetalol is unique in that it has combined α- and β-antagonist effects. It is not cardioselective, nor does it have intrinsic sympathomimetic activity. Therefore, it is assumed that

it is its α-adrenergic antagonist potential that causes it to be bronchoprotective.

Thus, among the seven drugs listed, atenolol and then metoprolol and probably labetalol are the three that can be used with relative safety in persons with obstructive lung disease, if absolutely necessary. However, these should always be given in conjunction with an aerosolized β_2-adrenergic agent. Calcium channel blockers may be a good alternative to β-blocking drugs, if indicated, because they also may have some bronchodilating capabilities.

The same findings have been shown to occur in asthmatic patients receiving timolol eye drops for glaucoma. There are many case reports of the adverse effects of topical ocular timolol, including a number of fatal cases of status asthmaticus.[110] Topically applied timolol is absorbed through the conjunctiva and bypasses the liver, resulting in a higher concentration than when given orally. A novel ocular β-adrenergic antagonist, betaxolol, has been shown to be safer in patients with known airway disease. There are scattered reports of β-blocker–associated interstitial pneumonitis.[111] Propafenone is an additional membrane-stabilizing antiarrhythmic agent that is structurally similar to propranolol and has the potential to aggravate bronchospasm.[112]

Tocainide and Flecainide

Tocainide is used in the treatment of refractory ventricular arrhythmias. There are well over 100 known cases of acute interstitial pneumonitis beginning 3 weeks to several months after initiation of therapy.[113] The response to discontinuing the drug is good; corticosteroids may be necessary in some cases. Flecainide, another antidysrhythmic agent, has been reported to be associated with the acute respiratory distress syndrome and an interstitial lymphocytic pneumonitis.[114,115]

ANTI-INFLAMMATORY AGENTS

Aspirin

Anti-inflammatory agents are among the most commonly used drugs, and many have pulmonary side effects. Aspirin is the most commonly used drug in the world. In the United States, there are over 200 proprietary drugs that contain aspirin. It is estimated that up to 5% of asthmatics are sensitive to aspirin; ingestion may cause fatal aggravation of bronchospasm.[116] The exact cause of aspirin-sensitive asthma is unknown. One theory is that acetylsalicylic acid and similar compounds inhibit cyclooxygenase, and thus prevent the generation of cyclooxygenase products. If bronchodilator prostaglandins (such as prostaglandin E_2), are normally released by these individuals, their inhibition could cause bronchospasm.

The aspirin-asthma triad consists of asthma, rhinitis, and nasal polyposis. Almost always there are other associated side effects, such as cutaneous rashes and gastrointestinal symptoms. These adverse reactions are not dose related, because they can occur with very small doses. In addition, salicylate-induced noncardiac pulmonary edema can occur when the serum salicylate level is greater than 40 mg/dL. This can occur without an intentional overdosage in patients chronically ingesting salicylates. It occurs more commonly in elderly persons who are smokers than in younger nonsmokers. The mechanism is unknown, although it may be a direct effect on the alveolar capillary wall as a result of an increase in the capillary permeability. It may be related to the effect of salicylates on platelets or prostaglandins or occur through a central nervous system effect. It does not occur in every individual with very high serum salicylate levels. Because of the respiratory center stimulation by salicylates, hyperventilation occurs, resulting in a low arterial P_{CO_2}, frequently less than 20 mm Hg. In spite of hyperventilation, the arterial P_{O_2} may be paradoxically low because of the presence of pulmonary edema. In one review of the 177 consecutive patients admitted to an intensive care unit for salicylate intoxication, 47% had respiratory failure, 94% required mechanical ventilation, abnormal clotting studies were noted in 38%, and 36% were acidemic.[117] There was a 15% mortality. Treatment of salicylate-induced noncardiac pulmonary edema depends on the severity of the edema; some patients require intubation and even hemodialysis. Treatment with forced alkaline diuresis is often recommended, but this is dangerous in patients who already have pulmonary edema.

Leatherman and Schmitz have described a pseudosepsis syndrome associated with chronic salicylate ingestion.[118] Most patients had fever, leukocytosis, hypotension, and multiple organ failure, including acute respiratory distress syndrome. This condition is easily missed unless salicylate intoxication is suspected and the blood salicylate level is measured.

Other Nonsteroidal Anti-inflammatory Drugs

Most of the nonsteroidal anti-inflammatory agents can produce the same side effects as aspirin, including aggravation of asthma, noncardiac pulmonary edema, drug-induced SLE, and pulmonary infiltrates with eosinophilia. Naproxen may be more commonly associated with an infiltrate and eosinophilia than are the other agents.[119] A few agents can cause hypervolemia and, in turn, pulmonary edema through the mechanism of increased sodium retention through the kidneys.

Gold

Gold has been used since ancient times for treating various immunologic disorders, including rheumatoid arthritis. There are now a number of reports of diffuse interstitial pneumonitis and fibrosis associated with gold that are believed to be separate from that of rheumatoid lung. Interstitial pneumonitis is more commonly observed in patients taking sodium aurothiomalate than in those taking aurothioglucose, but this may reflect the more

common use of the former drug. Symptoms of dyspnea with or without fever begin insidiously several weeks to months after initiation of weekly intramuscular injections of gold. A few reports have demonstrated peripheral blood eosinophilia, but this is uncommon. Pleural effusion is not associated with this reaction.

In diffuse interstitial pneumonitis and fibrosis, the chest roentgenogram shows a predominantly interstitial process. Bronchoalveolar lavage usually demonstrates a high percentage of lymphocytes. Histologically, the lung demonstrates fibrosis with an interstitial infiltrate of lymphocytes and plasma cells and focal hyperplasia of type II pneumocytes. Electron microscopy demonstrates electron-dense structures within lysosomes of endothelial cells of the alveolar capillaries and interstitial macrophages. Microanalysis with an electron probe shows that these electron-dense structures contain gold, suggesting that a direct toxic effect might be an important mechanism in the pathogenesis of gold-induced pulmonary reactions. However, there are no control studies of lungs in patients who are taking gold but do not develop gold pneumonitis.

Other associated complications of gold are often present, such as dermatitis, neuropathy, and proteinuria. Secondary infections have not been reported as a complication of gold pneumonitis, nor have there been deaths reported from irreversible lung fibrosis. The treatment may be as simple as withdrawing the drug and allowing the process to resolve spontaneously. However, a number of patients have required corticosteroids for reversal. Gold pneumonitis is not thought to be related to rheumatoid fibrosis, in that the parenchymal disease improves spontaneously with stopping gold or almost always regresses with use of corticosteroids.

Penicillamine

There are three possible pulmonary complications with the use of penicillamine with no apparent overlap: penicillamine-induced SLE, bronchiolitis obliterans, and Goodpasture's syndrome. Some patients with penicillamine-associated pneumonitis or alveolitis have high titers of antinuclear antibodies. Penicillamine-induced disease appears to be one of the more common causes of drug-induced SLE. This condition should always be considered in the patient receiving penicillamine, especially if a pleural effusion is present. A normal concentration of sugar in the effusion fluid virtually eliminates the possibility of a rheumatoid effusion.

Penicillamine-associated bronchiolitis obliterans is probably underestimated in its incidence and severity. There is little information on pulmonary function in rheumatoid patients before initiation of penicillamine that compares patients who subsequently develop bronchiolitis obliterans with those who do not experience obstructive physiology. Perhaps there is a predisposing obstructive lung disease in the rheumatoid patient that is worsened by penicillamine in the form of a bronchiolitis obliterans. Corticosteroids have little benefit in treating this condition, which usually presents in an advanced state.

There have also been several case reports of penicillamine-associated Goodpasture's syndrome with diffuse alveolar hemorrhage.[120] If recognized early enough, appropriate therapy with hemodialysis, plasmapheresis, and immunosuppression may prevent a serious outcome.

Leflunomide

Several new agents have in recent years been found to be efficacious in the treatment of inflammatory conditions with a considerably improved safety profile when compared to the previous regimens used. Leflunomide received its FDA approval in 1998 and is currently used to treat rheumatoid arthritis as well as psoriatic arthritis. It is a pyrimidine synthesis inhibitor via inhibition of the dihydroorotate dehydrogenase enzyme and exerts mainly an immunomodulating effect, although it was also found to exert significant anti-inflammatory effects. Its main described adverse effect is liver toxicity, and it may act synergistically with methotrexate with a heightened degree of hepatotoxicity. More recently, several patterns of lung injury have been observed with leflunomide, mostly consisting of hypersensitivity reactions. In a postmarketing surveillance study, significant lung toxicity was identified in 61 of 5053 patients, with 24 patient deaths directly related to the pulmonary complications. Preexisting lung disease, and to a lesser degree loading dose, a smoking history, and low body weight, were identified as independent risk factors in multivariate analysis. A recent case-control study did not document a higher incidence of lung toxicity in individuals treated with leflunomide without preexisting lung disease or prior methotrexate use.[121] True hypersensitivity pneumonias have also been reported in case series, as defined by interstitial infiltrates associated with ill-defined granulomas.[122] Nonspecific infiltrates with or without eosinophilia have also been reported. Diffuse alveolar hemorrhage and pulmonary alveolar proteinosis are rarely encountered.

Biologic Agents

These agents have truly revolutionized the management of a number of chronic inflammatory conditions such as rheumatoid arthritis, inflammatory bowel diseases, and psoriasis. Anti–tumor necrosis factor-α (TNF-α) medications such as infliximab (a chimeric monoclonal antibody targeting TNF-α) or etanercept (a soluble TNF-α receptor) have been used with various success in these conditions by directly interfering with the very first steps of the inflammatory cascade. Not unexpectedly, infections are a major complication of these treatments—tuberculosis in particular, which may easily reactivate in a context of impaired T-cell immunity. Tuberculosis skin tests or blood assays for *Mycobacterium tuberculosis* are mandatory prior to initiation of treatment. Extrapulmonary manifestations seem relatively common (40 of 70 patients in an initial report), with most cases occurring in areas with a low incidence of tuberculosis, perhaps because these drugs tend to be used in more

developed countries. Interestingly, other opportunistic infections, including fungal lung infections, although described, are less of a concern with these agents. Multiple patterns of lung injury have been described with infliximab, including acute hypersensitivity reactions with or without eosinophilia, nonspecific interstitial pneumonitis, de novo usual interstitial pneumonia (UIP), or exacerbation of rheumatoid arthritis–associated UIP and vasculitis.[123] Two other anti–TNF-α medications, adalimumab and etanercept, have also been described in association with pulmonary fibrosis, but these associations are relatively weak and mainly based on isolated case reports.

Leukotriene Antagonists

Recent reports have associated zafirlukast and related leukotriene antagonists with manifestations of Churg-Strauss syndrome.[124,125] These potent agents have been employed in treating asthma. As zafirlukast is added to an asthmatic treatment regimen, corticosteroids are frequently tapered. A number of cases have been described with patients exhibiting pulmonary infiltrates, cardiomyopathy, and eosinophilia while receiving zafirlukast. It is currently unknown whether these medications actually trigger these reactions, or whether they are unmasking a preexistent infiltrative eosinophilic disorder as the corticosteroids are withdrawn. In either event, the pulmonary reaction responds to discontinuation of zafirlukast and reinstitution of corticosteroids.

Corticosteroids

Corticosteroids given in immunosuppressive doses are well known for predisposing patients to the development of opportunistic infections. A most unusual adverse effect of corticosteroids is mediastinal lipomatosis, the deposition of mediastinal fat, which produces a widening of the mediastinum that mimics lymphadenopathy or other neoplasms (Fig. 72-6). Clinically, these patients have a cushingoid appearance, with rounded facies and a "buffalo hump." The same kind of fat that deposits in the buffalo hump occurs in the mediastinum. The chest roentgenogram does not show the lumpiness usually expected with adenopathy. Computed tomography can usually make this diagnosis by establishing radiographic fat density throughout the mediastinal mass (see Fig. 72-6). Mediastinal lipomatosis does not necessitate tapering corticosteroids because the fat does not compromise vital structures.

DRUG-INDUCED SYSTEMIC LUPUS ERYTHEMATOSUS

Over 50 drugs have been reported to induce the SLE syndrome, but only 5 regularly induce antinuclear antibodies in patients taking them: hydralazine, procainamide, isoniazid, hydantoins, and penicillamine. Only a small percentage of the patients on these drugs develop the clinical syndrome that involves the pleuropulmonary system in over half the cases (see the earlier discussion on mechanisms of drug-induced injury). It is thought that patients who develop antinuclear antibodies to these drugs are "slow acetylators." Symptoms almost always begin insidiously after the patient has been taking the drug for many months or even years. Systemic signs and symptoms of polyarthralgia, myalgia, fever, pleurisy, and cutaneous lesions are common. However, renal disease is very uncommon, possibly because complement is not as often involved in the drug-induced form of SLE compared to the spontaneous type.

The antinuclear antibody assay is positive in all patients with drug-induced SLE. However, the test for anti-native (anti–double-stranded) DNA is negative. The complement level may or may not be abnormal. A Coombs' test is positive in about one third of patients. An elevated erythrocyte sedimentation rate and hypergammaglobulinemia are common nonspecific findings.

The chest roentgenographic findings of the drug-induced form of the disease are indistinguishable from spontaneous-onset SLE and include pleural effusions in one third of patients, basilar infiltrates, pneumonitis with atelectasis, and apparent cardiomegaly from pericardial effusion. Pleural fluid glucose is normal or at least correlates with the blood glucose levels.

The symptoms usually resolve once the drug is discontinued. However, occasionally it is necessary to add corticosteroids for more rapid resolution of disabling symptoms. If the offending drug cannot be discontinued for clinical reasons, the lowest dose should be used, along with the addition of corticosteroids.

INHALANTS

Oil

Aspirated oil can produce a variety of pulmonary diseases, ranging from an asymptomatic solitary nodule to diffuse disease with severe respiratory insufficiency.[126,127] Most commonly, however, the diseases present in an asymptomatic individual with an incidental finding of an abnormal chest roentgenogram that mimics a more serious process such as bronchogenic carcinoma. Because patients rarely consider oily nose drops, oily eye lubricants, or mineral oil as a medication, they rarely volunteer that they are taking oil-containing medications.

There are three types of oil: mineral oils, neutral oils, and animal fats. Mineral oils are the most commonly aspirated oils. Oily droplets are taken up by macrophages that eventually disintegrate and release the oil, which in turn inhibits ciliary activity. Thus, the oil is not expectorated and the cycle is repeated again. Eventually, a fibrotic or granulomatous reaction occurs. Neutral or vegetable oils (e.g., olive or castor oil) do not elicit a local reaction and are removed by expectoration. Animal fats (e.g., milk, butter) are rapidly hydrolyzed, with the liberated fatty acids producing tissue necrosis and

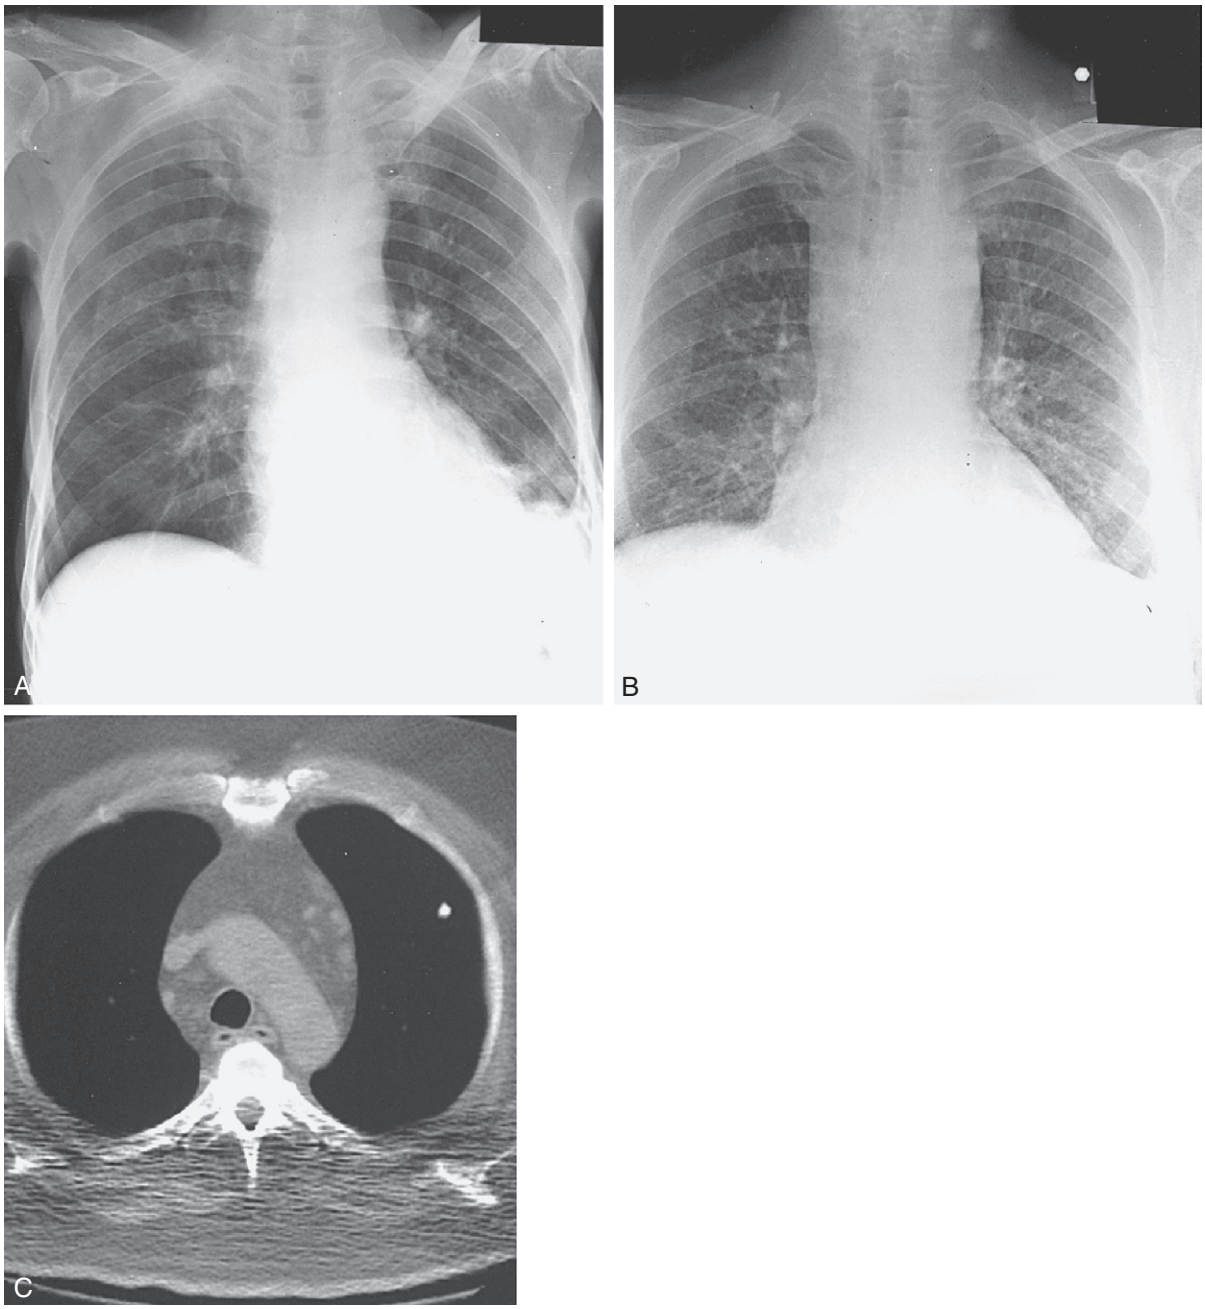

FIGURE 72-6 ■ Mediastinal lipomatosis in response to corticosteroids. **A,** Chest roentgenogram prior to systemic corticosteroid administration. **B,** Chest roentgenogram after corticosteroid administration shows widened mediastinum. **C,** Computed tomography scan of the chest shows mediastinal lipomatosis, with radiographic fat density surrounding the great vessels and tracheal shadows.

subsequent fibrosis. The diagnosis can be established with the demonstration of oil in the lung tissue. Computed tomography and magnetic resonance imaging have been used in diagnosing lipoid-induced infiltrates.[126] The "CT angiogram" sign, defined by the ability to distinguish the pulmonary vasculature within an area of consolidation, was once thought to be fairly specific for lipoid pneumonitis, but may be seen in a variety of unrelated conditions. Treatment involves the discontinuation of the oil-containing medication. Once this occurs, progression is unlikely.

Oxygen

Exposure to high concentrations of oxygen may contribute to or aggravate the acute respiratory distress syndrome. There are two theories as to the mechanism of oxygen-induced pulmonary disease. The first is that a high fraction of inspired oxygen induces formation and release of free oxidant radicals. These short-lived molecules damage DNA, destroy lipid membranes, and inactivate intracellular enzymes.[128] The other theory is that hyperoxia produces a direct injury to endothelial cells

and type I epithelial cells, which results in alveolar-capillary leak.[129]

Studies in volunteers breathing 100% oxygen for 6 to 48 hours produced variable effects, but in some a tracheobronchitis occurred, with symptoms of substernal burning, chest tightness, and nonproductive cough. It also produced a reduction in vital capacity and carbon monoxide diffusing capacity. The development of tolerance to hyperoxia appears to be related to the ability of the individual to increase the production of antioxidants, a mechanism that may be determined genetically.

The sequelae of oxygen toxicity are separable into two phases, the acute, or exudative, phase and the subacute proliferative phase; however, there is considerable overlap between the two phases, with the proliferative phase beginning after the fourth to seventh day. The exudative phase begins within 48 to 72 hours, depending on the fraction of inspired oxygen, and is associated with perivascular, interstitial, and alveolar edema with atelectasis, as well as alveolar hemorrhage. This phase appears to be reversible.

The proliferative phase is characterized by progressive resorption of exudates and hyperplasia of type II cells. This is followed by the deposition of collagen and elastin in the interstitium and hyaline membrane deposition. This is usually an irreversible phase. Clinically, hypoxemia and diminished compliance progress, requiring a greater fraction of inspired oxygen and assisted ventilation, further aggravating the problem. The chest roentgenogram shows an alveolar-interstitial pattern in an irregular distribution, with evidence of moderate loss of volume from patchy atelectasis.

There is no clinical way of diagnosing oxygen toxicity. A lung biopsy specimen may show changes consistent with oxygen toxicity, but the primary value of the biopsy is to exclude other causes of lung injury. Keeping the arterial P_{O_2} less than 80 mm Hg or the inspired fraction of oxygen below 0.40 to 0.50 minimizes the chance of oxygen toxicity developing. Barotrauma and ventilator-induced injury may accompany and be indistinguishable from oxygen toxicity.

TRANSFUSION-RELATED ACUTE LUNG INJURY

Acute alveolar damage as a result of transfusion reaction is probably one of the more rarely recognized adverse drug reactions, if one considers transfused blood or its products a form of drug. The damage is usually the result of donor antibodies against leukocyte antigens or donor leukocyte-specific immune cells reacting against the recipient's leukocytes.

In about 5% of the cases, the recipient's antileukocyte antibodies react against the donor leukocytes. The acute alveolar damage reaction is not a hemolytic transfusion reaction or an anaphylactic reaction. In a recently published nested case-control study, 74 (8%) of 901 critically ill patients who had received blood products developed transfusion-related acute lung injury (TRALI), as defined by onset within 6 hours of transfusion.[130] The main risk factors identified were sepsis and history of alcohol abuse. Transfusion with products from female donors, especially with a higher number of pregnancies, increased the odds of developing TRALI. The likelihood of a TRALI reaction also increased with the number of blood products given, the presence of anti–human leukocyte antigen class II antibodies and the concentration of lysophosphatidylcholine in the product.

The clinical presentation is that of onset of dyspnea, cough, fever, and hypotension within a few hours of receiving a transfusion. An urticarial rash occurs in about half of these patients. The onset of symptoms can occur in response to as little as 50 mL of transfused blood or blood products. Levels of C3 or C5 complement may decline within 12 to 36 hours of the onset of symptoms, further suggesting the diagnosis. The pulmonary artery wedge pressure is always normal. This is in contrast with transfusion-associated circulatory overload, which may present in a similar fashion, albeit with elevated left-sided filling pressures.

The source of the antibodies is almost always blood taken from multiparous women who have had three or more pregnancies. Approximately 7% of all multiparous women carry human leukocyte antigen antibodies in their blood.[131] It is recommended that donor blood of all multiparous women be screened for these antibodies and, if found, only the frozen or washed erythrocytes should be used.

The treatment of leukoagglutinin-mediated noncardiac pulmonary edema is supportive, including assisted ventilation if necessary and supplemental oxygen. It is unknown whether a short course of high-dose corticosteroids is beneficial, but it is certainly worth considering. The course of the noncardiac pulmonary edema is usually limited to 72 hours or less.

RADIOGRAPHIC CONTRAST MEDIUM–INDUCED LEUKOSTASIS

The symptoms and signs produced by complement-induced granulocyte aggregation associated with radiographic contrast media are frequently attributed to an allergic reaction and may cause noncardiac pulmonary edema. Anaphylaxis as a cause can be eliminated by the absence of urticaria or other rash, and by the absence of significant laryngeal edema or bronchospasm. Histologic examination of the lungs demonstrates aggregates of granulocytes obstructing microscopic pulmonary arterioles and capillaries. These findings can be overlooked if not carefully sought or if the autopsy or examination of lung tissue is not done within a few hours of the reaction.

Clinically, the onset of symptoms of dyspnea and hypoxemia begins within a few minutes to an hour of the injection of the radiographic contrast medium. There is not necessarily a history of an allergic reaction to iodine. Treatment is supportive and includes a trial of high-dose corticosteroids, although this may be ineffective.

The activation of complement and, in turn, the generation of C5a stimulates granulocytes to aggregate and to adhere to endothelium, releasing proteases and toxic

oxygen compounds. These, in turn, produce endothelial damage and capillary leakage. One study found high postmortem plasma histamine levels, which were thought to represent mast cell activation.[132]

MISCELLANEOUS DRUGS

Tocolytic-Induced Pulmonary Edema

Tocolytics are agents that have been widely used in the treatment of premature labor. The most commonly used drugs are terbutaline, albuterol, ritodrine, and other β-mimetic drugs. There are many reports of these agents inducing pulmonary edema in otherwise healthy women. The incidence varies from 0.5% to 5% of those receiving these drugs. Predisposing factors include the use of corticosteroids, twin gestation, fluid overload (particularly with saline), and anemia. The β-mimetic drugs typically stimulate β_2-adrenergic receptors, increase the maternal pulse rate and the cardiac output, and produce peripheral vasodilation. Hemodilution occurs and can be detected by a drop in the hemoglobin, hematocrit, and albumin. The blood pressure may drop as a result of the peripheral vasodilation and be a sign that too much tocolytic drug has been given.

A typical clinical scenario is as follows. In spite of the tocolytic agent, labor continues; the tocolytic agent is then stopped, and corticosteroids are added to accelerate fetal lung maturation. With the discontinuation of the tocolytic, the vasodilated vessels return to normal tone with a reduction of the intravascular volume. During delivery, further autotransfusion due to uterine contractions occurs, and pulmonary edema develops, usually in the postpartum period.

There are conflicting reports of the wedge pressure ranging from normal to elevated. In one study, patients with an elevated wedge pressure had normal left ventricular function by echocardiography. At this point, it is uncertain whether the pulmonary edema is truly cardiac or noncardiac in origin.

The treatment is oxygen and diuresis. In certain cases, consideration has been given to resuming the tocolytic agent merely to reproduce the peripheral vasodilation and allow an increase in the resumption of the intravascular volume that was present before the tocolytic agent was withdrawn. Corticosteroids aggravate the situation by their mineralocorticoid effect, which promotes fluid retention. The differential diagnosis includes aspiration of gastric contents, left-sided heart failure, amniotic fluid embolism, and overtransfusion.

Hydrochlorothiazide

There are over 40 reported cases of acute onset of diffuse pulmonary infiltrates associated with the ingestion of hydrochlorothiazide.[133] It may begin with the first dose or days later; 90% of cases occur in women who take the drug intermittently rather than daily, presumably for fluid retention. Symptoms consist of fairly rapid onset of dyspnea that clears within 48 to 72 hours of discontinuing the drug. A low-grade fever may be present. There is no eosinophilia and no positive antinuclear antibodies. The chest roentgenogram shows a diffuse bilateral alveolar-interstitial infiltrate. In the few cases studied, the pulmonary capillary wedge pressure was normal.

Methysergide, Bromocriptine, and Cabergoline

Methysergide, bromocriptine, and cabergoline are structurally similar and produce similar pleuropulmonary reactions. Methysergide is now rarely used to treat vascular headaches because there are better alternative drugs. Bromocriptine and cabergoline are used for the treatment of Parkinson's disease. The pleuropulmonary disease produced by both of these agents has an insidious onset. The predominant feature is pleural thickening and effusion, which is reversible by discontinuing the medication. Effusions are rarely large, are not commonly associated with pleuritic pain, and may show lymphocytosis.[134]

Dextran

Hyskon is a low-molecular-weight dextran that is capable of producing a noncardiac pulmonary edema.[135] It is used principally in hysteroscopic surgery, most often for improving fertility, during which the endometrial cavity is distended with approximately 500 mL of low-molecular-weight dextran. The incidence of noncardiac pulmonary edema increases significantly if more than 500 mL is used, endometrial surfaces are excessively irritated, or the procedure lasts more than 45 minutes. In addition to noncardiac pulmonary edema, coagulopathy can also occur.

Amphetaminergic Agents

In the 1960s, excess cases of pulmonary hypertension were associated with the potent anorexigen aminorex fumarate. More recently, pulmonary hypertension has been associated with dexfenfluramine, fenfluramine, and phenteramine.[136] Valvular heart disease has also been associated with these agents.[137] Although these agents have been removed from the market since 2004, a careful drug history must be taken to exclude this possibility in patients presenting with dyspnea, cardiovascular symptoms, or heart murmurs as manifestations typically persist despite discontinuation of the drugs. A recent retrospective study on 340 patients with pulmonary hypertension identified a history of stimulant use in 28.9% of them, including methamphetamine, amphetamine, and cocaine, emphasizing the importance of seeking this part of history that may not be easily volunteered by the patients.

Esophageal Variceal Sclerotherapy

Esophageal variceal sclerotherapy with either sodium morrhuate, sodium tetradecyl sulfate, or ethanolamine

oleate can lead to multiple abnormalities. Typically about 1 mL of one of these substances is injected into or around the varices, and up to 15 to 20 injections are made during a single procedure. Chest roentgenograms taken shortly after the procedure were abnormal in 85% of the cases at the Mayo Clinic, but this was rarely of clinical significance.[138] Pleural effusion occurred in about 25% of patients, mediastinal widening in 33%, atelectasis in 12%, and pulmonary infiltrates in 9%. Fever, chest pain, and difficulty in swallowing were common after the procedure but rarely amounted to a serious problem.

In the literature, pleural effusion occurred in anywhere from zero to 50% of the patients, and most of these patients were asymptomatic.[138] Effusions were more common when a large volume of fluid was injected and the volume per site was increased. Serious complications such as mediastinitis or frank esophageal rupture are rare, but should be suspected if the fever persists for more than 24 hours, the pleural effusion is large, or there is persistent chest pain. The acute respiratory distress syndrome can occur but happens in less than 1% of the patients in whom the procedure is carried out.

Tricyclic Antidepressant Overdose

Tricyclic antidepressant overdose is one of the more common causes of drug emergencies seen in the emergency room setting. About one third of the pulmonary complications that these patients develop are either noncardiac pulmonary edema or aspiration. If hypotension results, cardiac pulmonary edema can occur. Nearly 80% of the patients have an initially widened alveolar-arterial oxygen gradient. Mechanical ventilation may be required in up to three fourths of patients. The greater the drug level, the more likely the patient is to develop pulmonary complications. Nearly one half of the patients have an abnormal chest roentgenogram, and about 10% of the patients develop acute respiratory distress syndrome.

Hydantoin

There has been much confusion in the literature as to whether or not hydantoin produces parenchymal pulmonary disease and mediastinal adenopathy. Reports in the affirmative have been followed by a more detailed patient study refuting the possibility of pulmonary parenchymal disease.[139,140] The only two hydantoin-induced pulmonary diseases are drug-induced SLE and a few rare cases of hypersensitivity pneumonitis that show a predominance of lymphocytes found in the bronchoalveolar lavage fluid or biopsied tissue. The fact that hydantoin is one of the more commonly used drugs over extremely long periods of time and that it has not shown an obvious relationship for the induction of significant pulmonary disease makes it unlikely that there is a true relationship of any consequence.

Dantrolene

Dantrolene is a long-acting skeletal muscle relaxant used in treating patients with spastic neurologic disorders.[141] There have been several case reports of chronic pleural effusion or pericarditis, or both, associated with this drug. Peripheral blood eosinophilia was seen in some patients who were taking dantrolene.

Conclusion

Clinicians must maintain a high index of suspicion that unexplained pulmonary disease may be caused by medications. Most drug-induced pulmonary reactions are reversible if the drug is stopped in time. If necessary, additional measures such as judicious use of corticosteroids may be helpful. There are almost no diagnostic studies available that will confirm the presence of drug-induced lung disease. Rechallenging the patient with the suspected drug is dangerous and generally not indicated. If there is a question of whether or not a medication may be the cause of a particular pulmonary abnormality, one option is to call the medical director of the drug manufacturer, listed in the *Physicians' Desk Reference* (PDR). In addition, a useful website can be accessed at http://www.pneumotox.com.

KEY POINTS

- The frequency of drug-induced pulmonary toxicity may be underestimated, as the diagnosis is one of exclusion in the vast majority of cases.
- Most associations are based on anecdotal reports and circumstantial evidence.
- Potential mechanisms of lung injury include (1) oxidative injury, (2) direct cytotoxic effect, (3) accumulation of phospholipids, and (4) immune-mediated injury.
- Chemotherapy-induced lung toxicity should always be considered in the differential diagnosis of diffuse lung infiltrates as virtually all histopathologic presentations have been described.
- Even in situations in which cumulative toxicity is an issue, screening via serial imaging or physiologic studies is rarely helpful.

Parapneumonic Effusions and Empyema
Tuberculous Pleuritis
Actinomycosis
Nocardiosis
Fungal Infections
Viral Infections
Parasitic Diseases
Pulmonary Embolism
Abdominal Diseases
Miscellaneous Diseases

INTRODUCTION

The pleural space is bounded by two membranes, the visceral pleura covering the lung and the parietal pleura covering the chest wall and diaphragm. Into this space, normal liquid and protein enter from the systemic circulation and are removed by the parietal pleural lymphatics. Pleural pressure is subatmospheric and ensures inflation of the lung. Because the mesothelial boundaries are leaky, excess liquid can move across into this lower-pressure, high-capacitance space and collect as a pleural effusion. Thus, pleural effusions are common and of highly diverse etiologies. These effusions can form based on disease of the pleural membranes themselves or of thoracic or abdominal organs. Depending on the protein and lactate dehydrogenase (LDH) concentrations of the liquid and on the cellular composition, these effusions can be categorized initially as exudates or transudates. Exudative pleural effusions meet at least one of the following criteria, whereas transudative effusions meet none (Light's criteria): pleural fluid protein–to–serum protein ratio of more than 0.5, pleural fluid LDH–to–serum LDH ratio of more than 0.6, and pleural fluid LDH more than two thirds of the upper normal limit for serum. In this chapter, we discuss both the physiology and the pathophysiology of liquid movement in the pleural space.

THE PLEURA: FORM AND FUNCTION

These two pleural membranes meet at the hilar root of the lung. In the sheep, an animal with a pleural anatomy similar to that of humans, the surface area of the visceral pleura of one lung, including that invaginating into the lung fissures, is similar to that of the parietal pleura of one hemithorax, approximately 1000 cm^2.[1] The normal pleural space is approximately 18 to 20 μm in width, although it widens at its most dependent areas.[1] It has been shown that the pleural membranes do not touch each other and that the pleural space is a real, not a potential, space[1] (Fig. 73-1).

It is likely that the primary function of the pleural membranes is to allow extensive movement of the lung relative to the chest wall. If the lung adhered directly to the chest wall, its expansion and deflation would be more limited. Encased in its slippery coat, the lung, although still coupled mechanically to the chest wall, is able to expand across a breadth of several intercostal spaces. Nonetheless, in clinical and experimental studies, pleural symphysis has not been associated with large abnormalities in lung function.[2,3] The most common findings have been a decrease in volume of the affected lung and, in one study, of the opposite lung as well.[4] If pleural thickening accompanies pleural symphysis, abnormalities of lung function may result more from fibrothorax than from obliteration of the pleural space alone.

The visceral pleura may also provide mechanical support for the lung: contributing to the shape of the lung, providing a limit to expansion, and contributing to the work of deflation. Because the submesothelial connective tissue is continuous with the connective tissue of the lung parenchyma, the visceral pleura may help to distribute the forces produced by negative inflation pressures evenly over the lung. In this way, overdistention of alveoli at the pleural surface may be avoided, lessening the chance of rupture and pneumothorax.

One more recently recognized function of the pleural space is to provide a route by which edema can escape the lung.[5] As has been shown in several experimental studies of either hydrostatic or increased permeability lung edema,[6,7] the pleural space can function as an additional safety factor protecting against the development of alveolar edema. The formation of transudative effusions in patients with congestive heart failure (CHF) apparently reflects the movement of edema from the lung to a space where its effects on lung function are relatively small.

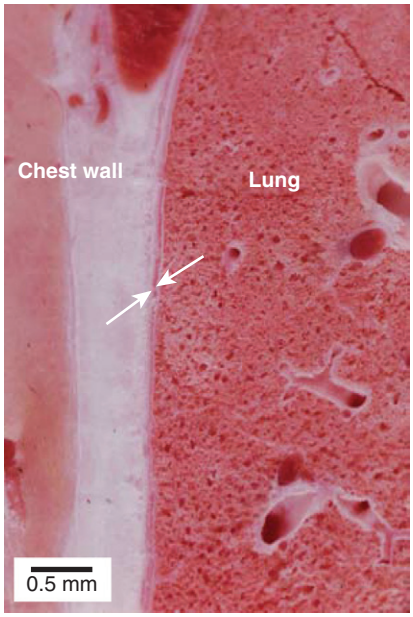

FIGURE 73-1 ■ The pleural space is depicted in a frozen sheep thorax by reflected-light microscopy. The pleural space is seen as a continuous dark band (between *arrows*) between the lung and the chest wall (labeled). (Courtesy of Kurt Albertine, PhD, University of Utah School of Medicine.)

EMBRYOLOGY AND ANATOMY

By 3 weeks of gestational age, the pleural, pericardial, and peritoneal spaces begin to form from the mesoderm and, by 9 weeks, the pleural cavity has become separated from both the pericardial and the peritoneal spaces.[8] Various cysts, diverticula, and defects can result from incomplete partitioning of the three mesodermal spaces. As the lung develops, the lung buds invaginate into the visceral pleura and, henceforth, retain a pleural covering.

The pleural membranes are smooth glistening coverings for the constantly moving lung. Overlying each pleural membrane is a single cell layer of mesothelial cells. These cells can vary in shape from flat to cuboidal or columnar, perhaps based on the degree of stretching of the underlying submesothelial tissue. These cells, the most numerous cell of the pleural space, may have a variety of functions important to pleural biology.[9] Mesothelial cells can secrete the macromolecular components of the extracellular matrix and organize them into mature matrix, phagocytose particles, produce fibrinolytic and procoagulant factors, and secrete neutrophil and monocyte chemotactic factors that may be important for inflammatory cell recruitment into the pleural spaces. The mesothelial cells also produce cytokines such as transforming growth factor-β, epidermal growth factor (EGF), and platelet-derived growth factor, cytokines that are important in pleural inflammation and fibrosis.

On their surface are microvilli, which are irregularly distributed over the pleural surfaces. Although microvilli presumably exist to increase surface area for metabolic activity, the function of these prominent features is unknown. Mesothelial cells produce hyaluronan but not mucin, express keratin microfilaments, stain negatively with epithelial-specific antibodies (Ber-EP4, B72.3, Leu. M1, and CEA), and stain positively for calretinin and mesothelin—all features that are important for histochemical and immunohistochemical identification of the cells in pleural effusions.[10,11]

The cells lie on a thin basement membrane overlying a varying region of connective tissue containing mostly collagen and elastin. Although the parietal pleural connective tissue layer is of a consistent thickness, the visceral connective tissue layer varies greatly. In a single individual, the visceral pleura varies from a thinner layer

at the cranial region to a thicker layer at the caudal region.[12] Analysis of the constituents of the visceral pleura has shown that there is more collagen relative to elastin than is found in the lung parenchyma, a finding consistent with a mechanical role for the pleura.[13] This connective tissue layer contains blood vessels and lymphatics and joins with the connective tissue of the lung.

Blood Supply

The parietal pleura is supplied by intercostal arteries[14] (Fig. 73-2A). The visceral pleura in humans, like that in sheep, is exclusively supplied by the bronchial circulation, which drains into pulmonary veins[12] (see Fig. 73-2B). The drainage route via pulmonary veins may have contributed to earlier confusion about whether the visceral pleural blood supply was from a systemic (bronchial) or a pulmonary circulation. Both pleurae in humans, therefore, have a systemic circulation, although the visceral pleural bronchial circulation may have a slightly lower perfusion pressure than the parietal pleural intercostal circulation because of its drainage into a lower-pressure venous system.

Lymphatics

If one injects carbon particles into the pleural space as a visible marker of lymphatic drainage pathways, one later finds that the black carbon has been taken up into lymphatics on the parietal side, not the visceral side (Fig. 73-3). The visceral pleura has extensive lymphatics, but they do not connect to the pleural space.[12] Demonstrated in rabbits, sheep, and now in humans, the parietal pleural lymphatics connect to the pleural space via stomata, holes of 8 to 10 μm in diameter that are formed by discontinuities in the mesothelial layer where mesothelium joins to the underlying lymphatic endothelium.[15–17] The stomata can accommodate particles as large as erythrocytes. In various experimental studies, these lymphatics have been shown to be the major route of exit of liquid from the pleural space.[18] From the stomata, liquid drains to lacunae, spider-like submesothelial collecting lymphatics, which then drain to infracostal lymphatics, to parasternal and periaortic nodes, to the thoracic duct, and into the systemic venous system. Lymphoid cells have been described lying within aggregates underneath morphologically different mesothelial cells, forming raised structures called *Kampmeier's foci* that may have an immune function, as shown for the peritoneal space.[9]

Nerve Supply

The parietal pleura contains sensory nerve fibers, supplied by the intercostal and phrenic nerves, and has long been thought to be the major site of pain sensation in the pleura. The costal and peripheral diaphragmatic regions are innervated by the intercostal nerves, and pain from these regions is referred to the adjacent chest wall. The central diaphragmatic region is innervated by

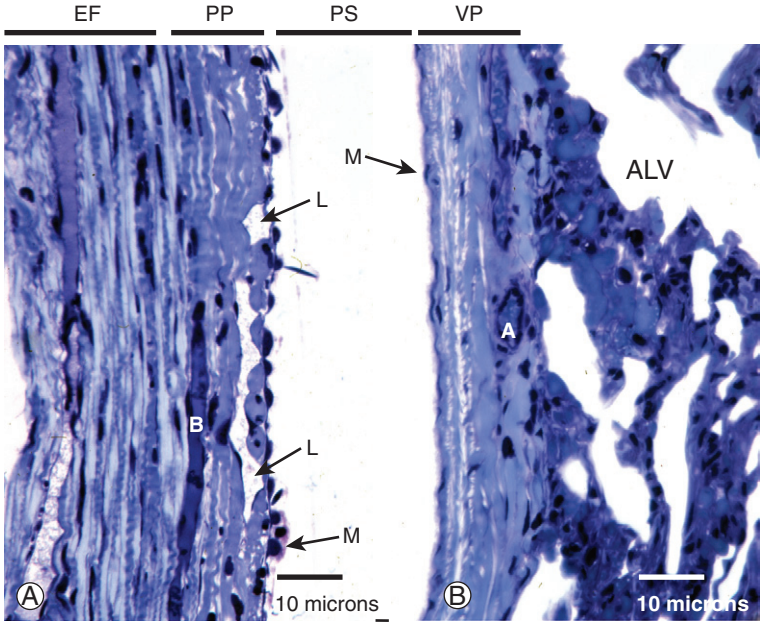

FIGURE 73-2 ■ Light micrograph shows the parietal and visceral pleurae of the sheep, an animal with a similar pleural anatomy to that of humans. Both membranes are covered by a single layer of mesothelial cells (M). The pleural membranes are shown separated by a distance similar to that for the pleural space (PS) of 18–20 microns. **A,** The parietal pleura (PP) is the layer of loose connective tissue between the PS and the dense connective tissue of the endothoracic fascia (EF). Within the loose connective tissue are blood microvessels (B) from the intercostal arteries, and lymphatic lacunae (L) that open into the pleural space via stomata. **B,** The visceral pleural (VP) lies between the pleural space (PS) and the alveoli (ALV). The blood supply to the visceral pleura is via the bronchial arteries (A), which drain into pulmonary veins. The pleura contains dense bands of elastin and collagen. FIGURE 73-4 ■ Schema shows normal pleural liquid turnover. The initial microvascular filtrate in the parietal and visceral pleura is partly reabsorbed (*dashed arrows*). The remaining low-protein interstitial liquid flows across the leaky pleural mesothelial layers into the pleural space. The pleural liquid exits the pleural space via the parietal pleural lymphatic stomata. (Redrawn from Staub NC, Wiener-Kronish JP, Albertine KH: Transport through the pleura: Physiology of normal liquid and solute exchange in the pleural space. *In* Chrétien J, Bignon J, Hirsch A [eds]: The Pleura in Health and Disease. New York: Marcel Dekker, 1985, p 182, by courtesy of Marcel Dekker.)

the phrenic nerve, and pain from this region is referred to the ipsilateral shoulder. The visceral pleura has more recently been shown to have sensory nerve fibers that may participate in pain or other sensations such as dyspnea.[19] In addition, pleural adhesions may contain pain fibers and contribute to post-thoracotomy or post-pleurodesis pain.[20]

PHYSIOLOGY OF THE PLEURAL SPACE

Normal Pleural Liquid and Protein Turnover

Since the 1980s, a consensus has developed that normal pleural liquid arises from the systemic pleural vessels in both pleurae, flows across the leaky pleural membranes into the pleural space, and exits the pleural space via the parietal pleural lymphatics[21,22] (Fig. 73-4). In this way, the pleural space is analogous to other interstitial spaces of the body. There are several lines of evidence for this view.

1. Intrapleural pressure is lower than the interstitial pressure of either of the pleural tissues. This pressure difference constitutes a gradient for liquid movement into but not out of the pleural space.
2. The pleural membranes are leaky to liquid and protein. Whether tested in vitro[23,24] or in situ,[25] the pleura offers little resistance to liquid or protein movement.
3. Mesothelial cells express various transporters and aquaporins but these have not been shown to have a role in reabsorption of effusions.[26] Although normal pleural liquid has been reported to be alkaline with higher bicarbonate than plasma, there is no evidence for active mesothelial participation in generating a bicarbonate gradient, which can more likely be explained by a passive response to protein gradients (Donnan equlibrium).[26a]
4. The entry of pleural liquid is slow and compatible with known interstitial flow rates. By noninvasive studies of the equilibration of radiolabeled albumin, the entry rate of pleural liquid is approximately 0.01 mL/kg/hr in a sheep, or about 0.5 mL/hr or

12 mL/day in an adult human.[27] The halftime of pleural liquid turnover in sheep and rabbits is 6 to 8 hours.[27,28]

5. The protein concentration of normal pleural liquid is low in sheep[27] and probably in humans, which implies sieving of the protein across a high-pressure gradient. The protein concentration of sheep pleural liquid (10 g/L) and pleural–to–plasma protein concentration ratio (0.15) are similar to those of filtrates from high-pressure systemic vessels. By comparison, a filtrate from low-pressure pulmonary vessels has a higher protein concentration (45 g/L) and ratio (lymph–to–plasma protein concentration ratio 0.69).[29]
6. The majority of liquid exits the pleural space by bulk flow, not by diffusion or active transport. This is evident because the protein concentration of pleural effusions remains constant as the effusion is absorbed, as is expected with bulk flow. If liquid were absorbed by diffusion or active transport, proteins would diffuse at a slower rate, and the protein concentration would progressively increase. In addition, erythrocytes instilled into the pleural space are absorbed intact and in almost the same proportion as the liquid and protein.[18] This indicates that the major route of exit is via holes large enough to accommodate sheep erythrocytes (6–8 μm diameter). The only possible exit is via the parietal pleural stomata (10–12 μm diameter) into the pleural lymphatics. Of note, these lymphatics have a large capacity for absorption. When artificial effusions were instilled into the pleural space of awake sheep, the exit rate (0.28 mL/kg/hr) was nearly 30 times the baseline exit rate (0.01 mL/kg/hr).[18]

Pleural Pressure

The pleural pressure in humans is approximately −5 cm H_2O at midchest at functional residual capacity and −30 cm H_2O at total lung capacity.[30] If the compliance of the lung decreased, pleural pressures at the same lung volumes would be more negative. In one study of patients undergoing thoracentesis, those with more negative pleural pressures had a smaller improvement in lung volume than those with less negative pressures, presumably reflecting the presence of underlying diseased, noncompliant lung.[31]

Although the pleural space pressure is subatmospheric, gases do not accumulate there. The sum of all partial pressures of gases in capillary blood is approximately 700 mm Hg, or 60 mm Hg below atmospheric (water pressure [PH_2O] = 47, carbon dioxide pressure [P_{CO_2}] = 46, partial pressure of nitrogen [PN_2] = 570, and oxygen pressure [P_{O_2}] = 40 mm Hg). The subatmospheric pressure of dissolved gases in capillary blood helps to maintain the pleural space free of gas and facilitates absorption of any gas that does enter the pleural space. Of note, to increase the gradient favoring absorption of gas, one can lower the P_{N_2} in the blood by having a patient breathe increased concentrations of inspired oxygen. The oxygen displaces alveolar nitrogen, thereby lowering the P_{N_2} in capillary blood; because of the limited absorption of oxygen due to the plateau of the oxygen-hemoglobin dissociation curve, the increase in inspired oxygen does not add greatly to the P_{O_2} in capillary blood.

PATHOPHYSIOLOGY OF THE PLEURAL SPACE

Pleural Effusions

For pleural liquid to accumulate to form an effusion, it is likely that *both* the entry rate of liquid must increase and the exit rate must decrease. If only the entry rate increased, it would require a sustained rate more than 30 times normal to exceed the reserve lymphatic removal capacity; if the exit rate decreased, it would take more than a month at the normal entry rate of 12 mL/day to produce an effusion detectable by chest radiograph.[22] Thus, in the clinical setting, it is most likely that excess pleural liquid accumulates due to changes in *both* entry and exit rates.

Increased entry of liquid may result from increased filtration across systemic or pulmonary capillaries or entry of another liqud (e.g., chyle, cerebrospinal fluid [CSF], urine, intravenous fluids). Decreased exit of liquid may result from interference with lymphatic function (e.g., obstruction of the parietal pleural stomata, inhibition of lymphatic contractility, infiltration of draining parasternal lymph nodes, or elevation of the systemic venous pressure into which the lymph drains).[22] There are few studies on the rate of removal of liquid in humans; however, decreases in lymphatic clearance have been confirmed in patients with tuberculous and malignant effusions[32] and in those with the yellow nail syndrome, a disease of lymphatic function.[33] In some cases, it is likely that the same disease process acts both to increase the entry and to decrease the exit of liquid, whereas, in other cases, different disease processes may act cooperatively to produce an effusion.

To determine the origin of effusions, a classic and useful distinction is between transudates and exudates (see later, "Separation of Exudates from Transudates").[34] Transudates form by leakage of liquid across an intact capillary barrier owing to increases in hydrostatic pressures or decreases in osmotic pressures across that barrier. Transudates generally indicate that the pleural membranes are not themselves diseased. Exudates form from leakage of liquid and protein across an altered capillary barrier with increased permeability. The protein ratio, the LDH ratio, and the absolute pleural LDH concentration constitute Light's criteria.

Transudates include various low-protein liquids that arise from noninjured capillary beds. The majority of transudates are caused by CHF. These transudates have been shown to form from leakage of edema across normal pulmonary capillaries into the pulmonary interstitium and then across the leaky visceral pleura into the pleural space.[6,35] Other transudates, those associated

with the nephrotic syndrome or atelectasis, may form because of altered pressures (osmotic or hydrostatic) across the pleural capillaries. Some transudates, usually small, may develop primarily because of an isolated decrease in exit rate.[36] Hepatic hydrothorax and effusions from peritoneal dialysis develop when liquid flows from the peritoneal space into the lower pressure pleural space across macroscopic holes in the diaphragm. Finally, other *very* low protein fluids such as urine or CSF or intravenous liquids may find their way to the pleural space if their normal course is disrupted.

Exudates arise from injured capillary beds, in either the lung, the pleura, or adjacent tissues. Most exudates, such as those associated with pneumonia or pulmonary embolism, probably form following lung inflammation and injury when a high-protein lung edema leaks into the pleural space. Another large category of exudates arises from pleural injury due to inflammation, infection, or malignancy. Exudates can also form when exudative liquid in the mediastinum (esophageal rupture or chylothorax), retroperitoneum (pancreatic pseudocyst), or peritoneum (ascites with spontaneous bacterial peritonitis or Meigs' syndrome) finds its way into the lower-pressure pleural space.

As stated, for either transudates or exudates, lymphatic obstruction may contribute to the accumulation of the effusion. Nonetheless, because lymphatic clearance does not alter the pleural fluid protein concentration, the protein concentration gives information about the formation of the fluid, not its removal.[22]

Effects of Pleural Effusions on Lung and Cardiac Function

In the presence of a space-occupying liquid in the pleural space, the lung recoils inward, the chest wall recoils outward, and the diaphragm is depressed inferiorly and is sometimes inverted.[37] If the lung and chest wall have normal compliances, the decrease in lung volume accounts for approximately a third of the volume of the pleural effusion, and the increase in the size of the hemithorax accounts for the remaining two thirds. As a result, lung volumes are reduced by less than the pleural effusion volume. If the lung is otherwise normal, there is no evidence that an effusion causes significant hypoxemia, presumably because ventilation and perfusion decrease similarly. In fact, in one study, hypoxemia was noted only after liquid was removed by thoracentesis,[38] when perfusion presumably was restored while ventilation remained inadequate. In another study using multiple inert gas techniques to quantify ventilation-perfusion (V/Q) distributions, pleural effusion was associated with a small intrapulmonary perfusion shunt (6.9%) that did not change significantly when measured again 30 minutes after thoracentesis of approximately 700 mL (6.1%).[39] It appears, therefore, that the effects of pleural effusion and thoracentesis on oxygenation are variable and may depend on the underlying lung function.

Large pleural effusions may impair cardiac function, most likely by decreasing the distending pressures on the cardiac chambers and cardiac filling. In a study of 27 patients with large effusions occupying more than half the hemithorax, clinical and echocardiographic findings of cardiac tamponade were identified in most patients. These findings, including elevated jugular venous pressure, pulsus paradoxus, right ventricular diastolic collapse, or flow velocity paradoxus, resolved in all patients when studied again 24 hours after thoracentesis of more than 1.0 L.[40] Large pleural effusions, especially left-sided effusions, should be considered as potentially reversible causes of cardiac dysfunction.[41]

Common symptoms of patients with effusions are pleuritic chest pain, cough, and dyspnea. It appears that the three symptoms are due to different causes. Pleuritic chest pain derives from inflammation of the parietal pleura and possibly the visceral pleura. Occasionally, this symptom is accompanied by an audible or palpable pleural rub, reflecting the movement of abnormal pleural tissues. Cough may be due to distortion of the lung, in the same way as cough follows lung collapse from a pneumothorax. Dyspnea is most likely caused by the mechanical inefficiency of the respiratory muscles that are stretched by the outward displacement of the chest wall and the downward displacement of the diaphragm.[37] After the removal of large amounts of pleural liquid, dyspnea is generally relieved promptly, although the reduction in pleural liquid volume is associated with only small increases in lung volume and little improvement, or an actual decrease, in P_{O_2}. In one study, nine patients underwent removal of over 1800 mL of pleural liquid, and despite increases in vital capacity of only 300 mL, all patients experienced immediate relief of dyspnea.[42] Although the vital capacity changed little, patients could generate a more negative pleural pressure at the same lung volume after thoracentesis than before, indicating an improved efficiency of the respiratory muscles following the return of the chest wall and diaphragm to a more normal position after thoracentesis. This improved efficiency of respiration may explain the relief of dyspnea after removal of pleural liquid.

APPROACH TO PATIENTS WITH PLEURAL EFFUSION

Physical findings of a pleural effusion include dullness to percussion, decreased breath sounds, egophony at the upper level of the effusion, and decreased tactile fremitus. With large effusions, signs can include asymmetrical chest expansion or even bulging of the intercostal spaces. A systematic review concluded that the most useful physical findings were dullness to percussion and decreased tactile fremitus.[43]

The possibility of a pleural effusion should be considered in any patient with an abnormal chest radiograph. Increased densities on the chest radiograph are frequently attributed to parenchymal infiltrates when they actually represent pleural fluid. Free pleural fluid gravitates to the most dependent part of the thoracic cavity, which is the posterior costophrenic sulcus when the patient is upright. Therefore, if the posterior costo-

TABLE 73-1. Differential Diagnoses of Pleural Effusions

TRANSUDATIVE PLEURAL EFFUSIONS
- Congestive heart failure
- Pericardial disease
- Hepatic hydrothorax
- Nephrotic syndrome
- Peritoneal dialysis
- Urinothorax
- Myxedema
- Fontan procedure
- Central venous occlusion
- Subarachnoid-pleural fistula
- Veno-occlusive disease
- Bone marrow transplantation
- Iatrogenic

EXUDATIVE PLEURAL EFFUSIONS
- Neoplastic diseases
  - Metastatic disease
  - Mesothelioma
  - Primary effusion lymphoma
  - Pyothorax-associated lymphoma
- Infectious diseases
  - Pyogenic bacterial infections
  - Tuberculosis
  - Actinomycosis and nocardiosis
  - Fungal infections
  - Viral infections
  - Parasitic infections
- Pulmonary embolism
- Gastrointestinal disease
  - Esophageal perforation
  - Pancreatic disease
  - Intra-abdominal abscesses
  - Diaphragmatic hernia
  - Postabdominal surgery
- Collagen vascular diseases
  - Rheumatoid pleuritis
  - Systemic lupus erythematosus
  - Drug-induced lupus
  - Immunoblastic lymphadenopathy
  - Sjögren's syndrome
  - Churg-Strauss syndrome
  - Wegener's granulomatosis
- Postcardiac injury syndrome
- Post–coronary artery bypass surgery
- Asbestos exposure
- Sarcoidosis
- Uremia
- Meigs' syndrome
- Ovarian hyperstimulation syndrome
- Yellow nail syndrome
- Drug-induced pleural disease

- Iatrogenic injury
- Hemothorax
- Chylothorax

phrenic angle is blunted or if the posterior part of the diaphragm is not visible on the lateral chest radiograph, bilateral decubitus chest radiographs or an ultrasonic examination of the pleural space should be obtained to ascertain whether free pleural fluid is present. If the distance between the inside of the thoracic cavity and the outside of the lung is less than 10 mm, the pleural effusion is not likely to be clinically significant and, in any case, will be difficult to obtain by thoracentesis. If the distance is greater than 10 mm, an effort should be made to determine the cause of the pleural effusion.

Differential Diagnosis of Pleural Effusion

Many different diseases may have an accompanying pleural effusion (Table 73-1). The vigor with which various diagnoses are pursued should depend on the likelihood that the person has that particular disease. Table 73-2 shows rough estimates of the annual incidence of the most common causes of pleural effusions. CHF and cirrhosis are responsible for almost all transudative pleural effusions. Pneumonia, malignant pleural disease, pulmonary embolism, and gastrointestinal disease account for at least 90% of all exudative pleural effusions.

Separation of Exudates from Transudates

A diagnostic thoracentesis should be performed on nearly every patient with free pleural fluid that measures more than 10 mm on the decubitus radiograph. If the patient has obvious CHF, consideration can be given to postponing the thoracentesis until the heart failure is treated. However, if the patient is febrile or has pleuritic chest pain or if the effusions are not of comparable size on both sides, a thoracentesis should be performed without delay.

TABLE 73-2. Approximate Annual Incidence of Various Types of Pleural Effusions in the United States

Type of Effusion	Incidence
Congestive heart failure	500,000
Pneumonia (bacterial)	300,000
Malignant disease	200,000
Lung	60,000
Breast	50,000
Lymphoma	40,000
Other	50,000
Pulmonary embolization	150,000
Viral disease	100,000
Post–coronary artery bypass surgery	60,000
Cirrhosis with ascites	50,000
Gastrointestinal disease	25,000
Collagen vascular disease	6,000
Tuberculosis	2,500
Asbestos exposure	2,000
Mesothelioma	1,500

Adapted with permission from Light RW: Pleural Diseases (5th ed). Philadelphia: Lippincott Williams & Wilkins, 2007.

Thoracentesis is a safe procedure when performed by an experienced operator. Because of the small-bore needle required, it can be safely performed in patients with coagulopathies and thrombocytopenia and in patients on positive mechanical ventilation.[44] Descriptions of technique emphasize proper positioning of the patient, identification of the area of decreased tactile fremitus that is a sensitive physical finding for the level of the effusion, and adequate local anesthesia of parietal pleura as well as of the skin. The needle should run over the top of the rib to avoid the neurovascular bundle that travels in each intercostal space. Of note, this bundle travels in the middle of the intercostal space from the spine for approximately 5 to 6 inches (13 cm) before taking its safer position beneath the upper rib.[44] Thus, one should avoid thoracentesis medial to the midclavicular line.

Complications from thoracentesis include pneumothorax and hemothorax. Estimates of each complication from prospective studies are low (2%–6% for pneumothorax; 1% for hemothorax), with only half of the pneumothoraces requiring chest thoracostomy.[45] Pneumothorax is often associated with procedural events such as aspiration of air, multiple needle passes, and development of new symptoms. The risk for pneumothorax appears to be higher in patients with prior radiotherapy to the chest, multiple prior thoracenteses, or the use of vacuum bottles. In an uncomplicated thoracentesis that is well tolerated by the patient, there appears to be no value for routine chest radiography. In addition, routine post-thoracentesis radiographs rarely show new findings.[45] Thoracentesis may be safer when guided by ultrasound, although given the safety of the procedure in uncomplicated cases and the cost or inaccessibility of ultrasound, ultrasound can be selected for higher-risk procedures. For example, it would be appropriate to use ultrasound guidance for thoracentesis on small or multiloculated effusions or in patients with poor lung function or bullous lung disease.[44]

The first question that should be answered with the diagnostic thoracentesis is whether the patient has a transudative or an exudative pleural effusion (see "Pleural Effusions," earlier). The identification of transudates or exudates is made by analysis of the levels of protein and LDH in the pleural fluid and the serum. Exudative pleural effusions meet at least one of the following criteria, whereas transudative pleural effusions meet none[34]: (1) pleural fluid protein–to–serum protein greater than 0.50; (2) pleural fluid LDH–to–serum LDH greater than 0.60; and (3) pleural fluid LDH greater than two thirds of the upper normal limit for serum. If none of these criteria is met, the patient has a transudative pleural effusion, and the pleural surfaces can be ignored while the CHF, cirrhosis, or nephrosis is treated. In the rare cases in which malignancy has been associated with a transudate, extrapleural effects of the tumor or other causes such as concurrent CHF are the most likely cause as evidenced by the rarity of a positive cytology in those effusions.[22,46]

The previously discussed criteria may misidentify a transudative effusion as an exudative effusion in as many as 25% of cases. If a patient appears to have a transudative effusion clinically, additional tests can be assessed to verify its transudative etiology. If the difference between the protein concentration of serum and the pleura exceeds 3.1 gm/dL, the patient in all probability has a transudative effusion.[47] If pleural concentrations of N-terminal brain natriuretic peptide (NT-BNP) are elevated (>1300 pg/mL), the patient likely has a transudate from a cardiac cause.[48]

Most studies dichotomize pleural effusions into transudates or exudates based on a single cutoff point. An alternative approach recommended by Heffner and coworkers[49] is to use likelihood ratios for identifying whether a pleural fluid is a transudate or an exudate. The idea behind this approach is that the higher a value (e.g., the pleural fluid LDH), the more likely the effusion is to be an exudate, and the lower the value, the less likely the effusion is to be an exudate. When these likelihood ratios are used in conjunction with pretest probabilities using Bayes theorem, posttest probabilities can be derived. The difficulty in using this approach is that estimates of pretest probabilities vary significantly from physician to physician. Moreover, most physicians do not understand the mathematics involved. Nonetheless, this approach does emphasize that it is important to take into consideration the absolute value of the measurements. Very high or very low measurements are almost always indicative of exudates and transudates, respectively, whereas values near the cutoff levels can be associated with either transudates or exudates and can be considered *indeterminate*.

When dealing with a patient who has a high likelihood of having a transudative pleural effusion, the most cost-effective use of the laboratory is to order only protein and LDH levels on the pleural fluid and obtain other laboratory tests only if the fluid turns out to be an exudate. In one study of 320 pleural fluid specimens submitted for analysis, 83 were found to be transudative.[50] For these 83 effusions, 725 additional laboratory tests had been ordered, increasing both the cost and the incidence of false-positive tests (7/9). If one suspects initially that the patient has an exudate or if the fluid turns out to be an exudate, specimens can then be sent for cytology, glucose, cell count and differential, and cultures.

Differentiating Exudative Pleural Effusions

Once it has been determined that the patient has an exudative pleural effusion, one should attempt to determine which of the diseases listed in Table 73-1 is responsible for the effusion, remembering that pneumonia, malignancy, and pulmonary embolism account for the great majority of all exudative pleural effusions. In all patients with undiagnosed exudative pleural effusions, the appearance of the fluid should be noted, and the pleural fluid protein and LDH levels (if not already measured), glucose level, differential cell count, and microbiologic and cytologic studies should be obtained.[51] In selected patients, other tests on the pleural fluid, such as pH, amylase level, antinuclear antibody (ANA)

level, rheumatoid factor level, adenosine deaminase (ADA), lipid analysis, and so forth, may be of value. It is certainly not cost-effective, however, to obtain all these tests routinely on patients with undiagnosed exudative pleural effusions.

Appearance of Pleural Fluid

The gross appearance of the pleural fluid should always be described and its odor noted. If the pleural fluid smells putrid, the patient has a bacterial infection (probably anaerobic) of the pleural space. If the fluid smells like urine, the patient probably has a urinothorax. If the pleural fluid is bloody, a pleural fluid hematocrit should be obtained. If the pleural fluid hematocrit is greater than 50% that of the peripheral blood, the patient has a hemothorax and the physician should strongly consider inserting chest tubes. If the pleural fluid hematocrit is less than 1%, the blood in the pleural fluid has no clinical significance. If the pleural fluid hematocrit is between 1% and 50%, the patient most likely has malignant pleural disease, a pulmonary embolus, or a traumatically induced pleural effusion.[52]

The supernatant of the pleural fluid should be examined if the pleural fluid is turbid, milky, or bloody. If the pleural fluid is turbid when originally obtained, but the turbidity clears with centrifugation, the turbidity is due to cells or debris in the pleural fluid. If the turbidity persists after centrifugation, the patient probably has a chylothorax or a pseudochylothorax. These two entities can be differentiated by the patient's history, examination of the sediment for cholesterol crystals, and lipid analysis of the supernatant. With chylothorax, the disease process is acute, the pleural surfaces are not thickened, there are no cholesterol crystals present, and the pleural fluid triglyceride level is usually above 110 mg/dL (1.24 mmol/L). With pseudochylothorax, the disease process is usually chronic, the pleural surfaces are usually thickened, there may be cholesterol crystals, and the pleural fluid triglyceride level is usually not elevated. (For further discussion of chylothorax and pseudochylothorax, see Chapter 74.)

Pleural Fluid Protein

The pleural fluid protein level tends to be elevated to a comparable degree with all exudative pleural effusions and is, therefore, not generally useful in the differential diagnosis of an exudative pleural effusion. However, if the protein level is above 5.0 g/dL, the likelihood of the diagnosis of tuberculous pleurisy is increased. If the pleural fluid protein level is *very* low (<0.5 g/dL), the patient probably has a urinothorax, an effusion secondary to peritoneal dialysis, a leak of CSF into the pleural space, or an effusion secondary to the misplacement of a central intravascular line.

Pleural Fluid Lactate Dehydrogenase

Whereas pleural liquid protein and LDH arise from filtration from serum and thus serve as indicators of vascular permeability, LDH, as an intracellular enzyme, may also indicate the degree of cell turnover and/or the degree of inflammation within the pleural space. The pleural fluid LDH level is increased to a comparable degree in patients with all categories of exudative pleural effusions and, therefore, is of no utility in the differential diagnosis of exudative pleural effusion.[34] Likewise, the pleural fluid LDH isoenzymes are of limited use in the differential diagnosis of exudative pleural effusions. However, pleural fluid LDH concentration should be measured every time a diagnostic thoracentesis is performed because the level of LDH in the pleural fluid reflects the degree of inflammation in the pleural space. If the pleural fluid LDH concentration increases with serial thoracentesis, the degree of inflammation in the pleural space is worsening and the physician should be more aggressive in pursuing the diagnosis. Alternatively, if the pleural fluid LDH level decreases with serial thoracentesis, the pleural disease is resolving and observation of the patient is indicated.[53]

Pleural Fluid Glucose

A low glucose concentration probably indicates the coexistence of two abnormalities: a thickened, infiltrated pleura leading to an impaired diffusion of glucose into the pleural space plus increased metabolic activity leading to increased glucose utilization within the pleural space. The glucose level should be measured in all undiagnosed exudative pleural effusions because the demonstration of a reduced pleural fluid glucose level (<60 mg/dL, 3.33 mmol/L) narrows the diagnostic possibilities to seven: parapneumonic effusion, malignant effusion, tuberculous effusion, rheumatoid effusion, hemothorax, paragonimiasis, or the Churg-Strauss syndrome.[53] If a patient with a parapneumonic effusion has a pleural fluid glucose level below 40 mg/dL (2.22 mmol/L), tube thoracostomy should be considered. Many patients with rheumatoid pleural effusions have a pleural fluid glucose level below 30 mg/dL (1.66 mmol/L).[54] In contrast, most patients with pleural effusion secondary to systemic lupus erythematosus (SLE) will have a pleural fluid glucose level above 80 mg/dL (4.44 mmol/L).[55] Patients with malignant pleural disease and a low pleural fluid glucose level usually have a positive pleural fluid cytology.[56]

Pleural Fluid White Cell Count and Differential

Pleural liquid that is submitted for white cell count and differential should be sent in a tube with an anticoagulant to prevent the cells from clumping.[57] In the normal pleural space, the cell count has been reported to be 1700 cells/mm^3.[58] In effusions, the cell count has limited diagnostic value. A pleural fluid white blood cell count of 1000/mm^3 roughly separates transudative from exudative pleural effusion, whereas a pleural fluid white blood cell count above 10,000/mm^3 is most common with empyemas and parapneumonic effusions, but is also seen with pancreatitis, pulmonary embolism, collagen

vascular diseases, and occasionally, with malignancy and tuberculosis.[52]

The differential cell count on the pleural fluid is much more useful than the white cell count itself. The normal pleural space contains predominantly macrophages (75%) followed by lymphocytes (23%).[58] A change in differential from this normal distribution provides a clue to the underlying disease process. For the pleural fluid differential cell count, the cells should be partitioned into the following categories: polymorphonuclear leukocytes, eosinophils, small lymphocytes, mesothelial cells, and other mononuclear cells. Pleural effusions due to an acute disease process such as pneumonia, pulmonary embolization, pancreatitis, intra-abdominal abscess, or early tuberculosis contain predominantly polymorphonuclear leukocytes. Pleural effusions due to a chronic disease process contain predominantly mononuclear cells.

Pleural fluid eosinophilia (≥10% eosinophils by differential count) is most commonly due to air or blood in the pleural space. Interleukin-5 (IL-5) appears to be an important factor because the number and percentage of eosinophils in the pleural space are closely correlated with the pleural liquid IL-5 levels.[59] Occasionally, no pleural fluid eosinophils are found in the initial thoracentesis, but many eosinophils are seen in a subsequent thoracentesis most likely due to entry of air or blood caused by the initial thoracentesis.[60] With traumatic hemothorax, pleural fluid eosinophilia does not occur until the second week. The eosinophilia appears to be due to production of IL-5 by $CD4^+$ T cells within the pleural space.[61] At times, the pleural fluid eosinophilia associated with a hemothorax can lead to eosinophilia in the peripheral blood.[62] The bloody pleural effusion complicating pulmonary embolism frequently contains many eosinophils.[63] With pneumothorax, pleural eosinophilia appears within 3 days of the pneumothorax and reaches a peak after 6 days.[64]

After excluding air or blood as the underlying cause, the etiologies of 392 cases of eosinophilic pleural effusions have been reported as follows: idiopathic 40%, malignancy 17%, parapneumonic 13%, tuberculosis 6%, pulmonary embolism 4%, transudates 8%, and other 13%.[65] If the etiology of the eosinophilia is not evident, several unusual diagnoses should be considered. Benign asbestos pleural effusions are frequently eosinophilic. In one series, 15 of 29 patients (52%) with benign asbestos pleural effusions had pleural fluid eosinophilia.[60] Patients with pleural effusions secondary to drug reactions (nitrofurantoin or dantrolene) typically have pleural fluid eosinophilia.[53] The pleural fluid of patients with pleural paragonimiasis is typically eosinophilic with low glucose, low pH, and high LDH level.[66] The Churg-Strauss syndrome is the only other disease that produces this constellation of pleural fluid findings.[67]

Mesothelial cells line the pleural cavities. It is unusual to find mesothelial cells in effusions due to tuberculosis. However, the absence of mesothelial cells is also common with other conditions in which the pleura becomes coated with fibrin, such as a complicated parapneumonic effusion.

Small lymphocytes, when accounting for more than 50% of the white blood cells in an exudative pleural effusion, indicate that the patient probably has a malignant or a tuberculous pleural effusion. Ninety of 96 exudative pleural effusions (94%) in two series with more than 50% small lymphocytes were due to tuberculosis or malignant disease.[52,68] Because these two diseases can be diagnosed with needle biopsy of the pleura, the presence of pleural fluid lymphocytosis should alert the physician to consider needle biopsy of the pleura for diagnosis. In general, separation of pleural lymphocytes into T and B lymphocytes has not been useful diagnostically, because most lymphocytic effusions contain a predominance of T cells ($CD4^+$) whether the diagnosis is malignancy or tuberculosis.[69] Such partitioning can be useful diagnostically, however, when a diagnosis of chronic lymphocytic leukemia or lymphoma is suspected. With these diseases, the pleural lymphocytes are usually of B-cell origin.[70]

Pleural Fluid Cytology

A pleural fluid specimen from every patient with an undiagnosed exudative pleural effusion should be sent for cytopathologic studies. The first pleural fluid cytologic study is positive for malignant cells in up to 60% of the effusions caused by pleural malignancy.[52] If three separate specimens are submitted, up to 90% of effusions due to pleural malignancy have positive cytopathology. The percentage of cases in which cytologic study of the pleural fluid establishes the diagnosis of a malignant pleural effusion ranges from 40% to 87%.[52,71,72] The frequency of positive pleural fluid cytologic tests is dependent on the tumor type. For example, less than 25% of patients with Hodgkin's disease have positive cytology,[73] whereas most patients with adenocarcinomas have positive cytology.[72] The percentage of positive diagnoses is higher if both cell blocks and smears are prepared by standard protocols and examined by an experienced cytologist.[74] Each additional sample may increase diagnostic yield in part by providing a higher percentage of fresher cells as older degenerated cells are largely removed by the earlier thoracenteses. During thoracoscopy, pleural lavage has been found to increase the diagnostic yield, perhaps by harvesting more fresh cells for analysis.[75] The percentage of positive diagnoses is obviously dependent on the skill of the cytologist. Immunohistochemical stains of malignant cells are used to confirm a diagnosis and to specify tumor type, with many new markers recently available.[11,74]

Other Diagnostic Tests for Malignancy

Cytology may be nondiagnostic either because of a problem of specificity (e.g., the malignant cells cannot be differentiated from reactive mesothelial cells and "atypical" benign cells) or because of a problem of sensitivity (e.g., the malignant cells are rare). Several assays are being evaluated for their ability to increase the specificity of cytology for diagnosis of malignancy.[76] Fluorescent in situ hybridization (FISH) with chromosome-

specific probes can confirm abnormal numbers of specific chromosomes (aneuploidy), thereby confirming that abnormal cells are indeed malignant.[77] Early findings of malignancy including DNA methylation can be detected by methylation-specific polymerase chain reaction (PCR),[78] and gene expression patterns can help distinguish mesothelioma and adenocarcinoma.[79] EGF-receptor mutations can predict response to EGF-receptor tyrosine kinase inhibitors. Conversely, biomarkers have generally been disappointing due to nonspecificity. However, serum or pleural fluid mesothelin measurements hold promise for the diagnosis of mesothelioma[80] (see Chapter 75).

Culture and Bacteriologic Stains

Pleural fluid from patients with undiagnosed exudative pleural effusions should be cultured for bacteria (both aerobically and anerobically), mycobacteria, and fungi. Gram's stain should also be obtained. In the case of a probable complicated parapneumonic effusion with an initial negative Gram's stain, the sediment of the pleural fluid should be stained because the bacteria will be precipitated in the sediment along with the white blood cells and the debris.

One potentially useful adjunct is detection of bacterial antigens by countercurrent immunoelectrophoresis (CIE)[81] or latex agglutination[82] or of bacterial DNA by PCR.[83] The antigen-specific assays may be especially useful in children, whose common pathogens, *Staphylococcus aureus*, *Streptococcus pneumoniae*,[83a] and *Hemophilus influenzae*, have antigens available for identification. Amplification and sequencing of bacterial 16S ribosomal RNA has identified bacteria in pleural empyema, showing in one study that the bacteriology of pleural infections differed from that of pneumonia (see later, "Parapneumonic Effusions and Empyema").[84]

Other Diagnostic Tests for Pleural Fluid

Pleural Fluid pH and P_{CO_2}

The pleural fluid pH can be reduced to less than 7.20 with 10 different conditions: (1) complicated parapneumonic effusion, (2) esophageal rupture, (3) rheumatoid pleuritis, (4) tuberculous pleuritis, (5) malignant pleural disease, (6) hemothorax, (7) systemic acidosis, (8) paragonimiasis, (9) lupus pleuritis, or (10) urinothorax.[53] The decreased pleural fluid pH appears to result from lactic acid and carbon dioxide accumulation in the pleural fluid.[85] The pleural fluid pH is most useful in determining whether chest tubes should be inserted in patients with parapneumonic effusions.[86] A fall in the pleural fluid pH appears to be a sensitive indicator that the patient has a highly inflammatory parapneumonic pleural effusion that will require drainage.

The routine measurement of pleural fluid pH is recommended only in patients with parapneumonic effusions. In general, pleural fluids with a low pH also have a low glucose[85]; thus, pleural fluid glucose can be used as an alternative to the pH measurement. When the pleural fluid pH is used as a diagnostic test, it must be measured with the same care as arterial pH. The fluid should be collected anaerobically in a heparinized syringe and placed on ice. If the sample is left open to air, a spuriously high pH value can be obtained because of the rapid loss of carbon dioxide. The pH must be measured with a blood gas machine; a pH meter or indicator paper is not sufficiently accurate.[87] Pleural fluid pH, but not glucose, may be significantly altered by residual air or lidocaine in the syringe.[88] The pleural fluid glucose may be a preferable test when the accuracy of pH measurements cannot be assured.

Pleural Fluid Amylase

The pleural fluid amylase is elevated in patients with pleural effusions secondary to esophageal perforation, pancreatic disease, or malignant disease. However, because such a small percentage of effusions are due to esophageal perforation or pancreatic disease, the routine measurement of pleural fluid amylase is not indicated.[89] In the case of esophageal rupture, the origin of the amylase is the salivary glands.[90] In animal models of esophageal rupture, the pleural fluid amylase concentration is elevated within 2 hours of esophageal rupture.[91] In effusions due to pancreaticopleural fistulas, the amylase concentration is extremely high (>4000 IU/mL), reflective of the concentrations in pancreatic secretions.[92] In approximately 10% of malignant effusions, the pleural fluid amylase level is mildly elevated. The site of the primary tumor in such patients is usually not the pancreas.[93] Malignancy can be differentiated from pancreatic disease with amylase isoenzymes because the amylase with malignant effusions is primarily of the salivary type.[94]

Tests for Collagen Vascular Diseases

About 5% of patients with rheumatoid arthritis[95] and 50% of patients with SLE[96] have a pleural effusion sometime during the course of their disease. At times, the effusions may be the first manifestation of the disease; therefore, these diagnostic possibilities should be considered in patients with undiagnosed exudative pleural effusion.

Measurement of the ANA titer is the best screening test for lupus pleuritis, although it is now evident that a positive pleural fluid ANA is not specific for the diagnosis. Although all patients with lupus pleuritis have a positive pleural liquid ANA (>1:40), the finding of a positive ANA has been found in between 11% and 27% of other effusions.[97] Neither the titer of ANA, the ratio of pleura-to-plasma ANA, or the pattern of staining has been found to increase the specificity for SLE.[98] In fact, a positive pleural fluid ANA in patients without SLE may be associated with malignancy.[98] In patients with SLE, the lack of ANA in pleural liquid may have a high negative predictive value; in one study of patients with SLE and a pleural effusion of uncertain etiology, a lack of ANA (dsDNA, extractable nuclear antigens [ENA]) in the pleural fluid argued against the diagnosis of lupus pleuritis.[99]

When a rheumatoid pleural effusion is suspected, the clinical picture usually establishes the diagnosis. If any question exists, the level of rheumatoid factor in the pleural fluid should be measured. Only patients with rheumatoid pleuritis have a pleural fluid rheumatoid factor titer equal to or greater than 1:320 and equal to or greater than the serum titer.[100]

Adenosine Deaminase

ADA, a product of activated lymphocytes, catalyzes the conversion of adenosine to inosine and is important for normal immune function. The pleural fluid ADA levels are elevated in almost all patients with tuberculous pleuritis, but not with other conditions even when associated with lymphocytic effusions.[101] Despite earlier concerns about false-negative values in human immunodeficiency virus (HIV)–positive patients, ADA remains a sensitive marker for tuberculous pleurisy in patients with HIV.[102] An occasional patient with empyema, lymphoma, or leukemia may have elevated pleural fluid ADA levels; however, these entities should be relatively easy to differentiate from tuberculosis clinically. Because it is a highly sensitive test, the ADA can be a useful test to exclude the diagnosis of tuberculosis when the ADA level is low (<40 U/L).[103]

Interferon-γ

Interferon-γ (IFN-γ), a T-cell lymphokine, plays a critical role in the effective clinical response to *Mycobacterium tuberculosis*. Pleural liquid IFN-γ is elevated almost exclusively in tuberculous effusions.[104] IFN-γ release assays, however, have had variable results and have not added to the use of ADA or IFN-γ measurements for the diagnosis or exclusion of active pleural tuberculosis.[105]

Molecular Techniques for Diagnosis of Mycobacterium tuberculosis

Four molecular techniques are now available: PCR to detect specific mycobaterial DNA sequences in clinical specimens (pleural liquid or biopsy), nucleic acid probes to identify the organism in culture, restriction fragment length polymorphism to compare strains in epidemiologic studies, and gene-based susceptibility studies to screen for known genes associated with drug resistance.[106]

In theory, PCR tests have a great potential for providing a rapid, highly sensitive and specific diagnosis of mycobacterial infection. In practice, PCR amplification of clinical samples has been limited by a low sensitivity, often little better than culture itself.[107,107a] The decreased sensitivity may be due to degradation of the target DNA by sample processing or by inhibitors of amplification in clinical fluids. Before wide application of PCR assays, considerations will also include its cost and its current inability to identify antibiotic resistance of the organism. In the future, molecular techniques for diagnosis of tuberculosis and for other slow-growing microorganisms will likely prove increasingly important.

Useful Radiographic Tests in Patients with Suspected Pleural Disease

The possibility of a pleural effusion should be considered whenever a patient with an abnormal chest radiograph is evaluated. Two main factors influence the distribution of free fluid in the pleural space. First, the fluid collects in the most dependent part of the thoracic cavity because the lung is less dense than the pleural fluid. Second, because of their elastic recoil, the lobes of the lung, if normal, maintain their traditional shape at all stages of collapse.

When the patient is upright, the fluid first accumulates between the inferior surface of the lower lobe and the diaphragm. If there is less than 75 mL of fluid, it may occupy this position only, without overflowing into the costophrenic sinuses. When more fluid accumulates, it spills over into the posterior costophrenic angle and obliterates the posterior part of the diaphragm on the lateral projection. The possibility of a pleural effusion should be suspected whenever the posterior part of one or both diaphragms is obscured. The presence of a clinically significant amount of free pleural fluid can be excluded if both posterior costophrenic angles are clear.

When there are larger amounts of pleural fluid, the lateral costophrenic angle on the posteroanterior radiograph becomes blunted. Collins and associates[108] demonstrated that at least 175 mL of pleural fluid had to be injected into the pleural space of cadavers before the lateral costophrenic angle was blunted. In some of their cases, more than 500 mL of pleural fluid could be present without blunting the lateral costophrenic angle. As more fluid accumulates, the entire outline of the diaphragm on the affected side is lost, and the fluid extends upward around the anterior, lateral, and posterior thoracic walls, producing opacification of the lung base and the typical meniscus shape of the fluid.

The changes just discussed are suggestive rather than diagnostic of the presence of pleural fluid. Lateral decubitus radiographs or ultrasonic examination should be obtained in most instances when free pleural fluid is suspected. If the entire hemithorax is opacified, decubitus radiographs are of no use because there is no air-containing lung in the hemithorax. The basis for the use of the lateral decubitus view is that free fluid gravitates to the most dependent part of the pleural space. When a patient is placed in the lateral recumbent position, the free pleural fluid on the dependent side accumulates between the chest wall and the lung (Fig. 73-5). As little as 5 mL of pleural fluid can be demonstrated with properly exposed decubitus radiographs.[109] The amount of pleural fluid can be semiquantitated by measuring the distance between the inner border of the chest wall and the outer border of the lung (see Fig. 73-5). As already stated, when this distance is less than 10 mm, the amount of pleural fluid is small, and a diagnostic thoracentesis is usually not attempted.

Pleural fluid may become encapsulated by adhesions anywhere between the parietal and the visceral pleurae

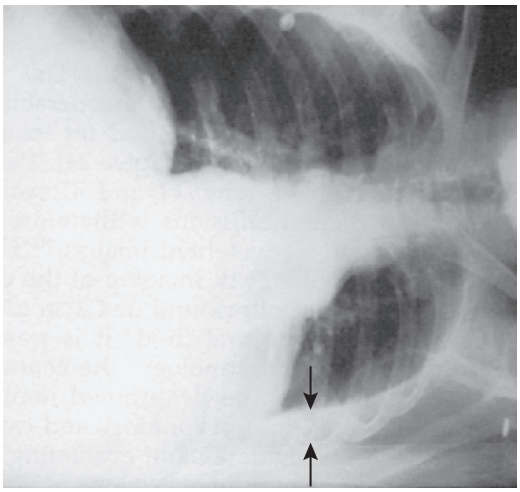

FIGURE 73-5 ■ Left lateral decubitus chest radiograph demonstrates the presence of free pleural fluid. The amount of pleural fluid can be semiquantified by measuring the distance between the two *arrows*.

or in the interlobar fissures. Such loculation occurs most frequently in association with conditions that cause intense pleural inflammation, such as complicated parapneumonic effusion or tuberculous pleuritis. When the loculation is situated between the lung and the chest wall, there is a characteristic radiographic picture. The loculation is D-shaped with the base of the D against the chest wall and the smooth convexity protruding inward toward the lung. The absence of air bronchograms helps differentiate a loculated pleural effusion from a parenchymal infiltrate. A definite diagnosis of loculated pleural effusion is best established by ultrasonography or computed tomography (CT).

Ultrasound

One way to document and locate loculated pleural fluid is with ultrasound. In the presence of pleural fluid, the proximal echoes from the skin, intercostal muscles, and parietal pleura are separated from the distal echoes arising from the visceral pleura and the lung by a central echo-free space. The advantages of ultrasound over CT are the ease and speed with which the examination can be performed, the lack of ionizing radiation, the relatively low cost, and the ability to provide continuous guidance for thoracentesis or pleural biopsy.[110]

The appropriate site for a thoracentesis can be identified using ultrasound, although its routine use is probably not cost-effective.[44] If a patient has a moderate or large effusion, ultrasound is indicated only if no fluid is obtained after two or three attempts. When ultrasound is used to identify the site for thoracentesis, it is important to perform the thoracentesis at the time of the ultrasonic examination. If the skin is marked and the patient returned to her or his room, thoracentesis is frequently unsuccessful, because the relationship between the skin and the pleural fluid may have changed. In addition, when the thoracentesis is performed at the time of the ultrasonic examination, there is immediate feedback that is valuable in improving the skill of the ultrasonographer (see Chapter 20).

Computed Tomography

CT is currently the best way to visualize the pleural space.[110] CT of the chest has its greatest utility in distinguishing parenchymal and pleural abnormalities. With current protocols involving the rapid injection of intravenous contrast medium, the unaerated perfused lung parenchyma will enhance, whereas the pleural abnormality will not.[111]

Chest CT is quite useful in distinguishing a parenchymal lung abscess located near the chest wall from an empyema with an air-fluid level. The most distinctive features are the margins of the abnormality. With empyema, the cavity walls are of uniform thickness both internally and externally and the adjacent lung is usually compressed. The angle of contact with the chest wall may be obtuse. In addition, most empyemas have a lenticular shape and demonstrate the "split-pleura" sign (Fig. 73-6A).[112] With lung abscess, the walls of the cavity are not of uniform thickness and the adjacent lung is not compressed. The angle of contact with the chest wall may be acute (see Fig. 73-6B).

In diffuse pleural disease, chest CT is useful in distinguishing malignant from benign causes. Features associated with malignancy include circumferential pleural thickening, pleural nodules, parietal thickening greater than 1 cm, and mediastinal pleural involvement.[113] The distinction of metastatic disease from mesothelioma can be difficult, although hilar adenopathy is more common with metastatic disease.[110]

CT angiography has become a first-line imaging test for the evaluation of pulmonary embolism[114] (see Chapter 51). The evaluation of a patient with a pleural effusion for pulmonary embolism can begin with a Doppler ultrasound of the lower extremities. If the ultrasound identifies thrombus, the patient can then be treated for thromboembolic disease. If it is negative, the patient may still have a pulmonary embolism. The standard approach had been to proceed to lung V/Q scanning. However, the interpretation of the perfusion lung scan is difficult in patients with pleural fluid because of shifting of the fluid when the patient moves from the supine position for the perfusion scan to the upright position for the ventilation scan. CT angiography instead is highly sensitive and specific for pulmonary emboli in the proximal, segmental pulmonary arteries.[114] In contrast to V/Q lung scanning, CT angiography can establish alternate diagnoses as well. Where CT angiography is not available, lung scanning can be used, perhaps after efforts to improve accuracy by withdrawing as much pleural liquid as possible. A diagnostic scan (normal or high probability) can then be used to either exclude the diagnosis or initiate anticoagulation. If nondiagnostic (e.g., of low or intermediate probability), the scan should be followed by pulmonary angiography.

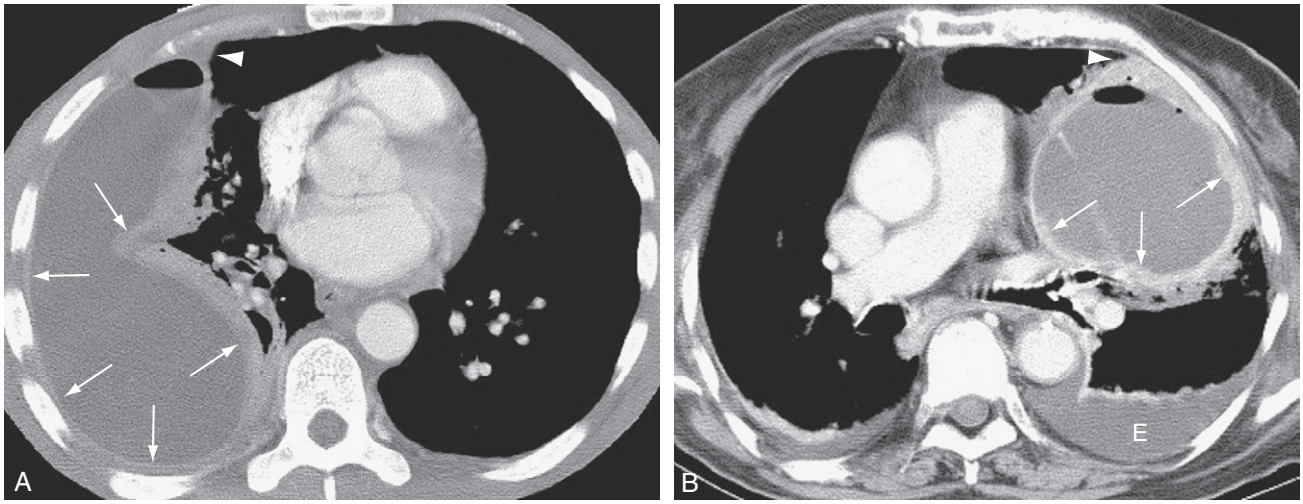

FIGURE 73-6 ■ Typical computed tomography (CT) features of a pleural empyema versus a lung abscess. **A,** Axial CT through the lower thorax in a patient with fever and pleuritic chest pain shows features typical of empyema, including the formation of obtuse angles between the lesion and the chest wall (*arrowhead*), a lenticular shape, a smooth internal surface (*arrows*), and mass effect on surrounding structures (note leftward shift of the heart and compression of intervening lung). Note enhancement and separation of the parietal and visceral pleura, representing the "split-pleura" sign (*arrows*) and the presence of an air-fluid level, indicating the presence of a bronchopleural fistula. **B,** Axial CT through the mid thorax in a patient with fever and cough productive of foul-smelling sputum shows features typical of a pulmonary abscess, including the formation of acute angles between the lesion and the chest wall (*arrowhead*), a round shape, a thick, irregular internal surface (*arrows*), and relatively little mass effect on the lung and mediastinum considering the large size of the lesion. The latter occurs because pulmonary abscesses tend to destroy adjacent lung more than they displace it. Note the presence of an associated pleural effusion (*E*). (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

Magnetic Resonance Imaging

Pleural effusions generally have long T1 and T2 values. The intensity of pleural effusions is therefore low to extremely low on T1-weighted images.[110] However, at the present time, magnetic resonance imaging (MRI) of the chest is less satisfactory than ultrasound or CT in identifying the presence of pleural fluid. It is possible that with improved MRI technology, the characteristics of pleural fluid can be determined noninvasively. At the present time, respiratory and cardiac motion is the major limitation in evaluating specific intensity patterns of fluid collections of various compositions.

Positron Emission Tomography and Positron Emission Tomography/Computed Tomography

Positron emission tomography (PET) visualizes tissues that are metabolically active by their concentration of the radioisotope ^{18}fluorodeoxyglucose. Because most malignant cells have a higher metabolic rate than non-malignant cells, PET can help differentiate malignant from benign lesions, help stage patients with malignancy, and help identify recurrence.[110] Introduced in 1998, PET/CT integrates the metabolic information of PET with the detailed anatomic information of CT. Compared with CT or PET alone, PET/CT can allow detection of additional lesions, localize them more accurately, characterize them as highly likely to be malignant, and discriminate malignant from surrounding normal tissue[115] (see Chapter 75).

Invasive Tests in Patients with Undiagnosed Exudative Pleural Effusions

In the patient with an undiagnosed exudative pleural effusion, there are several invasive tests that might be considered, including blind or image-guided needle biopsy of the pleura, bronchoscopy, pleuroscopy or video-assisted thoracoscopic surgery (VATS), and open biopsy of the pleura. It is important to remember that no diagnosis is ever established for approximately 20% of all exudative pleural effusions and that many resolve spontaneously, leaving no residua.[103,116] In patients with undiagnosed exudative pleural effusions, three factors should influence the vigor with which one pursues the diagnosis with invasive tests: (1) The symptoms and the clinical course of the patient. If the symptoms of the patient are minimal or if the symptoms are improving with time, a less aggressive approach is indicated. (2) The trend of the pleural fluid LDH level with time. If the pleural fluid LDH increases with serial thoracenteses, a more aggressive approach is indicated. (3) The attitude of the patient. If the patient is anxious to know the cause of the pleural effusion, a more aggressive approach should be taken.

Needle Biopsy of the Pleura

Small specimens of the parietal pleura can be obtained with needle biopsy, often called "blind" or "closed-needle" biopsy. The needles most commonly used for

this procedure are the Cope needle and the Abrams needle.[53] Because needle biopsy of the pleura is useful mainly to establish the diagnosis of malignant or tuberculous pleural effusions, this procedure should be considered when one of these diagnoses is suspected.

In malignant pleural disease, the needle biopsy of the pleura will be positive in 40% to 60% of patients.[116,117] Overall, the yield from pleural fluid cytology tends to be higher, probably because it samples cells dislodged from the entire pleura, whereas the needle biopsy can sample only from a localized area. In one series of 281 patients with malignant pleural effusions, the pleural biopsy was positive in 43%, whereas the pleural fluid cytology was positive in 58%.[116] In only 7% was the pleural biopsy positive and the pleural fluid cytology negative.[116] However, in a second series of 189 patients with malignant pleural effusions, the pleural biopsy was positive in 60%, whereas the cytology was positive in 52%. Both pleural fluid cytology and biopsy were positive in 33%, only the biopsy was positive in 27%, and only the cytology was positive in 19%.[117] A prudent approach to the patient with a suspected malignant pleural effusion is to obtain a pleural biopsy only if the cytology obtained at the time of the initial diagnostic thoracentesis is nondiagnostic. If the CT shows pleural thickening or nodularity, an image-guided pleural biopsy is an excellent option.[118]

Needle biopsy of the pleura has greater utility for the diagnosis of tuberculous pleuritis than of malignancy. The initial biopsy is positive for granulomas in 50% to 80% of patients.[119] The demonstration of granulomas on the pleural biopsy is virtually diagnostic of tuberculous pleuritis; caseous necrosis or acid-fast bacilli need not be demonstrated, although, on rare occasions, fungal diseases, sarcoidosis, or rheumatoid pleuritis can produce granulomatous pleuritis. When tuberculous pleuritis is suspected, a portion of the pleural biopsy specimen should be cultured for mycobacteria. In one series of 21 patients with tuberculous pleuritis, either the microscopic examination or the biopsy culture was positive in 20 of the 21 patients (95%).[120] If the initial biopsy is nondiagnostic and the patient has tuberculous pleuritis, a second biopsy will be diagnostic 10% to 40% of the time.[119,121]

The greatest value of needle biopsy for a patient with tuberculosis is obtaining material for culture of *M. tuberculosis* for the determination of drug susceptibility. Often, the presentation of a patient with a recent purified protein derivative (PPD) conversion and an exudative pleural effusion with lymphocytosis is classic and unlikely to be due to any diagnosis other than tuberculous pleurisy. The diagnosis can be further supported by measurements, where available, of pleural fluid ADA or IFN-γ. In those cases, treatment for tuberculosis can be offered with confidence without needle biopsy confirmation. However, when the patient may have been exposed to drug-resistant organisms, needle biopsy will increase the likelihood of obtaining organisms for culture and is recommended. Sputum induction can also be useful for culturing the organism, even when the patient is suspected to have only pleural involvement and the chest radiograph shows no pulmonary involvement; in this setting, sputum induction was shown to have a yield similar to that of culture of the pleural biopsy (52% vs. 62%).[122] Medical thoracoscopy has a higher yield than blind needle biopsy for obtaining pleural material for culture. When different approaches were compared in the same 51 patients, thoracoscopy obtained a positive culture of *M. tuberculosis* in 76% whereas the Abrams needle obtained a culture in 48%.[123] If the need for obtaining positive cultures is high, the more invasive diagnostic tests including medical thoracoscopy may be preferred.

The two major complications of needle biopsy of the pleura are pneumothorax and bleeding. Pneumothoraces large enough to require a chest tube occur in only about 1% of pleural biopsies.[116,124] It is likely that many pneumothoraces develop because of leakage of air through the biopsy needle and do not necessarily indicate puncture of the lung. A hemothorax can result if an intercostal artery or vein is inadvertently biopsied. In one older series, a fatal hemothorax occurred in 2 of 227 biopsy procedures.[124] The pleural biopsy needle can also be mistakenly inserted into the liver, spleen, or kidney, which can lead to hemorrhage in these organs. However, in general, bleeding complications are rare.

If no diagnosis is obtained after routine laboratory tests including cytology and one needle biopsy of the pleura, what can be said concerning the patient? Poe and colleagues[124] followed 143 such patients for 12 to 72 months, during which time 29 patients were diagnosed with malignant pleural disease and 1 patient with tuberculous pleuritis. In all 29 cases in which malignancy was eventually diagnosed, the diagnosis of malignant neoplasm was suggested by clinical criteria such as weight loss, constitutional symptoms, or a history of previous cancer. These authors concluded that most patients with undiagnosed exudative pleural effusions in whom the clinical picture does not suggest malignancy are best managed by observation. In those with symptoms suggestive of malignancy, image-guided pleural biopsy or thoracoscopy is probably the procedure of choice.

Image-Guided Pleural Biopsy

In patients with pleural abnormalities consistent with malignancy, CT-guided cutting-needle biopsies may supplant closed pleural biopsy for diagnosis.[125] In a randomized study of 50 patients with suspected malignant pleural effusions with negative cytology, those randomized to image-guided biopsy were more likely to be diagnosed (87% sensitivity) than those randomized to blind pleural biopsy (47%).[118] In situations in which the effusion is small or there is loculation or pleural thickening without an effusion, CT image-guided pleural biopsy is an excellent choice. PET/CT may increase the yield further by improving interpretation and selection of biopsy targets (see earlier).

Bronchoscopy

Another procedure that should be considered in the patient with an undiagnosed pleural effusion is bronchoscopy (see Chapter 22). If the patient has an

associated parenchymal lesion or hemoptysis, fiberoptic bronchoscopy will provide a diagnosis in nearly 75%.[126] Conversely, if the patient has neither a parenchymal abnormality nor hemoptysis, a diagnosis for the pleural effusion is established less than 10% of the time.[127] At the present time, CT scan of the chest should be performed in all patients with undiagnosed exudative pleural effusions. Bronchoscopy should then be performed only if the CT scan demonstrates parenchymal abnormalities or if the patient has hemoptysis. At the time of bronchoscopy, special attention is paid to those portions of the lung in which the parenchymal abnormalities were demonstrated.

Pleuroscopy or Video-Assisted Thoracoscopic Surgery

Pleuroscopy and VATS are discussed fully in Chapter 23. Pleuroscopy may be useful diagnostically in patients in whom the origin of a pleural effusion remains unclear after routine fluid analysis and needle biopsy of the pleura. In many cases, especially for the evaluation of malignancy, thoracoscopy may supplant needle biopsy because of a greater diagnostic yield and the added ability to provide a pleurodesis. Pleuroscopy can be performed by pulmonologists using local anesthesia and conscious sedation for direct visualization of the pleural surfaces, tissue sampling, and pleurodesis; thoracoscopy performed by thoracic surgeons, generally referred to as "video-assisted thoracoscopic surgery (VATS)," utilizes general anesthesia and single-lung ventilation by double-lumen intubation and allows greater access to the pleura and lung for surgical procedures.

Which patients with undiagnosed pleural effusions should undergo thoracoscopy? A diagnosis can be established in over 80% of patients with malignancy including those with mesothelioma.[128] Moreover, talc can be insufflated at the time of the procedure and this will control the effusion in the great majority of patients. Nonetheless, there are minor risks of the procedure, a need for postprocedure chest tube(s) and a procedure cost that should be considered. Pleuroscopy is, therefore, recommended for the patient with an undiagnosed pleural effusion after diagnostic thoracentesis and needle biopsy of the pleura in whom the diagnosis of malignancy is strongly suspected and in whom one wishes to establish this diagnosis.

Open Biopsy of the Pleura

Thoracotomy with direct biopsy of the pleura provides the best visualization of the pleura and the best biopsy specimens. Nowadays, the less invasive thoracoscopy can replace thoracotomy in most instances. The main indication for open pleural biopsy is progressive undiagnosed pleural disease that cannot be approached by or has failed to be diagnosed by thoracoscopy. In the past, for example, the diagnosis of malignant mesothelioma was usually made with open biopsy of the pleura, but now the diagnosis can be established in the majority of the cases with thoracoscopy.

It should be emphasized that open pleural biopsy does not always provide a diagnosis in patients with pleural effusions. Over the 11-year period from 1962 to 1972, 51 patients with pleural effusion at the Mayo Clinic had no diagnosis after an open pleural biopsy.[129] In 31 of these patients (61%), there was no recurrence of the pleural effusion, and no cause ever became apparent. However, 13 of the patients were eventually proved to have malignancy; 6 had lymphoma and 4 had malignant mesothelioma. Thus, observation of patients with undiagnosed pleural effusions is often warranted unless there is compelling reason to pursue the diagnosis of malignancy. Since the time of this study, there have been many improvements in diagnostic tests that may increase the diagnostic yield of invasive procedures.

TRANSUDATIVE PLEURAL EFFUSIONS

Transudative pleural effusions frequently accompany many common clinical disorders. It is noteworthy that the primary abnormality in most cases of transudative pleural effusions originates in organs other than the pleura or lungs, especially the heart, liver, and kidneys. This association emphasizes the fact that, although patients may visit their physicians for respiratory complaints, these symptoms may be caused by extrapulmonary disorders.

Congestive Heart Failure

CHF is probably the most common cause of pleural effusion.[53] The incidence of pleural effusion in patients with CHF is high. In one series of 60 patients with an exacerbation of stable CHF, chest CT scans demonstrated that 50 patients (83%) had a right-sided pleural effusion and 46 patients had a left-sided effusion. Approximately one third of the effusions had a volume that exceeded 700 mL.[130]

Pathophysiology

The pleural fluid that accumulates with CHF is related to the clearance of pulmonary interstitial fluid across a leaky mesothelium into the pleural space.[5] In studies in which sheep lungs were isolated in situ, volume loading led to an increased transudation across the lung into the pleural space.[6] The pleural fluid had the same protein concentration as that of the lung lymph and the interstitial edema liquid in the lung. The volume of pleural fluid constituted about 25% of all edema formed in the lung.[6] In the clinical situation, patients with CHF are much more likely to have a pleural effusion if there is radiologically apparent pulmonary edema.[131]

Clinical Manifestations

Patients with pleural effusion resulting from CHF usually have symptoms and signs of heart failure, such as dyspnea on exertion, orthopnea, nocturia, peripheral edema, distended neck veins, crackles, and a cardiac gallop. The

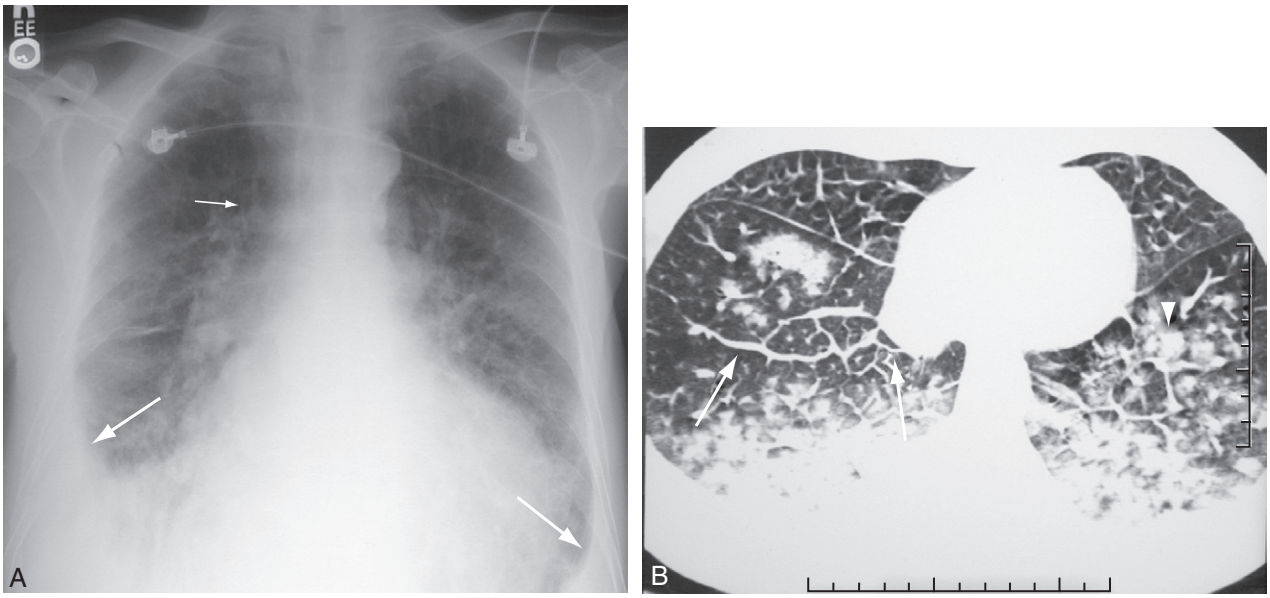

FIGURE 73-7 ■ Effusion from congestive heart failure. **A,** Frontal chest radiograph in a patient with pulmonary edema shows cardiomegaly, bilateral pleural effusions (*large arrows*), and central interstitial thickening, including Kerley's A lines (*small arrow*). Note that the right effusion is slightly larger than the left effusion. **B,** High-resolution computed tomography (HRCT) scan in a patient with pulmonary edema shows interstitial edema with bilateral, basilar centrilobular ground-glass opacity nodules (*arrowhead*) and smooth interlobular septal thickening (*arrows*). Bilateral pleural effusions are also present. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

chest radiograph almost always reveals cardiomegaly in addition to the pleural effusion.

The pleural effusions that occur with CHF tend to be bilateral, with larger effusions on the right (Fig. 73-7A). On CT imaging, interstitial and alveolar edema can often be detected by the presence of thickened septae and patchy infiltrates (see Fig. 73-7B). In an autopsy study of 250 patients with CHF and pleural effusion, 88% of the patients had bilateral pleural effusions, with the mean volume of pleural fluid in the right pleural space (1084 mL) slightly greater than the mean volume of fluid in the left pleural space (913 mL).[132] Moreover, of the 35 patients who did have unilateral pleural effusions, 46% had either pulmonary embolism or pneumonia.[132] Weiss and Spodick[133] reported that 73% of 51 patients with CHF had bilateral effusions, 19% had unilateral right-sided effusions, and 9% had unilateral left-sided effusions.

The reason that effusions are generally larger on the right side may lie in the fact that they originate from the larger lung on the right side.[36] In volume-overloaded sheep, the rate of liquid leakage from the right lung was higher than from the left, likely due to the larger volume and surface area of the right lung.[6] In another study in awake sheep, there was no difference in the rate of absorption of effusions from the right and left pleural spaces,[18] suggesting that differences in formation are the cause of the difference in size.[18,36]

Although CHF is by far the most common cause of bilateral pleural effusions, an alternate explanation should be sought if there is no cardiomegaly. In one series of 78 patients with bilateral effusions but a normal-sized heart, only 4% of the effusions were caused by CHF.[134]

Diagnosis and Management

The diagnosis is usually suggested by the clinical picture of CHF. A diagnostic thoracentesis should be performed if the pleural effusion is unilateral, if bilateral effusions are not comparable in size, if the patient is febrile, if the patient has pleuritic chest pain, or if the patient does not have cardiomegaly.[53] If none of these conditions is met, one can treat the CHF and perform a diagnostic thoracentesis only if the effusion does not resolve.

The pleural fluid from a patient with CHF is usually a transudate, as defined previously by Light's criteria.[34] However, if the patient has been on diuretics, the pleural fluid protein and LDH ratios may be increased sufficiently that the pleural fluid meets Light's exudative criteria. A similar phenomenon has been described in the ascites literature.[135] The LDH ratio can also increase if intrapleural LDH increases due to injury from repeated taps and if serum LDH falls when diuresis reduces liver congestion.[135] Generally, if the effusion protein and LDH values meet Light's criteria for an exudate, it is only by a small amount.[49] The transudative nature of the pleural fluids can be established in such patients if the serum minus the pleural fluid protein level is greater than 3.1 gm/dL.[47] Measurement of pleural fluid N-terminal brain natriuretic peptide (NT-BNP) is useful in this setting because levels exceeding 1300 pg/mL are virtually diagnostic of CHF.[48] Pleural fluid BNP does not correlate well with NT-BNP and is not as useful in establishing the diagnosis of CHF.[48]

Patients with CHF and pleural effusion should be treated with afterload reduction, diuretics, and inotropes, as needed. When the heart failure is successfully managed, the pleural effusion usually resolves. If the

patient is markedly dyspneic when first evaluated, a therapeutic thoracentesis to relieve the dyspnea should be considered. Rarely, despite intensive therapy of the CHF, a patient has persistent large effusions. If such patients are dyspneic and if their dyspnea is relieved by a therapeutic thoracentesis, consideration can be given to controlling the effusions with a pleurodesis using a sclerosing agent, such as doxycycline or talc slurry, or the insertion of an indwelling catheter.

Pericardial Disease

There is a high incidence of pleural effusion in patients with pericardial disease. In one series of 35 patients with constrictive pericarditis, 60% of the patients had radiologically demonstrable pleural effusions.[136] Weiss and Spodick[137] reviewed 124 patients with pericardial disease and found that 35 (28%) had a pleural effusion. Of the 35 patients, 21 had only a left-sided pleural effusion, 2 had only a right-sided pleural effusion, and the remaining 12 were bilateral. However, in another series of 21 patients with constrictive pericarditis and pleural effusion, the pleural effusion was right-sided only in 9 (43%) and was bilateral in the remaining 12 (57%).[136]

The mechanism responsible for the pleural effusion associated with pericardial disease is not clear. In constrictive pericarditis, one explanation for the effusions is that the pulmonary and systemic capillary pressures are elevated secondary to the pericardial disease, resulting in a transudative pleural effusion. However, one would expect these effusions to be bilateral. In inflammatory pericardial disease, however, the pleural effusion tends to be left-sided and, although the characteristics of the fluid has not been well described, it is probable that the effusion forms from extension of the pericardial inflammation to the adjacent pleura.[137]

Hepatic Hydrothorax

The incidence of pleural effusions with cirrhosis is approximately 6%.[138,139] The incidence appears to be much higher if ascites is present; however, in some patients with hepatic hydrothorax, no ascites can be detected, presumably because all ascitic fluid moves to the pleural space because of prevailing pressure gradients and low-resistance diaphragmatic defects.[36,140]

Pathophysiology

The predominant mechanism leading to a pleural effusion in a patient with cirrhosis and ascites appears to be the movement of the ascitic fluid from the peritoneal cavity through defects in the diaphragm into the pleural space.[141] The decreased plasma oncotic pressure is only a secondary factor.

The diaphragmatic defects have been demonstrated in many ways. Lieberman and coworkers[138] introduced 500 to 1000 mL of air into the peritoneal cavity of five patients with cirrhosis, ascites, and pleural effusions and found that a pneumothorax developed in all patients within 48 hours. In addition, they were able to demonstrate air bubbles coming through an otherwise undetectable diaphragmatic defect at thoracoscopy in one of their patients. In two of their patients, diaphragmatic defects were demonstrated at postmortem examination.[138] By thoracoscopy, different types of defects, such as blebs or fenestrations, have been documented.[142] There are no direct lymphatic connections between the peritoneal and the pleural spaces. Thus, the connections between the spaces are either preexisting developmental defects or defects caused by trauma or stretching.

Clinical Manifestations

The clinical situation in patients with pleural effusions from cirrhosis and ascites is usually dominated by the cirrhosis and ascites. At times, however, the presence of a large pleural effusion may produce severe dyspnea. The pleural effusion associated with cirrhosis and ascites is frequently large and can occupy the entire hemithorax. The large effusions occur because the diaphragmatic defect permits fluid to flow from the peritoneal cavity into the pleural cavity until the pleural pressure approaches the peritoneal pressure. The pleural effusions are usually right-sided (80%) but occasionally are left-sided (17%) or bilateral (3%).[141]

Diagnosis and Treatment

The diagnosis of hepatic hydrothorax is usually easily established from the clinical picture. If doubt exists, the diagnosis can be confirmed by scanning the chest after ^{99m}Tc sulfur colloid is injected into the peritoneal cavity.[143] Both a paracentesis and a thoracentesis should be performed to confirm that the ascites and the pleural fluid are both transudates. Xiol and associates[144] performed thoracentesis on 60 patients with cirrhosis and ascites. The pleural fluid analysis yielded a diagnosis other than hepatic hydrothorax in 18 (30%) including 9 spontaneous bacterial pleuritis, 2 tuberculosis, 2 adenocarcinomas, 2 parapneumonic effusions, and 3 undiagnosed exudates. The protein level with hepatic hydrothorax in the pleural fluid is usually higher than that in the ascitic fluid but is still below 3.0 g/dL.[138] If the polymorphonuclear cell count is greater than 500 cells/μL, the diagnosis of spontaneous bacterial pleuritis in conjunction with spontaneous bacterial peritonitis should be considered.[145]

The initial management of the pleural effusion associated with cirrhosis and ascites should be directed toward treatment of the ascites. The patient should be given a low-salt diet and treated with diuretics. If diet and diuretics do not control the effusion, the most definitive treatment is liver transplantation.[140] Chest tube insertion should be avoided because drainage of the ascitic fluid through the chest tube can lead to massive protein depletion and even fatal cardiovascular collapse.[140,140a] The next best approach and a potentially useful bridge to transplantation is probably implantation of a transjugular intrahepatic portal systemic shunt (TIPS). TIPS is usually effective in the management of hepatic hydrothorax. Kinasewitz and Keddissi[140] summarized the lit-

erature on 115 patients who received TIPS for refractory hepatic hydrothorax and reported that the procedure controlled the hydrothorax in 80%, but 12% of the patients developed encephalopathy. If neither TIPS nor liver transplantation is feasible, the best alternative treatment is probably videothoracoscopy with closure of the diaphragmatic defects and pleurodesis. Cerfolio and Bryant[146] performed this procedure on 41 patients and reported a success rate of 80%.

Spontaneous Bacterial Pleuritis

Spontaneous bacterial pleuritis is, by definition, infection of a preexisting hepatic hydrothorax in which a parapneumonic infection has been excluded. Originally termed "spontaneous bacterial empyema," we prefer the term *pleuritis* to emphasize its similarity to spontaneous bacterial peritonitis and to indicate that its treatment does not require tube thoracostomy. In one series in Spain, 16 of 120 patients (13%) admitted with a diagnosis of hepatic hydrothorax had a spontaneous bacterial pleuritis.[145] The diagnosis is made if the pleural fluid culture is positive, the pleural fluid neutrophil count is greater than 250 cells/μL, and a pneumonic process has been excluded. If the pleural fluid neutrophil count is greater than 500 cells/μL and the pleural fluid cultures are negative, culture-negative spontaneous bacterial pleuritis is diagnosed.[145] In the series from Spain, 10 of 24 episodes (43%) of spontaneous bacterial empyema were not associated with bacterial peritonitis.[145] Appropriate treatment of spontaneous bacterial pleuritis requires systemic antibiotics, but tube thoracostomy does not appear to be necessary. It remains to be seen whether spontaneous bacterial pleuritis is a common occurrence in the United States.

Nephrotic Syndrome

There is a high incidence of pleural effusion in patients with the nephrotic syndrome. In one study of 52 patients, 21% had pleural effusions.[147] The mechanism responsible for the transudative pleural effusion associated with the nephrotic syndrome is probably the combination of decreased plasma oncotic pressure and increased hydrostatic pressure. The increased hydrostatic pressure is due to salt retention, which produces hypervolemia. The pleural effusions in patients with a nephrotic syndrome are usually bilateral and are frequently infrapulmonary in location.[147]

A diagnostic thoracentesis should be performed in all patients with the nephrotic syndrome and a pleural effusion to prove that the pleural fluid is a transudate. Nonetheless, the possibility of pulmonary embolism should always be considered in patients with the nephrotic syndrome and a pleural effusion. In one series of 36 patients with the nephrotic syndrome, 22% had pulmonary emboli.[148] If the pleural fluid is an exudate, a CT angiogram should be obtained.

The treatment of the pleural effusion associated with the nephrotic syndrome should be aimed at increasing the level of protein in the serum by decreasing the protein loss in urine. If this is unsuccessful, pleurodesis with a sclerosing agent should be considered in selected patients who are symptomatic from the pleural effusion.

Peritoneal Dialysis

Peritoneal dialysis is occasionally complicated by the development of an acute hydrothorax. In a review of 3195 patients receiving continuous ambulatory peritoneal dialysis in Japan, 1.6% developed a pleural effusion as a result of the movement of the dialysate from the peritoneal cavity into the pleural cavity.[149] The effusion developed within 30 days of initiation of the dialysis in 50% of the patients, but 18% had been receiving dialysis for more than a year before the effusion developed.[149] The effusions are right-sided in about 90%.[149,150]

The pleural fluid in these patients is characterized by a glucose level intermediate between that of the dialysate and that of the serum, a protein level below 10 g/L, and a low LDH level. The LDH level is higher and the glucose level is lower in the pleural fluid than in the ascitic fluid.[150] Although the communication closes spontaneously in some patients, a surgical approach is usually required if continuous ambulatory peritoneal dialysis is to be continued. The treatment of choice is probably thoracoscopy with closure of the diaphragmatic defects, followed by pleurodesis. Alternative treatments are pleurodesis alone or thoracotomy with repair of the diaphragmatic defects.

Urinothorax

Obstruction of the urinary tract resulting in a retroperitoneal urine collection (urinoma) can lead to a pleural effusion.[151] The mechanism by which the pleural fluid accumulates is unknown, but it is thought that this retroperitoneal urine collection drains along pressure gradients into the pleural space. The collection of fluid actually represents urine, and the pleural fluid smells like urine. Patients with urinothoraces have pleural fluid creatinine levels higher than those in serum, but about 10% of other effusions also meet this criteria.[151] When the urinary tract obstruction is relieved, the pleural effusion rapidly disappears.

Myxedema

A pleural effusion sometimes occurs as a complication of myxedema. Most patients with myxedema and pleural effusion have a concomitant pericardial effusion. In one series of 25 patients with pericardial effusions secondary to myxedema, 13 of the patients (52%) had concomitant pleural effusion.[152] When the pleural effusion occurs simultaneously with a pericardial effusion, the pleural fluid is usually a transudate.[152] The isolated pleural effusion seen in conjunction with myxedema is generally borderline between a transudate and an exudate. Although the mechanism of formation of the effusion is unknown, a decrease in lymphatic function due to low thyroid levels may contribute.[22] Thyroid replacement is the obvious treatment for pleural effusions associated with myxedema.

Fontan Procedure

With the Fontan procedure, an anastomosis is created between either the superior vena cava, the right atrium, or the inferior vena cava and the pulmonary artery to bypass the right ventricle, usually because of tricuspid atresia or a univentricular heart. Pleural effusion occurs in many patients after surgery and contributes significantly to postoperative morbidity. Pleural effusions are more likely to occur in patients who have significant aortopulmonary collateral vessels before surgery; thus, Spicer and colleagues[153] recommended that these vessels be embolized during preoperative angiography. The amount of pleural drainage postoperatively is decreased by about 50% if the Fontan circuit is fenestrated to allow shunt of deoxygenated blood to the systemic circulation.[154] Although the etiology of the effusions is still unknown, prolonged pleural effusions have also been correlated with higher preoperative pulmonary artery pressure, pulmonary vascular compliance or postoperative levels of salt and water hormones.[154a,154b,154c] The treatment of choice for these effusions is usually insertion of a pleuroperitoneal shunt. Alternative treatments are creation of a late fenestration to create a right-to-left shunt or chemical pleurodesis.

Other Causes of Transudative Pleural Effusions

On rare occasions, a subarachnoid-pleural fistula can develop that results in the accumulation of CSF in the pleural space. The pleural fluid looks like CSF with a very low protein and LDH level. Subarachnoid-pleural fistulae can occur following ventriculopleural shunting and with penetrating injuries, fractures, or surgery of the thoracic spine.[53] If there is doubt about the diagnosis, measurement of the pleural fluid β_2-transferrin is useful because only CSF contains this molecule.[155] The fistula rarely closes without surgical intervention.

Large, persistent transudative effusions can result from central venous obstruction, perhaps due to increases in venous pressure leading to increased formation of liquid and to decreases in lymphatic clearance. Venous obstruction as a cause of persistent transudative effusions should be considered in situations with prior instrumentation and have been reported from occlusions of the hemiazygous vein, brachiocephalic vein and superior vena cava. Relief of the obstruction can lead to resolution of the effusion.[156]

Patients with pulmonary veno-occlusive disease frequently have small pleural effusions.[157] The characteristics of the pleural fluid have not been described, but it is probably a transudate because the effusions are likely related to the increased interstitial fluid. Patients with right failure secondary to pulmonary hypertension frequently have small bilateral pleural effusions.[158]

Pulmonary embolism has been reported to be associated with a transudative pleural effusion. However, in a study of the pleural fluid findings in patients with pulmonary embolism, all 60 pleural fluids were exudates.[63] Pleural amyloidosis is associated with transudative effusions, probably due to a combination of heart failure and pleural infiltration with amyloid.[159] Cytokines such as vascular endothelial growth factor (VEGF) may play a role because, in a recent series, three out of four patients with persistent pleural effusions due to primary systemic amyloid improved with treatment with an antibody against VEGF, bevacizumab.[160]

EXUDATIVE PLEURAL EFFUSIONS

Exudative pleural effusions are common clinical problems. These effusions may develop as a result of inflammation, injury, or malignancy, which can involve the pleural surfaces, the adjacent lung, or more distant tissues, such as mediastinal or abdominal organs. Further discussion of effusions secondary to pleural tumors is presented in Chapter 75, and special types of effusions (chylothorax and hemothorax) are discussed in Chapter 74.

Parapneumonic Effusions and Empyema

A parapneumonic effusion is any pleural effusion associated with bacterial pneumonia, lung abscess, or bronchiectasis. Parapneumonic effusions are probably the most common exudative pleural effusion in the United States. The annual incidence of bacterial pneumonia in the United States is estimated to be 4 million.[161] Approximately 20% to 40% of patients hospitalized with bacterial pneumonia have an accompanying pleural effusion.[86,162] The morbidity and mortality in patients with pneumonia and pleural effusion are higher than in patients with pneumonia alone. In one study of patients with community-acquired pneumonia, the relative risk of mortality was 7.0 times higher for patients with bilateral pleural effusions and 3.4 times higher for patients with unilateral pleural effusions of moderate or greater size than for those without effusions.[163] Although it is possible that comorbidity from diseases such as CHF might cause both the effusions and the excess mortality, at least some of the increase in morbidity and mortality may be due to improper management of the pleural effusion.

When one is managing a patient with a parapneumonic effusion, the main decision to make is whether or not chest tubes should be inserted. The term *complicated parapneumonic effusion* was developed to refer to parapneumonic effusions that require tube thoracostomy for their resolution. An empyema is, by definition, pus in the pleural space. Approximately 60% of empyemas are parapneumonic, whereas 20% arise after thoracic surgical procedures, and the remaining 20% arise as complications of various conditions, such as thoracic trauma, esophageal perforation, thoracentesis, and subdiaphragmatic infection.[53]

Pathophysiology

The evolution of a parapneumonic pleural effusion can be divided into three stages, which are not sharply defined but rather represent a continuous spectrum. In

TABLE 73-3. Categorizing Risk for Poor Outcome in Patients with Parapneumonic Effusion

Pleural Space Anatomy		Pleural Fluid Bacteriology		Pleural Fluid Chemistry	Category	Risk of Poor Outcome	Drainage
A_o Minimal, free-flowing effusion (<10 mm on lateral decubitus)	*And*	B_x Culture and Gram stain results unknown	*And*	C_x pH, glucose unknown	1	Very low	No
A_1 Small to moderate free-flowing effusion (>10 mm and <half of the hemithorax)	*And*	B_o Negative culture and Gram stain	*And*	C_o pH ≥ 7.20 glucose > 60 mg/dL	2	Low	No
A_2 Large, free-flowing effusion (≥half of the hemithorax), loculated effusion, or effusion with thickened parietal pleura	*Or*	B_1 Positive culture and Gram stain	*Or*	C_1 pH < 7.20 glucose < 60 mg/dL	3	Moderate	Yes
		B_2 Pus			4	High	Yes

From Colice GL, Curtis A, Deslauriers J, et al: Medical and surgical treatment of parapneumonic effusions: An evidence-based guideline. Chest 118:1158–1171, 2000, with permission.

the first stage, the exudative stage, a focus of parenchymal infection leads to increased pulmonary interstitial fluid, some of which traverses the visceral pleura and causes the accumulation of a small sterile pleural effusion. The pleural fluid in this stage is an exudate with primarily polymorphonuclear leukocytes, a normal glucose level, and a normal pH. With institution of appropriate antibiotic therapy during this stage, both the pneumonic process and the pleural effusion resolve.

The next stage is the fibropurulent stage, characterized by infection of the previously sterile pleural fluid with the offending bacteria. In this stage, more pleural fluid accumulates and contains many polymorphonuclear leukocytes, bacteria, and cellular debris. In addition, fibrin is deposited as continuous sheets that cover both the visceral and the parietal pleura in the involved area. As this stage progresses, there is a tendency for the fibrin membranes to partition the involved pleural space into multiple locules. This loculation hinders extension of the empyema but makes complete drainage of the pleural space with chest tubes increasingly difficult. The pleural fluid pH and glucose levels decrease, and the LDH level increases progressively as this stage evolves.

In the last stage, the organization stage, fibroblasts grow into the exudate from both the visceral and the parietal pleural surfaces to produce an inelastic membrane. This membrane, sometimes called a *pleural peel*, can encase the lung and hinder the reexpansion of the underlying lung when the pleural fluid is evacuated. If the underlying lung cannot reexpand, consideration should be given to decortication, because it is virtually impossible to eradicate the infection if the space persists after the fluid is evacuated. However, if the infection is already controlled, the peel frequently resolves spontaneously over the ensuing 3 to 6 months.

Classification

An expert panel from the American College of Chest Physicians has developed a new categorization of patients with parapneumonic effusions.[164] This categorization is modeled somewhat on the tumor-node-metastasis (TNM) classification of tumors and is based upon the anatomy of the effusion, the bacteriology of the pleural fluid, and the chemistry of the pleural fluid (Table 73-3).

The *category 1* effusion is a small (<10 mm thickness on decubitus, CT or ultrasound studies) free-flowing effusion. Because the effusion is small, no thoracentesis is performed and the bacteriology and chemistry of the fluid are unknown. The risk of a poor outcome with a category 1 effusion is very low.

The *category 2* effusion is small to moderate in size (>10 mm thickness and < half the hemithorax) and is free flowing. The Gram stain and culture of the pleural fluid are negative and the pleural fluid pH is more than 7.20 or the glucose more than 60 mg/dL. The risk of a poor outcome with a category 2 effusion is low.

The *category 3* effusion meets at least one of the following criteria: (1) the effusion occupies more than half the hemithorax or is loculated or is associated with a thickened parietal pleura; (2) the Gram stain or culture is positive, or (3) the pleural fluid pH is less than 7.20 or the pleural fluid glucose is less than 60 mg/dL. The risk of a poor outcome with a category 3 effusion is moderate.

The *category 4* effusion is characterized by pleural fluid that is pus. The risk of a poor outcome with a category 4 effusion is high.

Bacteriology

The most recent comprehensive report on the bacteriology of complicated parapneumonic effusions comes from the large trial of intrapleural streptokinase in the United Kingdom.[84] In this study of 434 patients, the Gram stain was positive in 250 (58%) patients, the cultures grew a single aerobic growth in 151 (35%) patients, a single anaerobic growth in 29 (7%) patients, and a polymicrobial growth in 52 (12%) patients. Pleural fluid was available for molecular microbiologic analysis in 404 of the subjects. For 70 of the culture-negative cases, bacteria were identified by subsequent nucleic acid amplification. Overall, a microbiologic diagnosis was obtained in 320 patients (74%). In patients with

community-acquired pneumonia, the organisms most commonly responsible were *Streptococcus intermedius-anginosus-constellatus* (milleri) group (80), *S. pneumoniae* (71), other streptococcus species (25), *S. aureus* (34) (7 methicillin-resistant *Staphylococcus aureus* [MRSA]), gram-negatives (29), and anaerobes (67). In patients with hospital-acquired parapneumonic effusions, the most common organism was *S. aureus* (21) of which 15 were MRSA. The authors concluded that pleural infection differs from pneumonia in its bacteriology and, for community-acquired infection, should be treated with antibiotics for both aerobic and anaerobic bacteria.

Clinical Manifestations

Aerobic Bacterial Infections. Patients with aerobic bacterial pneumonia and pleural effusion initially have an acute febrile illness consisting of chest pain, sputum production, and leukocytosis. The incidence of pleuritic chest pain and the degree of leukocytosis are comparable whether or not there is an accompanying pleural effusion.[86]

Anaerobic Bacterial Infections. Patients with anaerobic bacterial infections involving the pleural space usually present with a subacute illness. In one series, the duration of symptoms before presentation averaged 10 days, with 70% of the patients having symptoms for more than 7 days.[165] Most patients with anaerobic pleuropulmonary infections have significant weight loss (mean, 13.2 kg in one series) as well as leukocytosis and mild anemia.[165] In addition, most patients have risk factors for aspiration of an anaerobic inoculum; these risk factors include alcoholism, an episode of unconsciousness, and infected gums.

Because of the nonspecificity of the symptoms associated with empyema, the diagnosis may not be considered and thus be delayed. In one series of 119 patients from England in the late 1980s, empyema was considered the most likely diagnosis by the admitting doctor in only 35 patients (29%).[166] In this same series, the diagnosis was delayed for more than 1 week after admission in 28 patients and for more than 1 month after admission in 5 patients.[166] In this series, the most common symptom was malaise (73%), and only 56% of the patients were febrile. In a more recent series from Canada, the mean delay from admission to the time of correct diagnosis was 44 days.[167]

Diagnosis

Parapneumonic effusion and empyema should be included in the differential diagnosis of all undiagnosed exudative effusions. The possibility of a parapneumonic effusion should be considered whenever a patient with a bacterial pneumonia is initially evaluated. If costophrenic angles show blunting or if the diaphragm is not visible throughout its length, bilateral decubitus chest radiographs or ultrasound should be obtained to evaluate the possibility of a pleural effusion.

With the involved side dependent, the amount of free pleural fluid can be semiquantitated by measuring the distance between the inside of the chest wall and the outside of the lung. If this distance is less than 10 mm, the effusion is not clinically significant, and thoracentesis is not indicated.[86,164] If the thickness of the fluid exceeds 10 mm, then a thoracentesis should be performed immediately.[164,168] Only by examining the pleural fluid can one distinguish a complicated from an uncomplicated parapneumonic effusion. The pleural fluid should be examined grossly for color, turbidity, and odor. Aliquots are sent for determination of the glucose, LDH, protein concentration, pH (if it can be performed with a blood gas machine),[87] a differential and total leukocyte count, Gram's stain, and aerobic and anaerobic bacterial cultures. In most instances, the pleural fluid should also be submitted for mycobacterial and fungal smears and cultures.

Not all patients with an acute illness, parenchymal infiltrates, and pleural effusion have an acute bacterial pneumonia. This clinical picture may also be seen with pulmonary embolization, acute pancreatitis, tuberculosis, Dressler's syndrome, and other diseases. The diagnostic workup of each patient should be individualized based on the clinical situation.

Treatment

When a patient with pneumonia and a pleural effusion is initially evaluated, an appropriate antibiotic must be selected, and the decision whether to initiate invasive therapy for the pleural effusion must be made. Bacterial cultures of the sputum, blood, and pleural fluid should be obtained before antibiotic therapy is instituted. Antibiotic therapy for bacterial pneumonia is discussed in Chapter 32.

Prognostic Factors. Findings that suggest that a more aggressive approach will be necessary for a parapneumonic effusion are listed in Table 73-4. The more purulent the pleural fluid, the lower the glucose level, and the lower the pH, the more likely the patient is to require increasingly invasive procedures for complete drainage. Other pleural fluid measurements that have been reported to be useful as markers for identifying complicated parapneumonic effusions include the pleural fluid myeloperoxidase level,[169] the complement

TABLE 73-4. Factors Suggesting That a More Invasive Approach Will Be Necessary for the Resolution of a Parapneumonic Effusion*

1. Pus is present in the pleural space.
2. Positive pleural fluid Gram stain.
3. Pleural fluid glucose < 60 mg/dL.
4. Pleural fluid pH < 7.20.
5. Positive pleural fluid culture.
6. Pleural fluid lactate dehydrogenase > three times upper normal limit for serum.
7. Loculated pleural fluid.

*Listed in order of decreasing seriousness.

activation product SC5b-9,[170] and the polymorphonuclear elastase level.[171] Additional studies are necessary to assess the utility of these measurements.

Overall Treatment Plan. The treatment options for patients with parapneumonic effusions and empyema, in order of increasing invasiveness, are diagnostic thoracentesis, therapeutic thoracentesis, tube thoracostomy, tube thoracostomy with thrombolytics, thoracoscopy, and thoracotomy with decortication. If the patient has any of the poor prognostic factors, it is likely that one of these treatments will be necessary. It is important not to continue any one treatment that is not working for more than a day or so.[172,173]

The effectiveness of a given treatment is evaluated by the clinical status of the patient together with the amount and the characteristics of the pleural fluid. If the patient appears to be responding, if the amount of pleural fluid is not large, and if the characteristics of the fluid are improving, the treatment should be considered successful. More invasive procedures are not indicated for pleural thickening or loculation alone. Chest CT scans are very useful in evaluating the adequacy of drainage of the pleural space.

Diagnostic versus Therapeutic Thoracentesis. To determine whether the patient has any of the prognostic factors listed in Table 73-4, a thoracentesis must be performed. Should a therapeutic or a diagnostic thoracentesis initially be performed? Because the risks of a diagnostic thoracentesis and a therapeutic thoracentesis are comparable, and a therapeutic thoracentesis might obviate the necessity for further procedures, a therapeutic thoracentesis is recommended.[172] If the pleural fluid never recurs, one need not worry about the pleural fluid. If the pleural fluid recurs after a therapeutic thoracentesis, poor prognostic findings in the initial pleural fluid indicate the need for more drainage—either an additional therapeutic thoracentesis or a tube thoracostomy. The absence of poor prognostic findings in a patient who is improving clinically indicates that additional drainage is not necessary. No more than three therapeutic thoracenteses are recommended.[172] If the pleural fluid cannot be completely removed because it is loculated, tube thoracostomy should be performed if any of the other poor prognostic factors listed in Table 73-4 are present. An alternative to therapeutic thoracentesis is to insert a small pigtail catheter.

Chest Tubes. Once it is decided that tube thoracostomy is necessary, there should be no delay in its performance, because a complicated parapneumonic effusion can progress from free-flowing pleural fluid to loculated pleural fluid within hours. In one older series of 47 anaerobic empyemas, 5 patients died, and all deaths were attributed to a delay in obtaining adequate pleural drainage.[165] In a subsequent series, a delay in instituting chest tube drainage was associated with a mortality increase from 3% to 16%.[174] The chest tube should be positioned in the most dependent part of the effusion.

There is no consensus on the optimal size of the chest tube for drainage.[168] In the past, relatively large (26–36 French) chest tubes were recommended because of the belief that smaller tubes would become obstructed by the thick fluid. However, it appears that many patients can be managed with much smaller tubes. In one study, 103 patients with empyema were treated with 8- to 12-French pigtail or 10- to 14-French Malecot catheters inserted with the Seldinger technique under either ultrasound or CT scan.[175] In this study, these small catheters served as the definitive treatment in 80 of the 103 patients (78%).[175] These results are as good as those reported in some series in which larger tubes were utilized.[174,176] The small chest tubes in the aforementioned two series were inserted percutaneously by interventional radiologists. It is likely that the excellent results are related to accurate image-guided placement of the catheter. If small tubes are used, regular flushing and suction is recommended to avoid catheter blockage.[168] If the pleural fluid is frank pus, it is still preferable to insert a large chest tube. The chest tube should be left in place until the volume of the pleural drainage per 24 hours is less than 50 mL and until the draining fluid becomes clear yellow.

Successful closed-tube drainage of a complicated parapneumonic effusion is associated with improvement in the clinical and radiologic status of the patient within 24 to 48 hours. If there is no significant improvement after this period, either the pleural drainage is unsatisfactory or the patient is receiving the wrong antibiotic. In such situations, the culture results should be reviewed and the adequacy of the pleural drainage should be assessed by chest radiographs, CT scans, or ultrasonic examination. If the pleural space is inadequately drained, another chest tube should be inserted, saline or a fibrinolytic agent can be injected intrapleurally (see later), or a more extensive surgical procedure should be performed. Inadequate drainage can be caused by poor positioning of the tube, obstruction of the chest tube, loculated pleural fluid, or inadequate expansion of the underlying lung caused by coating of the visceral pleura.

Intrapleural Thrombolytic Agents. Difficulties arise in the drainage of complicated parapneumonic effusions as a result of pleural loculations that are produced by fibrin membranes. The theory behind the use of intrapleural fibrinolytics is that they will degrade the fibrin membranes and facilitate drainage of the pleural fluid. However, in the most important study on the use of intrapleural fibrinolytics for the treatment of complicated parapneumonic effusion, the administration of streptokinase was not beneficial, even in subgroup analysis.[177] In this multicenter, randomized, controlled, double-blind study, 454 patients were randomized to receive 250,000 IU streptokinase or saline at a total volume of 30 mL twice a day. There was no difference in mortality, the need for surgical intervention, or the length of hospitalization. Accordingly, fibrinolytics are not recommended for routine use at the present time. An alternative fibrinolytic agent is tissue plasminogen activator (t-PA).[178] A second controlled trial is underway in the United Kingdom to assess the efficacy of t-PA, recombinant DNase, and the combination of the two agents. A study in rabbits demonstrated that the combination of t-PA and recombinant DNase drained empyema fluid better than either agent alone.[179] Although relatively safe, the issue of safety is still unre-

solved especially in those with coagulopathies or those receiving anticoagulant therapy.[179a]

Thoracoscopy. When the patient is not improving despite tube thoracoscopy, a more invasive procedure is needed. With thoracoscopy, the fibrin membranes creating the loculations are broken down and removed, the peel covering the visceral pleural can sometimes be removed and, at the end of the procedure, a chest tube is placed optimally in the pleural space.[180] Prior to thoracoscopy, a chest CT should be obtained to provide anatomic information about the size and the extent of the empyema cavity. The finding of a thickened visceral pleural peel without septations suggests that the empyema may be chronic and probably will not be amenable to thoracoscopic débridement alone. Most patients who undergo thoracoscopy need no additional therapy. When four studies with a total of 232 patients are combined, thoracoscopy was the definitive procedure in 77% of the patients.[181-184] After thoracoscopy, the median hospital stay ranged from 5.3 to 12.3 days, the median time for chest tube drainage postprocedure ranged from 3.3 to 7.1 days, and the overall mortality was 3%.[181-184]

Decortication. This procedure should be considered in patients who require additional drainage after tube thoracostomy and thoracoscopy.[180] With this procedure, a full thoracotomy is performed to remove all fibrous tissue and pus from the pleural space. The primary advantage that thoracotomy has over thoracoscopy is that decortication is easier to perform with thoracotomy. Decortication eliminates the pleural sepsis and allows the underlying lung to expand. Decortication is major thoracic surgery and should not be performed on patients who are markedly debilitated. It should not be performed just to remove thickened pleura, because such thickening usually resolves spontaneously over several months. After 6 months, however, if the pleural thickening persists and the pulmonary function is sufficiently reduced to limit the patient's activities, decortication should be considered.

Open Drainage (Eloesser Flap). With this relatively minor surgical procedure, which can be performed under local anesthesia, a U-shaped incision is made to provide a skin flap overlying the lower part of the empyema collection; the exposed rib segments and underlying parietal pleura are excised to open the empyema cavity; then, the skin flap is sutured inside the cavity to create a semipermanent opening into which one or more large-bore short tubes are inserted. The open-drainage procedure allows more complete drainage and frees the patient from attachment to chest-tube bottles.[185] After the procedure, the cavity should be irrigated daily with a mild antiseptic solution, and the drainage from the tubes can be collected in a colostomy bag placed over the tubes. Open drainage is preferred to decortication only in those patients who are thought to be too ill to tolerate the more extensive procedure. Patients treated by open drainage can expect to have an open chest wound for a prolonged period. In one series of 53 patients treated by an open-drainage procedure, the median time for healing the drainage site was over 120 days.[186]

Bronchopleural Fistula Complicating Empyema

When an empyema is complicated by the presence of a bronchopleural fistula, adequate pleural drainage is crucial. The pleural fluid that is not drained exteriorly with chest tubes is likely to drain interiorly throughout the tracheobronchial tree, producing a severe diffuse pneumonia. A bronchopleural fistula should be suspected whenever the chest radiograph reveals an air-fluid level or when the patient expectorates copious quantities of sputum while lying on one side (due to drainage of the empyema by gravity into the bronchial tree) and not while lying on the other side.

At times, it is difficult to determine whether an air-fluid level is in the lung or in the pleural space. It is important to make this differentiation because a lung abscess should be treated with antibiotics alone, whereas it is imperative to drain the pleural space if a bronchopleural fistula exists. Chest CT is quite valuable in making this differentiation, as described earlier in this chapter (see Fig. 73-6).

Postpneumonectomy Empyema

The incidence of empyema after pneumonectomy is about 7.5%.[187] This diagnosis should be suspected in any patient who undergoes pneumonectomy and becomes febrile, starts expectorating large amounts of sputum, has purulent drainage from the thoracotomy wound, or has a mediastinum that is midline or shifted to the contralateral side. The diagnosis is established with a diagnostic thoracentesis that reveals organisms on Gram stain or culture.

A postpneumonectomy empyema is an extremely serious complication because it is impossible to eliminate the space containing the infection and, consequently, it is difficult to sterilize the pleural space. Approximately 60% to 80% of patients with postpneumonectomy empyema have a bronchopleural or an esophagopleural fistula.[187,188] Therefore, all patients with this complication should undergo a chest CT scan and a bronchoscopy.

The treatment of a postpneumonectomy empyema involves two different aspects, draining the infected pleural fluid and closing the bronchopleural fistula. The pleural fluid is best drained by tube thoracostomy if the empyema develops in the first few days after pneumonectomy. Subsequently, most patients require open drainage. If the patient does not have a bronchopleural fistula, operative irrigation and filling of the residual space with an antibiotic-containing solution or thoracoscopic débridement may be curative.[188]

If a bronchopleural fistula is present, it must be treated. Attempts can be made to close the fistula bronchoscopically, but a thoracotomy with surgical closing of the fistula by use of an intrathoracic muscle transposition or a pedicled omental flap are usually required.[188]

Tuberculous Pleuritis

In many parts of the world, the most common cause of an exudative pleural effusion is tuberculosis. However,

in the United States, the annual incidence of tuberculous pleural effusion is below 1000; approximately 1 in every 30 cases of tuberculosis is tuberculous pleuritis.[189] In some African countries, the percentage of patients with tuberculosis who have a pleural effusion exceeds 30%.[190] The effect of HIV on the incidence of tuberculous pleurisy is still uncertain; in some studies, HIV appears to increase the incidence and in others not.[190] The confusion may lie in part due to the state of immunocompromise. The prevalence of tuberculous pleurisy is also higher in patients with CD4 counts above 200 than in those with CD4 counts below 200,[191] in keeping with our current understanding of the role of delayed hypersensitivity in the development of the effusion.

A pleural effusion as a manifestation of tuberculosis has been likened to a primary chancre as a manifestation of syphilis. Both are self-limited and of little immediate concern, but both may lead to serious disease many years later. Most instances of pleural effusion secondary to tuberculosis resolve spontaneously; however, if patients are not treated with antituberculous therapy, they have about a 50% likelihood of developing active tuberculosis in the subsequent 5 years.[192]

Pathogenesis

A tuberculous pleural effusion can either be a sequel to a primary infection acquired 3 to 6 months previously or represent reactivation tuberculosis. A molecular epidemiologic study has confirmed that tuberculous pleurisy is usually an early manifestation of tuberculosis infection.[193] Delayed hypersensitivity appears to play a large role in the pathogenesis of tuberculous pleuritis. In animal models, the intrapleural injection of tuberculous protein in sensitized animals results in the rapid appearance of an exudative pleural effusion.[194] When the animals are given antilymphocyte serum, the development of the effusion is suppressed. The observation that pleural fluid cultures are negative in approximately 80% of patients with tuberculous pleuritis suggests that delayed hypersensitivity also plays a large role in the development of tuberculous pleural effusions in humans. Although delayed hypersensitivity to tuberculous protein is believed to be primarily responsible for tuberculous pleuritis, approximately one third of patients with tuberculous pleuritis have a negative tuberculin skin test result when first evaluated. The negative skin test is thought to be due to the sequestration of circulating PPD-reactive lymphocytes or to suppressor cells, either adherent monocytes or Fc-bearing lymphocytes, which are found in the blood but not in the pleural space.[194]

Clinical Manifestations

Tuberculous pleuritis occurs as an acute illness in about two thirds of cases and as a chronic illness in the remaining one third. The acute illness is marked by cough and chest pain in about 75% of patients and often mimics a bacterial pneumonia with parapneumonic effusion. The chronic form is characterized by low-grade fever, weakness, and weight loss.

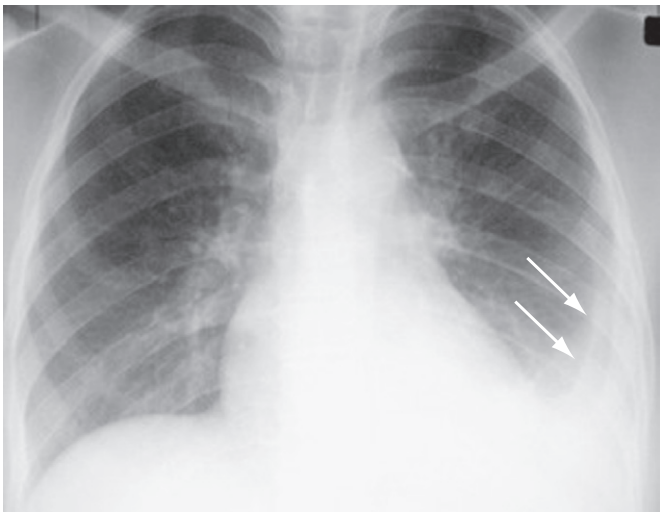

FIGURE 73-8 ■ Tuberculous effusion. Frontal chest radiograph in an immunocompromised patient with *Mycobacterium tuberculosis* infection shows left lower lobe consolidation (note absence of left diaphragm contour) and left pleural effusion (*arrows*). Smears and cultures of sputum were positive for *M. tuberculosis*. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

Effusions secondary to tuberculous pleuritis are almost always unilateral (Fig. 73-8) and are usually small to moderate in size, although they may occupy the entire hemithorax. Up to 86% of patients will have coexisting parenchymal disease.[195] In such patients, the pleural effusion is almost always on the side of the parenchymal infiltrate and invariably indicates active parenchymal disease (see Fig. 73-8). It is likely that even in cases with no radiographic evidence of parenchymal involvement, the effusion is associated with a subpleural focus of infection. Evidence to support this contention is provided by a study in which the yield of sputum induction for *M. tuberculosis* was as high in patients with no radiographic evidence of parenchymal involvement (55%) as in those with evidence of parenchymal disease (45%).[122]

Pleural Fluid. The pleural fluid from patients with tuberculous pleuritis is an exudate that usually contains predominantly small lymphocytes. If symptoms have been present only a few days, neutrophils may be predominant. The pleural fluid glucose level is usually similar to that of serum but, at times, it is reduced. A pleural fluid protein level above 5.0 g/dL is suggestive of tuberculous pleuritis.

Diagnosis

The possibility of tuberculous pleuritis should be considered in every patient with an undiagnosed exudative pleural effusion, even though only a small percentage of such effusions are due to tuberculosis in the United States.[53] Since the late 1950s, the most common way to establish the diagnosis of tuberculous pleuritis has been via needle biopsy of the pleura. However, in recent years, three tests that can be performed on pleural fluid

have been developed that may be useful in establishing or excluding the diagnosis of tuberculous pleuritis: (1) the level of ADA in the pleural fluid, (2) the level of IFN-γ in the pleural fluid, and (3) the PCR for mycobacterial DNA. These studies are described in detail earlier in this chapter; as mentioned, one disadvantage of these tests is that they do not provide bacterial cultures for antibiotic sensitivity testing.

In all patients with an undiagnosed exudative pleural effusion, pleural fluid should be cultured for mycobacteria and have one of the aforementioned three tests performed on their pleural fluid. An induced sputum should also be sent for smear and culture because it will be positive in approximately 50%.[122] If the culture of the fluid or sputum is positive, treatment for tuberculosis should be initiated. If one of the other tests is positive for tuberculosis, the patient should also be treated for tuberculosis unless the patient has a disease that is known to be associated with a positive result or if there is no pleural fluid lymphocytosis. In areas with a high likelihood of resistant tuberculosis, one may also want to obtain pleural tissue for cultures via needle biopsy of the pleura or thoracoscopy. If the patient does not respond to therapy, then further investigations are warranted; needle biopsy of the pleura can be performed in questionable cases, but unless the likelihood of tuberculosis is high, the invasive diagnostic test of choice is usually thoracoscopy.

Treatment

Patients with tuberculous pleuritis should be treated with antituberculous medications in the same treatment regimens that are administered to patients with pulmonary tuberculosis; these are fully discussed in Chapter 34. With treatment, patients generally become afebrile within about 2 weeks, and the pleural effusion resolves within 6 weeks. On occasion, the pleural effusion worsens after antituberculous therapy is initiated[196] or a pleural effusion develops while a patient is being treated for tuberculosis.[197] In these situations, the possibility of a wrong diagnosis must be considered, but the paradoxical worsening can occur with the correct diagnosis and appropriate antituberculous medications.[196,197] Mild degrees of pleural fibrosis are present a year after therapy is begun in about 50% of patients. The presence of fibrosis is not related to the initial pleural fluid findings and is of limited clinical significance.[198]

The role of systemic corticosteroids in the treatment of tuberculous pleuritis remains controversial. A systematic literature review concluded that there was insufficient data to support evidence-based recommendations regarding the use of adjunctive corticosteroids in those with tuberculous pleurisy.[199] Use of corticosteroids may be considered for those who are markedly symptomatic, but only after the institution of appropriate antituberculosis therapy. Therapeutic thoracentesis is indicated if the patient has a moderate-sized or larger pleural effusion producing symptoms. Otherwise, complete drainage of the pleural space has no significant effects on the long-term outcome.[200]

Actinomycosis

More than 50% of patients with thoracic actinomycosis have pleural involvement.[201] In one series of 15 patients, 6 had pleural effusion, and an additional 6 had marked pleural thickening.[201] The characteristic chest radiographic finding is a localized lung lesion extending to the chest wall with pleural thickening or effusion. The pleural fluid with actinomycosis may be either frank pus with predominantly polymorphonuclear leukocytes or serous fluid with predominantly lymphocytes.

The diagnosis of actinomycosis should be considered when a chronic infiltrative pulmonary lesion extends to adjacent lobes through intralobar fissures. The presence of chest wall abscesses or draining sinus tracts suggests the diagnosis, as do bone changes consisting of periosteal proliferation or bone destruction. The definitive diagnosis is established with the demonstration of *Actinomyces israelii* by anaerobic cultures. Patients with pleural actinomycosis should be treated with high doses of penicillin or another suitable antimicrobial for prolonged periods. The management of the pleural effusion is similar to that for patients with any other bacterial pneumonia.

Nocardiosis

Pleural effusions develop in approximately 50% of patients with pulmonary nocardiosis.[202] Patients with pleural effusion secondary to nocardiosis almost always have an associated parenchymal infiltrate. The pleural fluid can range from serous fluid to frank pus, and pleural fluid cultures may or may not be positive. Because most patients who develop nocardiosis are immunosuppressed,[202] this diagnosis should be considered in the immunosuppressed patient with a parenchymal infiltrate and a pleural effusion. The diagnosis is established with aerobic cultures, which should be observed for at least 2 weeks, because *Nocardia asteroides* is a slow-growing organism. Patients with pleural nocardiosis should be treated with sulfonamides or suitable alternative antimicrobials, and the pleural effusion should be managed as any pleural effusion complicating a pneumonia.

Fungal Infections

Fungal infections of the lungs are discussed in Chapter 36. This section considers the pleural complications of aspergillosis, blastomycosis, coccidioidomycosis, cryptococcosis, and histoplasmosis. In addition, *Pneumocystis jirovecii* (formerly *carinii*) has been included.

Aspergillosis

The pleural space occasionally becomes infected with *Aspergillus*, usually *Aspergillus fumigatus*.[203] Pleural aspergillosis usually arises in one of two settings. Most commonly, it occurs in patients who were treated in the past with artificial pneumothorax therapy for tuberculosis. Pleural aspergillosis may also complicate lobectomy or pneumonectomy, in which situation, a bronchopleural fistula is almost always present.

The diagnosis of pleural aspergillosis should be suspected in any patient with a history of artificial pneumothorax therapy for tuberculosis who has signs and symptoms of a chronic infection, such as weight loss, malaise, low-grade fever, and chronic cough. The chest radiograph reveals increasing degrees of pleural thickening and usually an air-fluid level in the pleural space, indicating the presence of a bronchopleural fistula.[203] In some patients, fungus balls or mycetoma may be evident in either the lungs or the pleural space. The diagnosis is confirmed by the demonstration of *Aspergillus* on fungal cultures of the pleural fluid. Patients with pleural aspergillosis almost always have positive precipitin blood test results for antibodies against *Aspergillus*.

The optimal treatment for pleural aspergillosis is surgical removal of the involved pleura and resection of the involved lobe or the entire ipsilateral lung, if necessary.[203] Lung resection is usually necessary because the infection tends to invade and destroy the underlying lung. Surgery should be performed as early as possible to avoid progressive destruction of the lung. Itraconazole or amphotericin B should be administered systemically before and after the surgery to prevent postoperative pleural infection with *Aspergillus*. Some patients with pleural aspergillosis are too debilitated to undergo a major surgical procedure. Such patients should undergo open drainage (Eloesser flap) with daily insertion of gauze impregnated with amphotericin B.[204]

The clinical picture of postoperative *Aspergillus* pleural infections is similar to that of other postpneumonectomy infections. Once the diagnosis is established, a chest tube should be inserted, and the pleural space should be irrigated daily with 25 mg of amphotericin B or 75,000 U of nystatin. Over an extended period, most patients are cured with this treatment.

Blastomycosis

Infection with *Blastomyces dermatitidis* produces a pleural effusion in about 10% of patients, and an additional 40% or more have pleural thickening.[205] Patients with pleural blastomycosis have signs and symptoms similar to those of tuberculous pleuritis. The pleural fluid is usually an exudate with predominantly small lymphocytes, although polymorphonuclear leukocytes may predominate. Because pleural biopsy may reveal noncaseating granulomas, one should consider the diagnosis of blastomycosis in patients with a clinical picture compatible with tuberculous pleuritis and granulomas on pleural biopsy. The diagnosis is established by demonstrating the organism in secretions, pleural fluid, or histologic sections. Patients with pleural blastomycosis should be treated with itraconazole or amphotericin B, as described in Chapter 36.

Coccidioidomycosis

Two types of pleural disease arise in association with coccidioidomycosis. The first is associated with a primary benign infection and may or may not have concomitant parenchymal involvement. The second occurs when a coccidioidal cavity ruptures to produce a hydropneumothorax.

Primary Coccidioidomycosis. The incidence of pleural effusion in hospitalized patients with primary coccidioidomycosis is about 15%.[206] Most patients are febrile and have pleuritic chest pain. The pleural effusion is almost always unilateral and can occupy more than 50% of the hemithorax.[206] There is a coexisting parenchymal infiltrate in about 50%. The pleural fluid is an exudate containing predominantly small lymphocytes and frequently eosinophils; at times, the pleural fluid is pus.[206] Pleural fluid cultures are positive for *Coccidioides immitis* in about 20%, whereas cultures of pleural biopsy specimens are almost always positive.

Most patients with primary coccidioidomycosis and pleural effusion require no systemic antifungal therapy. Only patients with a negative skin test result or other evidence of dissemination should be treated. The complement fixation titers are usually high in patients with coccidioidal pleural effusion, and a high titer alone should not be used as an indication for treatment.

Rupture of Coccidioidal Cavity. Hydropneumothoraces develop in 1% to 5% of patients with chronic cavitary coccidioidomycosis. The rupture of the cavity into the pleural space is usually heralded by the development of an acute illness with systemic signs of toxicity. These patients should undergo tube thoracostomy immediately to drain the air and fluid from the pleural space. Most patients require a thoracotomy with a partial or total lobectomy, and most require some degree of decortication.

Cryptococcosis

Pleural involvement with cryptococcosis appears to result from extension of a primary subpleural cryptococcal nodule into the pleural space. About 50% of patients with pleural cryptococcosis have disseminated disease, and most have an accompanying parenchymal abnormality. Most patients who have a cryptococcal pleural effusion are immunosuppressed, and many of the patients have acquired immunodeficiency syndrome (AIDS).[207,208] The pleural fluid is an exudate, usually with a predominance of small lymphocytes.

Not all patients with pleural cryptococcosis require treatment with systemic antifungal therapy. Treatment should be initiated in patients with cryptococcal antigen in their blood or CSF; in immunosuppressed patients, including those with AIDS; and in those with enlarging effusions, especially if pleural cell counts and LDH concentrations are increasing.[53]

Histoplasmosis

Pleural effusion is rare with histoplasmosis. In one review of 259 patients with pulmonary histoplasmosis, only 1 had a pleural effusion.[209] Patients with pleural effusions secondary to histoplasmosis usually have a subacute illness characterized by low-grade fever and pleuritic chest pain. The chest radiograph usually reveals an infiltrate or a subpleural nodule in addition to the pleural effusion.[210] The pleural fluid is an exudate in which

lymphocytes predominate, and the pleural biopsy usually reveals noncaseating granulomas. No systemic treatment is usually necessary for a pleural effusion secondary to histoplasmosis because the effusion normally resolves spontaneously over several weeks. Systemic therapy should be administered if the effusion persists over 3 to 4 weeks or if the patient is immunosuppressed (see Chapter 36).

Pneumocytis jirovecii

Pleural effusions are rare in patients with *P. jirovecii* pneumonia (see Chapter 80), but they have been reported. The pleural effusion appears to be an extension of the pulmonary process, and concurrent pneumothoraces are common. The pleural fluid is an exudate with a relatively low protein level but an LDH level above the upper normal limit for serum. At times, organisms can be visualized in the pleural fluid.

Viral Infections

Viral infections probably account for a sizable percentage of undiagnosed exudative pleural effusions. However, the diagnosis is rarely established because it usually depends on the isolation of the virus or the demonstration of a significant increase in antibody titers to the virus. These studies are not routinely obtained on patients with undiagnosed pleural effusions.

Primary Atypical Pneumonia

The incidence of pleural effusions with so-called primary atypical pneumonia (usually caused by *Mycoplasma* or viruses) is as high as 20%.[211] The effusions associated with atypical pneumonia are usually small, are exudative, and contain predominantly neutrophils. Thoracentesis should be performed in such patients to exclude a complicated parapneumonic effusion.

Other Viruses

Viral infection is probably responsible for a much higher percentage of pleural effusion without parenchymal infiltrates than is generally recognized. In one epidemic, 559 soldiers in Turkey had an acute febrile illness characterized by pleuritic chest pain and a mononuclear cell–predominant pleural effusion without parenchymal infiltrates. No pathogens were demonstrated, and it was assumed that this self-limited disease was due to a virus, although serologic studies were not performed.[212]

Almost all patients with the hantavirus pulmonary syndrome (see Chapter 31) have a pleural effusion. Initially, the fluid is a transudate, probably resulting from cardiac dysfunction, but subsequently, the fluid becomes exudative.[213] Almost all patients with severe cases of dengue hemorrhagic fever also have pleural effusions, which are either right-sided or bilateral.[214] Pleural effusions have also been reported to result from infection with hepatitis, infectious mononucleosis, respiratory syncytial virus, influenza viruses, measles after the administration of inactivated virus vaccine, cytomegalovirus, herpes simplex virus, and Lassa fever virus.

Acquired Immunodeficiency Syndrome

As discussed in Chapter 80, pleural effusions occur in patients with AIDS, although less commonly than parenchymal infiltrates. In a series of 1225 consecutive hospital admissions of patients with AIDS in Jacksonville, FL, the incidence of pleural effusion was 15%.[215] The distribution of the diseases responsible for pleural effusions in patients with AIDS varies widely from series to series. In series from industrialized countries that included predominantly intravenous drug users, the most common cause is parapneumonic effusions; in contrast, in series with predominantly homosexuals, the most common cause is Kaposi's sarcoma. In series from Africa, tuberculosis is the most common cause.[216] Other causes of pleural effusions in patients with AIDS include body-cavity lymphoma, *P. jirovecii* (formerly *carinii*), opportunistic infections, renal failure, and CHF.

Patients with AIDS and parapneumonic effusions should be managed as any patient with a parapneumonic effusion, but the incidence of complicated parapneumonic effusion is higher in patients with AIDS.[217] The incidence of pleural effusion with pulmonary Kaposi's sarcoma is approximately 50%. Most patients with a pleural effusion due to Kaposi's sarcoma have bilateral parenchymal infiltrates. The diagnosis of pleural involvement is difficult and often depends on the demonstration of pulmonary Kaposi's sarcoma, by either bronchoscopic examination, high-resolution CT, or thoracoscopy. The pleural fluid is an exudate that is usually serosanguineous or hemorrhagic. Pleural fluid cytologic examinations are invariably negative with pleural Kaposi's sarcoma; pleural biopsy results are also usually negative because the parietal pleura is not involved.

Patients with AIDS with an exudative pleural effusion should have a diagnostic thoracentesis that includes bacterial, mycobacterial, and fungal cultures and measurement of the pleural fluid ADA or IFN-γ. If this does not establish a diagnosis, consideration should be given to performing thoracoscopy, at which time, a pleurodesis may be considered in symptomatic patients.

Parasitic Diseases

Parasitic infections of the lungs are discussed in Chapter 37. Those that may also involve the pleura—amebiasis, echinococcosis, and paragonimiasis—are also considered in this section.

Amebiasis

Pleural effusions arise by two different mechanisms in conjunction with amebic liver abscess. First, an amebic liver abscess may irritate the diaphragm and produce a sympathetic pleural effusion in a manner analogous to that of pyogenic liver abscess. Second, a pleural effusion develops when an amebic liver abscess ruptures into the pleural space through the diaphragm.[218]

The sympathetic effusion caused by pleural irritation by the amebic liver abscess is more common than the effusion caused by rupture of an abscess through the diaphragm.[218] The pleural fluid has not been well characterized. The diagnosis can be established by positive gel diffusion, indirect hemagglutination, or enzyme-linked immunosorbent assay (ELISA) tests, the results of which are positive in more than 98% of patients with extraintestinal invasive amebiasis.[218] Patients with amebic abscess and a sympathetic pleural effusion should be treated with antiamebic drugs, as described in Chapter 37.

The transdiaphragmatic rupture of an amebic liver abscess is usually heralded by an abrupt exacerbation of pain in the right upper quadrant and may be accompanied by a tearing sensation.[219] Shortly thereafter, progressive respiratory distress, sepsis, and occasionally shock develop. The pleural effusion is frequently massive, with opacification of the entire hemithorax and shift of the mediastinum to the contralateral side.[219] The diagnosis of amebic abscess with transdiaphragmatic rupture is suggested by the discovery of "anchovy paste"– or "chocolate sauce"–like pleural fluid on diagnostic thoracentesis. Patients with transdiaphragmatic rupture should undergo tube thoracostomy. The patients should also be treated with the same antiamebic drugs recommended for patients with amebic sympathetic effusions. Because bacterial infection of the pleural space complicates the process in about one third of patients, bacterial cultures of the pleural fluid should be obtained routinely. If bacterial infection is present, appropriate antibiotic therapy should be initiated.

Echinococcosis

Pleural involvement with hydatid disease can develop in one of three situations: (1) a pulmonary hydatid cyst may rupture into the pleural space; (2) a hepatic hydatid cyst or, on rare occasions, a splenic cyst may rupture through the diaphragm into the pleural space; or (3) the pleura maybe be primarily involved by the slowly enlarging cyst.[220] When a cyst ruptures into the pleural space, either an empyema or a pneumothorax can result.[220] In a series of 474 patients with pulmonary hydatid disease, 6% had pleural thickening or effusion.[221]

When a hydatid cyst ruptures into the pleural space, the patient develops acute symptoms, with sudden tearing chest pain, dyspnea, and shock from the antigenic challenge to the body. The cyst frequently also ruptures into the tracheobronchial tree, producing a bronchopleural fistula with a hydropneumothorax that may become secondarily infected.

The diagnosis of pleural echinococcosis is established by the demonstration of echinococcal scolices with hooklets in the pleural fluid or the pleural biopsy specimen. Eosinophils are frequently present in the pleural fluid unless it is secondarily infected. Patients with pleural echinococcosis should be immediately subjected to thoracotomy to remove the parasite, to excise the original cyst, and to close the bronchopleural fistula.[220] Patients with hydatid cysts should be treated with antiprotozoal therapy if all the cysts cannot be removed or when rupture of a cyst has occurred.

Paragonimiasis

Pleural disease is common with paragonimiasis (see also Chapter 37). In one series of 71 patients, 43 (61%) had pleural disease, including 20 with unilateral pleural effusions, 6 with bilateral pleural effusions, 6 each with unilateral and bilateral hydropneumothorax, and 5 with pleural thickening.[222] Paragonimiasis can occur in natives of the United States who have never left the country.

Patients with pleural paragonimiasis present with a chronic illness. There is a concomitant parenchymal infiltrate in approximately 50% of patients. The pleural fluid in patients with pleural paragonimiasis is characteristic. It is an exudate with a glucose level of less than 10 mg/dL (0.56 mmol/L), an LDH level of more than three times the upper limit of normal for serum, a pH below 7.10, and a differential revealing a high percentage of eosinophils.[66] In addition, cholesterol crystals are frequently present.[66] Pleural paragonimiasis is one of only two conditions in which the pleural fluid is characterized by a low pH, a low glucose level, and many eosinophils; the other is Churg-Strauss syndrome. Usually, there are no ova in the pleural fluid.

The diagnosis of pleural paragonimiasis is strongly suggested by the unique pleural fluid findings. The diagnosis is established definitively by demonstrating the typical operculated eggs in sputum, stool, or pleural fluid. A complement fixation titer above 1:8 for *Paragonimus westermani* is strongly suggestive of the diagnosis.[66] The treatment for paragonimiasis is discussed in Chapter 37.

Pulmonary Embolism

The diagnosis most commonly overlooked in the differential diagnosis of a patient with an undiagnosed pleural effusion is pulmonary embolism. It has been estimated that at least 500,000 persons develop venous thromboembolism annually in the United States. Because at least 30% of patients with pulmonary emboli have an associated pleural effusion,[223] over 150,000 pleural effusions secondary to pulmonary emboli should occur annually. Therefore, one should expect to see more cases of pleural effusion secondary to pulmonary embolization than to bronchogenic carcinoma. Nevertheless, in most large series, pulmonary embolization accounts for fewer than 5% of pleural effusions. The diagnosis and treatment of pulmonary embolism are discussed in Chapter 51.

Clinical Manifestations

Patients with pulmonary embolism can be divided into three categories, depending on their presenting symptoms: (1) pleuritic pain or hemoptysis, (2) isolated dyspnea, and (3) circulatory collapse. In the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, 56% of the patients with pleuritic pain or hemoptysis had pleural effusion, and 26% of those with isolated dyspnea had pleural effusion, but none of the patients with circulatory collapse had pleural effusion.[223]

Approximately 50% of patients with paraembolic effusions have parenchymal infiltrates seen on chest radiographs.[224] The infiltrates are usually in the lower lobes, are pleural-based, and are convex toward the hilum. Paraembolic effusions are usually small; in one series, 48 of 56 patients (86%) had only blunting of the costophrenic angle, and no patient had an effusion that occupied more than one third of a hemithorax.[223] The pleural effusions may be unilateral or bilateral. In one study of 63 patients with pulmonary emboli and pleural effusion, the effusions were bilateral in 16 (25%).[225] Interestingly, in other studies using spiral CT angiography in patients suspected of having pulmonary embolism, those patients found to have pulmonary embolism were no more likely to have pleural effusions than those without embolism (50% vs. 58%[226]; 57% vs. 56%[227]). Patients suspected of having pulmonary embolism likely have other underlying conditions that predispose them to pleural effusions, such as CHF or pneumonia.

Pleural fluid analysis is of limited value in establishing the diagnosis of paraembolic effusion because there is nothing characteristic about the fluid. The pleural fluid is almost always an exudate.[63] The pleural fluid red blood cell count exceeds 100,000/μL in fewer than 20% and is below 10,000/μL in at least 30%. The pleural fluid white blood cell count can vary from under 100 to over 50,000/μL. The differential white blood cell count may reveal predominantly polymorphonuclear leukocytes or mononuclear cells.

Diagnosis

The diagnosis of pulmonary embolism is discussed in Chapter 51. The possibility of pulmonary embolization should be considered in every patient with a pleural effusion, even in the patient with obvious CHF. In an autopsy series of 290 patients with CHF and pleural effusion, 60 (21%) had pulmonary emboli.[132] When a paraembolic effusion is strongly suspected, the patient should be started on heparin treatment and a test for pulmonary embolism should be performed before a thoracentesis is attempted.[157]

In the patient with an undiagnosed pleural effusion for whom pulmonary embolism is suspected, CT angiography appears to be the preferred test because it also provides information about the lung parenchyma, the mediastinum, and the pleural surfaces that may provide clues to the etiology of the pleural effusion. Another reason to obtain the CT scan rather than a perfusion scan in patients with pleural effusions suspected of having pulmonary emboli is that the presence of the effusion makes the lung scan more difficult to interpret.

Treatment

The treatment of the patient with a paraembolic effusion is the same as for any patient with pulmonary emboli (see Chapter 51). The presence of bloody pleural fluid is not a contraindication to the administration of heparin or, if indicated, thrombolytic therapy.[224] Paraembolic effusions usually reach their maximum size within the first 3 days.[228] If the effusion increases in size after this time, the patient probably has recurrent emboli, a pleural infection, or a hemothorax and thus, a diagnostic thoracentesis should be performed. If the pleural fluid hematocrit value is greater than 50% of the peripheral hematocrit, a hemothorax is present. In this instance, anticoagulation should be discontinued, and tube thoracostomy should be performed.

Abdominal Diseases

As discussed in Chapter 83, many abdominal diseases can cause pulmonary signs and symptoms. This section describes the most important of these disorders that cause pleural effusion. The pleural effusions occurring in patients with chronic liver disease and ascites and in those with infectious hepatitis have already been discussed.

Esophageal Perforation

The diagnosis of esophageal rupture should always be considered in the differential diagnosis of exudative pleural effusions because, if this condition is not rapidly treated, the mortality increases, with current estimates ranging between 30% and 60%. Approximately 60% of patients with esophageal perforation have a pleural effusion, whereas about 25% have a pneumothorax.[229] The pleural effusion is usually left-sided (Fig. 73-9), but it might be right-sided or bilateral.

Esophageal perforation most commonly occurs as a complication of esophagoscopy and is more likely to occur when there is an attempt to remove a foreign body or to dilate an esophageal stricture.[230] Overall, the incidence of esophageal perforation with esophagoscopic

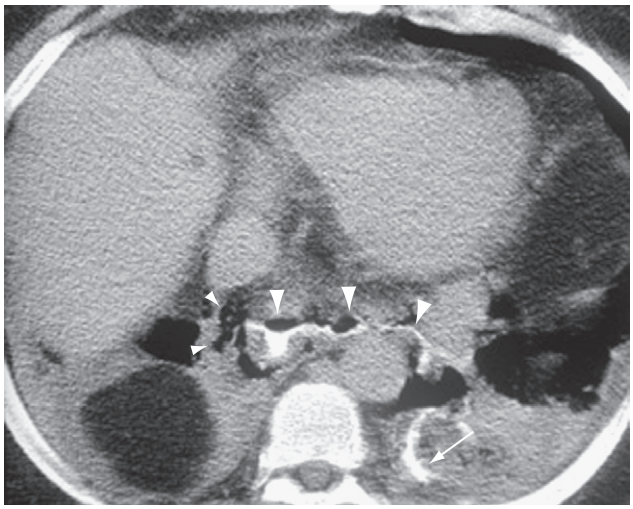

FIGURE 73-9 ■ Effusion due to esophageal perforation. Axial CT image through the lower thorax in a patient with chest pain shows pneumomediastinum (*small arrowheads*) and leakage of water-soluble oral contrast from the ruptured esophagus (*large arrowheads*) through the mediastinum into the left pleural space (*arrow*). (From Fadoo F, Ruiz DE, Dawn SK, et al: Helical CT esophagography for the evaluation of suspected esophageal perforation or rupture. AJR Am J Roentgenol 182:1177–1179, 2004.)

examination is 0.15% to 0.70%.[229] The insertion of a Blakemore-Sengstaken tube for esophageal varices can be complicated by esophageal rupture. Frequently, the diagnosis is missed in these patients because of the severity of their illness and the multiple coexisting problems.[229] Esophageal perforation may also result from transesophageal echocardiography, foreign bodies, esophageal carcinoma, gastric intubation, chest trauma, chest surgery, or vomiting (Boerhaave's syndrome).

Clinical Manifestations. The symptoms associated with esophageal perforation result from the acute mediastinitis produced by contamination of the mediastinum by the oropharyngeal contents. Most of the morbidity from esophageal perforation is caused by infection of the mediastinum and the pleural space by the oropharyngeal bacterial flora.[91]

A patient with an esophageal perforation is usually acutely ill. With a spontaneous rupture, there is frequently a sensation of tearing or bursting in the lower part of the chest or the epigastrium. The chest pain is characteristically excruciating and is often unrelieved by opiates. More than 50% of patients have small amounts of hematemesis. The presence of subcutaneous emphysema in the suprasternal notch is suggestive of the diagnosis. However, less than 10% of patients have subcutaneous emphysema within the first 4 hours of rupture.[231] When the esophagus is perforated during esophagoscopy, the endoscopist generally does not realize it; however, the patients usually develop persistent chest or epigastric pain within a few hours after the procedure.

Diagnosis. The diagnosis of esophageal rupture should be considered in all acutely ill patients with an exudative pleural effusion. The best screening test for esophageal rupture appears to be the level of amylase in the pleural fluid.[231] The pleural fluid amylase level is elevated owing to saliva, with its high amylase content, entering the pleural space.[90] The pleural fluid pH is usually decreased below 7.00 in patients with pleural effusion secondary to esophageal perforation due to the intense inflammatory response resulting from the mediastinitis and not the regurgitation of gastric juice into the pleural space. The demonstration of either squamous epithelial cells or food particles in the pleural fluid is highly suggestive of the diagnosis. Other findings suggestive of esophageal rupture are a chest tube output more than 500 mL/day or polymicrobial flora in the pleural fluid. The diagnosis is established when esophageal perforation is confirmed by contrast studies of the esophagus (see Fig. 73-9).

Treatment. The treatment of mediastinitis from esophageal perforation and other causes is discussed in detail in Chapter 83.

Pancreatic Disease

Three different types of nonmalignant pancreatic disease can have an accompanying pleural effusion: acute pancreatitis, chronic pancreatitis with pseudocyst, and pancreatic ascites.

Acute Pancreatitis. In a study of 133 patients with their first attack of acute pancreatitis, 50% of the patients had a pleural effusion on chest CT scan.[232] The effusion was bilateral in 51 (77%), unilateral left-sided in 10 (15%), and unilateral right-sided in 5 (8%). Patients with acute pancreatitis and a pleural effusion had more severe disease and a higher mortality rate than did those without effusions.[232] The exudative pleural effusion accompanying acute pancreatitis results from the diaphragmatic inflammation and transdiaphragmatic transfer of the exudative fluid arising from acute pancreatic inflammation.

The clinical picture is usually dominated by abdominal symptoms, including pain, nausea, and vomiting. However, at times, respiratory symptoms consisting of pleuritic chest pain and dyspnea may dominate the clinical picture. In addition to the small to moderate-sized pleural effusion, the chest radiograph may reveal an elevated diaphragm and basilar infiltrates. Demonstration of an elevated pleural fluid amylase level is highly suggestive of the diagnosis, but the diagnosis of esophageal rupture must be excluded. The pleural fluid is an exudate with predominantly polymorphonuclear leukocytes and a normal glucose level.

Patients with pancreatitis and a pleural effusion should be treated for their pancreatitis in the usual manner (see Chapter 83).

Chronic Pancreatic Pleural Effusion. Patients with chronic pancreatic disease sometimes have a large chronic pleural effusion. If the pancreatic ductal system is disrupted, a pseudocyst may form in the pancreas. A sinus tract may extend from the pseudocyst through the aortic or esophageal hiatus into the mediastinum. Once the sinus tract reaches the mediastinum, the process may be contained to form a mediastinal pseudocyst or it may rupture into one or both pleural spaces, resulting in a large chronic pleural effusion[92] (Fig. 73-10).

The clinical picture of patients with chronic pancreatic disease and pleural effusion is usually dominated by chest symptoms, such as dyspnea, cough, and chest pain. Most patients do not have abdominal symptoms

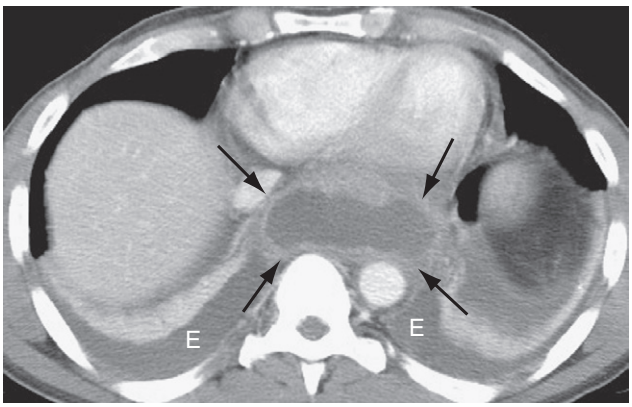

FIGURE 73-10 ■ Effusion due to pancreatic pseudocyst. Axial CT image through the lower thorax in a patient with chronic pancreatitis shows bilateral pleural effusions (E) and a cystic mass in the middle mediastinum (*arrows*) representing a pseudocyst. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

because the pancreaticopleural fistula decompresses the pseudocyst. The pleural effusion is usually massive and recurs rapidly after thoracentesis.[92] The effusion is usually left-sided but may be right-sided or bilateral.

The key to the diagnosis is a markedly elevated pleural fluid amylase level, generally greater than 1000 U/L, whereas the serum level of amylase may be only mildly elevated. Patients with chronic pancreatic pleural disease are generally easily differentiated from those with malignant pleural effusion, who also may have an elevated pleural fluid amylase level, because the amylase level is much higher with the pseudocyst. In rare cases in which the differentiation is not obvious, the diagnosis can be made by measuring amylase isoenzymes because the amylase associated with malignancy is of the salivary, not the pancreatic, type.[94] Both ultrasound and CT are useful in establishing the diagnosis of pancreatic pseudocyst. Endoscopic retrograde cholangiopancreatography usually documents the fistulous tract or other pancreatic pathology.

Patients with chronic pancreatic pleural effusions should be given a trial of conservative therapy for 2 to 3 weeks consisting of nasogastric suction, no oral intake, suppression of pancreatic secretion with atropine, and repeated therapeutic thoracenteses.[92] The administration of a continuous infusion of somatostatin may decrease the secretions through the fistula and facilitate closure.[233] Conservative treatment is successful within 4 weeks in about 40% of patients. If conservative treatment fails, a laparotomy should be performed. The anatomy of the pancreatic ductal system should be assessed before surgery with endoscopic retrograde cholangiopancreatography or at the time of operation with operative pancreatography. If a sinus tract is found, it should be ligated or excised. The pancreas should be partially resected, drained with a Roux-en-Y loop, or both, depending on the pancreatographic findings.[92] An alternative approach is to attempt percutaneous abdominal pseudocyst drainage by use of CT guidance. Decortication of the pleura may be necessary for some patients in order to remove the thick pleural peel created by the intense inflammation caused by the presence of pancreatic enzymes.

Pancreatic Ascites. Some patients with pancreatic disease develop ascites characterized by high amylase and protein levels. If such patients should happen to have or develop a defect in their diaphragm, they develop a large pleural effusion as a result of the flow of fluid from the peritoneal cavity to the pleural cavity. The treatment for pancreatic ascites is the same as for pancreatic pleural effusion, except serial paracenteses rather than serial thoracenteses are performed.

Intra-abdominal Abscesses

Pleural effusions frequently occur with intra-abdominal abscesses. The possibility of an intra-abdominal abscess should be considered strongly in any patient with an undiagnosed exudative pleural effusion containing predominantly polymorphonuclear leukocytes, particularly when there are no pulmonary parenchymal infiltrates. The mechanism responsible for the development of the exudative pleural effusion is probably diaphragmatic irritation.

Subphrenic abscess is the intra-abdominal abscess most commonly associated with a pleural effusion; pleural effusions occur in approximately 80% of patients with subphrenic abscess.[234] The approximate incidence of effusions with other intra-abdominal abscesses is 40% in pancreatic abscesses, 30% in splenic abscess, and 20% in intrahepatic abscesses. With pancreatic abscess, the pleural fluid has a high amylase level.

Clinical Manifestations. Subphrenic abscess most commonly develops as a postoperative complication 1 to 3 weeks after intra-abdominal surgery.[234] Splenectomy and gastrectomy are particularly likely to be complicated by left subphrenic abscess. There is no antecedent abdominal surgery in approximately 10% of patients with subphrenic abscess.[234] The abscess may result from perforation of the stomach, duodenum, appendix, colon, or a diverticulum or from diverticulitis, cholecystitis, pancreatitis, or trauma. Most patients have fever, leukocytosis, and abdominal pain, but frequently, there are no localizing signs or symptoms.

Most patients with pyogenic intrahepatic abscesses have fever and anorexia. Abdominal pain is common, but frequently, it is not localized to the right upper quadrant. On physical examination, an enlarged, tender liver can be demonstrated. Laboratory tests reveal leukocytosis, anemia, elevated alkaline phosphatase levels, and hyperbilirubinemia.[235]

Pancreatic abscess usually follows an episode of acute pancreatitis. This diagnosis should be suspected if the patient does not respond to the initial therapy or if fever, abdominal pain, and leukocytosis develop within 3 weeks of the episode of acute pancreatitis. Splenic abscess is uncommon and usually occurs in patients with systemic infection. Bacterial endocarditis is the most common underlying infection.

The pleural fluid that accumulates in patients with intra-abdominal abscesses is an exudate with predominantly polymorphonuclear leukocytes. The pleural fluid white blood cell count may exceed 50,000/μL, but the pleural fluid pH and glucose concentration usually remain above 7.20 and 60 mg/dL (3.33 mmol/L), respectively. Only rarely does the pleural fluid become infected.

Diagnosis and Treatment. The diagnosis of intra-abdominal abscess is best established with an abdominal CT scan.[236] An abdominal CT scan should be obtained in every patient with an undiagnosed exudative neutrophilic pleural effusion if there are no parenchymal infiltrates. The appropriate treatment for a patient with an intra-abdominal abscess and a pleural effusion is drainage of the abscess combined with parenteral antibiotics.

Abdominal Surgery

Approximately 50% of patients undergoing abdominal surgery develop a pleural effusion in the first few days after surgery.[237,238] The incidence of postoperative pleural effusion is greater in patients undergoing upper abdominal surgery, in patients with postoperative atelectasis,

and in patients with free abdominal fluid at surgery.[237,238] The accumulation of pleural fluid within the first 72 hours after abdominal surgery is probably related to either diaphragmatic irritation or transdiaphragmatic movement of intra-abdominal fluid. A postoperative patient with a significant amount of pleural fluid, particularly when associated with fever, should have a diagnostic thoracentesis to rule out pleural infection as a cause of the effusion. In addition, the possibility of pulmonary embolization should be considered. If the effusion develops more than 72 hours after surgery, it is probably not related to the surgical procedure itself, and alternative explanations must be sought, such as pulmonary embolization, intra-abdominal abscess, and hypervolemia.

Liver Transplantation

Most patients who undergo an orthotopic liver transplantation develop a pleural effusion after surgery. In one study, 68% of 300 patients undergoing liver transplantation developed a pleural effusion, and the effusion occupied more than 25% of the hemithorax in 21 patients (7%).[239] The effusion was unilateral right-sided in 153 and bilateral in 53. The effusions are large enough to require therapeutic thoracentesis or tube thoracostomy in approximately 10%.[239] The natural history of these effusions is that they increase in size over the first 3 postoperative days and then gradually resolve over several weeks to several months. The pathogenesis of these effusions is probably related to injury or irritation of the right hemidiaphragm caused by the extensive right upper quadrant dissection. These pleural effusions can be largely prevented if a fibrin sealant is sprayed on the undersurface of the diaphragm around the insertion of the liver ligaments at the time of the transplantation.[240]

Bilious Pleural Effusion

Bilious pleural effusions are due to a fistula from the biliary tree to the pleural space.[241] The fistula may be secondary to trauma, suppurative complications of biliary tract infections, or surgery, particularly when biliary obstruction is present. The diagnosis should be suspected in any patient with an obstructed biliary tract. The pleural fluid usually appears bilious but, at times, the diagnosis may depend on the demonstration that the ratio of pleural fluid to serum bilirubin is greater than 1.0. Appropriate treatment consists of reestablishment of biliary drainage. The incidence of empyema with bilious pleural effusion is approximately 50%. Most patients who have a bilious pleural effusion require decortication and diaphragmatic repair.[53]

Miscellaneous Diseases

Rheumatoid Pleuritis

The pleura is occasionally involved in the course of rheumatoid arthritis. Approximately 5% of patients with rheumatoid arthritis have a pleural effusion, and approximately 20% experience pleuritic chest pain.[95,242] Rheumatoid pleurisy has a striking male predominance, despite the higher prevalence of rheumatoid disease in women; more than 10% of men, but less than 2% of women, with rheumatoid disease have a pleural effusion.[95,242] Additional information about rheumatoid pleuritis and other pulmonary manifestations of rheumatoid arthritis is found in Chapter 58.

Clinical Manifestations. Almost all patients with rheumatoid pleural effusions are older than 35 years. Approximately 80% are men and approximately 80% have subcutaneous nodules. The pleural effusion usually develops only after the arthritis has been present for several years[95] but, on rare occasions, a patient may present with a pleural effusion.

Patients with rheumatoid pleuritis may be asymptomatic or symptomatic with pleuritic chest pain, fever, or both[95,100] and some patients experience dyspnea secondary to the presence of pleural fluid. In most patients, the chest radiograph reveals a small or moderate-sized pleural effusion. In approximately 25% of patients, the effusion is bilateral.[95] With time, the effusion may alternate from one side to the other or may come and go on the same side. Other intrathoracic manifestations of rheumatoid disease are present in up to one third of patients.[95]

Diagnosis. The diagnosis is suggested by the clinical picture of rheumatoid arthritis and the presence of a pleural effusion. The pleural fluid with rheumatoid pleuritis is distinctive, characterized by a glucose level less than 30 mg/dL (1.67 mmol/L), a high LDH level (>twice the upper limit of normal), a low pH (<7.20), and a high rheumatoid factor titer (>1 : 320 and ≥ the serum titer).[100] Occasionally, the pleural fluid glucose is not reduced when the patient is first seen, but serial pleural fluid glucose determinations reveal progressively lower pleural fluid glucose levels. Another interesting characteristic of rheumatoid pleural effusions is their tendency to contain cholesterol crystals or high levels of cholesterol.[243] A unique cytologic appearance of elongated comet-shaped or "tadpole" cells is also considered specific for the diagnosis.[244]

With the characteristic pleural fluid findings, the primary alternative diagnosis to exclude is complicated parapneumonic effusion. The incidence of complicated parapneumonic effusion is high in patients with rheumatoid pleuritis,[245] so this differentiation is important. It is particularly important to examine the Gram stain of the pleural fluid and to culture the fluid both aerobically and anaerobically.

Prognosis and Treatment. The natural history of rheumatoid pleuritis varies. Most patients experience a spontaneous resolution within 3 months, but the effusion is persistent in an occasional patient, and massive pleural thickening sometimes develops. There are no studies that demonstrate that anti-inflammatory therapy has any influence on the course of rheumatoid pleuritis. The results after intrapleural corticosteroids have been mixed.[53] Decortication should be considered in patients with thickened pleura, who are symptomatic with dyspnea. This procedure is particularly difficult in

patients with rheumatoid pleuritis because it is not easy to develop a plane of dissection between the lung and the fibrous peel.

Lupus Pleuritis

Approximately 40% of patients with SLE or drug-induced lupus have a pleural effusion during the course of their disease.[96]

Clinical Manifestations. Most patients with lupus pleuritis have arthritis or arthralgias before the development of a pleural effusion. Almost all patients with lupus pleuritis have pleuritic chest pain, and most are also febrile. Lupus pleuritis frequently develops in association with an exacerbation of the underlying disease. The pleural effusions secondary to lupus are usually small and are bilateral in about 50% of patients.[246]

Many medications have been incriminated for producing drug-induced lupus erythematosus (see Chapter 72).[53] Hydralazine, procainamide, isoniazid, phenytoin, and chlorpromazine are the ones most commonly associated with drug-induced lupus, but there are more that 70 other drugs that possibly induce lupus. The presenting signs, symptoms, and radiographic abnormalities are similar, whether the pleuritis is due to spontaneous or to drug-induced lupus. The symptoms associated with drug-induced lupus characteristically abate within days of discontinuing the offending drug.

Diagnosis. The possibility of lupus pleuritis should be considered in any patient with an exudative pleural effusion of unknown cause. The pleural fluid can contain a predominance of either polymorphonuclear or mononuclear cells, depending on the timing of the thoracentesis in relation to the development of the symptoms.[55] Although it was believed in the past that elevated ANA titers in the pleural fluid were diagnostic of lupus pleuritis, it appears that such elevated titers are neither specific nor sensitive for diagnosing lupus pleuritis.[97,247] The diagnosis is based primarily on the clinical picture and the serologic findings for lupus.

Treatment. In contrast to rheumatoid pleuritis, the pleuritis with SLE responds to corticosteroid administration. It is recommended that patients with lupus pleuritis be treated with oral prednisone, 80 mg every other day, with rapid tapering once the symptoms are controlled. At times, the effusion is large, is symptomatic, and does not respond to corticosteroid therapy. In such a situation, consideration should be given to chemical pleurodesis. Of course, if the patient has drug-induced lupus, the offending drug should be withdrawn.

Post–Cardiac Injury Syndrome

This syndrome, which is also known as the postpericardiectomy or the post–myocardial infarction (Dressler's) syndrome, is characterized by combinations of pericarditis, pleuritis, and pneumonitis that develop after injury to the myocardium or pericardium.[248] In one report, noncomplicated post–cardiac injury syndrome (PCIS) was defined as the presence of temperature greater than 100.5°F, patient irritability, pericardial friction rub, and a small pericardial effusion with or without pleural effusion following cardiac trauma.[249] A complicated PCIS is defined as a noncomplicated PCIS plus the need for hospital readmission with or without the need for pericardiocentesis or thoracentesis.[249] PCIS has occurred after myocardial infarction, cardiac surgery, blunt chest trauma, percutaneous left ventricle puncture, and implantation of a pacemaker.[248] The incidence of PCIS is approximately 1% after myocardial infarction and is somewhat higher after cardiac surgery.[53] The exact pathogenesis of this syndrome is unknown, but it appears to have an immunologic basis.

Clinical Manifestations. The syndrome typically develops about 3 weeks after the injury, but it can occur any time between 3 days and 1 year. The two cardinal symptoms are fever and chest pain. The chest pain often precedes the onset of fever and can vary from an agonizing crush to a dull ache. At times, it may have a pleuritic component. Most patients have a pericardial friction rub, and echocardiography can demonstrate pleural fluid in more than 50% of the patients. Pulmonary infiltrates are present in about 50% of patients, and laboratory evaluation reveals leukocytosis with an elevated erythrocyte sedimentation rate.

A pleural effusion occurs in about two thirds of patients with PCIS.[248] The pleural effusions are bilateral and small in most patients. The pleural fluid is an exudate that is frequently serosanguineous or bloody. The pleural fluid differential may reveal either predominantly polymorphonuclear leukocytes or mononuclear cells, depending on the acuteness of the process.[248]

Diagnosis. The diagnosis of PCIS should be considered in any patient who develops a pleural effusion after injury to the heart. The diagnosis of the syndrome is established by the clinical picture and by excluding CHF, pulmonary embolism, and pneumonia.

Treatment. PCIS usually responds to treatment with anti-inflammatory agents, such as aspirin or indomethacin. Corticosteroids may be necessary in more severe cases.

Post–Coronary Artery Bypass Surgery

More than 600,000 patients undergo coronary artery bypass graft (CABG) surgery in the United States each year. Because approximately 10% of patients who undergo CABG surgery will develop a pleural effusion that occupies more than 25% of their hemithorax in the subsequent month,[250] CABG surgery is one of the more common causes of pleural effusions in the United States. The prevalence of small pleural effusions is high following CABG surgery. In one study, the prevalence of pleural effusions in 47 patients as detected by ultrasound was 89% at 7 days, 77% at 14 days, and 57% at 30 days.[251] In a study of 349 patients post-CABG, the prevalence of pleural effusion on chest radiograph 30 days postoperatively was 62%; 40 of the 349 patients (11%) had an effusion that occupied more than 25% of the hemithorax.[250] The pleural effusions after CABG surgery tend to be left-sided or bilateral, and if bilateral, the effusion is usually larger on the left.[250]

The primary symptom of a patient with a large pleural effusion post-CABG is dyspnea.[250] The presence of either chest pain or fever should alert the physician to an alternative diagnosis. When all patients with large pleural effusions after CABG surgery are considered, the effusions can be divided into those that are bloody and those that are serous. The bloody effusions are probably secondary to bleeding into the pleural space. They reach their maximal size within 30 days of surgery, are frequently associated with pleural fluid or peripheral eosinophilia or both, have a high pleural fluid LDH level,[252] and respond to one or two therapeutic thoracenteses.[252] In contrast, the cause of the serous pleural effusions is unknown. They tend to reach their maximal size more than 30 days after surgery, have more than 50% small lymphocytes, and have a relatively low pleural fluid LDH level.[252] Most of these late effusions can also be managed with one or two therapeutic thoracenteses,[250] but some are very refractory. It is unknown whether anti-inflammatory agents or diuretics are beneficial in the treatment of these effusions.

Other Collagen Vascular Diseases

Pleural effusions occasionally occur in the course of Churg-Strauss syndrome, Wegener's granulomatosis, and Sjögren's syndrome, which are described in detail in other chapters. The pleural disease that occurs with these diseases constitutes a relatively minor portion of the clinical picture.

Lung Transplantation

With lung transplantation, the lymphatics that normally drain the lung are severed. Accordingly, the fluid that normally leaves the lung via these lymphatics likely drains into the pleural space. The presence of chest tubes in the first few days after lung transplantation prevents the accumulation of pleural fluid. Pleural complications such as hemothorax, empyema, and persistent air leak contribute substantially to the postoperative morbidity and mortality. The incidence of pleural effusions at 3 months posttransplant is about 30% to 60%.[253,254] The incidence of effusion at 12 months is less than 10%.[254] The effusions are characteristically a lymphocyte-predominant exudate with a benign course.[253] However, patients who develop complications after lung transplantation are likely to develop pleural effusions. In one study, pleural effusions occurred with 74% of 19 episodes of acute rejection, 88% of 8 instances of chronic rejection, 55% of 11 episodes of infection, and 75% of 4 instances of lymphoproliferative disease.[255] (More details about lung transplantation are provided in Chapter 95.)

Asbestos Exposure

An otherwise unexplained pleural effusion may occur after exposure to asbestos, which may have been brief or intermittent, and in the immediate or distant past. Epler and coworkers[256] reviewed the medical histories of 1135 asbestos workers whom they had followed up for several years and found that 35 (3%) of the workers had pleural effusions for which there was no other ready explanation. The heavier the asbestos exposure, the more likely the patient is to develop a pleural effusion. The pleural effusion sometimes develops within 5 years of the initial exposure but, in one large series, the mean latency was 30 years.[257]

The pathogenesis of the pleural effusion occurring after asbestos exposure is unknown.[10] Asbestos fibers, both long and short, may move from the lung to the pleural space and lodge in the parietal pleura, where they appear to be concentrated in specific locations that correlate with the lymphatic drainage. Here, their presence leads to a continuous low-grade inflammation. This chronic inflammation can either decrease the lymphatic clearance of the pleural space or increase the permeability of the capillaries in the parietal pleura, either of which could lead to the development of an exudative pleural effusion. An immune mechanism has been invoked to explain the fluctuations in the degree of pleuritis with time.[257]

Clinical Manifestations. Patients with pleural effusion secondary to asbestos exposure have surprisingly few symptoms. In the series of Epler and coworkers,[256] 66% had no symptoms. The chest radiograph usually reveals a small to moderate-sized effusion, which is bilateral in about 10%. The pleural fluid is an exudate, and the pleural fluid differential can reveal either predominantly polymorphonuclear leukocytes or mononuclear cells. Interestingly, pleural fluid eosinophilia was present in 15 (52%) of the 29 patients with asbestos pleural effusions for whom pleural fluid differentials were reported.[60]

Diagnosis. The diagnosis of benign asbestos effusion is one of exclusion. It requires the following criteria: history of direct or indirect exposure to asbestos; exclusion of other causes, notably infection, pulmonary embolism, and malignancy; and follow-up of at least 2 years to verify that the effusion is benign.[257]

Prognosis. The natural history of the patient with an asbestos pleural effusion is one of chronicity, with frequent recurrences and sometimes the development of extensive fibrosis of the parietal pleura.[256] On average, the pleural effusion persists for 3 months but eventually clears and leaves no residual pleural disease. Massive pleural fibrosis develops in about 20% of patients, and ipsilateral blunting of the costophrenic angle occurs in another 20%.[256] Rounded atelectasis also develops in about 10% of patients. There is no known treatment for asbestos pleural effusion. Further information about asbestos-induced lung disease is provided in Chapter 65.

Sarcoidosis

The prevalence of pleural effusion with sarcoidosis (see Chapter 59) is about 1%.[258,259] Patients with pleural effusion due to sarcoid usually have extensive parenchymal sarcoidosis and, frequently, extrathoracic sarcoidosis.[258] The symptoms of pleural involvement with sarcoidosis vary; many patients have no symptoms, although an equal number have pleuritic chest pain or dyspnea.

The pleural effusions with sarcoidosis are usually small and are bilateral in approximately one third of cases. The pleural fluid is almost always an exudate, and its cell differential is characterized by predominantly small lymphocytes.[258,259] In the patient with known sarcoidosis, one can attribute the presence of the pleural effusion to sarcoid only when other causes of exudative lymphocyte-predominant pleural effusions, such as tuberculosis, are excluded. The pleural effusion secondary to sarcoidosis may resolve spontaneously, or corticosteroid therapy may be required for its resolution.

Uremia

Uremia may be complicated by a fibrinous pleuritis and pleural effusion.[53] The pathogenesis of the pleural effusion associated with uremia is unclear. It is probably somewhat analogous to that for uremic pericarditis because more than half of the patients with uremic pleuritis also have uremic pericarditis. The incidence of pleural effusions with uremia is approximately 3%. A close relationship does not appear to exist between the degree of uremia and the occurrence of a pleural effusion. The incidence of pleural effusion seen on chest CT in patients who are receiving chronic hemodialysis is approximately 50%. The etiologies of 100 effusions occurring in hospitalized patients with uremia were as follows: heart failure, 46; uremia, 16; parapneumonic, 15; atelectasis, 11; and miscellaneous, 12.[260]

The pleural effusion seen with uremia frequently occupies more than 50% of the hemithorax and is bilateral in about 20% of patients.[261] More than 50% of patients are symptomatic from the pleural disease, with fever (50%), chest pain (30%), cough (35%), and dyspnea (20%) being the most common symptoms. The pleural fluid is an exudate that is frequently serosanguineous or bloody. The differential white blood cell count reveals predominantly lymphocytes.[261] Pleural biopsy specimens invariably demonstrate chronic fibrinous pleuritis.

The diagnosis of uremic pleuritis is one of exclusion in the patient with chronic renal failure. After beginning dialysis, the effusion gradually disappears within 4 to 6 weeks in about 75% of patients. In the remaining patients, the effusion persists, progresses, or recurs. An occasional patient develops marked pleural thickening that may require decortication.

Meigs' Syndrome

Meigs and Cass[262] originally described a syndrome characterized by ascites and pleural effusion in association with solid benign ovarian tumors. Subsequently, it has become apparent that a similar syndrome can occur with benign cystic ovarian tumors, with benign tumors of the uterus (fibromyomas), and with low-grade ovarian malignant tumors without evidence of metastases.[53] The ascites appears to result from the secretion of large amounts of fluid by the tumors. VEGF plays an important role in the pathogenesis of the ascites and pleural fluid, because VEGF levels are high in both the ascites and the pleural fluid.[263] It is thought that the pleural effusion results from the ascitic fluid passing through defects in the diaphragm into the pleural space.

Patients with Meigs' syndrome usually have a chronic illness characterized by weight loss, pleural effusion, ascites, and a pelvic mass. It is important to realize that not all patients with this constellation of symptoms have a disseminated malignancy. Approximately 70% of the effusions are right-sided, and 20% are bilateral. The pleural fluid is usually an exudate with a relatively low white blood cell count (<1000/μL) and occasionally is bloody. The level of CA-125 in the pleural fluid may be elevated, and this should not be taken as an indication of malignancy.[263]

The diagnosis of Meigs' syndrome should be considered in all women who have a pelvic mass, ascites, and a pleural effusion. If the cytology of the pleural fluid is negative in such patients, a diagnostic laparoscopy or an exploratory laparotomy should be performed to determine whether there are peritoneal metastases. The diagnosis is confirmed when the ascites and the pleural fluid resolve after the primary neoplasm is removed and do not recur. The pleural fluid disappears from the chest within the first 2 weeks after surgery.

Endometriosis

An occasional patient with severe endometriosis presents with massive ascites. In one review, 10 of 27 patients (37%) also had a pleural effusion.[264] The effusions are usually right-sided but may be bilateral. The pleural fluid is a bloody or a chocolate-colored exudate. The serum carcinoembryonic antigen level may be elevated, suggesting ovarian carcinoma. Hormonal therapy, including gonadotropin-releasing hormone agonists, may be attempted, but frequently it is ineffective, and many patients require total abdominal hysterectomy plus bilateral salpingo-oophorectomy.[264]

Ovarian Hyperstimulation Syndrome

This syndrome is a serious complication of ovulation induction. The dramatic clinical picture is characterized by massive ovarian enlargement with multiple cysts, hemoconcentration, and the third-space accumulation of fluid.[263] The full-blown syndrome may be complicated by renal failure, hypovolemic shock, thromboembolic episodes, acute respiratory distress syndrome, and death. Although the pathophysiology of this syndrome is incompletely understood, it is likely that the increased capillary permeability is due to the up-regulation of VEGF expression in the ovarian granulosa cells by the exogenous human chorionic gonadotropin.[263]

Patients with the syndrome present within 2 to 3 weeks of receiving the human chorionic gonadotropin. Patients typically present with abdominal pain and distention, nonproductive cough, and dyspnea caused by the ascites, pleural effusion, or both. The pleural effusion is usually bilateral, and the pleural fluid is an exudate with predominantly neutrophils and a relatively low LDH level. The treatment of severe cases requires restoration of intravascular volume, correction of electrolyte abnormalities, and venous thromboembolism prophylaxis.[263]

Yellow Nail Syndrome

This syndrome consists of the triad of deformed yellow nails, lymphedema, and pleural effusions. The three entities may become manifest at widely disparate times and, therefore, are not all concurrently present in every patient. The basic abnormality responsible for this syndrome appears to be hypoplasia of the lymphatic vessels.[265,266]

Typically, the nails are pale yellow to greenish in color and are excessively curved from side to side. They are also thickened and may show transverse ridging or onycholysis (separation of nail from bed). The pleural effusions are bilateral in about 50% of cases and can be massive. Once a pleural effusion has developed with this syndrome, it tends to persist and to recur rapidly after thoracentesis.[265] The pleural fluid is usually a clear exudate with predominantly lymphocytes.[265] The pleural fluid LDH tends to be relatively low relative to the pleural fluid protein level.[53]

The diagnosis is usually established by the presence of the triad of pleural effusion, lymphedema, and yellow nails. The diagnosis may be difficult to establish if the pleural effusion is the first manifestation of the syndrome. There is no specific treatment for the syndrome, but if the effusion is large and is producing symptoms, the effusion can be treated with pleurodesis, parietal pleurectomy, or a pleuroperitoneal shunt.[53]

Drug Reactions Producing Pleural Effusions

Lupus-like syndromes occur in conjunction with the administration of many different medications and have been discussed earlier in this chapter and in Chapter 72. Although there are case reports of pleural disease associated with administration of many drugs,[267] the following drugs are known to induce pleural disease.

Nitrofurantoin. Pleuropulmonary reactions occasionally result from the administration of nitrofurantoin. Such reactions can have an acute or a chronic presentation.[268] The acute presentation occurs within 1 month of initiation of therapy and is manifested by dyspnea, nonproductive cough, and fever. About 20% of patients have an infiltrate and an effusion, and about 3% have only an effusion. Most patients have both peripheral eosinophilia (>350/μL) and lymphopenia (<1000/μL).[269] The chronic syndrome occurs when the patient has been taking nitrofurantoin for 2 months to 5 years and is much less common than the acute syndrome. Pleural effusion occurs in less than 10% of patients, and no patient with the chronic syndrome has had a pleural effusion without an infiltrate.[268]

The diagnosis of nitrofurantoin pleuropulmonary reaction should be suspected in all patients with a pleural effusion who are taking nitrofurantoin. If the drug is discontinued, the patient usually improves clinically within 1 to 4 days, and the chest radiograph becomes normal within a week with the acute syndrome, whereas the time course is much longer for the chronic syndrome.[268]

Dantrolene. Dantrolene sodium is a long-acting skeletal muscle relaxant with a chemical structure similar to that of nitrofurantoin. Its administration can lead to the development of pleural or pericardial disease.[270] The pleural effusion is unilateral and develops 2 months to 12 years after the initial administration of dantrolene. Patients may be febrile and may have pleuritic chest pain. The pleural fluid is an eosinophilic exudate with a normal glucose level.[270] When dantrolene is discontinued, the patient improves symptomatically within days, but it may take several months for the pleural effusion to resolve completely.

Methysergide. The administration of methysergide can lead to a pleuropulmonary disease similar to that seen with nitrofurantoin.[271] Symptoms consisting of chest pain, dyspnea, and fever develop 1 month to 3 years after methysergide therapy is initiated. The chest radiograph commonly shows bilateral loculated pleural effusions and pleural thickening.[271] When methysergide is discontinued, the symptoms of the patients improve. However, in one series of 13 patients, severe pleural fibrosis persisted in the 2 patients who had continued to take the drug for the longest period (18 and 36 mo) after the onset of the pleurisy.[271]

Ergot Alkaloids. The administration of ergot alkaloid drugs such as bromocriptine, ergotamine, dihydroergotamine, nicergoline, pergolide, and dopergine in the long-term treatment of Parkinson's disease can lead to pleuropulmonary changes.[267] As of 1988, a total of 23 patients had been reported. All the patients were men, and the drug had been taken for 6 months to 4 years before symptoms developed. Two to 5% of patients receiving long-term ergot alkaloid therapy develop pleuropulmonary disease. The incidence of pleural disease is higher if the patient has previous exposure to asbestos.[272] The chest radiograph reveals unilateral or bilateral pleural thickening or effusion in most patients. Analysis of the pleural fluid reveals an exudate with predominantly lymphocytes and frequently eosinophilia.[273] The natural history of pleuropulmonary disease during ergot alkaloid therapy is unclear. The disease progresses only in some of the patients who continue taking the drug.[273]

Procarbazine. There have been two detailed case reports in which pleuropulmonary reactions consisting of chills, cough, dyspnea, and bilateral pulmonary infiltrates with pleural effusion occurred after treatment with procarbazine.[53] In both cases, symptoms developed within hours after procarbazine therapy; in both instances, rechallenge with procarbazine again produced the infiltrates and pleural effusions. With discontinuation of the drug, the symptoms and radiographic changes resolved within several days.

Amiodarone. Amiodarone is an antiarrhythmic that may produce severe pulmonary toxicity (see Chapter 72). Pleural effusions occur as a manifestation of amiodarone toxicity, but they are uncommon. Most cases have concomitant parenchymal involvement, but cases have been reported in which there is none.[267] The pleural fluid is an exudate and may have predominantly lymphocytes, macrophages, or polymorphonuclear leukocytes.[267]

Interleukin-2. Recombinant IL-2 is sometimes used in the treatment of malignancies, especially melanoma or renal cell carcinoma. One of the primary side effects

of IL-2 administration is the development of pulmonary infiltrates and pleural effusion that are probably related to a generalized capillary leak syndrome.[53] The incidence of pleural effusion after IL-2 administration is approximately 50%.[267] The characteristics of the pleural fluid have not been described. After the IL-2 therapy is stopped, the effusions tend to disappear. However, in one study, 17% of patients still had a pleural effusion 4 weeks after cessation of therapy.[274]

Dasatinib. Dasatinib is an inhibitor of multiple tyrosine kinase receptors, used primarily for treating adults with chronic myeloid leukemia with resistance to prior therapy. Use of dasatinib is associated with a high incidence of pleural effusion. Qunitas-Cardama and associates[275] reported that effusions occurred in 35% of 135 patients receiving the drug and about half the effusions occupied more than 25% of the hemithorax. The effusions were bilateral in 80% of the patients. The effusions were mostly exudates. The effusions went away when dasatinib was discontinued or when steroids were administered. In a recent study, the effusions were less common when dasatinib was administered once rather than twice per day (14% incidence compared to 23–26% incidence), without loss of efficacy.[275a]

Trapped Lung

Effusions that are remarkably stable over time, recur after thoracentesis, and are resistant to diagnosis may be due to an underlying trapped lung (Fig. 73-11). Following an earlier episode of inflammation, a fibrous peel may form over the visceral pleura and can prevent the underlying lung from expanding fully, thereby "trapping" the underlying lung. The resulting negative pleural pressure leads to the development of a chronic pleural effusion.[276,277]

Patients with a chronic pleural effusion secondary to trapped lung are often asymptomatic but may have symptoms of dyspnea. Symptoms of acute pleural inflammation, such as pleuritic chest pain and fever, are distinctly uncommon, but the patient often gives a history of such events in the past. One characteristic of the pleural effusion secondary to trapped lung is that the amount of fluid is quite constant from one study to another. With trapped lung, the pleural fluid is often a borderline exudate; the ratio of pleural fluid to serum protein is about 0.5, and the ratio of pleural fluid LDH to serum LDH is about 0.6.

The diagnosis of pleural effusion secondary to trapped lung should be suspected in any patient with a stable, chronic pleural effusion, particularly if the patient has a history of uremia, thoracic radiation, or prior thoracic surgery.[277] The thickened visceral pleura can be demonstrated if 200 to 400 mL of air is injected into the pleural space at the time of a thoracentesis. At some institutions, pleural manometry is used routinely during a therapeutic thoracentesis; if the pleural pressure falls rapidly (>14–15 cm H_2O/L pleural fluid removed), air is allowed to enter the pleural space to return the pleural pressure to a more normal range (−5 cm H_2O) so that an air-contrast chest CT scan can be obtained to evaluate the visceral pleura.[277]

The definitive therapy for trapped lung is thoracotomy with decortication. However, this major surgery is indicated only in patients who are symptomatic from the trapped lung. If the patient is asymptomatic or minimally

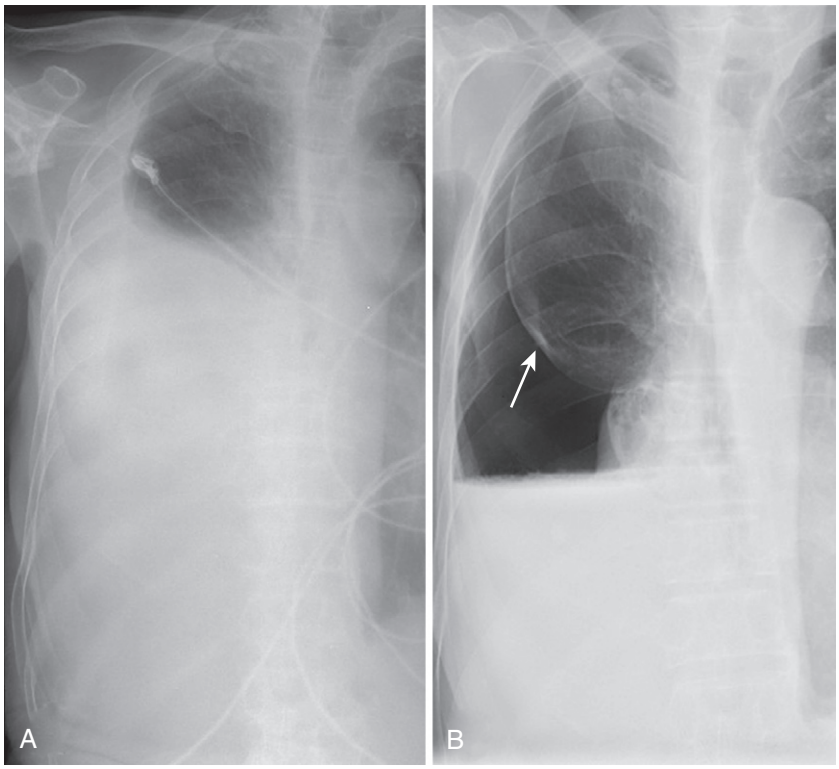

FIGURE 73-11 ■ Effusion with trapped lung. **A,** Frontal chest radiograph shows a large right pleural effusion. **B,** On a subsequent radiograph, the effusion has been partially drained, revealing the underlying lung with some visceral pleural thickening (*arrow*). The lung failed to reexpand despite negative intrapleural pressures. The intrapleural air entered the pleural space from the atmosphere along the drainage track. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

symptomatic, the patient can be observed if the clinical picture, pleural fluid findings, and pleural pressure measurements are all compatible with the diagnosis of trapped lung.

Pleural Effusions Due to Misplaced Catheters

Both internal jugular and subclavian vein catheterization can be complicated by misplacement of the catheter tip into the mediastinum or pleural space that results in a large unilateral or bilateral pleural effusion. The pleural fluid may have the characteristics of the intravenous fluid, or it may be bloody from laceration of the blood vessels.[278] If the patient is receiving lipids through a central line, the fluid may look chylous.[279] The diagnosis of a misplaced central venous catheter should be considered in all patients with such lines who rapidly develop pleural effusions, and the patients should be evaluated by diagnostic thoracentesis.

Small pleural effusions may also develop after translumbar aortographic examination and after percutaneous transhepatic coronary vein occlusion. The effusions in these circumstances are usually small and resolve spontaneously.

In the past several years, the development of soft, flexible, small-bore polyurethane feeding tubes has made nasogastric and nasoenteric feeding more practical and comfortable for patients. However, misplacement of these tubes can lead to serious pleural complications. Pneumothorax is the most common complication, but infusion of the enteral formula into the pleural space, or the development of an empyema, or both, also occur relatively frequently.[280] These small flexible tubes are inserted with a stylet in place that enables easier advancement of the device. However, with the stylet in place, the tubing becomes stiff enough that it can perforate structures relatively easily. The risk is much greater if the patient has an endotracheal tube in place or is obtunded.[280] To prevent these complications, these tubes should be inserted only by experienced persons, and the tube should be immediately removed if the patient starts coughing. The tube should not be advanced if resistance is felt, and before feeding is initiated, the position of the tip of the tube should be confirmed radiographically.[281,282] If enteral solutions enter the pleural space, tube thoracostomy should be performed to remove the solution. In addition, the patient should be carefully observed for the development of an empyema.[280]

KEY POINTS

- Entry of normal fluid into the pleural space is slow, consistent with that found in other interstitial spaces of the body. Exit of fluid is mainly via parietal pleural lymphatics, which have a large reserve capacity and can accommodate increases in fluid formation without the development of an effusion.
- Pleural effusions develop when disease or combinations of diseases lead to an increase in fluid entry into the pleural space and a decrease in removal from the pleural space; both changes may be necessary for formation of an effusion.
- Excess fluid anywhere in the body can move to and enter the pleural space due to (1) subatmospheric pleural pressure (−5 to −30 cm H_2O), (2) the leaky mesothelial layer, (3) the high capacitance of the pleural space.
- Transudates usually result from systemic changes in hydrostatic and/or osmotic pressures that lead to collection of a relatively low protein and LDH fluid (pleural–to–serum protein ratio < 0.5 *and* pleural/serum LDH < 0.6 *and* LDH < two thirds the upper limit of normal [Light's criteria]).
- Transudates with a *very* low protein concentration (<0.5 g/dL) come from entry of CSF, urine, peritoneal dialysis fluid, or intravenous fluids into the pleural space.
- Exudates result from pleural or extrapleural injury or inflammation that can be due to a multitude of inflammatory, infectious, or malignant diseases, leading to effusions with a relatively high protein and/or LDH concentration.
- Most transudates arise from CHF. When the cause is unclear or when the protein and LDH ratios are not clearly transudative, as can happen after diuresis, the NT-BNP is a sensitive and specific marker for a cardiac etiology.
- Most exudates arise from either pneumonia, malignancy, or pulmonary embolism.
- No diagnosis is ever established for approximately 20% of all exudative pleural effusions and many resolve spontaneously, leaving no residua. The degree to which a diagnosis is pursued by invasive procedures will depend on (1) the symptoms and the clinical course of the patient, (2) the trend of the pleural fluid LDH level with time, and (3) the eagerness of the patient for a diagnosis.

INTRODUCTION

A pneumothorax is present when there is air in the pleural space. Pneumothoraces are classified as *spontaneous pneumothoraces,* which develop without preceding trauma or other obvious cause, and *traumatic pneumothoraces,* which develop as a result of direct or indirect trauma to the chest, including diagnostic or therapeutic maneuvers (*iatrogenic pneumothoraces*). Spontaneous pneumothoraces are subclassified as *primary* or *secondary.* A primary spontaneous pneumothorax presents in an otherwise healthy person without underlying lung disease. A secondary spontaneous pneumothorax complicates an underlying lung disease, most commonly chronic obstructive pulmonary disease (COPD).

Most pleural effusions prove to be either an exudate or a transudate according to the criteria provided in Chapter 73. Occasionally, the liquid contents turn out to be chyle, pseudochyle, or blood. This chapter describes the pathogenesis and clinical manifestations of chylothorax, pseudochylothorax, and hemothorax. Fibrothorax, the sequela of chronic organizing pleural disease of any origin, is also considered.

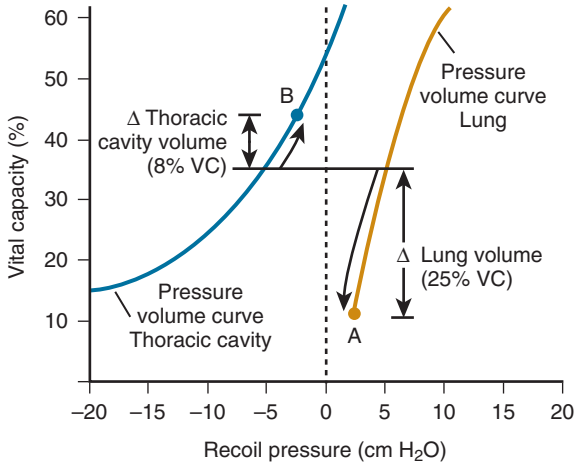

FIGURE 74-1 ■ Influence of a pneumothorax on the volumes of the lung and hemithorax. In this illustration, the pneumothorax has caused the intrapleural pressure to rise from –5 to –2.5 cm H_2O. The lung and thoracic cavity move on their respective pressure-volume curves (*dashed lines*) to new volumes for the lung **(A)** and thoracic cavity **(B).** Note that the volume of the hemithorax becomes larger as the volume of the lung becomes smaller. The changes in volumes of the hemithorax and lung are unequal because of the differences in the slopes of two pressure-volume curves. VC, vital capacity. (Redrawn from Light RW: Pleural Diseases [4th ed]. Philadelphia: Lippincott Williams & Wilkins, 2001, p 286.)

PATHOPHYSIOLOGY OF PNEUMOTHORAX

In normal subjects, the pressure in the pleural space is negative with respect to the alveolar pressure during the entire respiratory cycle. The pressure gradient between the alveoli and the pleural space—the transpulmonary pressure—is the result of the inherent elastic recoil of the lung. During spontaneous breathing, the pleural pressure is also negative with respect to the atmospheric pressure. The functional residual capacity, or resting end-expiratory volume of the lung, is the volume at which the inherent outward pull of the chest wall is equal to, but opposite in direction to, the inward pull (recoil) of the lung.[1]

When a communication develops between an alveolus or other intrapulmonary air space and the pleural space, air will flow from the alveolus into the pleural space until there is no longer a pressure difference or until the communication is sealed. Similarly, when a communication develops through the chest wall between the atmosphere and the pleural space, air will enter the pleural space until the pressure gradient is eliminated or the communication is closed. The influence of a pneumothorax on the volume of the hemithorax and the lung is illustrated in Figure 74-1. In this example, sufficient air has entered the pleural space to elevate the pleural pressure from −5 to −2.5 cm H_2O, so that the transpulmonary or recoil pressure has decreased from 5 to 2.5 cm H_2O. The amount of air necessary to effect this change in the pleural pressure can be seen to be equal to 33% of the patient's vital capacity: most of this pleural air (25% of the vital capacity) is accounted for by air displaced from the lung and the rest is accounted for by the expansion of the thoracic cavity along its pressure-volume curve (by 8% of the vital capacity). The rise in the pleural pressure also causes a shift of the mediastinum to the contralateral side, an enlarged hemithorax, and a depressed hemidiaphragm. These findings are expected and do not necessarily indicate that a tension pneumothorax is present.[1]

The main physiologic consequences of a pneumothorax are a decrease in the vital capacity (as illustrated in Fig. 74-1) and the arterial P_{O_2}. In patients with primary spontaneous pneumothorax, the decrease in the vital capacity is usually well tolerated. If the lung function of the patient is abnormal before the development of the pneumothorax, the decrease in vital capacity may lead to respiratory insufficiency with alveolar hypoventilation and respiratory acidosis.

Most patients with a pneumothorax have a reduced arterial P_{O_2} and an increase in the alveolar-arterial oxygen tension difference. In a series of 12 patients with spontaneous pneumothorax, the arterial P_{O_2} was below 80 mm Hg in 9 (75%) and was below 55 mm Hg in 2 patients, both of whom had secondary spontaneous pneumothorax.[2]

The reduction in arterial P_{O_2} appears to be due to the creation of regions of the lung both with low ventilation-perfusion ratios and with absent ventilation (shunt), and, occasionally, due to alveolar hypoventilation. Norris and coworkers[2] reported that the average right-to-left shunt in their 12 patients with spontaneous pneumothorax was more than 10%. Larger pneumothoraces were associated with greater shunts. When the pneumothorax

occupied less than 25% of the hemithorax, the shunt was not increased.[2]

After air is evacuated from the pleural space, the arterial P_{O_2} usually improves, but the improvement may take several hours. Norris and colleagues[2] evacuated the pleural air from three patients with an initial shunt above 20%; within 90 minutes, the shunt had decreased below 10% but it nonetheless remained above 5% in all patients. The delay in improvement may be related to the duration of the pneumothorax and the time necessary to expand collapsed alveoli.

PRIMARY SPONTANEOUS PNEUMOTHORAX

Incidence

In a study from the United Kingdom, the incidence of spontaneous pneumothorax was 24.0 and 9.8 per 100,000 per year for men and women, respectively,[3] and about one half of the pneumothoraces were primary spontaneous pneumothoraces. Extrapolating from these data, the annual incidence in the United States would be about 22,500.

Etiologic Factors

Primary spontaneous pneumothorax (PSP) is traditionally believed to result from rupture of a subpleural emphysematous bleb, which is usually located in the apex of the lung.[4] Blebs can be found in more than 75% of patients undergoing thoracoscopy for treatment of PSP.[4] The pathogenesis of these subpleural blebs and the trigger(s) of their rupture are unclear. Such blebs have been attributed to congenital abnormalities, inflammation of the bronchioles, and disturbances of the collateral ventilation.[4] There is a strong association between smoking and the development of a PSP. When four separate series of patients with PSP are combined, 461 of 505 patients (91%) with PSP were smokers or ex-smokers.[1] The occurrence of a spontaneous pneumothorax is related to the level of cigarette smoking. In men, the relative risk of a pneumothorax is 7 times higher in light smokers (1 to 12 cigarettes/day), 21 times higher in moderate smokers (13 to 22 cigarettes/day), and 102 times higher in heavy smokers (>22 cigarettes/day) than in nonsmokers.[5] It is probable that smoking-induced disease of small airways contributes to the development of the subpleural blebs.

Patients with PSP tend to be taller and thinner than control persons. In one study, military recruits with a pneumothorax were on average 2 inches taller and 25 pounds lighter than the typical military recruit.[1] An increased length of the chest may contribute to the formation of the subpleural blebs. Because pleural pressure falls about 0.20 cm H_2O per centimeter of vertical height, pleural pressure will be more negative at the apex of the lung in taller people; accordingly, the alveoli at their lung apex are subjected to a greater mean distending pressure. Over an extended period, this could lead to the formation of subpleural blebs in subjects genetically predisposed to bleb formation.

A tendency for the development of a PSP can be inherited. Some cases are due to an autosomal dominant gene with incomplete penetrance, the penetrance being lower in women (21%) than in men (50%). The Birt-Hogg-Dubé syndrome is an autosomal dominant condition characterized by an increased incidence of spontaneous pneumothorax, benign skin tumors, and renal tumors.[6] The genetic abnormality resides on chromosome 17p11.2 and involves mutations in the folliculin gene.[6] Approximately 40% of patients with the mutation will have a pneumothorax.[6] Pneumothorax also occurs with increased frequencies in those with the Marfan syndrome and homocystinuria.

Recent data have challenged the traditional concepts of air leak from one bleb supplied by one single airway. A study using inhaled fluorescein suggested that air may leak from more areas than just the blebs,[7] raising the possibility of "pleural porosity," in which the air leaks from multiple pores on the visceral pleura. Endobronchial one-way valve studies also found that occlusion of multiple segmental bronchi are necessary to stop air leaks.[8] This suggests that air is leaking either via multiple sites or via collateral ventilation, or both.

Clinical Manifestations

PSP most commonly occurs in those in their early 20s, and rarely after age 40. PSP usually develops while the patient is at rest, and rarely during heavy exercise.[1]

Chest pain and dyspnea are the two main symptoms. The chest pain usually has an acute onset and is localized to the side of the pneumothorax. A rare complication of PSP is Horner's syndrome, which is thought to result from traction on the sympathetic ganglion produced by a shift of the mediastinum.

On physical examination, the vital signs are usually normal, with the exception of a moderate tachycardia. A tension pneumothorax should be suspected if the pulse rate exceeds 140 beats/min or if hypotension, cyanosis, or electromechanical dissociation is present. The side with pneumothorax may be larger than the contralateral side and move less during the respiratory cycle. Tactile fremitus is absent, the percussion note is hyperresonant, and the breath sounds are absent or reduced on the affected side. In those with a right-sided pneumothorax, the lower edge of the liver may be shifted inferiorly. With a large pneumothorax, the trachea may be shifted toward the contralateral side.

Diagnosis

The diagnosis is usually suggested by the clinical history and the physical examination. The diagnosis is established by demonstrating a pleural line on the chest radiograph (Fig. 74-2). A visceral pleural line can be distinguished from other lines such as skinfolds by the following criteria. This line is defined by air density on either side of the line, whereas a skinfold is really an edge without air density on either side. A pleural line

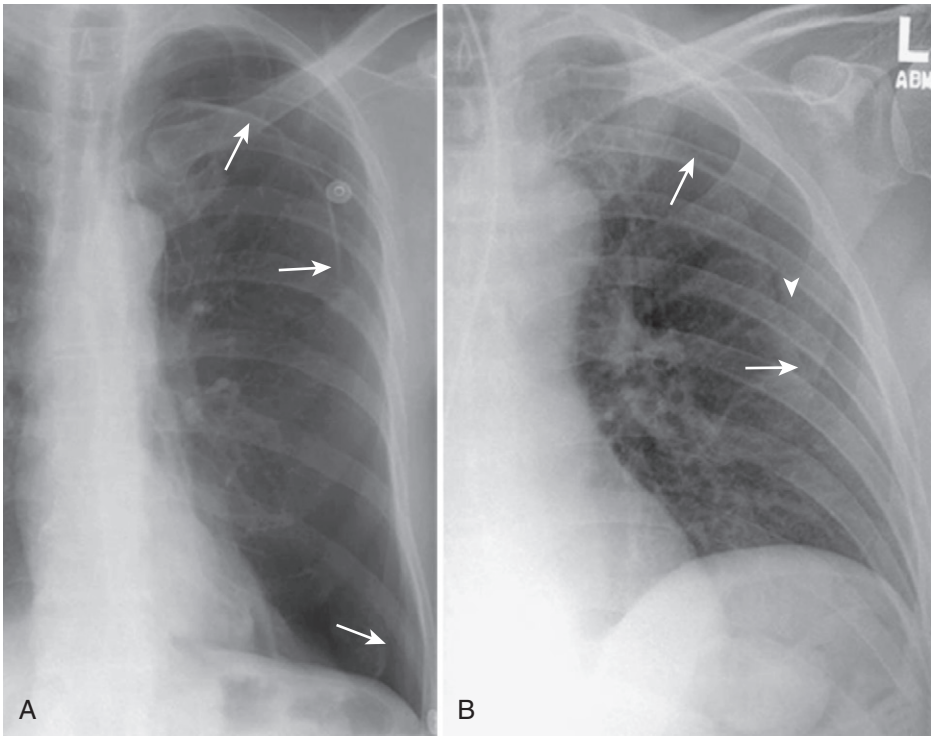

FIGURE 74-2 ■ **A,** Chest radiograph of a pneumothorax. The pleural line has lucency on either side, representing air in the pleural space on one side of the line and air in the lung on the other. The line is sharply demarcated and can be traced along its course (*lower arrow*). No blood vessels can be seen beyond the superior (*upper arrow*) and lateral (*middle arrow*) extent of the line. **B,** Chest radiograph of a skinfold (*arrows*) that could be mistaken for a pneumothorax. The border is more of an edge, with lucency on only one side. The edge is poorly defined and cannot be followed continuously (*lower arrow*). Blood vessels can be traced beyond the border of the fold (*arrowhead*). (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

should generally be sharp and well-defined, whereas a skinfold is often poorly defined, at least on one side. A pleural line can be followed continuously, roughly paralleling the chest wall inner contour so that, in the upright patient, it caps the apex of the lung (assuming no adhesions) and often tapers toward the lung base; a skinfold usually is not continuous, often fades at both ends, and often does not follow an anatomically sensible configuration. Finally, a pleural line should not be crossed by lung vessels, whereas a skinfold can show lung vessels beyond its edge.

In doubtful cases, lateral decubitus films (with the affected side up), or a computed tomography (CT) scan may facilitate the diagnosis. Expiratory films are only slightly more sensitive than inspiratory films in detecting pneumothoraces and are not routinely recommended.[4] A small pleural effusion is associated with a PSP in approximately 15% of cases and is manifested radiographically as an air-fluid level. When the pleural fluid is analyzed, it frequently contains a large percentage of eosinophils.[9] On rare occasions, spontaneous pneumothorax is complicated by brisk bleeding into the pleural space, producing a hemopneumothorax.[10] If the patient's vital signs are unstable in this situation, emergency surgery is indicated.[10]

When one is managing a patient with a pneumothorax, the amount of lung collapse should be estimated. One can first measure the lung and hemithorax "diameter": the distance from the lung root to the visceral pleural line (lung diameter) or to the chest wall (hemithorax diameter). Because the volumes of the lung and the hemithorax are roughly proportional to the cube of their diameters, one can estimate the degree of collapse (percent pneumothorax, or PTX%) by measuring average diameters of the lung and the hemithorax, cubing these diameters, and using the following equation, known as the Light index[1]:

$$\text{PTX\%} = 100\% \times [1 - (\text{diameter of the lung} / \text{diameter of the hemithorax})^3]$$

There is an excellent correlation ($r = 0.84$) between the Light index and the amount of air that can be aspirated from a pneumothorax.[11]

Recurrence Rates

Following a PSP, a patient is at risk of recurrence particularly in the months immediately after the first episode. Sadikot and associates[12] followed 153 patients with PSP for a mean of 54 months and reported that 39% had a recurrent ipsilateral pneumothorax, most within the first year. Of the 153 patients, 15% also developed a pneumothorax on the contralateral side.

There have been several attempts to predict who will develop recurrent pneumothorax. Patients who are tall, patients with a low body mass index, and those who

continue to smoke are more likely to have a recurrence.[13] Yet, there is no relationship between the number of blebs or the size of the blebs on CT, or the appearance of the lung at thoracotomy, and the risk of recurrence.[1] Once a patient has had one recurrence, the risk of another recurrence increases to more than 50% if no measure is taken to prevent the recurrence.[1]

Treatment

There are two goals to managing a patient with a PSP: to rid the pleural space of its air and to decrease the likelihood of a recurrence. Treatment options include observation, supplemental oxygen, simple aspiration of the pneumothorax, simple tube thoracostomy, tube thoracostomy with instillation of a pleurodesing agent, thoracoscopy with oversewing of the blebs and pleurodesis, and open thoracotomy. When selecting treatment for any given patient, it should be remembered that PSP is mainly a nuisance and rarely life-threatening. Recently, the American College of Chest Physicians[14] and the British Thoracic Society[15] have published guidelines on the treatment of spontaneous pneumothorax. The former guideline emphasized how few controlled studies exist on the treatment of pneumothorax.[14]

Observation

Once the communication between the alveoli and the pleural space is eliminated, the residual air in the pleural space will be gradually reabsorbed, albeit slowly. Kircher and Swartzel[16] estimated that 1.25% of the volume of the hemithorax is absorbed each 24 hours. For a patient with a 20% pneumothorax, it will take 16 days for pleural air to be absorbed spontaneously. Therefore, it is recommended that only asymptomatic patients with pneumothoraces occupying less than 15% of the hemithorax be considered for observation treatment. If the patient is hospitalized, supplemental oxygen should be administered to increase the rate of pleural air absorption.

Supplemental Oxygen

In pneumothorax, gases move in and out of the pleural space from the capillaries in the visceral and parietal pleura. The movement of each gas depends on the gradient between its partial pressure in the capillaries and in the pleural space, the blood flow per unit surface area available for gas exchange, and the solubility of each gas in the surrounding tissues. Normally, the sum of all the partial pressures in the capillary blood with a patient breathing room air is about 706 mm Hg (P_{H_2O} = 47, P_{CO_2} = 46, P_{N_2} = 573, and P_{O_2} = 40 mmHg). If it is assumed that the pleural pressure is approximately 0 when there is a pneumothorax, then the net gradient for gas absorption is only 54 mm Hg (760 − 706). If the patient is placed on 100% oxygen, however, the sum of all the partial pressures in the capillary blood will probably fall below 200 mm Hg (the P_{N_2} will approach 0, whereas the P_{O_2} will remain < 100 mm Hg). Accordingly, the net gradient for gas absorption will exceed 550 mm Hg or be 10 times greater than it was with the patient breathing room air.[1]

Indeed, the administration of supplemental oxygen accelerates the rate of pleural air absorption in clinical and experimental situations. Chernick and Avery[17] demonstrated that the administration of humidified 100% oxygen to rabbits with experimentally induced pneumothoraces increased the rate of absorption by about sixfold. Subsequent studies in patients with a spontaneous pneumothorax have demonstrated that pleural air is absorbed about four times faster when the patients are given high concentrations of supplemental oxygen to breathe.[18] It is recommended that hospitalized patients with any type of pneumothorax who are not subjected to aspiration or tube thoracostomy be treated with supplemental oxygen at high concentrations.

Simple Aspiration

The initial treatment for most patients with PSP greater than 15% of the volume of the hemithorax should be simple aspiration.[15,19] This procedure is successful in approximately 60% of patients with spontaneous pneumothorax. If successful, simple aspiration avoids hospitalization and there is less pain from the smaller tube. The recurrence rates appear to be similar after simple aspiration and after tube thoracostomy.[15,19]

With this procedure, a relatively small needle (~16 gauge) with an internal polyethylene catheter is inserted into the second anterior intercostal space at the mid-clavicular line after local anesthesia. An alternative site is selected if the pneumothorax is loculated or if adhesions are present. After the needle is inserted, it is extracted, leaving the catheter tip in the pleural space. A three-way stopcock and a 60-mL syringe are attached to the catheter. Air is manually withdrawn until no more can be aspirated. The catheter is then occluded for several hours. If the chest radiograph confirms that there has been no recurrence, the catheter is removed and the patient is discharged. Alternatively, the patient can be observed overnight or can be discharged with a Heimlich one-way valve attached to the catheter. If the total volume of air aspirated exceeds 4 L and no resistance has been felt, it is assumed that there has been no reexpansion, and alternative procedures are initiated.

Patients with their first PSP should be managed initially with simple aspiration on an outpatient basis. Consideration can be given to overnight observation in hospital for those who reside a long distance from the hospital. Patients should return in 24 to 72 hours for a follow-up chest radiograph. If aspiration is unsuccessful, then either thoracoscopy or tube thoracostomy should be undertaken.[20] Because of a low (<50%) likelihood of recurrence and because a PSP is a nuisance rather than life-threatening, maneuvers to prevent recurrence are usually unnecessary for patients with a first episode. Simple aspiration is not recommended for patients with secondary spontaneous pneumothoraces or with recurrent PSPs.

Tube Thoracostomy

For the past several decades, most patients with PSP have been managed initially with tube thoracostomy. It is recommended if simple aspiration proves ineffective and thoracoscopy is not readily available. It rapidly results in the reexpansion of the underlying lung and does not require prolonged hospitalization. In one series of 81 patients treated with tube thoracostomy, the average duration of hospitalization was only 4 days (range 3 to 6 days). Only three patients (4%) had persistent air leaks after several days of chest tube drainage.[21]

When a spontaneous pneumothorax is managed with tube thoracostomy, relatively small tubes (8 to 16 French) or pigtail catheters (8 to 10 French) appear to be as effective as larger tubes.[15] Because the risk of reexpansion pulmonary edema is greater when the lung is reexpanded rapidly, it is advisable to use a water-seal chamber and to avoid suction for the first 24 hours of tube thoracostomy.

After the lung has reexpanded and the air leak has ceased for 24 hours, the chest tube can be removed. Air leaks are present when there is bubbling through the water-seal chamber of the drainage system. If there is no bubbling on quiet respiration, the patient should be asked to cough. The absence of bubbling indicates there is no air leak. Whether clamping the tube before its removal is beneficial remains controversial.[14,15] If the lung remains unexpanded or if there is a persistent air leak 72 hours after tube thoracostomy, thoracoscopy or thoracotomy should be considered. There is no evidence that the intrapleural injection of a pleurodesing agent facilitates closure of a bronchopleural fistula.[21]

Tube Thoracostomy with Instillation of a Pleurodesing Agent

Because many patients with a PSP will have a recurrence, efforts have been made to diminish the recurrence rates by injecting pleurodesing agents into the pleural space at the time of the initial episode. The two agents most commonly used are talc slurry and doxycycline. The administration of one of these agents will reduce the recurrence rates from approximately 40% to 25% (Fig. 74-3).[22] However, because thoracoscopy with stapling of blebs and pleural abrasion reduces the recurrence rate to less than 5%,[23] the thoracoscopic procedure is preferred if available. If talc is used for pleurodesis, large-particle-size talc should be used to minimize the risks of acute lung inflammation.[24] A tetracycline derivative (e.g., doxycycline 500 mg) is preferred by some. Because the injection of a tetracycline derivative can be very painful, particularly in a patient with a pneumothorax and relatively normal pleura, heavy sedation should be given before sclerosis is attempted. (See also Chapter 75 on pleurodesis.) Bleomycin is not recommended for pneumothoraces because it does not produce a pleurodesis in animals with a normal pleura,[25] and has not been studied with pneumothorax in humans.

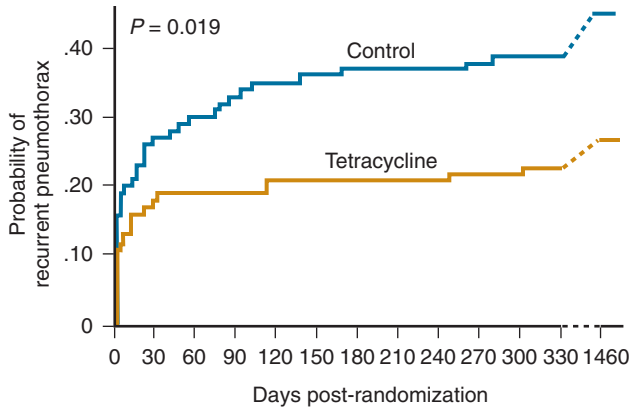

FIGURE 74-3 ■ Probability of recurrent pneumothorax after assignment to the tetracycline or the control group in the Veterans Administration cooperative study on spontaneous pneumothorax. (Redrawn from Light RW, O'Hara VS, Moritz TE, et al: Intrapleural tetracycline for the prevention of recurrent spontaneous pneumothorax. JAMA 264:2224–2230, 1990.)

Thoracoscopy

Patients with spontaneous pneumothorax are increasingly being managed with video-assisted thoracoscopic surgery (VATS) (see also Chapter 23). VATS is the procedure of choice if aspiration fails or if the patient has a recurrent pneumothorax. During VATS, attempts are made to eliminate the blebs responsible for the pneumothorax and to create a pleurodesis. The primary means by which the blebs are treated is with endo-stapling, which requires expensive consumables.[26] When this is a concern, the apical blebs and bullae can be managed by thoracoscopic suturing.[26] Pleurodesis is probably best induced by pleural abrasion.[27,28] Bleb stapling without pleurodesis has a higher recurrence rate, and is not recommended.

VATS is an effective management for PSP. In a meta-analysis of 27 studies, the recurrence rate was 5.4%. The most common complication of VATS for the treatment of PSP is a persistent air leak, which occurs in less than 5% of cases. VATS is preferred to thoracotomy because the hospitalization times are shorter (median 3 days) and the patient incurs less morbidity.[29]

Some have proposed that medical thoracoscopy or pleuroscopy with the insufflation of talc is the preferred way to manage PSP.[30] In one study of 59 patients, pleuroscopy with the insufflation of talc had a recurrence rate of 5% during a follow-up period of 5 years.[31] With pleuroscopy, the anesthesia is local and no treatment is provided for the blebs. Controlled studies are needed to determine whether pleuroscopy (which does not provide stapling of the blebs and pleural abrasion) is as effective as VATS.

Open Thoracotomy

When VATS is not available, open thoracotomy with oversewing of the blebs and pleural abrasion is a reasonable alternative. If a thoracotomy is performed for pneumothorax, a transaxillary mini-thoracotomy should be

performed to minimize the trauma and the length of the scar.[31] In a recent meta-analysis, the recurrence rate after open thoracotomy was only 1.1%, which was significantly less than that for thoracoscopy.[23] Various methods have been used for scarification of the pleural surfaces, ranging from visceral and parietal pleurectomy to pleural abrasion with dry sponges. Because all appear to be similarly effective, pleural abrasion with dry gauze is recommended because it is less traumatic than pleurectomy and does not appear to interfere with a subsequent thoracotomy.

Summary of Treatment

Most patients with their first PSP should be managed initially with simple aspiration of the pleural air with a plastic catheter. If this is ineffective, VATS should be performed promptly, with endo-stapling of blebs and pleural abrasion to create a pleurodesis. An alternative to VATS is open thoracotomy, which is associated with a significantly lower recurrence rate but which requires a longer hospital stay and produces more postoperative morbidity. When thoracoscopy is unavailable, patients who fail aspiration should be managed with tube thoracostomy with an attempt at pleurodesis with either doxycycline or talc, or thoracotomy. If, after 3 days of thoracostomy drainage, there is a persistent air leak or the lungs have not reexpanded, thoracotomy should be considered. Patients with recurrent PSP should undergo VATS or thoracotomy.

SECONDARY SPONTANEOUS PNEUMOTHORAX

A secondary spontaneous pneumothorax (SSP) complicates an underlying lung disease and thus is more serious than a primary pneumothorax because it further decreases the pulmonary function of a patient whose reserve is already diminished. In addition, the presence of the underlying lung disease makes management of the pneumothorax more difficult.

Incidence

The incidence of SSP is similar to that of PSP.[32] An estimated 15,000 new cases of SSP occur annually in the United States. Men over the age of 75 have the highest per capita rate of pneumothorax, 60 per 100,000 per year.[3]

Etiologic Factors

COPD is the most common underlying disease in patients with SSP, although almost every lung disease has been associated with SSP. In one series of 505 patients with SSP, 348 patients had COPD, 93 had tumors, 26 had sarcoidosis, 9 had tuberculosis, 16 had other pulmonary infections, and 13 had miscellaneous diseases.[33] Among patients with COPD, the incidence of SSP increases with progressive severity of the COPD. In the Veterans Administration cooperative study[22] on pneumothorax, 27% of the 229 participants had an FEV_1/FVC ratio below 0.40. One of the more common causes of SSP is *Pneumocystis jirovecii* (formerly *carinii*) infection in patients with acquired immunodeficiency syndrome (AIDS).[34] There is also a high incidence in cystic fibrosis. Of the more than 28,000 patients on the Cystic Fibrosis Foundation Registry, the incidence of pneumothorax was 3.4%.[35] Patients with lymphangioleiomyomatosis (Fig. 74-4; see Chapter 62) and histiocytosis X[36] (Langerhans cell histiocytosis; see Chapter 57) also have a high incidence of spontaneous pneumothorax.

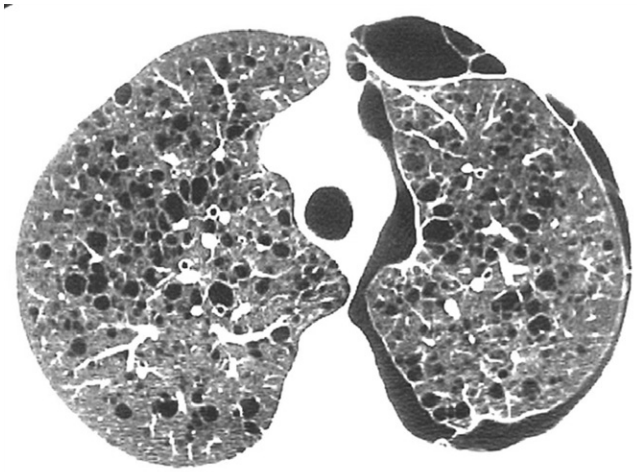

FIGURE 74-4 ■ Chest computed tomography scan of a patient with lymphangioleiomyomatosis. Note the numerous thin-walled cysts, rounded and relatively uniform in shape, and a pneumothorax on the left. (Courtesy of Dr. Lisete Teixeira, University of Sao Paulo, Brazil.)

Clinical Manifestations

In general, the clinical symptoms associated with SSP are more severe than those associated with PSP. In one series of 57 patients with COPD and pneumothorax,[37] all patients were dyspneic, 74% had chest pain on the side of the pneumothorax, 9% were cyanotic, and 7% were hypotensive. Although earlier studies reported a mortality rate that exceeded 10% with pneumothorax secondary to COPD,[37] in the large Veterans Administration cooperative study, the mortality rate from pneumothorax was only 1%.[22]

Diagnosis

The possibility of a pneumothorax should be considered in every patient with COPD who has a sudden increase in shortness of breath, particularly if there is associated chest pain. The physical examination of a patient with a SSP is less helpful in establishing the diagnosis than it is in a patient with a PSP. Patients with underlying disease may already have hyperexpanded lungs, decreased tactile fremitus, a hyperresonant percussion note, and distant breath sounds over both lung fields. Accordingly,

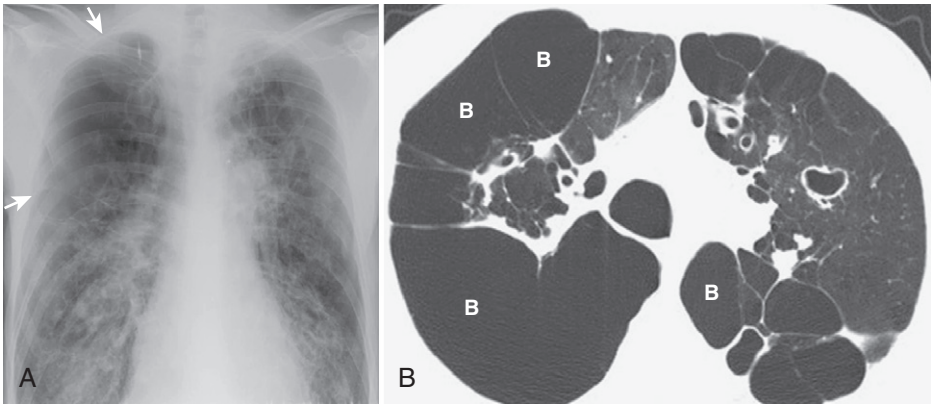

FIGURE 74-5 ■ **A,** Posteroanterior chest radiograph of a patient with cystic fibrosis and extensive bullous disease of the right apex that was initially mistaken for a pneumothorax. Note lucent area (*arrows*) within the right upper lung field. **B,** Computed tomography scan confirms the presence of bullae (B) and excludes pneumothorax. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

when a pneumothorax develops, side-to-side differences in the physical examination may not be apparent.

The diagnosis of SSP is established by the demonstration of a pleural line on the chest radiograph. This line can be difficult to see in radiographs of patients with COPD because of their hyperlucent emphysematous lungs. Frequently, the presence of the pneumothorax is overlooked, particularly when the radiograph is overexposed. In patients with lung disease, the radiographic appearance of the pneumothorax can be altered by the underlying abnormalities. Areas of normal lung collapse more evenly and completely than do diseased areas with large bullae or severe emphysema, which have decreased elastic recoil and may trap gas.

It is important to distinguish a spontaneous pneumothorax from a large, thin-walled, air-containing bulla in patients with COPD. The apparent pleural line with a large bulla is usually concave toward the lateral chest wall because it represents the medial border of the bulla, whereas the pleural line with a pneumothorax is usually oriented convexly toward the lateral chest wall. At times, CT examination of the chest is necessary to make this differentiation (Fig. 74-5).

Recurrence Rates

The recurrence rates for SSPs are higher than those for PSPs if measures are not taken to prevent a recurrence. The recurrence rates are higher in those with SSP (~45%) than in patients with PSP (~30%) over a 3- to 5-year observation period.[12,22]

Treatment

Urgent evaluation is indicated for any patient suspected of having a SSP, because death has occasionally been reported before a chest tube can be inserted. Such deaths were reported in 3 of 57 patients (5%) with pneumothorax secondary to COPD[37] and in 3 of 15 patients (20%) with cystic fibrosis.[38] The high immediate mortality rate emphasizes that an important secondary treatment goal for these patients is reducing the likelihood of a recurrence.

The initial treatment for nearly every patient with a SSP should be tube thoracostomy. Simple aspiration is not recommended because it frequently is ineffective and cannot prevent recurrence. The evacuation of even a small pneumothorax can lead to a rapid improvement in symptoms. In patients requiring mechanical ventilation, a chest tube should be placed immediately because the pneumothorax is likely to enlarge during mechanical ventilation.

In those treated with tube thoracostomy, it is more difficult to expand the lung and air leaks persist longer in patients with SSP than in patients with PSP. In SSP caused by COPD, the median time for lung expansion is 5 days compared with 1 day for PSP,[37] and more patients require prolonged chest tube drainage. After 7 days of tube thoracostomy drainage, the lung remains unexpanded or the air leak persists in about 20% of patients with SSP.[37]

Following thoracostomy, most patients with SSP should be considered for thoracoscopy. Thoracoscopy should certainly be performed in patients with a persistent air leak or an unexpanded lung after 72 hours of tube thoracostomy. If the lung expands and the air leak ceases within the first 72 hours, an attempt should be made to prevent a recurrence. For preventing recurrences, thoracoscopy is superior to chemical pleurodesis (recurrence rates of about 5% vs. 20%, respectively).[12,22] If thoracoscopy is unavailable, chemical pleurodesis should be performed (as discussed earlier) to prevent a recurrent pneumothorax. Thoracotomy should be considered if air leak persists after 5 days and thoracoscopy is unavailable.

One consideration for patients with SSP is the effect that a pleurodesing agent might have on a future lung transplantation. In the past, prior attempts of ipsilateral pleurodesis excluded patients from lung transplantation due to the risk of excess bleeding. In 1998, however, a consensus conference statement on lung transplantation in cystic fibrosis stated that pleurodesis is not a

contraindication to lung transplantation.[39] However, pleurodesis is likely to make future lung transplantation more difficult, and consultation with a transplant surgeon is advisable.

Pneumothorax Secondary to *Pneumocystis* in Patients with AIDS

Patients with AIDS and *P. jirovecii* infection have a relatively high incidence of spontaneous pneumothorax. Approximately 5% of patients with AIDS who receive prophylactic pentamidine will have a spontaneous pneumothorax. Most patients with AIDS who have a spontaneous pneumothorax have a history of *P. jirovecii* infection, many are taking prophylactic pentamidine, and most have a recurrence of *P. jirovecii* infection.[1,34] The presence of multiple subpleural lung cavities, often associated with subpleural necrosis, may explain the high incidence of spontaneous pneumothorax.[1] Once such a patient has a pneumothorax, he or she is likely to experience a contralateral pneumothorax. It should be noted that iatrogenic pneumothoraces, particularly those related to mechanical ventilation or pulmonary procedures, are also common in patients with AIDS.[1,34]

Perhaps due to the necrotic lung surrounding the ruptured cavity, the spontaneous pneumothorax associated with AIDS and *P. jirovecii* infection is notoriously difficult to treat. In one report of 20 patients, the median duration of tube thoracostomy was 20 days; 11 patients underwent pleurodesis, whereas 5 patients had thoracotomy.[40]

Patients with AIDS and a spontaneous pneumothorax should be treated with tube thoracostomy. If the air leak persists for more than a few days, there are two options: a Heimlich valve or VATS. The intrapleural injection of a pleurodesing agent has not been shown to be effective in expediting closure of the leak. In general, the Heimlich valve is preferred because the patient can be managed as an outpatient.

If the patient cannot be managed with a Heimlich valve because the airflow through the bronchopleural fistula is too high, VATS can be performed. Wait[41] reported that 30 of 32 patients with AIDS and spontaneous pneumothorax were managed successfully with talc insufflation without endo-stapling. If operative intervention is planned, it should be carried out early to avoid prolonged air leak, hospitalization, and morbidity.

Pneumothorax Secondary to Tuberculosis

Between 1% and 3% of patients hospitalized for pulmonary tuberculosis will have a pneumothorax.[42] All such patients should be treated initially with tube thoracostomy. In one series of 28 patients, 7 of the 11 patients treated by observation or repeated pleural aspiration died,[42] compared with 1 of the 17 patients treated with tube thoracostomy (64% vs. 6%, respectively). Antituberculous chemotherapy should be given concomitantly with the tube thoracostomy. Thoracotomy should not be considered until the patient has received antituberculous chemotherapy for at least 6 weeks.

IATROGENIC PNEUMOTHORAX

Iatrogenic pneumothoraces are probably more common than PSPs and SSPs combined. In a study of 3430 patients in 12 intensive care units in France, 3.0% developed a pneumothorax.[43] The etiologies of the pneumothoraces in this study were mechanical ventilation in 42, central venous catheters in 28, thoracentesis in 21, and miscellaneous in 3.[43]

Currently, the leading cause of iatrogenic pneumothorax is transthoracic needle aspiration. The incidence of iatrogenic pneumothorax with this procedure is about 25%, and about 10% of the patients with pneumothorax receive tube thoracostomy.[1] This procedure is more likely to result in a pneumothorax if the patient has COPD, if the lesion is deep within the lung, or if the angle of the needle route is wide.[44,45] Various maneuvers such as positioning the patient with the biopsied side down or using the blood patch technique have not proved useful in diminishing the incidence of pneumothorax. A recent paper did demonstrate a significant reduction in pneumothoraces if the puncture access was sealed by instillation of NaCl 0.9% solution during extraction of the guide needle.[46]

Mechanical ventilation is another risk factor. In one early series of 553 patients undergoing mechanical ventilation, 4% developed a pneumothorax.[47] The frequency of the pneumothorax was increased if the patient had aspiration pneumonia (37%), was treated with positive end-expiratory pressure (15%), had intubation of the right main-stem bronchus (13%), or had COPD (8%).[47] In another study, the incidence of pneumothorax in 725 patients with acute respiratory distress syndrome was 6.9%.[48] In patients with acute respiratory distress syndrome, the incidence of barotrauma is higher if the ventilator plateau pressure exceeds 35 cm H_2O or if the lung compliance is below 30 mL/cm H_2O.

Other common causes of iatrogenic pneumothorax (with approximate incidences) are thoracentesis (2.5%), pleural biopsy (8%), and transbronchial lung biopsy (6%). Iatrogenic pneumothorax also frequently complicates cardiopulmonary resuscitation. Other procedures associated with the development of an iatrogenic pneumothorax include subclavian or internal jugular vein catheterization, tracheostomy, intercostal nerve block, mediastinoscopy, liver biopsy, and the insertion of small nasogastric tubes.[1] Radiofrequency ablation is increasingly used to treat lung tumors and carries a high incidence of pneumothorax (~30%).[49,50] In a series of 137 procedures, 27 resulted in symptomatic pneumothoraces requiring chest tube drainage.[51] In another series, the risks of pneumothorax was associated with the number of tumors ablated, electrode positions, and the electrode trajectory through aerated lung.[50]

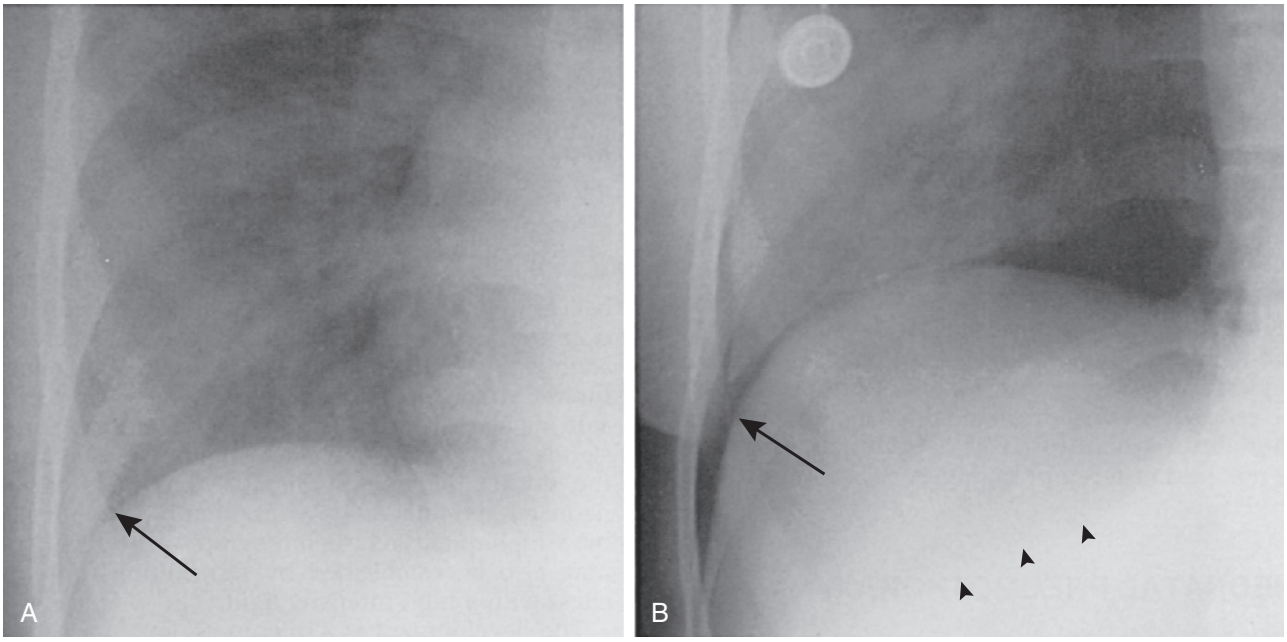

FIGURE 74-6 ■ Detailed views of the right costophrenic angle from successive supine chest radiographs taken before **(A)** and after **(B)** the development of a pneumothorax. Both illustrations show diffuse infiltrations in the right lower lung field. Note change in costophrenic angles (*arrows*) caused by air in the pleural space between the diaphragm and chest wall: the "deep sulcus" sign. Air in the anterior pleural space can also be recognized by an air-tissue interface (*arrowheads*).

Diagnosis

Iatrogenic pneumothorax should be suspected in any patient treated by mechanical ventilation whose clinical condition suddenly deteriorates. A sensitive indicator of the development of a pneumothorax in such patients is increased peak and plateau pressures if the patient is on a volume-cycled ventilator or a decreased tidal volume if the patient is on a pressure-cycled ventilator. The diagnosis should also be suspected in any patient who becomes more dyspneic after a medical or surgical procedure that is known to be associated with the development of a pneumothorax. It should be emphasized that symptoms from the pneumothorax may not be evident for 24 hours or longer after the procedure.[52] The diagnosis is readily confirmed by a chest radiograph. In patients with extensive pulmonary infiltrates, there may be little evidence of lung collapse, but the air in the pleural space may instead be indicated by the "deep sulcus" sign (Fig. 74-6).

Treatment

The treatment of iatrogenic pneumothorax differs from that of spontaneous pneumothorax in that preventing recurrence is not an issue. If the patient has at most minimal symptoms and the pneumothorax occupies less than 15% of the volume of the hemithorax, the patient can be observed. The administration of supplemental oxygen increases resolution (see previous section). If the patient has more than minimal symptoms or if the pneumothorax occupies more than 15% of the hemithorax, the procedure of choice is simple aspiration with a plastic catheter,[53] as described for PSP. If simple aspiration fails, tube thoracostomy should be performed. Small-bore chest tubes with Heimlich valves are quite effective in this situation.[54]

The management of patients with an iatrogenic pneumothorax secondary to positive-pressure mechanical ventilation should include tube thoracostomy to prevent the development of a tension pneumothorax. In a patient on positive pressure ventilation, tension pneumothorax can easily develop because the positive pressure during inspiration forces air into the pleural space under high pressure until it soon exceeds atmospheric pressure. If the patient continues to receive mechanical ventilation, the chest tube should be left in place for at least 48 hours after the air leak stops. At times, a bronchopleural fistula is so large that a high percentage of the total inspired volume exits through the chest tube. The air exiting through the chest tube still provides effective ventilation, however, because it contains levels of carbon dioxide similar to those of exhaled gas.[55] Although the use of high-frequency ventilators has been recommended in this situation, two studies in adults[56,57] have demonstrated that high-frequency ventilation does not consistently improve gas exchange or decrease the flow through the fistula.

TRAUMATIC (NON-IATROGENIC) PNEUMOTHORAX

The incidence of pneumothorax after blunt trauma depends on the severity of the trauma. The incidence of pneumothorax has exceeded 35% in some series.[58]

Mechanism

A traumatic pneumothorax can result from either penetrating or nonpenetrating chest trauma. With penetrating chest trauma, the wound allows air to enter the pleural space via the chest wall or via the visceral pleura from the tracheobronchial tree. With nonpenetrating trauma, a pneumothorax may develop if the visceral pleura is lacerated secondary to a rib fracture or dislocation. In the majority of patients with pneumothorax secondary to nonpenetrating trauma, however, there are no associated rib fractures. It is thought that the sudden chest compression abruptly increases the alveolar pressure, which may cause alveolar rupture. Air then enters the interstitial space and dissects toward either the visceral pleura or the mediastinum. A pneumothorax develops when either the visceral or the mediastinal pleura ruptures, allowing air to enter the pleural space.

Diagnosis and Treatment

The diagnosis of pneumothorax is made by the chest radiograph or the chest CT. A pneumothorax that is apparent on the chest CT, but not on the chest radiograph, is called an *occult* pneumothorax.[1] About 40% of traumatic pneumothoraces are occult.[59] In recent years ultrasonography performed by emergency room physicians or surgeons has been used increasingly to determine whether a pneumothorax is present.[59] Ultrasound is more sensitive that supine chest radiographs in identifying pneumothoraces,[59] but false positives are known to occur, especially in patients with underlying lung diseases (especially COPD).[60] (For additional information on ultrasonography, see Chapter 20.)

Most traumatic pneumothoraces should be treated initially with tube thoracostomy. If the patient has an occult pneumothorax or if the distance between the lung and chest wall does not exceed 1.5 cm, however, tube thoracostomy is probably not indicated unless the patient is receiving mechanical ventilation.[61] In one series, 333 patients with pneumothoraces less than 1.5 cm were initially managed without chest tubes, and only 33 (10%) subsequently required tube thoracostomy.[61] When traumatic pneumothoraces are treated with tube thoracostomy, the lung usually expands and the air leak ceases within 24 hours.[61] If the leak persists for more than a few days, consideration should be given to performing thoracoscopy to identify and repair the site of the air leak.[62]

Immediate thoracotomy is indicated for two uncommon diagnoses in any patient with a traumatic pneumothorax. The first diagnosis is fracture of the trachea, or a major bronchus, which usually occurs in the presence of an anterior or lateral fracture of one or more of the first three ribs. Most patients will have at least some hemoptysis.[63] Therefore, in patients with a traumatic pneumothorax, the presence of a large pneumothorax with continued leakage of air into the pleural space after tube thoracostomy, a fracture of one or more of the first three ribs, or hemoptysis should serve as an indication for fiberoptic bronchoscopy to assess the possibility of a bronchial tear.[63] Primary surgical repair of the tear usually results in full restoration of function of the distal lung.[63]

The second diagnosis to consider is traumatic rupture of the esophagus, which is almost always accompanied by a hydropneumothorax. A reliable screening test for esophageal rupture is measurement of the pleural fluid amylase concentration.[64] If this level is elevated, contrast radiographic studies of the esophagus should be performed. It is important to establish the diagnosis of esophageal rupture expeditiously because the mortality approaches 100% if surgical treatment is not performed promptly.

Air Travel and Pneumothorax

For patients who have suffered a pneumothorax, the Aerospace Medical Association suggests that flying be allowed 2 to 3 weeks after radiologic resolution of the pneumothorax.[65] One study of 12 patients with traumatic pneumothorax reported that the 10 patients who waited at least 14 days before travel were all asymptomatic in-flight, whereas 1 of 2 patients who flew earlier than 14 days developed respiratory distress in-flight with symptoms suggesting a recurrent pneumothorax.[66]

NEONATAL PNEUMOTHORAX

A spontaneous pneumothorax is present shortly after birth in 1% to 2% of all infants, and the pneumothorax is symptomatic in approximately half of these.[17,67] The incidence of spontaneous neonatal pneumothorax is twice as high in male as in female infants. Affected infants are usually full- or post-term.[17] Usually, the infant has a history of fetal distress requiring resuscitation or a difficult delivery with evidence of aspiration of meconium, blood, or mucus.[17]

There is a high incidence of pneumothorax in infants with neonatal respiratory distress syndrome. In one series of 295 newborn infants with the syndrome, 19% had a pneumothorax.[68] Pneumothorax developed in 29% of those requiring intermittent positive-pressure ventilation with positive end-expiratory pressure, in 11% of those requiring continuous positive airway pressure (CPAP), and in only 4% of those not requiring respiratory assistance.[68] In a series of 26,007 babies with birth weights between 401 and 1500 g born in 1999, the incidence of pneumothorax was 6.3%, but, in babies weighing less than 750 g, the incidence was 15%.[69]

Pathogenesis

The development of a spontaneous neonatal pneumothorax is related to the mechanical problems of expanding the lung for the first time. During the first few breaths of life, the transpulmonary pressures average 40 cm H_2O, with occasional pressures as high as 100 cm H_2O.[1] At birth, the alveoli usually open in rapid sequence, but, if bronchial obstruction is present from the aspiration of blood, meconium, or mucus, high transpulmonary pres-

sures may lead to rupture of the lung. A transpulmonary pressure of 60 cm H_2O ruptures an adult lung,[17] whereas a transpulmonary pressure of 45 cm H_2O ruptures a neonatal rabbit lung.[1]

Clinical Manifestations

With neonatal spontaneous pneumothorax, the signs vary from none to severe acute respiratory distress, depending on the size of the pneumothorax. With a small pneumothorax, there may be mild apneic spells with some irritability or restlessness. With a large pneumothorax, there may be severe respiratory distress with marked tachypnea, grunting, retractions, and cyanosis.[17] In newborn babies, the detection of pneumothorax by physical examination is often difficult because breath sounds are widely transmitted in the small neonatal thorax from the contralateral lung. The most reliable sign is a shift of the apical heart impulse away from the side of the pneumothorax.[17] The diagnosis of neonatal spontaneous pneumothorax is confirmed by a high-quality chest radiograph.

The development of a pneumothorax in a patient with neonatal respiratory distress syndrome is usually heralded by a change in the vital signs. In one series of 49 patients, cardiac arrest marked the development of the pneumothorax in 12 patients (24%); most of the other patients had a decrease in the blood pressure, pulse, or respiratory rate.[68] In another series, however, the earliest signs were an increase in the blood pressure, heart rate, or pulse pressure.[70] A pneumothorax in an infant with the neonatal respiratory distress syndrome is associated with mortalities exceeding 60% in some studies.

Treatment

An infant with a spontaneous pneumothorax who is asymptomatic or mildly symptomatic can be observed closely because the pneumothorax will usually resolve within a few days. It is necessary to observe the patient closely in case the pneumothorax enlarges or a tension pneumothorax develops.[17] Supplemental oxygen can hasten the resolution of the pneumothorax, but it should be administered with care because of the dangers of retrolental fibroplasia.[17] Tube thoracostomy should be performed on any neonate who is more than mildly symptomatic. One study demonstrated that 18-gauge venous catheters were comparable to 12-French chest tubes in managing pneumothorax in neonates.[71] Tube thoracostomy should be performed in virtually all infants with the neonatal respiratory distress syndrome and pneumothorax, because the pneumothorax further compromises the ventilatory status of the patient and tends to increase in size.

CATAMENIAL PNEUMOTHORAX

A catamenial pneumothorax is a pneumothorax that occurs in conjunction with menstruation (Fig. 74-7). Up until 2004, 229 cases had been reported.[72] However, catamenial pneumothorax is probably underdiagnosed and underreported. With catamenial pneumothorax, respiratory symptoms usually develop within 24 to 48 hours of the onset of the menstrual flow.[73] Most pneumothoraces are right sided, but left-sided and bilateral pneumothoraces have been reported.[73] Catamenial pneumothoraces tend to be recurrent. On average, patients have about five pneumothoraces before the diagnosis is recognized.

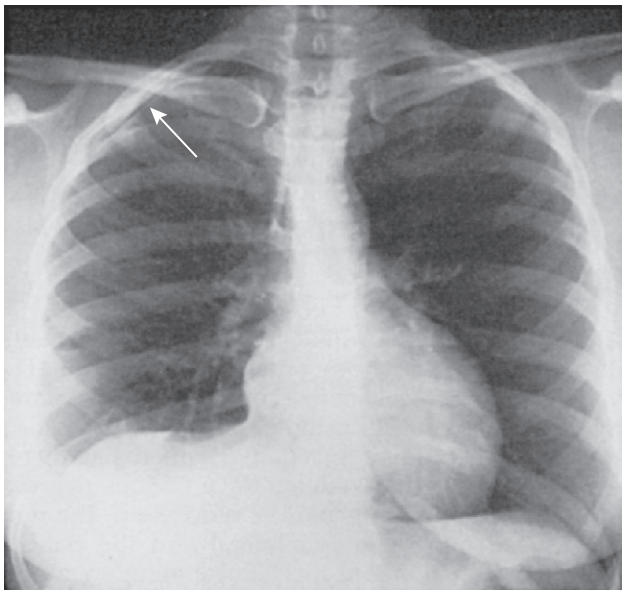

FIGURE 74-7 ■ Posteroanterior chest radiograph from a 32-year-old woman showing a small right-sided pneumothorax (*arrow*). This was the fourth episode with onset during menses. (Courtesy of Dr. Louis S. Lehman, San Francisco.)

Pathogenesis

The pathogenesis of catamenial pneumothorax is not definitely established. When the syndrome was initially described by Maurer and colleagues,[74] it was hypothesized that air gained access to the peritoneal cavity during menstruation and then entered the pleural cavity through a diaphragmatic defect. In a subsequent review of 18 patients who had undergone thoracotomy, however, diaphragmatic defects were demonstrable in only three, whereas six had pleural or diaphragmatic endometriosis.[75] However, in a more recent series of eight cases in which a careful thoracoscopic examination was performed, diaphragmatic abnormalities were detected in all; four patients had both diaphragmatic defects and endometriosis, three patients had only diaphragmatic endometriosis, and one patient had only a diaphragmatic defect.[76] It has been suggested that, with diaphragmatic endometriosis, the endometrial tissue undergoes cyclical necrosis leading to a diaphragmatic defect.[77] These authors concluded that diaphragmatic abnormalities play a fundamental role in the pathogenesis of catamenial pneumothorax.[77]

Diagnosis and Treatment

Any woman who has a spontaneous pneumothorax within the first 48 hours of her menstrual period should be suspected of having a catamenial pneumothorax. The treatment of catamenial pneumothorax is aimed at treating endometriosis, known or suspected, by suppressing the ectopic endometrium. This can be attempted by suppression of ovulation with oral contraceptives or by suppression of gonadotropins with danazol or gonadotropin-releasing hormone to produce a medical oophorectomy.[72] However, these measures are effective in less than 50% of patients.[72] Alternative treatments include thoracoscopy with stapling of blebs, closure of diaphragmatic defects and parietal abrasion or pleurectomy, or pleurodesis.[72]

TENSION PNEUMOTHORAX

A tension pneumothorax is present when the intrapleural pressure exceeds the atmospheric pressure throughout expiration and often during inspiration as well.[1] Most patients who develop a tension pneumothorax are receiving positive pressure to their airways, either during mechanical ventilation or during resuscitation.[1] For a tension pneumothorax to develop in a spontaneously breathing person, some type of one-way valve mechanism must be present so more air enters the pleural space on inspiration than leaves the pleural space on expiration, so air accumulates in the pleural space under positive pressure.[1]

Pathophysiology

The development of a tension pneumothorax is usually heralded by a sudden deterioration in the cardiopulmonary status of the patient. The explanation for this sudden deterioration is probably related to the combination of a decreased cardiac output due to impaired venous return and profound hypoxia due to ventilation-perfusion mismatches. In mechanically ventilated sheep, an induced tension pneumothorax (mean pleural pressure of +25 cm H_2O) reduced the cardiac output from 3.5 to 1.1 L/min.[78] The arterial P_{O_2} also fell from a baseline value of 159 to 59 mm Hg. Comparable reductions in cardiac output and oxygen saturation were seen in pigs[79] and in dogs[80] following induction of tension pneumothoraces. Similarly, in patients on mechanical ventilation who develop tension pneumothorax, there is a large drop in the cardiac output.[81]

Clinical Manifestations

Patients most commonly have a tension pneumothorax while they are receiving positive-pressure mechanical ventilation, during cardiopulmonary resuscitation,[82] or as a complication of hyperbaric oxygen therapy.[1] Occasionally, a tension pneumothorax will evolve during the course of a spontaneous pneumothorax. Tension pneumothorax can develop from improper connection of one-way flutter valves with small-caliber chest tubes.[83]

The clinical picture associated with the development of a tension pneumothorax is striking. The patient appears distressed, with rapid labored respirations, cyanosis, marked tachycardia, and profuse diaphoresis. The physical findings are those of a very large pneumothorax. Arterial blood gases reveal marked hypoxemia and sometimes respiratory acidosis.

Tension pneumothorax should be suspected in patients receiving mechanical ventilation who suddenly deteriorate. In this situation, the peak pressures on the ventilator usually increase markedly if the patient is on volume-type ventilation, whereas the tidal volumes decrease markedly if the patient is on pressure-support ventilation.[1] Tension pneumothorax should also be suspected in any patient undergoing cardiopulmonary resuscitation in whom ventilation becomes difficult. In one series of 3500 autopsies, an unsuspected tension pneumothorax was found in 12 cadavers; 10 of these had received mechanical ventilation, and 9 had undergone cardiopulmonary resuscitation.[84] Tension pneumothorax should also be suspected in patients with a known pneumothorax who deteriorate suddenly or in patients who have undergone a procedure known to cause a pneumothorax.

Diagnosis and Treatment

A tension pneumothorax is a medical emergency. One should not waste time trying to establish the diagnosis of tension pneumothorax radiologically because the clinical situation and the physical findings usually strongly suggest the diagnosis.[1] The patient should immediately be given high-flow supplemental oxygen to alleviate the hypoxia. Once the abnormal hemithorax is identified, a large-bore (14- to 16-gauge) catheter with needle should be immediately inserted into the pleural space through the second anterior intercostal space.[1] After the catheter and needle are inserted into the chest, the needle is removed and a large syringe containing a few milliliters of sterile saline is attached to the indwelling catheter. The plunger is then pulled out of the syringe. If air bubbles through the saline after withdrawing the plunger, the diagnosis of tension pneumothorax is established. If the fluid enters the pleural space from the syringe, the patient does not have a tension pneumothorax and the catheter should be removed.

If the procedure just described confirms the diagnosis of a tension pneumothorax, the catheter should be left in place and in communication with the atmosphere until air ceases to exit through the syringe. Additional air can be withdrawn from the pleural space with the syringe and the three-way stopcock. The patient should be prepared for immediate tube thoracostomy.

REEXPANSION PULMONARY EDEMA

Unilateral pulmonary edema (*reexpansion pulmonary edema*) may develop in certain patients whose lung has

rapidly reinflated after a period of collapse secondary to a pneumothorax or a pleural effusion. Patients with reexpansion pulmonary edema have various degrees of hypoxia and hypotension. On occasion, the pulmonary edema becomes bilateral, and the patient requires intubation and mechanical ventilation. On rare occasions, the syndrome is fatal; the seriousness of the syndrome is emphasized by the fact that it has been fatal in otherwise healthy, young persons. Although the incidence of reexpansion pulmonary edema is not known, it is probably relatively low because there were no instances of reexpansion pulmonary edema in the Veterans Administration cooperative study of more than 200 patients with spontaneous pneumothorax.[22] In a retrospective study of 320 episodes of pneumothorax, reexpansion pulmonary edema occurred in 3 patients (1.0%).[85] A literature review in 1988 revealed 53 cases of reexpansion pulmonary edema that was fatal in 11 (21%) cases.[86] This is likely an overestimation as nonfatal cases are less likely to be reported and many patients can be asymptomatic.[86a]

Pathophysiology

Reexpansion pulmonary edema appears to be due to increased permeability of the pulmonary vasculature. In both experimental animals and humans, the edema fluid has a high protein content, suggesting that edema forms due to increased capillary leak rather than increased hydrostatic pressure. It has been hypothesized that the mechanical stresses applied to the lung during reexpansion damage the capillaries and lead to pulmonary edema. Reperfusion injury due to reactive oxygen species (ROS) is another possibility. However, several animal studies[87-90] demonstrated that the administration of ROS-scavenging compounds such as dimethylthiourea, catalase, or superoxide dismutase all partially inhibit the neutrophilic infiltration associated with the development of reexpansion pulmonary edema, but do not impressively decrease the amount of edema in the experimental situation. Moreover, neutrophil depletion does not affect the amount of edema.

In humans, most cases of reexpansion pulmonary edema develop when the pneumothorax or pleural effusion has been present for at least 3 days and when negative pressure has been applied to the pleural space. Similar findings have been confirmed in experimental animal studies.

Clinical Manifestations

Patients with reexpansion pulmonary edema typically have pernicious coughing or chest tightness during or immediately after tube thoracostomy or thoracentesis. The symptoms usually progress for 12 to 24 hours, and serial chest radiographs reveal progressive ipsilateral pulmonary edema, which may progress to involve the contralateral lung. Treatment is primarily supportive, with the administration of supplemental oxygen and diuretics, and intubation and mechanical ventilation when necessary. One report suggested that the syndrome could be aborted if the patient is treated with CPAP within the first hour of the development of the syndrome.[90] Chest tubes should be placed to underwater-seal drainage if the syndrome develops.

Prevention

Because reexpansion pulmonary edema can be fatal, it is important to prevent it when possible. The possibility of its development should be considered in any patient with a large pneumothorax or pleural effusion subjected to tube thoracostomy or thoracentesis. When tube thoracostomy is performed for spontaneous pneumothorax, the tubes should initially be connected to an underwater-seal drainage apparatus rather than to negative pleural pressure. If underwater-seal drainage does not cause reexpansion of the underlying lung within 24 to 48 hours, then negative pressure can be applied to the pleural space.[1]

When a thoracentesis is performed, the procedure should be terminated if the patient develops tightness of the chest or experiences coughing. In a series of 941 thoracenteses, including 119 that drained more than 1500 mL, infiltrates consistent with reexpansion pulmonary edema were noted in only two patients (0.2%) from whom 1000 and 1200 mL of pleural fluid had been removed: neither was symptomatic or required treatment.[91]

CHYLOTHORAX

Pleural fluid can be milky or turbid. When this cloudiness persists after centrifugation, it is almost always due to high lipid content in the pleural fluid. High levels of lipid can accumulate in pleural liquid through two separate mechanisms. In one, chyle enters the pleural space following disruption of the thoracic duct, producing a chylothorax or chylous pleural effusion. In the second, large amounts of cholesterol or lecithin-globulin complexes accumulate in a pleural effusion to produce a pseudochylothorax or chyliform pleural effusion.[92] It is important to recognize and differentiate these two conditions because their etiology and management are completely different.

Pathophysiology

A chylothorax forms when the thoracic duct, which carries dietary fat in the form of chylomicrons, becomes disrupted. Chylomicrons are formed in the intestine, after which they enter the intestinal lacteal vessels and are then transported to the cisterna chyli. The thoracic duct leaves the cisterna chyli and passes through the aortic hiatus of the diaphragm on the anterior surface of the vertebral body between the aorta and the azygos vein into the posterior mediastinum. The thoracic duct then ascends extrapleurally in the posterior mediastinum along the right side of the anterior surface of the vertebral column. Between the level of the fourth and sixth thoracic vertebrae, the duct crosses to the left side of the vertebral column and continues cephalad to enter

the superior mediastinum between the aortic arch and the subclavian artery and the left side of the esophagus. As a result, rupture of the thoracic duct below the sixth thoracic vertebrae tends to produce right-sided chylothoraces, and rupture of the ascending duct above the sixth thoracic vertebra tends to produce left-sided chylothoraces.[92] Once the thoracic duct passes the thoracic inlet, it arches above the clavicle and passes anterior to the left subclavian artery, vertebral artery, and thyrocervical trunk to terminate in the region of the left jugular and subclavian veins.

Although the route just described is the typical one, there are wide anatomic variations throughout the course of the duct. For example, duplication or even triplication of the thoracic duct is present in 40% of the population. Also, many collateral vessels and lymphaticovenous anastomoses are known to exist. Presumably these channels transport the chyle to the blood following therapeutic ligation of the thoracic duct.

Chyle, the liquid drained from the thoracic duct, is a milky, opalescent fluid that usually separates into three layers on standing: a creamy uppermost layer containing chylomicrons, a milky intermediate layer, and a dependent layer containing cellular elements. Chyle is bacteriostatic,[92] is not irritating, and seldom induces pleural thickening.

The thoracic duct normally conveys between 1500 and 2500 mL of chyle daily. Ingestion of fat can increase the flow of lymph in the thoracic duct by 2- to 10-fold for several hours. Ingestion of liquid, but not protein or carbohydrate, also increases the flow, whereas starvation decreases chyle flow. The primary cellular component of chyle is the T lymphocyte. Prolonged loss of chyle can result in severe nutritional depletion, dehydration, electrolyte loss, and hypolipidemia as well as depletion of T- and B-cell lymphocytes and immunodeficiency.[92]

Etiology

Chylothorax can result from traumatic (including surgical) and nontraumatic causes: their relative frequencies vary among series. In a summary of five separate series totaling 143 patients, greater than 50% of chylothoraces were caused by tumors, especially lymphoma, followed by trauma.[1] However, a single institute series of 203 patients revealed trauma/surgery as the most common (50%) cause compared to nontraumatic causes (44%).[93] Idiopathic chylothorax accounts for 5% to 10% of cases.

The unpredictable anatomy of the thoracic duct and associated accessory lymphatics makes them vulnerable to injury during cardiovascular or thoracic surgical procedures, especially those involving the posterior mediastinum. Esophagectomy, for example, is complicated by chylothorax in 1% to 4% of cases.[94] Overall, the incidence of chylothorax after cardiothoracic operations is generally low (0.5% to 2.5%[95,96]). Surgical procedures that involve mobilization of the left subclavian artery are particularly likely to be complicated by chylothorax. Transplantation of the lung and heart (or both) can sever the lymphatic drainage and result in chylothoraces.[97] Chylothorax has been reported as a complication of a wide range of other operations, including esophagoscopy, stellate ganglion blockade, thoracic sympathectomy, high translumbar aortography, lung resections, thyroid surgery, and spinal surgery.[1] Bilateral chylothoraces can develop following bilateral neck dissection.[98] In the pediatric setting, chylothorax is particularly common after surgical repair of congenital diaphragmatic hernia (up to 10% of cases) and is usually left-sided.[99]

To aid in the identification of the thoracic duct during surgery, ingestion of cream (to increase the flow and size of the thoracic duct) before high-risk operations (e.g., esophagectomy) has been advocated.[100]

Nonsurgical trauma can also lead to chylothorax. The thoracic duct may be disrupted with penetrating injuries involving the neck or thorax. Nonpenetrating trauma in which the spine is hyperextended or a vertebra is fractured can lead to chylothorax, particularly if the injury occurs shortly after the ingestion of a fatty meal. Less impressive traumas such as weight lifting, straining, severe bouts of coughing or vomiting, childbirth, and vigorous stretching while yawning have been associated with chylothorax.[92] Chylothoraces secondary to closed trauma are usually on the right side, with the site of rupture in the region of the 9th or 10th thoracic vertebra.

Chylothoraces can also arise from transdiaphragmatic movement of chylous ascites,[101] as shown by radioisotope studies. Causes of chylous ascites include many of the causes of chylothorax. In addition, cirrhosis may be a cause of chyloascites and associated chylothorax. These chylothoraces are transudative, probably from dilution by low-protein cirrhotic ascitic fluid.

There are many other causes of chylothorax, but altogether they account only for a small percentage of all chylothoraces. Pulmonary lymphangioleiomyomatosis is discussed later in this chapter (see also Chapter 62).[102] Other disease entities associated with chylothorax are abnormalities of the lymphatic vessels, such as pulmonary lymphangiectasis, yellow nail syndrome, lymph node enlargement, mediastinal fibrosis, lymphangitis of the thoracic duct, tuberous sclerosis, amyloidosis, and Gorham's syndrome. Elevated pressure of the venous system into which the thoracic duct drains (e.g., superior vena caval or subclavian vein thrombosis/obstruction) is another cause of chylothorax.[92] In postsurgical patients, those with central venous thrombosis were five times more likely to develop chylothorax.[103] Chylothorax accounts for about one fifth of pleural effusions in patients with superior vena cava syndrome.[104]

Chylothorax with no identifiable cause is labeled *idiopathic*. Lymphoma, however, must be excluded.

Fetal and Neonatal Chylothorax

Fetal chylothorax is an uncommon but important condition that requires monitoring and management to avoid serious complications, including spontaneous abortion or death after birth.[105] Fetal chylothoraces are often termed *primary* fetal pleural effusions, as no obvious cause can be identified in most cases.[105] Congenital

lymphangiectasis is a rare condition that can produce fetal chylothorax.[106] Cytogenetic analysis of the cells (mainly lymphocytes) may help detect underlying chromosomal abnormalities.

Chylothorax is the most common type of neonatal pleural effusion.[105] It may be a result of persistent fetal chylothorax,[105] but can also be due to rupture of the thoracic duct from trauma during delivery, or to developmental abnormalities of the thoracic duct.[107] Increased venous pressure, especially from congenital heart diseases or from thrombosis of central venous catheters, is another recognized mechanism of neonatal chylothorax.[105] In many cases, the chylothorax is idiopathic. Of note, the pleural fluid remains clear rather than milky until milk feeding begins.[105]

Several molecules have been implicated in the development of chylothorax based on preclinical studies. The integrin $\alpha_9\beta_1$ is widely expressed in smooth muscles and is a receptor for extracellular matrix proteins and vascular cell adhesion molecule-1. Animal studies suggested that the α_9 subunit is required for the normal development of the lymphatic system, including the thoracic duct. Mice with homozygous null mutation of the α_9 subunit develop large bilateral congenital chylothoraces.[108] Vascular endothelial growth factor (VEGF)-C and -D were important in tumor-related lymphangiogenesis and chyloascites formation in mice bearing ovarian carcinoma. Chy-3–mutant mice, which carry a chromosomal deletion that includes VEGF-C, develop hypoplastic dermal lymphatic drainage and resultant chyloascites and lymphedema.[109] Another strain of transgenic mice with mutations in the *Pi3kca* (phosphoinositide 3-kinase) gene also develop defective lymphatics and chyloascites.[110]

Clinical Manifestations

The symptoms, physical findings, and radiographic features of chylothorax are the same as those encountered in patients with comparably sized pleural effusions of any cause. Pleuritic chest pain and fever are rare because chyle is not proinflammatory. Concurrent chylopericardium or chyloascites can occur.

With nontraumatic chylothorax, insidious onset of dyspnea on exertion is common. With traumatic chylothorax, there is usually a latent period of 2 to 10 days between the trauma and the clinical presentation of the pleural effusion.[111] During this latent period, chyle may accumulate in the posterior mediastinum to form a chyloma—visible radiologically as a posterior mediastinal mass[1]—which eventually ruptures into the pleural cavity, giving rise to a chylothorax.

Neonatal chylothorax may present with respiratory distress in the first few days of life. Fifty percent of the infants have symptoms within the first 24 hours, whereas 75% have symptoms by the end of the first week. Most neonatal chylothoraces are either right-sided or bilateral; only rarely are they left-sided.[107] There is a high frequency of neonatal chylothoraces in infants with hydramnios.[107] Fetal chylothorax is often diagnosed only on ultrasonography.

The main threat to life with chylothorax is inanition from malnutrition if the chyle is drained externally. The daily loss of 1.5 to 2.5 L of fluid rich in protein, fats, electrolytes, and lymphocytes will rapidly render patients malnourished and immunocompromised.

Diagnosis

The distinctive white, odorless, milky appearance should suggest the diagnosis, though chylothorax must be differentiated from empyema and pseudochylothorax. In empyema, the milky appearance is caused by suspended leukocytes and debris, which will sediment upon centrifugation, leaving a clear supernatant. In chylous and chyliform pleural effusions, the milky appearance is caused by high lipid levels and the supernatant will remain cloudy after centrifugation. The lipids in chyliform effusion are cholesterol or lecithin-globulin complexes rather than chylomicrons (as in chylothoraces).[112] It should be emphasized that the pleural fluid with chylothorax can occasionally be bloody or even clear yellow.

Pleural fluid and serum triglyceride and cholesterol levels should be measured. Patients who have a chylothorax usually have a pleural fluid triglyceride level above 110 mg/dL (1.24 mmol/L), a ratio of the pleural fluid to the serum triglyceride of greater than 1.0, and a ratio of the pleural fluid to the serum cholesterol of less than 1.0.[101] However, it should be remembered that fasting may significantly reduce the triglyceride level in the pleural fluid and produce false-negative results.[112a] If doubt persists after the lipid measurements, one approach is to feed the patient a high-fat meal before sampling the pleural fluid. Alternatively, the demonstration of chylomicrons in lipoprotein analysis of the pleural fluid confirms the diagnosis of chylothorax.[113] The latter is particularly valuable if the triglyceride level is in the equivocal range (50 to 110 mg/dL). It is important to differentiate chylous from chyliform pleural fluid (see later).

Typical chylous effusions are lymphocyte-rich effusions with exudative protein levels but low lactate dehydrogenase (LDH). The electrolyte composition of chyle is similar to that of serum, and the protein content is usually around 3 g/dL. Transudative chylothorax is usually due to concurrent conditions (especially hepatic cirrhosis) known to produce transudates. An elevated LDH in chylothorax should raise concerns of concurrent conditions (e.g., infection).[114] Magnetic resonance imaging (MRI) can confirm the high fat density of the pleural effusion and may support the diagnosis of chylothorax.

After establishing the diagnosis of a chylothorax, it is important to determine the cause. Because lymphoma is the most common (and treatable) cause of nontraumatic chylothorax, CT of the mediastinum and abdomen is mandatory to search for lymphadenopathy and is also useful in the diagnosis of lymphangioleiomyomatosis.

Bipedal lymphangiography or lymphoscintigraphy (e.g., with technetium-99m–labeled human serum albumin) is useful to help pinpoint the site of chyle leak along the thoracic duct.[115-117] Combination of

lymphoscintigraphy with three-dimensional MRI can provide additional anatomical and functional details of the lymphatic channels.[118]

It should be emphasized that examination of the pleura is unlikely to provide insight to the etiology of the chylothorax. Hence, pleural biopsy or thoracoscopy is not usually indicated in the workup of patients with a chylothorax.

Treatment

General Approaches

Management strategies for chylothoraces should be directed toward (1) maintaining nutrition and reducing the flow of chyle, (2) relieving dyspnea by removing the chyle, and (3) closure of the defect (Table 74-1).

Maintaining Nutrition and Reducing the Flow of Chyle. The main dangers to the patient are malnutrition and immunodeficiency from removal of a large volume of chyle; hence it is important to initiate definitive treatment of the chylothorax promptly.

Regardless of the cause, closure of the thoracic duct leak may be facilitated by reducing the flow of chyle. This can be achieved by using parenteral hyperalimentation to provide nutrition. Alternatively, a low-fat diet with most fats in the form of medium-chain triglycerides can reduce chyle flow because the medium-chain triglycerides are absorbed directly into the blood.[92] Input from an experienced dietitian is recommended.

A range of compounds have been tested to hasten the closure of thoracic duct leak. Most studies have used octreotide (a somatostatin analog)[119–122] in postoperative pediatric patients in uncontrolled trials, but evidence on its use in adults and for nontraumatic chylothoraces is relatively scarce; large controlled studies are urgently needed. In a series of chylothoraces in 85 children, 85% responded to dietary manipulation. Somatostatin therapy was successful in half of the remaining 15% of cases, but no factors were identified to predict octreotide response.[123] The mechanism of its action is not clear but is believed to be related to a reduction of intestinal fat (especially triglyceride) absorption and increased fecal fat excretion.[119] Common side effects include flushing, nausea, and diarrhea. Other agents examined include etilefrine[124]—a sympathomimetic drug that aimed to induce contraction of smooth muscles around the main thoracic duct—and factor XIII; the results of these agents need further verification.

TABLE 74-1. Management of a Chylothorax

Maintaining Nutrition and Reducing the Volume of Chyle Circulation
Dietary: medium-chain triglyceride diet or total parenteral nutrition
Octreotide
Relieving Dyspnea by Removing Chyle from the Pleural Cavity
Thoracentesis (short term only)
Tube thoracostomy (short term only)
Pleuroperitoneal or pleurovenous shunting
Pleurodesis
Treatment of the Underlying Defect
Thoracic duct embolization
Ligation of the thoracic duct (thoracoscopy or thoracotomy)
Clipping or fibrin glue to the thoracic duct leak
Radiotherapy for mediastinal lymphoma

Relieving Dyspnea by Removing Chyle. Thoracentesis or tube thoracostomy may be used initially, but every attempt should be made to minimize the duration of tube drainage to avoid malnutrition or immunosuppression.

Pleuroperitoneal shunts are advisable if the chylothorax fails to resolve quickly. This minimizes the risks of malnourishment or immunodeficiency because the lymph is not removed from the body. Some authors recommend pleuroperitoneal shunts as the first line of management as soon as the diagnosis is established. To date, most series on pleuroperitoneal shunts are based in pediatric populations. Pleuroperitoneal shunting is contraindicated if ascites is present, and is less likely to be successful if the chylothoraces result from central venous thrombosis.[125] Redirection of the chyle back into the systemic circulation has been performed successfully via pleurovenous shunts.[126] Use of indwelling pleural catheters for ambulatory drainage of chylothoraces has been reported in a retrospective series of 10 patients.[127]

Closure of the Defect. With traumatic chylothorax, the defect in the thoracic duct frequently closes spontaneously. If the pleuroperitoneal shunt is ineffective in draining the pleural space, or if the patient has a chest tube and the drainage of chyle continues unabated beyond 7 days, a more aggressive treatment plan is needed. In a series of 27 patients with chylothorax following lung resection, those with large-volume drainage (>500 mL per 24 hours) despite total parenteral nutrition were more likely to require reoperation.[96] In another series of patients with post–lung resection chylothorax, 13 of the 15 patients with lower initial drainage volume (mean 300 mL/day) responded to conservative treatment, whereas only 6 of 11 patients with larger drainage volume responded.[128]

Several options exist to control the chyle leak. Talc pleurodesis by slurry or poudrage has been successful in some reports.[129] Recently, lymphatic embolization and blockade has been shown in a large series of 42 patients to be safe, with a complete or partial response rate of 74%.[130] The thoracic duct is punctured transabdominally via a peritoneal cannula under fluoroscopic guidance and the duct is embolized with various devices (e.g., microcoils). In patients whose thoracic duct cannot be cannulated, disruption of the duct with needles may be sufficient to reduce or stop the chyle leak.[130] Retrograde embolization of the cisterna chyli has been attempted via a microcatheter passed through the thoracic duct for the treatment of chylous ascites.[131] Coils, gelatin sponge, and doxycycline have been used as embolization material.[131]

Surgical repair of the thoracic duct defect should be considered if lymphatic embolization is unavailable or

fails. Surgical ligation can often be achieved via VATS, but thoracotomy is sometimes required. The duct is ligated above and below the site of the leak or at the lowest point in the chest.[132] Various technical advances have been tried, including fibrin glue application around the leak,[133] use of robotic ligation,[134] and thermofusion of the thoracic duct using a computer-controlled diathermy system.[135] Ligation of the thoracic duct by laparoscopy has also been attempted with success.[136]

Ideally, the site of the leak should be identified preoperatively by a lymphangiography or lymphoscintigraphy. The identification of the thoracic duct can also be facilitated with preoperative oral administration of cream.[137]

If for technical reasons, the thoracic duct cannot be successfully ligated during VATS, a pleurodesis (e.g., partial pleurectomy or talc insufflation) should be performed to obliterate the pleural space during the operation.

Special Considerations

Nontraumatic Chylothorax. If the patient is known to have either lymphoma or metastatic carcinoma, the chylothorax can respond to mediastinal radiation. In one series, mediastinal radiation adequately controlled the chylothorax for the remainder of the patient's life in 68% of those with lymphoma and in 50% of those with metastatic carcinoma.[138] If radiation therapy fails, embolization, pleurodesis, or pleuroperitoneal shunting should be considered.[139]

If the cause of a nontraumatic chylothorax is unknown, the initial management is similar to that for a patient with a traumatic chylothorax, as discussed previously. A pleuroperitoneal shunt should be inserted to allow time for a thorough evaluation. If chest CT and lymphangiography are normal, the chylothorax can be assumed to be due to minor trauma, and spontaneous closure can be expected within weeks.

Fetal and Congenital Chylothorax. Congenital chylothorax, diagnosed either in utero or after birth, can cause developmental abnormalities and at times be fatal.[105] Congenital chylothorax was present in 3.2% of 598 patients with hydrop fetalis in one series, with a mortality of 5.9%.[140] If diagnosed in utero, maternal dietary restriction should be initiated.[141] Thoracentesis can be performed under ultrasound guidance to evacuate the chylothorax,[142] as large effusions can cause pulmonary hypoplasia and respiratory distress at birth.[105] If the chylothorax reaccumulates, pleuro-amniotic shunting should be considered.[143] In a small number of reported cases, ultrasound-guided intrapleural administration of OK-432[144] or maternal blood[145] has offered effective control of the chylothorax, presumably via creating a pleurodesis.

If the congenital chylothorax is diagnosed after birth, the baby should be treated conservatively with repeated thoracenteses to avoid respiratory compromise while nutrition is maintained by the parenteral route or with medium-chain triglycerides.[146] Feeding with centrifuged breast milk (which removes the fat content) was attempted in one small study.[147] Although the evidence supporting octreotide remains limited, it has a good safety profile and can be tried. If the chylothorax recurs after the third pleural aspiration, however, a pleuroperitoneal shunt should be placed. If the shunt is unsuccessful, thoracic duct ligation is recommended.[105]

Pulmonary Lymphangioleiomyomatosis. Pulmonary lymphangioleiomyomatosis (LAM) is a rare condition, affecting mostly women of reproductive age, and is characterized by progressive dyspnea, recurrent pneumothoraces, and chylous effusions (see Chapter 62). The reported incidence of chylothorax in patients with LAM ranges from 10%[148] to 30%.[149] It can occur in both the sporadic and the tuberous sclerosis complex–associated types of LAM—the former is associated with a higher incidence of chylothorax.[148] Whereas the mean age of presentation of LAM is in the early 30s,[150] the mean age of presentation of chylothorax is in the early 40s.[148] The chylothorax is usually unilateral but can be bilateral[148] or associated with chyloascites. The chylothorax is thought to be the result of the combination of perilymphatic proliferation of smooth muscle leading to lymphatic obstruction and of infiltration of the lymph nodes in the mediastinum and retroperitoneal space by immature smooth muscle cells.[151] CT scan is usually diagnostic for LAM (see Fig. 74-4). Typical LAM cell clusters can also be found in the chylous pleural fluid.[152]

The general principles for the management of a chylothorax secondary to LAM are similar to those for any nontraumatic chylothorax. The course of these chylothoraces is highly variable.[148] In some cases, simple thoracentesis for symptomatic relief is adequate.[148] However, in two series combined, 12 of the 19 LAM patients with chylothoraces required either pleurodesis or thoracic duct ligation to control the reaccumulation of chyle.[148,153]

It should be emphasized that lung transplantation is a treatment option for a proportion (19% in one series[154]) of patients with LAM. The morbidity and mortality of transplantation is increased in these patients, especially from intraoperative bleeding,[155] which is attributed to pleural adhesions from recurrent pneumothoraces. Although pleurodesis is not an absolute contraindication for future transplantation, a transplant surgeon should be consulted before subjecting LAM patients with a chylothorax to pleurodesis or surgical ligation of the thoracic duct.

PSEUDOCHYLOTHORAX (CHYLIFORM PLEURAL EFFUSIONS; CHOLESTEROL PLEURAL EFFUSIONS)

A pseudochylothorax (chyliform pleural effusion) may also produce milky turbid pleural fluid. The turbidity is related to high levels of cholesterol or lecithin-globulin complexes in the fluid. Pseudochylothoraces, with fewer than 200 reported cases in the literature,[156] are much less common than chylothoraces.

Pathogenesis

Although pseudochylothorax was first reported over a century ago, its precise pathogenesis remains unknown. Most patients with a pseudochylothorax have pleural surfaces that are markedly thickened and sometimes calcified, and the effusion is usually long-standing. It appears that, if an exudative effusion persists for a lengthy period—months to years—in a fibrotic area of grossly thickened pleura, it has a high tendency to become enriched with cholesterol.[92] However, increasing reports of pseudochylothoraces without chronic pleuritis or grossly thickened pleura challenge the traditional belief.[157]

Most of the cholesterol in chyliform pleural effusions is associated with high-density lipoproteins, in contrast to the cholesterol in acute exudates, which is mostly bound to low-density lipoproteins.[158] It has been hypothesized that, during acute inflammation, there is increased filtration of cholesterol into the pleural fluid.[158] In addition, the cholesterol can originate from degeneration of erythrocytes and leukocytes that enter the pleural space as part of the underlying disease process.[159] The thickened pleura inhibits the exit of cholesterol out of the pleural space.[158] Serum cholesterol levels and systemic cholesterol metabolism appear to be normal in patients with pseudochylothorax.

The most common situations in which chyliform pleural effusions occur are after tuberculous pleurisy (54%), including those cases treated with artificial pneumothorax. Successful treatment of an acute tuberculous pleurisy does not preclude the development of a pseudochylothorax.[156] Pseudochylothorax can develop in association with chronic rheumatoid pleurisy (9% of pseudochylothoraces) and rarely with paragonimiasis and trauma (including thoracic surgery).[160]

Clinical Manifestations

Pseudochylothorax commonly but not inevitably develops in patients with long-standing pleural effusions. The mean duration of the effusion is 5 years before it turns chyliform, but much shorter times of onset have been reported.[157,161] Many patients with chyliform pleural effusions are asymptomatic or at least no more symptomatic than when they initially developed the pleural effusion. When symptoms occur, they are usually related to the underlying disease process or to the pulmonary restriction produced by the effusion and the thickened pleura. In some cases, the effusion gradually enlarges with time, with resultant progressive dyspnea.[92]

Diagnosis

The pleural effusion is often chronic and associated with thickened or calcified pleura. The fluid is milky, and the differential diagnoses of chylothorax and empyema need exclusion (see earlier). The pleural fluid should be examined for cholesterol crystals—a diagnostic feature of pseudochylothorax. The cholesterol crystals give a distinct satin-like sheen to the pleural fluid and microscopically have a typical rhomboid appearance. Not all patients with chyliform pleural effusion have cholesterol crystals in their pleural fluid; however, most have an elevated pleural fluid cholesterol level (>250 mg/dL, or 6.45 mmol/L).[1] Pleural fluid triglyceride levels can be high in pseudochylothorax. CT chest scan can reveal a layering of fat in nondependent sites, as shown in a series of pseudochylothorax patients.[162]

Treatment

Tuberculosis should always be considered in patients with a pseudochylothorax, although tuberculous pseudochylothorax is usually culture negative.[156] We advise drainage only in symptomatic cases and treating with antituberculous chemotherapy only those patients with positive stain or culture for tuberculosis and those with enlarging effusions of suspected tuberculous origin (see Chapter 34).

When the patient's exercise capacity is limited by breathlessness, a therapeutic thoracentesis should be performed and can improve exercise tolerance.[159] Thoracentesis can be difficult because of the frequently thickened pleura and negative intrapleural pressure.[92] Limited evidence exists to support surgical decortication, which should only be considered if the patient is symptomatic and the underlying lung is believed to be functional.

HEMOTHORAX

Hemothorax is the presence of blood in the pleural space, specifically when the hematocrit of the pleural fluid is at least 50% that of the peripheral blood.[1] When bloody pleural fluid is obtained with a diagnostic thoracentesis, the hematocrit should always be measured. Frequently, even though the pleural fluid appears to be pure blood, the hematocrit of the fluid will be less than 5%.[1]

Traumatic Hemothorax

Blood may enter the pleural space from injury to the chest wall, diaphragm, lung, blood vessels, or mediastinum. On entering the pleural space, the blood coagulates rapidly but, presumably as a result of the physical agitation produced by movement of the heart and lungs, the clot may be defibrinated. Loculation may develop early in the course of hemothorax.

Diagnosis

The diagnosis of traumatic hemothorax should be suspected in any patient with penetrating or nonpenetrating trauma of the chest (Fig. 74-8). It should be emphasized that the hemothorax may not be apparent on the initial chest radiograph. In one series of 130 patients with hemothorax secondary to nonpenetrating trauma, the hemothorax was not appreciated on the initial chest radiograph in 24% of the patients.[163] Although

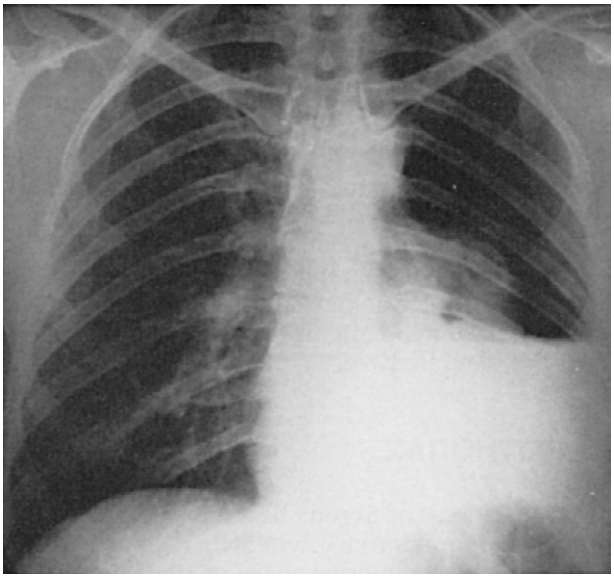

FIGURE 74-8 ■ Posteroanterior chest radiograph from a patient who suffered multiple injuries in an automobile accident. The patient had a hemopneumothorax. With the prompt institution of tube thoracostomy, the air and blood were evacuated from the pleural space and the chest radiograph was normal 1 week later.

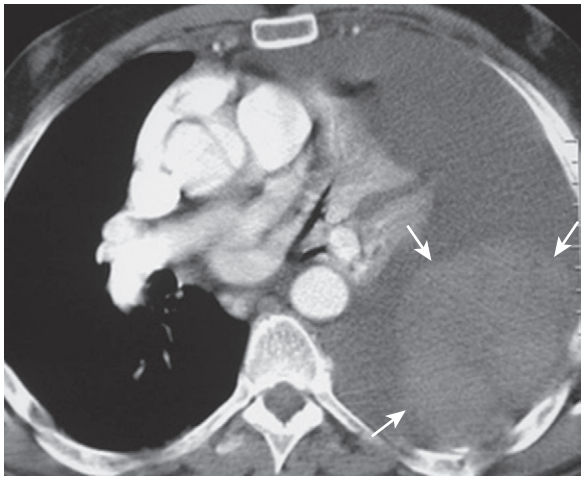

FIGURE 74-9 ■ Axial computed tomography scan of a patient with a large left hemothorax. The hyperdense region (*arrows*) indicates a retracted thrombus. Occasionally, unclotted erythrocytes can settle to the dependent area, creating a "fluid-fluid level," representing the so-called hematocrit sign. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

the hemothorax was missed in some of the patients because the initial radiograph was obtained with the patient supine, other patients had no evidence of a hemothorax on the erect radiograph.[163]

The CT scan is more sensitive than the chest radiograph in detecting hemothoraces. In a study of 103 patients with blunt trauma,[58] thoracic CT detected a hemothorax in 21 patients (20%) in whom the routine chest radiograph showed no pleural fluid. When patients experience severe thoracic trauma, a CT scan of the chest is indicated for its ability to identify hemothorax as well as pneumothoraces, lung contusion, and bone fractures.[58] The diagnosis is established if the pleural fluid hematocrit is greater than 50% of that of the peripheral blood.

Ultrasound is now available in many emergency rooms, and has been applied for the detection of traumatic hemothoraces. In one study of 240 patients, ultrasonography was comparable to initial chest radiograph in detecting hemothoraces, with a specificity and sensitivity of 100% and 96%, respectively.[164] On CT scans, hyperdensity, due to the high hemoglobin content of retracted clot or sedimented blood, may point toward a hematoma (Fig. 74-9).[165]

Delayed hemithorax has been reported and, in one study of 36 patients, occurred in one third at 18 hours to 6 days following the initial blunt trauma. Most of these patients had multiple or displaced rib fractures.[166] However, in another series of 100 patients with penetrating thoracic trauma, none developed a hemothorax after 3 hours.[167]

A patient with a traumatic hemothorax should undergo immediate tube thoracostomy: it permits nearly complete evacuation of the blood from the pleural space; it can stop the bleeding from pleural lacerations by bringing the two pleural surfaces into apposition; it enables quantification of the degree of continued bleeding; and it may decrease the incidence of subsequent empyema. The blood drained from the pleural space may be autotransfused. The rapid evacuation of the blood from the pleural space may decrease the incidence of a subsequent fibrothorax.

It is recommended that the chest tube be inserted relatively high (fourth or fifth intercostal space) in the midaxillary line because the ipsilateral hemidiaphragm may be elevated secondary to the trauma. Alternatively, it should be inserted under image guidance. Large-bore chest tubes should be used because the blood frequently clots. Chest tubes should be removed as soon as they stop draining or cease to function, because they can serve as conduits for pleural infection.

Approximately 20% of patients with hemothorax require surgical intervention for suspected cardiac tamponade, vascular injury, pleural contamination, débridement of devitalized tissue, chest wounds, major bronchial air leaks, or continued pleural hemorrhage. Posttraumatic hemithorax was traditionally managed exclusively by thoracotomy, but advances in VATS have made it the procedure of choice in many centers,[168] with thoracotomy reserved only for massive acute hemorrhages. There are no precise criteria for the amount of pleural bleeding that should serve as an indication for thoracoscopy or thoracotomy, and each case must be individualized; however, if the bleeding is more than 200 mL/hr and shows no signs of slowing, surgical intervention should be seriously considered.

In a recent series, patients with active hemothorax drainage over 200 mL/hr were subjected to contrast-enhanced CT scan, which allowed identification of sites of bleeding intercostal arteries (by tracking the extravasation of the contrast). In all five patients, transcatheter arterial embolization successfully stopped the bleeding.[169]

Complications

The four main potential pleural complications of traumatic hemothorax are the retention of clotted blood in the pleural space, pleural infection, pleural effusion, and fibrothorax. In one retrospective series, 24 (1.4%) of 1728 chest trauma patients had a residual hemothorax.[170] Most patients with small to moderate amounts of clotted blood remaining in their pleural space have no residual pleural abnormalities even if no intervention is undertaken.[171] If more than 30% of the hemithorax is occupied by clotted blood, the hemithorax should be evacuated. Decisions regarding thoracoscopic evacuation should not be made from the plain chest radiograph alone and require CT studies.[172] VATS is the mainstay of management, and conversion to thoracostomy is seldom required.[168] The clotted blood should be evacuated within 7 days because after this time it begins to become organized and is much more difficult to remove.[168] In a prospective, randomized trial, VATS was more effective than thoracostomy tube drainage for removing retained hemothoraces. In this study, both the length of hospital stay (7 vs. 3.6 days) and the duration of tube drainage (4.5 vs. 2.5 days) were shorter in the group receiving VATS.[173] In another series, thoracoscopic evacuation performed within 3 days of admission was associated with a lower operative difficulty score (and shorter operation time) and shorter inpatient stay, compared with patients operated at later time points.[170]

Once the source of the bleeding is controlled, intrapleural administration of fibrinolytic agents (e.g., streptokinase or urokinase) may be safe in patients with hemothorax and retained clots, according to several descriptive studies.[174] However, there have been no comparative studies to confirm the efficacy of fibrinolysis versus conservative management or surgical evacuation.

Empyema occurs in 1% to 4% of patients with traumatic hemothoraces.[171,175] Empyema is more frequent in patients who are admitted in shock, have gross contamination of their pleural space, have associated abdominal injuries, or undergo prolonged pleural drainage.[171,175] The administration of prophylactic antibiotics (e.g., cefazolin 500 mg every 6 hours until tube removal) results in a significant decrease in the incidence of pleural infection.[176] The treatment of empyema complicating hemothorax is similar to that of any bacterial infection of the pleural space (see Chapters 32 and 73).

In more than 10% of patients with a traumatic hemothorax, a pleural effusion will develop after the chest tubes are removed.[171,175] Most such pleural effusions resolve spontaneously, leaving no residual pleural abnormalities. It is important to perform a diagnostic thoracentesis in such patients, however, to verify that no pleural infection is present.

Fibrothorax develops in less than 1% of patients with hemothorax. Fibrothorax appears to develop more frequently when a hemopneumothorax is present or when a hemothorax becomes infected. The definitive treatment for fibrothorax is decortication. Decortication for fibrothorax should be delayed for several months after the injury, however, to allow time for spontaneous resolution of the pleural thickening, which is often considerable.

Iatrogenic Hemothorax

Whenever a hemothorax is discovered, the possibility of an iatrogenic origin should be considered. The most common cause of iatrogenic hemothorax is thoracic surgery,[177] but perforation of a central vein or artery by a percutaneously inserted catheter[178] or leaking from the aorta after translumbar aortographic study are also common. Iatrogenic hemothorax can also follow thoracentesis, pleural biopsy, chest tube insertion, percutaneous lung aspiration or biopsy, transbronchial biopsy, endoscopic esophageal variceal therapy, and cardiopulmonary resuscitation. Patients with iatrogenic hemothoraces should be managed, as are patients with traumatic hemothoraces, with chest tubes and thoracoscopy or thoracotomy as needed.

Nontraumatic Hemothorax

Nontraumatic hemothoraces are distinctly uncommon. The most common cause is malignant pleural disease and the second most common cause is a complication of anticoagulation therapy for pulmonary embolization.[179] The cause of the hemothorax in some patients remains unknown despite exploratory thoracotomy.

A spontaneous hemothorax may result from rupture of an abnormal intrathoracic blood vessel, such as subpleural arteriovenous malformations, aneurysm of the aorta or pulmonary artery, patent ductus arteriosus, or coarctation of the aorta. Other causes of a spontaneous hemothorax include a complication of bleeding disorders (such as hemophilia or thrombocytopenia), a complication of spontaneous pneumothoraces, bronchopulmonary sequestration, thoracic endometriosis, chickenpox pneumonia, or intrathoracic extramedullary hematopoiesis. Spontaneous hemothorax is a rare but potentially life-threatening complication of neurofibromatosis, either from aneurysmal changes in large arteries (e.g., aorta) or from dysplastic changes in small vessels.

Mediastinal tumors can also produce a spontaneous large hemothorax, which can be bilateral. Blood can also accumulate in the pleural space due to pathologies of abdominal organs, such as rupture of a splenic artery aneurysm through the diaphragm, pancreatic pseudocysts, and rupture of hepatocellular carcinomas.

Hemothoraces can complicate anticoagulant therapy (warfarin[180] or heparin—low molecular weight[181] or unfractionated[179]) or intrapleural fibrinolytic therapy.[180] The hemothorax usually becomes apparent 4 to 7 days after anticoagulation therapy is initiated, but it may occur much later. When the hemothorax develops, the coagulation studies may be within the acceptable therapeutic range.[179]

Chest tubes should be inserted into patients with spontaneous hemothorax to remove the blood from the pleural space and to quantify the rate of bleeding. If brisk (>100 mL/hr) bleeding persists, emergency thoracotomy should be performed.

FIBROTHORAX

Dense fibrous tissue may form over the pleural surface for a variety of reasons. Pleural fibrosis usually follows intense inflammation of the pleura; however, the mechanisms following the inflammatory process leading up to fibrosis are unclear. Profibrotic cytokines, especially transforming growth factor-β (TGF-β), probably play a significant role. In various animal models, TGF-β, administered directly or via vector transfection, induces pleural fibrosis, and anti–TGF-β antibodies can inhibit pleural adhesion formation in empyema.[182]

A fibrothorax most commonly develops as a complication of an empyema or a hemothorax. Fibrothorax has also developed as a complication of tuberculosis, collagen vascular diseases, uremia, paragonimiasis, and drug reactions. Pleural fibrosis can be idiopathic, and isolated familial cases have been reported.[183] Whereas tuberculous pleuritis is common, fibrothorax is a rare complication.[184] In one study, restrictive functional sequelae were found in 10% of 81 patients with tuberculous pleuritis, but were mostly mild.[185] Neither the early drainage of the pleural effusion[186] nor the use of systemic corticosteroids[187] has significant impact on subsequent development of pleural thickening or restrictive lung function in patients with tuberculous pleuritis. Pleural fluid inflammatory markers are, at best, weak predictors of eventual pleural thickening.[185]

Asbestos exposure may also lead to a fibrothorax (also called diffuse pleural thickening), which is usually bilateral.[188] In these cases, extensive fibrosis of the visceral pleura develops, together with areas of adhesion with the parietal surfaces, thus obliterating the pleural space.[188] Diffuse pleural thickening is known to follow benign asbestos pleural effusions, and it has been suggested that this is a necessary precursor of fibrothorax.[189] In one series of 44 patients with diffuse pleural thickening, half had a history of benign asbestos effusion; conversely, 54% of those who had a benign asbestos effusion had residual pleural thickening.[189] Diffuse pleural thickening is usually,[188] but not inevitably, associated with heavy asbestos exposure, and its incidence increases with increasing time since first exposure.[189] The pleural fibrosis is often progressive, resulting in restrictive lung defects, especially if the costophrenic angle is obliterated.[190]

Pleural (with or without concurrent pulmonary) fibrosis can also occur with the use of ergot alkaloids (e.g., bromocriptine, pergolide, and methysergide).[180,191] It has been suggested that subjects with asbestos exposure may be more susceptible to bromocriptine-induced pleural fibrosis.[192] Onset of dyspnea from ergot-induced pleural fibrosis is usually insidious and in the majority of cases presents at least 6 months after starting the medication.[180] The pleural thickening is usually bilateral but can be unilateral, and may be associated with pleuritic pain. Constitutional symptoms and elevated serologic inflammatory markers have also been reported.[191] In the case of bromocriptine, the fibrothorax will stop progressing on cessation of the drug use, and may regress,[180] though complete resolution is rare. Corticosteroids are often administered, but their effectiveness has never been established.[180] Pleural fibrosis is often bilateral (if due to systemic causes) and may be associated with concurrent peritoneal fibrosis.[193]

Although pleural fibrosis is usually an undesirable event, it is commonly used therapeutically (pleurodesis) to control pleural effusions and pneumothoraces. Pleurodesis is the iatrogenic induction of pleural fibrosis, leading to symphysis of the visceral and parietal pleurae to obliterate the pleural space to prevent fluid or air reaccumulation.[194] Interestingly, pleurodesis has no major impact on pulmonary function, even after decades. A retrospective review of young patients treated 22 to 35 years ago for spontaneous pneumothoraces showed that those who received talc pleurodesis (n = 80) had a higher incidence of pleural thickening on radiographs, but minimal restrictive changes in their lung function when compared with those treated by simple drainage (n = 34).[195] Several small human and animal studies also revealed no significant impairment in lung volumes and gas exchange at rest or during exercise following pleurodesis.[194] Such observations imply that, for a fibrothorax to be clinically significant, it must involve either very extensive pleural fibrosis (in excess of therapeutic pleurodesis) or concomitant parenchymal fibrosis.

Diagnosis

In one large population screening study of over 70,000 subjects, pleural thickening was reported in 3.6% of radiologic examinations.[196] In typical cases, the diagnosis of fibrothorax can easily be made from the radiographic findings plus a history of a predisposing cause (e.g., an old injury or infection). Radiologically, a peel of uniform thickness surrounds the lung. Calcification occurs frequently on the inner aspect of the peel (Fig. 74-10) and provides an indicator by which the thickness of the peel may be accurately measured. Apparent pleural thickening can occur, especially in obese subjects (body mass index >30), presumably the result of extrapleural fat deposition.[197] A CT scan can easily discriminate between fat and thickening.

Recently, a new CT scoring system that quantifies the thickness of the pleura and the fractional circum-

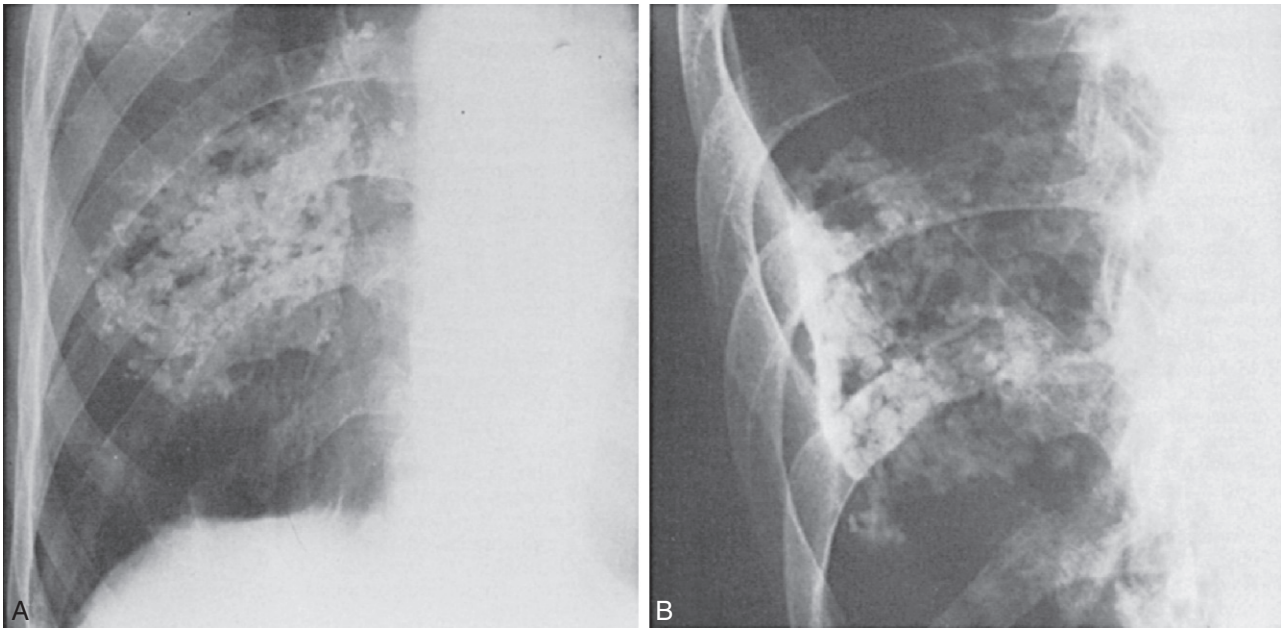

FIGURE 74-10 ■ Detailed views from posteroanterior **(A)** and oblique **(B)** chest radiographs of a 62-year-old man showing a localized fibrothorax with calcified plaque on the right. The patient had had right-sided empyema 32 years before. (From Hinshaw HC, Murray JF: Diseases of the Chest. Philadelphia: WB Saunders, 1980, p 912.)

ference of the hemithorax involved (as well as other pleural changes, such as rounded atelectasis and pleural plaques) has been shown to correlate with impairment in pulmonary function measures (especially total lung capacity and diffusing capacity).[198]

Routine pulmonary function testing usually reveals mild to severe restrictive ventilatory dysfunction.[189] In the case of asbestos-induced diffuse pleural thickening, the restriction arises from inflammatory involvement of the costal surfaces of the diaphragm and lower costal pleura, thus producing a pleurodesis that limits the movement of both the diaphragm and rib cage during inspiration.[199] The reduction in rib cage expansion is the main cause of restriction, because the diaphragm can still contribute by flattening of its dome on inspiration.[199] In one study, 95% of patients with asbestos-induced diffuse pleural thickening complained of exertional dyspnea.[200] Objective reduction of exercise work capacity had also been shown.[201]

Pulmonary function may be severely compromised in patients with an extensive fibrothorax. As a result of the marked pleural thickening, the hemithorax becomes contracted, and its mobility is reduced. As the fibrothorax progresses, the intercostal spaces may narrow, the size of the involved hemithorax may diminish, and the mediastinum may be displaced ipsilaterally. In patients with bilateral fibrothorax resulting from asbestos exposure, hypercapnic respiratory failure may develop and may be amenable to home noninvasive ventilation.[202]

Treatment

It should be emphasized that patients with a recent hemothorax, empyema, or tuberculous pleuritis frequently show marked spontaneous improvement in their symptoms and the degree of pleural thickening in the 3 to 6 months after the acute episode.[203] Patients with a fibrothorax should avoid drugs that can induce pleural fibrosis.

Decortication—surgical removal of the fibrous peel from the pleural surface—has been attempted to treat fibrothorax. However, the degree of improvement after decortication varies, with many series showing disappointing results.[204,205] Success in part depends on the condition of the underlying lung. If the underlying lung is normal, the vital capacity may improve after decortication but, if there is extensive parenchymal disease, the vital capacity may even decrease. The duration of the fibrothorax does not seem helpful in predicting the outcome. Surgical morbidity and mortality are not insignificant.[206] Therefore, decortication should be considered only if the pleural thickening has been present for several months and if the patient is significantly affected by exertional dyspnea. Decortication is a major surgical procedure and should not be performed on patients debilitated by other diseases.

If CT scans reveal significant parenchymal disease, decortication is not advisable. The results of decortication in patients with bilateral fibrothoraces secondary to asbestos exposure have been disappointing, probably a result of concomitant pulmonary fibrosis.[207]

KEY POINTS

- Simple aspiration is the recommended first step of air evacuation in most cases of primary spontaneous pneumothorax.
- Secondary spontaneous pneumothorax is potentially life-threatening, and prevention of recurrence should be considered even at the first episode of pneumothorax.
- Chylothorax is characterized by milky fluid and the presence of chylomicrons. Early intervention is advocated because prolonged drainage of chylous effusion can lead to malnutrition.
- Pseudochylothorax is characterized by cholesterol crystals, and should be differentiated from chylothorax because the etiology and management are different.
- A traumatic hemothorax should be drained and, if the bleeding rate is greater than 200 mL/hr, intervention targeting the underlying bleeding site by surgical or interventional radiologic means should be considered. Traumatic hemothorax can be complicated by retention of clotted blood in the pleural space, pleural infection, pleural effusion, and rarely fibrothorax.
- Pleural thickening may improve spontaneously during the 3 to 6 months after acute hemothorax, empyema, or tuberculous pleuritis. Decortication should be considered only if the pleural thickening has been present for several months and if the patient is significantly affected by exertional dyspnea.

PRIMARY EFFUSION LYMPHOMA

PYOTHORAX-ASSOCIATED LYMPHOMA

INTRODUCTION

Tumors of the pleural space can be primary or secondary. The secondary tumor due to metastatic spread of malignancy usually from lung or breast cancer is the most common and is discussed first. Pleural metastatic disease is estimated to affect 200,000 persons/yr in the United States and serves as the most common cause of exudative pleural effusion after infection.[1] Unfortunately, because it represents metastatic spread, treatment goals are generally that of palliation, not cure. Survival is poor, with a median of 4 months.[2] Primary tumors of the pleural space are less common. The most common primary tumor, malignant mesothelioma, affects approximately 3000 persons/yr in the United States, although the incidence is growing worldwide.[1] Interestingly, despite its grim reputation, mesothelioma offers better survival than does metastatic pleural disease, with a median survival of less than 12 months.[3] Although curative treatments are not yet available, progress is being made. Other rare but interesting tumors such as solitary fibrous tumor of the pleura, primary effusion lymphoma, and pyothorax-associated lymphoma are discussed.

METASTATIC PLEURAL DISEASE

Types of Tumor

Certain tumors appear to have a predilection for metastasis to the pleura, particularly lung cancer, breast cancer, and lymphomas, and less commonly gastrointestinal and genitourinary malignancies (Table 75-1). In approximately half the cases of metastatic pleural disease, the patient will have an associated pleural effusion, most often exudative.[4] However, in up to 10% of the malignant pleural effusions, the tumor of origin is not identified.[5] After infectious diseases, malignant pleural effusions are the leading cause of exudative effusions.[1]

The pattern of metastatic spread can provide some clues to the identity of the primary tumor. Whereas malignant mesotheliomas generally originate on the parietal pleura and then spread to the visceral pleura, metastases due to bronchogenic carcinoma usually are first found on the visceral pleura and then spread to the parietal pleura. Metastatic pleural involvement is rarely found exclusively on the parietal pleura.[4] In addition, the side of a malignant effusion is usually the same as the tumor of origin in most cases of bronchogenic carci-

TABLE 75-1. Primary Tumors Responsible for Malignant Pleural Effusion*

Primary Tumor Site	Total (%)
Lung	37.5
Breast	16.8
Lymphoma	11.5
Gastrointestinal	6.9
Genitourinary	9.4
Other	7.3
Unknown	10.7

*A compilation of data from five different reports with a total of 2040 patients. The "other" category includes ovarian carcinoma, sarcomas, uterine and cervical carcinomas, and other carcinomas.

noma, with 17 out of 24 cases ipsilateral in one autopsy series.[6] In patients with pleural metastasis due to other cancers, evidence from two autopsy series suggests that the malignancy initially involves the visceral pleura and moves to the pleural space from there.[4,6]

Clinical Features

The most common symptom associated with malignant pleural disease is dyspnea, most often from the presence of a pleural effusion (see Chapter 73). Cough may also be caused by the presence of a pleural effusion. If the effusion is the cause of these symptoms, both dyspnea and cough can be relieved promptly by thoracentesis. When a thoracentesis fails to relieve these symptoms, tumor infiltration of lung or pleura or another medical condition should be suspected. Chest pain is often described as a "dull ache"; this may indicate involvement of the chest wall and sensory neurons of the parietal pleura and chest wall. Because sensory neurons are now known to lie in the visceral pleura, pain may not necessarily mean involvement of the parietal pleura and chest wall.[7] In one series, 34% of patients with malignant pleural effusion described a dull chest ache and 24% described a pleuritic chest pain.[8] Patients with benign causes of their effusions were more likely to describe pleuritic chest pain.[8] Systemic symptoms may include malaise and anorexia.

Malignant Pleural Effusions

Malignant pleural disease can exist without pleural effusion. In autopsy studies of patients with malignancy, malignant pleural disease was associated with an effusion in 55%[4] to 60%[6] of cases. It is increasingly recognized that malignant cells can reach the pleural space without effusion because cytology of pleural lavage can be positive in patients undergoing resection for lung cancer who have no effusion. In one study of more than 1200 patients with lung cancer without effusion undergoing curative surgical resection, 7.0% had positive pleural cytology on lavage at the time of resection.[9] The development of an effusion may depend on characteristics of the tumor cells because of either their secretion of bioactive mediators or their ability to initiate inflammatory, angiogenic, or fibrinolytic processes.[10]

Lung cancer is the most common cause of malignant pleural effusions[11] (see Table 75-1). Lung cancer and breast cancer together account for more than half of all malignant pleural effusions. Of the histologic types of bronchogenic cancers, adenocarcinomas are most frequently associated with malignant pleural effusions, but effusions may be seen with all types.[12]

Breast cancer is the second most common cause of malignant pleural effusions.[11,13] The time course of development of the effusion from the time of initial diagnosis of breast cancer is usually 2 years, but can be up to 20 years. The effusion usually is ipsilateral to the side of the original tumor (50%) but can also be contralateral (40%) and, less commonly, bilateral (10%).[14]

Lymphoma is the third most common cause in most series[11] but is possibly the most common cause in young adults.[13] Pleural effusions are common in both non-Hodgkin and Hodgkin lymphoma.[15] In patients with non-Hodgkin lymphoma, approximately 16% will develop malignant effusions and most will have the effusion at the time of initial diagnosis in association with evidence of disease elsewhere.[16] The high yield of pleural fluid cytology suggests frequent invasion of the pleural space.[17] Chylothorax may also develop in some patients with non-Hodgkin lymphoma. In Hodgkin lymphoma, effusions may be caused by hilar or mediastinal lymph node involvement as well as pleural involvement.[15]

Malignancies probably produce pleural effusions by both increasing the entry of liquid and by decreasing the normal exit of liquid (Table 75-2) (see Chapter 73). The entry of liquid can be increased by several mechanisms: (1) increased permeability of the pleural vessels by direct invasion of tumor cells, inflammatory and vasoactive cytokines (e.g., vascular endothelial growth factor [VEGF]), or injury (e.g., radiation-induced), (2) increased permeability of *pulmonary* vessels by infection, pulmonary embolism, or pulmonary infarct with movement of liquid from lung to pleural space, (3) increased hydrostatic forces due to venous obstruction or hypoproteinemia, and (4) entry of other sources of liquid such as chyle from a disrupted thoracic duct. The exit of liquid from the pleural space can be decreased by several mechanisms that would reduce lymphatic drainage: (1) infiltration of parietal pleural lymphatics or mediastinal lymph nodes, (2) lowered pleural pressure due to atelectasis from bronchial obstruction, or (3) elevated downstream central venous pressure, as from a superior vena cava (SVC) syndrome. We suspect that several factors combine to form a pleural effusion in association with malignancy.[18] The malignancy alone may be sufficient to tip the balance between the entry and the exit of liquid toward accumulation of excess pleural liquid. Alternatively, the malignancy may alter the balance gradually without the development of an overt effusion; the advent of another nonmalignant condition, such as heart failure or pneumonia, may then tip the balance and precipitate

TABLE 75-2. Pathophysiologic Mechanisms (Neoplastic and Paraneoplastic) by which Malignancy May Cause Pleural Effusions*

Means of Increasing Liquid	Mechanism	Site/Source	Examples
Increased entry	Increased vascular permeability	Pleural vessels	Invasion by tumor
			Cytokines (e.g., VEGF)
			Injury (e.g., radiation)
		Pulmonary vessels	Infection (e.g., postobstructive pneumonitis)
			Cytokines/injury
	Increased vascular hydrostatic gradient	Pleural vessels	Decreased pleural pressure (e.g., atelectasis)
			Increased venous pressure (e.g., SVC syndrome)
			Decreased plasma osmotic pressure (e.g., hypoproteinemia)
	Nonvascular source	Thoracic duct	Chylothorax
Decreased exit	Increased resistance to lymphatic flow	Pleural lymphatics	Infiltration of parietal pleura
		Lymph nodes	Infiltration of mediastinal lymph nodes
	Increased pressures opposing lymphatic flow		Decreased pleural pressure (e.g., atelectasis)
			Increased venous pressure (e.g., SVC syndrome)

*Most likely, both an increase in entry and a decrease in exit are required to produce a stable pleural effusion. Paraneoplastic refers to mechanisms taking place outside the pleural space.
SVC, superior vena cava; VEGF, vascular endothelial growth factor.
Adapted from Broaddus VC: Physiology: fluid and solute exchange in normal physiological states. *In* Light R, Lee Y (eds): Textbook of Pleural Diseases. London: Hodder Arnold, 2008, pp 43–48.

the appearance of a symptomatic pleural effusion. In these cases, malignancy may contribute to but not be the sole cause of the effusion.[18] Such processes may explain how malignancy can be associated with transudative effusions.[19]

In several animal studies, bioactive molecules involved in angiogenesis and permeability, such as VEGF, have been identified that may play key roles in accumulation of effusions in malignancy.[10] Understanding the mechanisms of effusion formation could lead to new therapeutic approaches such as inhibition of VEGF or the VEGF receptor or interfering with multiple actions including permeability and angiogenesis.

Pleural Fluid Analysis

The pleural fluid is almost always an exudate. The effusion may meet exudative criteria by the lactate dehydrogenase (LDH) only (either the ratio or the absolute level) and not by protein criteria.[20] Such an observation may indicate that an increased cell turnover and cell lysis is the source of the elevated LDH, whereas an increased vascular permeability needed to produce pleural fluid with increased protein concentration is not present. In some studies, perhaps 5% of malignant effusions are found to be transudates.[21] In most of these cases, the primary cause of these "malignant" transudative effusions appears to be congestive heart failure or other known cause of a transudate (e.g., SVC, volume overload), whereas the malignancy is in a secondary, contributing role.[21] Malignancy could be the primary cause of a transudate if, for example, the malignancy interfered with lymphatic absorption of pleural liquid.[18] In such cases, one could imagine that the accumulation of normal pleural liquid as an effusion would produce a transudate. In one interesting case report, a patient with metastatic colon cancer, but without other comorbid conditions, presented with transudative pleural effusions and negative cytology; within 1 month, the effusions were exudative with positive cytology.[22] Biopsy showed parietal pleural lymphatic infiltration, suggesting that the cause of the initial transudative effusion was primarily blockage of pleural liquid lymphatic clearance, followed by invasion of the pleural space and development of an exudate.

The effusion may be grossly bloody; indeed, malignant disease is the most common cause of bloody effusions.[23] However, about half of malignant effusions are not bloody in appearance and have pleural fluid red blood cell counts under 10,000 cells/μL.[23] On cell differential, a predominance of lymphocytes is usual, but a mononuclear or eosinophilic predominance does not exclude the diagnosis. The presence of pleural fluid eosinophilia (>10% eosinophils) has been thought to be unusual in malignant effusion and to argue against the diagnosis.[24] However, in a more recent study of 460 effusions, 20% of the eosinophilic effusions were found to be malignant; of note, 20% of non-eosinophilic effusions were also found to be malignant, showing not only that eosinophilic effusions could be malignant but also that the presence of eosinophilia did not alter the likelihood of malignancy.[25] Eosinophilia in many of these situations may be caused by other factors, such as the prior entry of air or blood into the pleural space. In another study in which care was taken to study only the initial thoracentesis to avoid artifacts due to prior entry of air or blood, eosinophilia was present in 12.6% of all effusions tapped and the presence of eosinophilia did not differentiate malignant from benign etiologies.[26]

The pleural glucose concentration is lower than 60 mg/dL in approximately 20% of malignant pleural

effusions.[27] Effusions with a low glucose level also tend to have a low pleural pH and may have a larger tumor burden in the pleural space. It would therefore be expected that those patients with a low pleural glucose or pH would have a shorter survival and a poorer response to pleurodesis, as has been reported.[28,29] However, more recent studies have found that pleural fluid pH may not be an accurate predictor of survival[30,31] and may also fail to predict which patients will respond to a pleurodesis.[30,32] Therefore, the pleural fluid pH or glucose should not be relied upon for selecting patients for pleurodesis. In fact, for survival, the best predictor may not lie in the pleural space; in one study, the best criteria for predicting survival was the Karnofsky score, a scale from 0 to 100 based on results of the history and physical examination (see "Prognosis and Staging," later).[31]

Pleural fluid amylase concentration is elevated in 10% of patients with malignant pleural effusions.[33] The origin of the amylase is not the pancreas, as shown by its identification as salivary rather than pancreatic amylase.[34] In one series of consecutive effusions, a very high amylase in malignant pleural fluid (>600 IU/L) was a poor prognostic factor.[33]

Radiographic Evaluation

The size of malignant effusions may vary greatly. Some may be small, amounting to a few milliliters and causing only blunting of the costophrenic angle, whereas others are large enough to obscure the hemithorax. In fact, malignancy is the most common cause of effusions that are either large, opacifying more than two thirds of hemithorax, or massive, opacifying the entire hemithorax. In one retrospective series of 766 patients, malignancy was found as the cause of 55% of large and massive effusions[35]; the other causes were pleural empyema and tuberculous effusions. Of these large malignant effusions, most were caused by lung or breast cancer. Interestingly, cytologic examination was no more likely to be positive in these large/massive effusions as in smaller ones (63% yield from large effusions; 53% from small).[35]

If the effusion is large, it is important to note the position of the mediastinum. It is expected that in an uncomplicated situation, the mediastinum will be shifted away from a large effusion. If the mediastinum is midline, one can suspect one of two things: (1) the pleural pressures are equal on the two sides, implying that significant lung collapse is present, offsetting the increase in pressure expected from the presence of the effusion or (2) the mediastinum is fixed in position and cannot shift in response to a pressure differential. If the mediastinum is shifted toward the side of the effusion, the pressure is most likely lower on the side of the effusion than on the other side; in that case, the lung must be unable to expand fully in response to this abnormally low pressure. Because the lung is restricted from expanding or is trapped, due either to mainstem bronchial obstruction or to infiltration by tumor, it is unlikely to reinflate with chest tube thoracostomy. In situations in which the mediastinum is shifted toward a massive effusion, placement of chest tubes is not recommended. Instead, a bronchoscopy would be a reasonable next step to investigate for bronchial obstruction as a possible reason for the failure of lung expansion.

Computed tomography (CT) has the advantage of providing detailed information about the pleural surfaces as well as about the lung parenchyma, chest wall, and mediastinum. Thus, one obtains clues about the identity of the tumor of origin as well as staging information. The typical features found in malignant pleural disease are pleural thickening (>1 cm), irregularity, and nodules (Fig. 75-1). In a prospective CT study of 40 patients with suspected malignant effusions, these pleural characteristics discriminated well between malignant and benign disease, with a sensitivity for malignancy of 84% and a specificity of 100%.[36] In a larger CT study of 211 consecutive patients with effusions, the most specific findings for malignancy were pleural nodules and nodular thickening.[37] Pleural thickening alone was not as specific and was seen in malignancy as well as empyema. Whereas the presence of pleural nodules was highly specific, it was not sensitive because only 17% of malignant effusions had associated pleural nodules. Interestingly, half of the patients with malignant effusions had no pleural abnormalities on the CT; other CT findings suggested malignancy such as the presence of a pulmonary mass, chest wall involvement, large mediastinal nodes, and hepatic metastases.[37]

Although magnetic resonance imaging (MRI) is not advocated for routine evaluation of malignant effusions, its excellent soft tissue contrast may be useful for detailed evaluation of tumor invasion.[38] It may be particularly useful in evaluating the chest wall and pleura in the apices of the hemithoraces.

Positron emission tomography (PET) with [^{18}F]fluorodeoxyglucose can be very useful for differentiating benign pleural abnormalities from malignancy[39] and provides useful information for staging in cases of

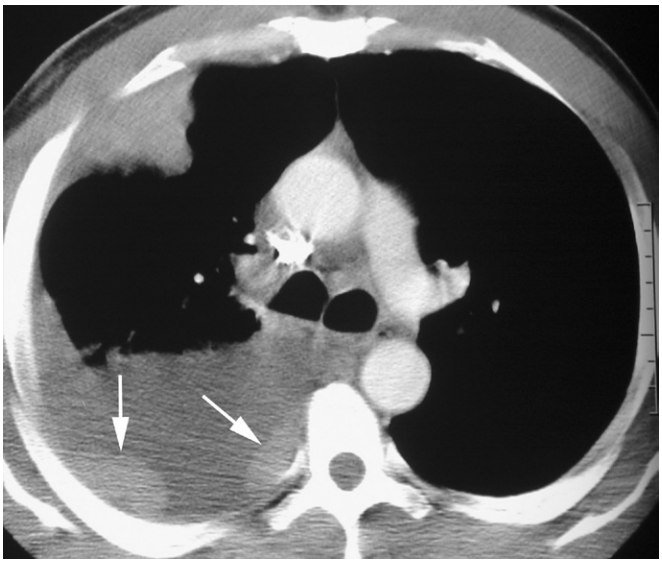

FIGURE 75-1 ■ Metastatic adenocarcinoma. Axial contrast-enhanced thoracic computed tomography (CT) scan shows right pleural effusion associated with enhancing nodular masses (*arrows*) emanating from the parietal pleura, later shown to be metastatic adenocarcinoma.

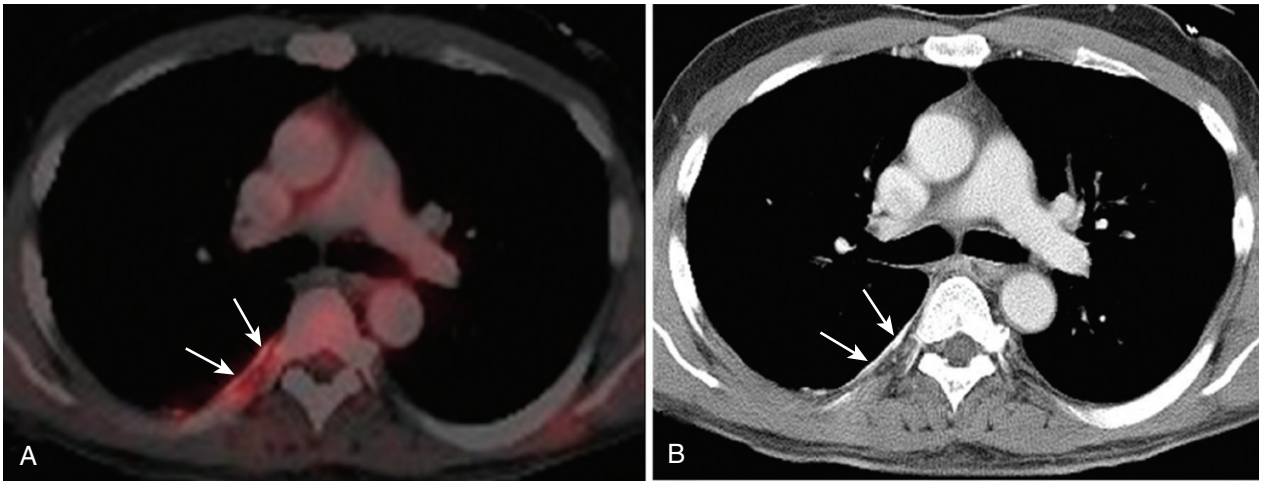

FIGURE 75-2 ■ Increased positron emission tomography (PET) scan activity at site of talc pleurodesis. **A,** A PET/CT scan obtained in a patient with a prior talc pleurodesis for recurrent pneumothorax shows increased pleural uptake (*arrows*). **B,** The axial thoracic CT image confirms that the area of increased PET uptake corresponds to an area of high attenuation characteristic of talc deposits. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

documented malignancy. However, it may not always be able to differentiate pleural malignancy from benign pleural inflammation, such as that due to talc pleurodesis[40] (Fig. 75-2). In a patient with a history of talc pleurodesis, PET/CT can allow correlation of the increased uptake with areas of increased attenuation characteristic of talc deposits.[41]

Diagnosis

Cytology is reportedly diagnostic in approximately 60% of patients,[42] but the diagnostic yield varies with the type of tumor, extent of tumor involvement of the pleural space, and the skill of the cytologist (see Chapter 73). Cytology is more likely to be positive in adenocarcinoma than in squamous cell lung cancer, for example, perhaps because of the increased tendency of adenocarcinoma to invade the pleural space.[23] Interestingly, cytologic yield does not vary greatly with the size of the effusion; as mentioned, in one study, cytology was positive as often in large or massive effusions (63%) as in small or moderate-size effusions (53%).[35]

Biopsy may be necessary when cytology is negative or indeterminate. In the past, closed (or "blind") pleural biopsy was performed as a next step in cases in which cytology was negative. However, the patchy involvement of the parietal pleura by malignancy appears to make closed pleural biopsy a "hit or miss" technique and, not surprisingly, image-directed biopsies have been shown to be more accurate. In one randomized study comparing CT-guided biopsy with closed pleural biopsy using an Abrams needle, CT-guided biopsy was significantly more sensitive (87% vs. 47%) with a better negative predictive value (80% vs. 44%).[43] Pleuroscopy is a well-tolerated procedure that permits excellent visualization of the entire pleural surface (see also Chapter 23). Directed biopsies of suspicious areas detected metastatic pleural disease in nearly 100% of cases.[44] This technique has additional advantages, including the ability to provide large biopsies for immunohistochemical analysis or electron microscopy, the ability to provide information about the gross appearance of tumor, the ability to provide information for staging, the ability to lyse adhesions, and the ability to drain the pleural space for talc pleurodesis. It is worth remembering that metastatic disease can sometimes be diagnosed by fine-needle aspirates of abnormal lymph nodes in the cervical, supraclavicular, or other regions, bypassing invasive tests directed at the pleural space.

Biologic markers for malignancy may be identified as the molecular biology of cancer is better understood. Biomarkers in pleural fluid would potentially assist the cytologic diagnosis (see Chapter 73). Unfortunately, biomarkers have had indeterminate sensitivity and specificity, leading to overlap between malignant and nonmalignant conditions. One approach has been to combine tumor markers to improve diagnostic yield, although one may predict malignancy as well by using clinical characteristics (time of symptoms > 1 mo, absence of fever, serosanguineous fluid, and chest CT findings of malignancy).[45] For mesothelioma, detecting the molecule, mesothelin, a product of mesothelial cells, may have diagnostic utility in certain circumstances (see section on "Mesothelioma," later). The future of diagnosis may lie in genetic testing, either for features of malignancy (DNA methylation, mutations, microsatellites, telomerase, aneuploidy) or in the genetic expression fingerprint (microarray) characteristic of tumors.[46,47] Most exciting is the possibility that genetic testing of pleural cells may lead to the selection of therapy; for example, finding an epidermal growth factor receptor (EGFR) mutation in malignant pleural cells may predict response to appropriate EGFR inhibitors, such as gefitinib.[48]

Therapy and Palliation

The therapeutic and palliative approach to malignant pleural effusions is guided by several factors (Table 75-3).

TABLE 75-3. Options for Control of Symptomatic Malignant Effusions

Option	Patient Eligibility and Considerations
Chemotherapy	Chemoresponsive tumor
Thoracentesis	Slowly recurring effusion
	For patients with very short life expectancy
Pleurodesis	
Via chest tube	Lung able to reinflate
Via pleuroscopy	Can free up lung tacked down by adhesions
	When pleuroscopy already indicated for biopsies
Indwelling tunneled catheter	Good for outpatient situation
	Good for trapped lung
Pleuroperitoneal shunt	Patient must operate pump
	Good for trapped lung
	Excellent for chylothorax
Pleurectomy	
Via pleuroscopy	When other less invasive options have failed
Via thoracotomy	For patients with good status and life expectancy

The options are several and of increasing invasiveness. First of all, the clinician should determine that the effusion is causing either dyspnea or cough, symptoms that can be due to the volume of the effusion and its effect on lung and cardiac function (see Chapter 73). The most common and debilitating symptom caused by malignant effusions is dyspnea, and control of dyspnea can often be the primary focus of palliative therapy. Symptomatic effusions indicate the need to control the effusion, usually by obliterating the pleural space or by draining the effusion, either internally or externally. Important issues that help the clinician decide on the approach are whether the lung can reinflate fully, the clinical status of the patient, and the availability of approaches such as pleuroscopy. Obviously, the overall goal is to provide the greatest relief of symptoms using the least invasive, least morbid, and least expensive therapy. Management issues mainly focusing on palliation have been addressed in guidelines from the European Respiratory Society/American Thoracic Society (ERS/ATS)[49] and the British Thoracic Society.[11]

Systemic therapy with chemotherapy may be considered as dictated by the primary malignancy. Malignant pleural effusions that may respond to chemotherapy include those due to breast cancer, small cell lung cancer, and lymphoma.[14,50,51] Radiation therapy may be useful for treatment of the primary tumor or to treat local areas of chest wall invasion but is limited by the radiosensitive organs adjacent to the pleura, such as the lung and heart.

Repeated thoracentesis to remove a symptomatic effusion may be used in those unusual circumstances when the fluid reaccumulates slowly and the patient prefers this approach. Nonetheless, most malignant effusions recur rapidly and would need frequent drainage, making this approach useful in only a few cases, such as in a patient with a very short life expectancy.

Chemical pleurodesis can be considered when the lung can reinflate so it comes in contact with the parietal pleura. Even if contact can be achieved over a large but partial pleural surface area, pleurodesis may still be effective at preventing the rcurrence of large symptomatic effusions. Pleurodesis with talc is successful in most (70%–100%) cases[52] and is more effective than pleurodesis with other agents, including tetracycline and bleomycin.[49,52] Talc pleurodesis can be painful and, in a small percentage of patients, can lead to pulmonary edema and acute respiratory failure.[1] Evidence suggests that the smaller talc particles (<10 μm) can exit the pleural space and distribute systemically; in a randomized study, pleurodesis with graded talc (with most particles <10 μm removed) was associated with fewer complications than a mixed talc that included small particles.[53] Alternative sclerosing agents have been investigated, but currently, talc is the preferred agent because it is reported to have the highest success rates, followed by the tetracyclines and bleomycin. Nonetheless, there is significant variability in the practice of pleurodesis, as shown in a survey of pulmonologists in five countries.[54] Other agents include iodopovodine, nitrogen mustard, *Corynebacterium parvum*, OK432, and silver nitrate.[52]

The optimal mode of administration of talc is still unclear. Prospective trials have shown no benefit of large-bore tubes over small-bore tubes (12 French) for pleurodesis, although talc was used in a minority of these patients,[55] and no benefit from rotation of patients as determined by instillation of radiolabeled talc and by outcome.[56] Newer approaches that have shown promise include use of a small-bore catheter followed by outpatient talc instillation and removal of chest tubes as early as 24 hours after talc instillation.[57] Talc can be administered via slurry through chest tubes or by poudrage (insufflation) via pleuroscopy or video-assisted thoracoscopic surgery (VATS). In a prospective, randomized trial, talc slurry and poudrage were similar in efficacy; 71% of patients had a successful 30-day outcome following talc slurry and 78% following poudrage.[58] Interestingly, for the subgroup of patients with breast or lung cancer, poudrage may have been better than slurry (82% success with poudrage vs. 67% with slurry).[58] Pleuroscopy or VATS also has the ability to drain the pleural space completely at the time of talc instillation and lyse adhesions, steps that may increase the success of pleurodesis.

Chronic indwelling catheters have been shown to be effective alternatives to chemical pleurodesis. The catheter is inserted under local anesthesia and the patient drains the effusion via a daily or every other day protocol as an outpatient. This approach may be the only alternative when pleurodesis is not possible as, for example, when the lung cannot reexpand. It has now been recognized that not only can the indwelling catheters control symptoms but also, in many cases, can induce a symphysis allowing the tube to be removed without recurrence of the effusion. In a review of 263 patients with

malignant pleural effusions treated with indwelling, tunneled pleural catheters until drainage was less than 50 mL/day, the catheters could be removed in 58% of patients.[59] The average indwelling time for the catheter overall was 29 days. The success of the catheter alone was greater in those with breast and gynecologic tumors (70%–72%) and in those without a history of chest wall irradiation, those with positive cytology, and those with complete reexpansion of the underlying lung.[59] An added benefit of this outpatient approach is a reduction in hospitalization time, particularly attractive for a palliative procedure.[59a]

Pleuroperitoneal shunting is another alternative for palliation when the lung cannot reexpand or pleurodesis is unsuccessful, but is reserved primarily for patients with chylous effusions. Although it is a more invasive procedure, the pleuroperitoneal shunt allows the drainage of chyle into the abdomen, where it can be absorbed, and thus minimizes depletion of protein and lymphocyte populations. Rarely, malignant seeding along the chest wall can develop at the site of shunt insertion. Importantly, improvement in dyspnea is achieved in most patients (95%).[60] Of note, the external pump chamber must be manually compressed several times each day to move the pleural fluid into the peritoneal space.

Pleurectomy via thoracotomy can achieve a pleural symphysis when other treatment fails, but should be reserved for patients with an expected survival of longer than 6 months. This technique is reportedly very effective, but the operative mortality is relatively high (12.5%).[61] Pleurectomy via VATS has a lower operative mortality and morbidity. However, in a prospective study of 19 patients, the hospital stay was a median of 5 days and 2 patients developed recurrent effusions,[62] making chronic indwelling catheter placement more appealing for many of these patients.

Prognosis

The overall prognosis is poor for most patients with malignant pleural effusions. In an analysis of several studies with a total of over 400 patients, the median survival was 4.0 months.[2] The survival varied by tumor of origin; patients with malignant effusions from lung cancer had a lower median survival of 3.0 months, whereas those with pleural effusions from cancer of the breast had 5.0 months, from mesothelioma 6.0 months, and from lymphoma 9.0 months. When used to predict survival for any individual patient, pleural fluid pH or glucose is not sufficiently robust.[2] One of the strongest predictors appears to be the Karnofsky Performance Scale; in a prospective trial of 85 consecutive patients with malignant pleural effusions referred for pleuroscopic pleurodesis, those with a Karnofsky score above 70 had a median survival of 13.2 months, whereas those with a score below 30 had a median survival of 1.1 months.[31] Interestingly, in this study, when compared with other measures such as pleural fluid pH, glucose, or extent of carcinomatous involvement of the pleural surface, performance scoring was the only significant predictor of survival.

The poor life expectancy of patients with lung cancer and malignant pleural effusion has led to a revised staging classification for malignant pleural effusions[63] (see Chapter 47). In the 6th edition of the tumor-node-metastasis (TNM) classification, effective since 1997, malignancy of the pleural space was considered a T4 lesion, with a similar prognosis as other invasive lesions, and patients were staged as IIIB. However, in a comprehensive reassessment of staging and its effect on survival, patients with malignant pleural effusions were found to have a poorer prognosis than other T4M0 patients (8 mo vs. 13 mo), a prognosis that was closer to patients with metastatic disease to the opposite lung (10 mo).[63] In the revised staging system, pleural malignancy (malignant effusions or pleural nodular malignancy) is considered along with contralateral lung nodules as intrathoracic metastatic disease (M1a). Intrathoracic metastatic disease (M1a) is classified separately from extrathoracic metastatic disease (M1b) because of a somewhat better prognosis.[63]

MESOTHELIOMA

Incidence and Etiology

Malignant pleural mesothelioma is uncommon but can no longer be considered rare with almost 3000 cases/year diagnosed in the United States alone. The number of cases is anticipated to continue to increase in the United States and Western Europe until approximately 2020[64] due to the increase in occupational exposures to asbestos and asbestos-containing products that occurred after World War II. During the heyday of excitement about asbestos, asbestos was viewed as a modern breakthrough and was even used in such products as toothpaste[65] and cigarette filters![66] Unfortunately, after extensive use in industry and in building materials, asbestos fibers were discovered to be harmful, with multiple toxic effects leading to fibrosis and malignancy[67] (see later).

After 2020, the number of cases is anticipated to plateau and then gradually decline in these countries owing to the reduction in occupational exposures caused by restrictions on asbestos use, worker protection, and asbestos abatement efforts that were instituted from the mid-1970s to 1990s; nonetheless, many individuals will continue to be exposed incidentally (e.g., while performing home renovations). In those industrialized countries where the control of asbestos was delayed by several decades, as in Japan, the "epidemic" of mesothelioma will also be delayed by several decades. Unfortunately, asbestos continues to be mined, and its use is actually increasing in many developing countries.[68] Globally, there is a great disparity in asbestos use, with some countries adopting "asbestos bans" and others using asbestos without regulation. Interestingly, the United States does not have a ban although asbestos use has fallen to less than 1% of its historical peak.[69] In high-use countries, asbestos-induced lung cancer will also increase because of the multiplicative effects of

asbestos inhalation (including chrysotile) and cigarette smoking.[70]

Those with significant asbestos exposure and increased rates of mesotheliomas include workers in the asbestos industry, insulators, pipefitters, shipyard workers, brake mechanics, railroad workers, construction trades, carpenters, plumbers, electricians, painters, nonasbestos miners, welders, machinists, manufacturers of mineral products, and workers who perform maintenance and repair in buildings with asbestos insulation.[71] In addition, it is not uncommon to see women with asbestos-induced mesothelioma whose only clear asbestos exposure was from exposure to their spouses' contaminated clothing.[71a] Children who have been incidentally exposed can develop mesothelioma in early adult life. Incidence may rise due to recent population exposures such as from the dust that settled after the collapse of the World Trade Center.[72] In addition, recent use of nanoparticles and nanotubes raises concerns for unforeseen toxic effects analogous to those of asbestos.[73]

Other causes of mesothelioma have been postulated. Recently, there has been a great deal of controversy as to whether a simian virus (SV40) that contaminated the polio vaccine administered from 1955 through 1961 may be contributing to the development of mesotheliomas in the United States and other countries. SV40 is an intriguing candidate because it can immortalize cells by binding and inactivating both the retinoblastoma (Rb) protein and p53, key control steps for proliferation and apoptosis, respectively. In a review of 15 studies, mesothelioma tissues were 17 times more likely to have evidence of SV40 than were control tissues.[74] In cell and animal studies, SV40 may cooperate with asbestos in inducing damage and generating mesothelioma.[75] However, in humans, a causal relationship has not been established and epidemiologic studies to date have not shown an increase in the incidence of mesotheliomas in populations exposed to this virus.[76,77] Further complicating the analysis is the recognition that the presence of SV40 DNA sequences alone does not prove its role in tumor development. Viral proteins must be expressed and impair the function of cell proteins necessary for normal cell function. At this time, SV40 is still a subject of intense discussion, more as a possible co-carcinogen with asbestos than as a primary cause of mesothelioma. See arguments addressing the evidence for[78] and against[79] SV40 as a cause of mesothelioma.

Cigarette smoking is not associated with an increased incidence of mesotheliomas.[80] Silica or man-made vitreous fibers (rock/slag wool and fiberglass) have not been found to be associated with occupational mesotheliomas.[81,82] Excess cases of mesotheliomas have been identified in oil refinery workers; this risk was once thought to be due to exposure to petroleum oil and its products but is now attributed to occupational asbestos exposure.[83] Ionizing radiation may be a cause as well with a small increased risk in patients exposed to the radioactive contrast medium Thorotrast and in those who received therapeutic radiation for the treatment of lymphoma or breast cancer.[84]

Environmental asbestos exposures have been associated with the development of mesothelioma. Low-dose exposure in large populations may produce only "background" levels of asbestos in lung tissue but, because of the number of individuals exposed in that way, lead to an increase in the number of mesothelioma cases (similar to widespread exposure to sunlight and melanoma development). Exposure of occupants in buildings with asbestos-containing materials is generally not associated with increased asbestos fiber burden in the lung or an increase in mesothelioma incidence, unless the building materials are disturbed. Naturally-occurring asbestos can also be released into the air by home-building or road paving, leading to concern about increased risk for mesothelioma in exposed populations.[85] In Turkey, an extraordinarily high incidence of mesothelioma is found in certain villages in central Turkey with exposure to erionite dust, a nonasbestos crystalline fibrous form of the mineral zeolite. Finally, chronic inflammation of the pleura as in familial Mediterranean fever has been postulated to cause mesothelioma. At least four cases of mesothelioma have been reported in patients with this disease, presumably due to recurrent serositis.[86] Asbestos may still be an underlying cause or contributing factor in patients without a clear occupational exposure, given that fiber burden studies suggest that most urban dwellers have some asbestos fibers in their lungs.[87]

Although millions of workers have been exposed to significant amounts of asbestos, only a few develop mesothelioma, making it likely that there are genetic factors that increase susceptibility. Supporting the notion of genetic susceptibility is the identification of multiple clusters of this disease in families,[88] although clusters may also be explained by common environmental exposure to asbestos. Nonetheless, in the Cappadocian region of Turkey, where exposure to erionite is widespread, the susceptibility to mesothelioma appears to be inherited in an autosomal dominant pattern.[89]

Genetic Characteristics

Mesothelioma is characterized by a high degree of aneuploidy, but there is no single oncogene or tumor suppressor gene that has yet been found to underlie the tumor. The tumor suppressor genes most frequently implicated in mesothelioma are $p16^{INK4A}$-$p14^{ARF}$(9p21) and the neurofibromatosis type 2 (NF2) gene (22q12).[90] p53, a tumor suppressor mutated in most lung cancers and other solid tumors, is not frequently mutated in mesothelioma.[91] (For discussion of genetic abnormalities in lung cancer, see Chapter 45.) Nonetheless, abnormalities in the pathway that controls p53 function may still be present. Kras, a protooncogene frequently activated in lung cancer, is also not found to be abnormal in mesothelioma.[92] Studies of cytogenetics and loss of heterozygosity show consistent losses of chromosomal regions, suggesting that these regions may contain genes for key tumor suppressors. Losses are consistently found in regions 1p, 3p, 6q, 9p, 15q, and 22q. Growth-promoting genes suspected to play a role in mesothelioma include those coding for growth factors or growth factor

receptors (e.g., platelet-derived growth factor, EGFR). Gene expression profiling may provide additional insights into genetic abnormalities critical for mesothelioma and, in so doing, may also provide prognostic information, help with diagnosis, guide therapy, and suggest future therapeutic approaches.[93,94]

The long latency period between exposure to asbestos and development of mesothelioma suggests that multiple genetic abnormalities are required. Unlike the situation for bronchogenic carcinoma in which the natural history can be studied by repeatedly accessing the bronchial epithelium, the pleural space is not easily sampled, making the natural history of mesothelioma more opaque. Owing to their long, thin shape, asbestos fibers are inhaled deep into the lung and translocate from the lung to the pleural space; the fibers accumulate at the parietal pleura, where they can interact with mesothelial cells over decades. Along the way, the fibers are ingested by macrophages and induce a chronic inflammation. The fibers may also be internalized by mesothelial cells where they can both interfere with chromosome segregation leading to chromosome damage and generate reactive oxygen species via their iron content leading to oxidant injury to DNA.[95,96] In the process, the cells develop unregulated proliferation and an increased resistance to apoptosis.[97] The ability of asbestos fibers to produce the combination of chronic inflammation and of chromosomal and DNA damage may explain their potent carcinogenic effect. Damage or loss of key genetic areas containing tumor suppressors may be critical steps in generating mesothelioma. If SV40 contributes to this process, it may be by binding and inactivating key regulators of cell growth and survival, Rb and p53 proteins.

Clinical Features

The mean age at presentation is 60 years because of the long latency (usually 30–40 yr) from the time of first exposure to asbestos to the development of clinically evident disease.[64] The incidence is higher in men, presumably because more men have worked in asbestos-related trades.

Symptoms and physical findings are generally not specific for the disease. Most patients present with nonpleuritic chest pain or dyspnea.[98] Compared with that of metastatic pleural diseases, the pain from mesothelioma can be severe, aching, and often very difficult to control. Less common complaints are cough, fevers, chills, sweats, and fatigue. Fatigue, cachexia, and pain are common in advanced disease. Physical examination is usually only remarkable for signs related to the presence of a pleural effusion or mass. Later in the course of disease, one can often appreciate volume loss and decreased mobility of the chest wall on the side of the primary tumor. Occasionally, the tumor may extend directly into the chest wall and be detected as a tender or nontender chest wall mass.

Laboratory findings are also nonspecific and include anemia and thrombocytosis. Thrombocytosis (platelets >400,000/mm^3) can be seen in 40% of patients, may be due to production by the tumor of interleukin-6, and augurs a poor prognosis.[99,100] Measurement of mesothelin-family proteins in serum shows future promise for the diagnosis of mesothelioma and for monitoring of disease progression.[101]

Radiographic Evaluation

The most common findings on chest radiograph are a moderate to large unilateral pleural effusion or unilateral pleural thickening (nodular or smooth)[98] (Fig. 75-3). In a study of 99 patients with malignant mesothelioma, the most common finding on CT was a rindlike extension of tumor on the pleural surfaces (70%).[102] Other findings included circumferential lung encasement by multiple nodules (28%), pleural thickening with an irregular margin between the lung and the pleura (26%), and pleural thickening with pleural-based nodules (20%). Invasion of soft tissues and the chest wall with rib destruction may also be seen.[102] As the disease progresses and the lung becomes more encased with tumor, there is often volume loss with a shift of the mediastinum toward the side of the primary tumor (see Fig. 75-3). Signs of lymphatic metastasis may be seen but are more commonly evident late in the course of disease. Further tumor progression may lead to invasion into the contralateral chest. It is important to note that pleural plaques are often not visible; less than 20% of patients with mesothelioma may have radiographically apparent plaques.[103] Large mediastinal lymph nodes are more consistent with metastatic disease than with mesothelioma. Mediastinal adenopathy on chest radiographs or CT as the initial presentation of mesothelioma has been reported but is exceedingly rare,[104] although PET scanning often identifies active nodes that are normal in size and shape on imaging.[105] Radiographic features that favor the diagnosis of malignant mesothelioma over metastatic pleural disease were found by multivariate analysis to include

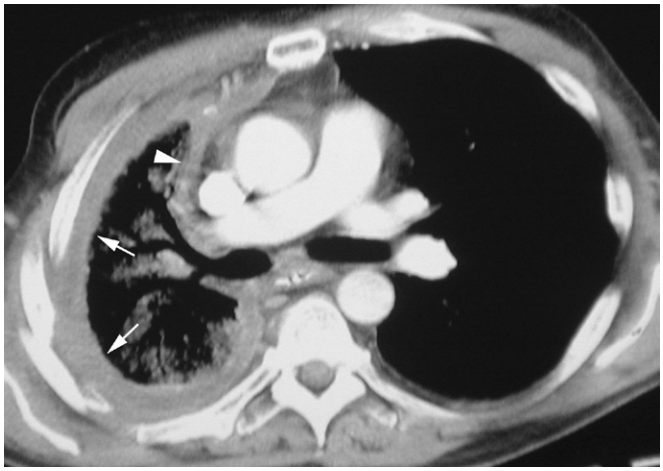

FIGURE 75-3 ■ Mesothelioma. Axial thoracic CT scan shows diffuse right pleural thickening (*arrows*) associated with marked volume loss in the right thorax. Note the presence of mediastinal pleural involvement (*arrowhead*).

FIGURE 75-4 ■ Mesothelioma. Magnetic resonance imaging (MRI) of the same patient as in Figure 75-3 with malignant mesothelioma shows invasion across the diaphragm by tumor (*arrow*).

rindlike pleural involvement, mediastinal pleural involvement, and pleural thickness more than 1 cm.[102]

Some clinicians prefer MRI over CT for staging and preoperative evaluation because, as reported in one study, MRI may demonstrate extent of disease and in particular chest wall and diaphragmatic invasion better than CT[106] (Fig. 75-4). However, this has not yet been shown to confer an important clinical advantage. In an earlier study, Heelan and coworkers[107] also found MRI superior in detection of tissue invasion in these areas, nonetheless, they found no improvement in staging and no alteration in therapy due to its use.

FDG-PET and particularly PET/CT show promise as tools to differentiate benign from malignant disease and as adjunctive tools for staging (Fig. 75-5). In a comparison of different diagnostic imaging techniques in patients with mesothelioma who then underwent surgery, PET/CT was more accurate than either PET, CT, or MRI alone.[108] It is hoped that functional assessment by PET may also be useful for monitoring response to therapy.[109]

In patients being considered for an extensive debulking procedure such as extrapleural pneumonectomy, every effort should be made to define the extent of disease, in particular to exclude patients with unsuspected extension beyond the pleura. A combination of imaging techniques may be selected to identify tumor spread.[110] However, even in patients with negative imaging, invasive approaches are often used to assure lack of tumor spread, such as preoperative endoscopic ultrasound with biopsy of suspicious nodes, mediastinoscopy, laparoscopy or thoracoscopic visualization of the contralateral pleura (see "Surgical Therapy," later).[111]

Diagnosis

The role of pleural fluid cytology in establishing a diagnosis is controversial, with some groups demonstrating a high level of diagnostic specificity and others demanding tissue histopathology.[112,113] Patterns of gene expression by microarray in cytologic samples may also help with diagnosis.[47] The only serum biomarker that is clinically useful is serum mesothelin which, in the serum, has a high specificity (>90%) but only a 50% sensitivity for the diagnosis.[101] Mesothelin biomarker levels in pleural fluid may also become useful in diagnosis.[114]

Closed pleural biopsy often misses malignant tissue, although it may be improved using CT guidance. In one study in which patients were randomly assigned to closed pleural biopsy or CT-guided biopsy, mesothelioma was diagnosed by closed pleural biopsy with a sensitivity of 55% (6/11) and by CT-guided biopsy with a sensitivity of 88% (8/9); although the difference was not significant because of small numbers, a similar diagnostic advantage of CT-guided biopsy was found for other pleural malignancies.[43] With current immunohistochemical stains, mesothelioma can usually, although not always, be differentiated from metastatic adenocarcinoma. It is often harder to differentiate mesothelioma from the benign mesothelial cell hyperplasias that often accompany inflammatory processes in the pleura. In uncertain cases, surgical biopsy is required to establish a definitive diagnosis. A surgical biopsy not only provides larger specimens for immunohistochemistry but also provides critical information about the biologic behavior of the tumor. The behavior of mesotheliomas is unique in that they usually start on the parietal pleural surface with multiple colonies of cells that coalesce and spread to the visceral pleura. Distant metastases are generally a very late finding. In contrast, metastatic adenocarcinomas are usually more prominent on the visceral pleural surface and often associated with distant metastasis. Benign inflammation lacks the surface irregularity usually (but not always) seen with malignant disease.

The preferred technique for surgical biopsy is via pleuroscopy (see Chapter 23). Not only does pleuroscopy have the advantage of obtaining large samples, but also it permits the drainage of effusions and the freeing up of a trapped lung.[115] In addition, if the lung is not trapped, talc can be insufflated at the end of the procedure to achieve a pleurodesis. The insertion site of the thoracoscope is an important consideration if tumor debulking is attempted in the future owing to the tendency of mesotheliomas to seed biopsy and chest tube sites.[112] Misdiagnosis with pleuroscopy has rarely been reported and, in those cases, was thought due to adhesions preventing access to the primary tumor.[116] If pleuroscopy cannot be performed due to the absence of pleural effusion, an incisional biopsy has an equally high diagnostic yield.

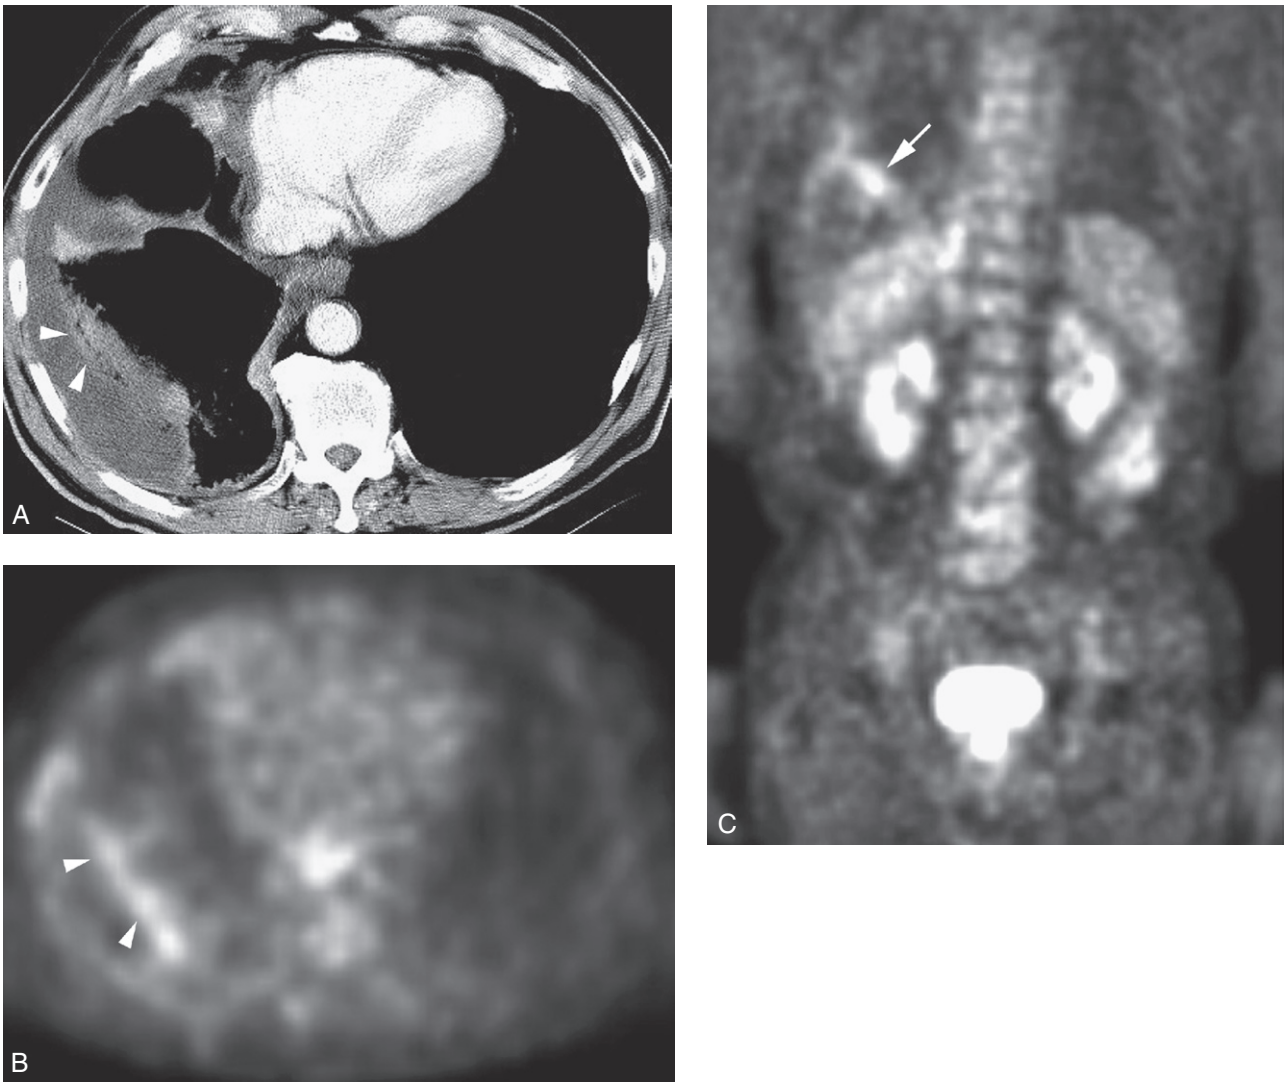

FIGURE 75-5 ■ Mesothelioma. **A,** Axial CT scan shows mesothelioma of the right chest with effusion and a thickened visceral pleura with underlying pulmonary atelectasis (*arrowheads*). **B,** Axial PET scan image indicates high activity in the area of thickened pleura, indicating likely involvement by tumor, suggesting at least a T2 lesion by International Mesothelioma Interest Group (IMIG) staging (*arrowheads*). The bright central uptake appears to indicate malignant involvement, either of a mediastinal lymph node or of the mediastinal pleura. **C,** Coronal view of PET also shows high activity of the visceral pleura in the fissure (*arrow*). (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

Intraoperative talc insufflation has been reported to have a greater than 95% success rate of preventing recurrent pleural effusion in this setting.[117] Talc pleurodesis does not apparently interfere with later attempts at surgical debulking. Talc pleurodesis does interfere with any intrapleural therapy that might be considered, such as intrapleural gene therapy now in clinical trials, so this potential therapeutic approach should be considered before pursuing pleurodesis. Talc pleurodesis can also confound interpretation of PET, which can show increased activity in areas of talc deposition for long periods of time following pleurodesis[40] (see Fig. 75-2 and discussion of PET, earlier). In such cases, PET/CT may be helpful by localizing the increased activity to areas of increased attenuation due to talc.[40]

Pathologic Features

The dilemma for the pathologist can be in differentiating mesothelioma both from metastatic adenocarcinoma and from reactive mesothelium. Because of the difficulties in establishing the diagnosis in some cases, an expert panel of pathologists from the United States and Canada was formed.[118] In their statement, they stressed the need for the pathologist to have information about the biologic behavior of the tumor from both radiographic and intraoperative observations. In addition, they stressed the need to obtain larger specimens to permit multiple immunohistochemical stains and perhaps electron microscopy. Ultrastructural features seen with electron microscopy that are typical of mesothelioma include cytoplasmic tonofilaments and long, sinuous, branching

microvilli.[119] In contrast, the microvilli of adenocarcinomas are relatively short, wide, and straight. For electron microscopy, some biopsy material must be preserved in glutaraldehyde, whereas formalin-fixed specimens can be analyzed by immunohistochemistry. Although a variety of immunohistochemical stains have been used to differentiate adenocarcinoma of the lung and mesothelioma, none is specific, especially with less well differentiated tumors. Use of a panel of immunohistochemical stains is recommended, with calretinin and cytokeratin 5/6 (or WT1) favoring mesothelioma, and CEA and MOC-31 (or B72.3, Ber-EP4, or BG-8) favoring adenocarcinoma.[120] Sarcomatous and biphasic mesothelioma raise special issues, usually in differentiating from other sarcomatous tumors.[120] Currently, immunohistochemical staining has been highly effective in diagnosis of mesothelioma, making electron microscopy usually unnecessary.

Prognosis and Staging

The median survival for patients with malignant mesothelioma is between 4 and 12 months from the time of diagnosis.[121] Regardless of therapy, patients with the epithelial cell type do best and those with the sarcomatous cell type the worst, with mixed or biphasic falling between the two other types.[121] In two separate studies, age, male gender, performance status, leukocytosis, and presence of chest pain were associated with a poorer prognosis.[100,122] Pathologic findings of microvessel density and tumor necrosis are poor prognostic factors.[123,124]

Staging is an issue for those patients in whom surgery is contemplated and continues to be controversial. Prior to the proposal of a TNM-based staging system by the International Mesothelioma Interest Group (IMIG),[125] there had been at least six other systems proposed for staging of mesotheliomas. None of the six was clearly shown to predict survival, including the most widely used Butchart staging system.[126] The TNM-based staging system is organized in a manner similar to the system currently in use for non–small cell carcinoma of the lung (Table 75-4). Further surgical studies at the Memorial Sloan Kettering supported the prognostic value of this system.[127,128] For example, patients with stage I disease had a median survival of 30 months and those with stage IV had a median survival of 8 months.[128] However, the Brigham group found it less useful for determination of surgical resectability and have proposed yet another staging system that is also widely used[129] (Table 75-5). It should be noted that this staging system requires resection to determine the involvement of surgical margins, limiting its applicability mostly to postsurgical staging.

Staging systems may be supplemented by prognostic scoring systems that do not require surgical staging. Prognostic scoring systems proposed by the European Organisation for Research and Treatment of Cancer (EORTC) and by the Cancer and Leukemia Group B (CALGB) incorporate performance status, histopathology, and other laboratory studies.[100]

TABLE 75-4. International Mesothelioma Interest Group Staging System for Malignant Pleural Mesothelioma

T1	Tumor limited to ipsilateral parietal pleura
T1a	No involvement of visceral pleura
T1b	Some scattered foci involving visceral pleura
T2	Tumor involving entire ipsilateral pleura, both visceral and parietal, plus one of the following: Invasion of diaphragmatic muscle, Or, confluent involvement of visceral pleura, including the fissures Or, invasion from visceral pleura into pulmonary parenchyma
T3	Tumor locally advanced but potentially resectable
T4	Tumor locally advanced and technically unresectable
NX	Regional nodes cannot be assessed
N0	No lymph node metastasis
N1	Metastasis to ipsilateral bronchopulmonary or hilar lymph nodes
N2	Metastasis to subcarinal or *ipsilateral* mediastinal nodes
N3	Metastasis to *contralateral* mediastinal or internal mammary nodes, or to any supraclavicular node
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis present

Stage	Description
Stage I	
Ia	T1aN0M0
Ib	T1bN0M0
Stage II	T2N0M0
Stage III	Any T3M0
	Any N1M0
	Any N2M0
Stage IV	Any T4
	Any N3
	Any M1

Therapy and Palliation

Surgical Therapy

The two potential goals of surgical therapy for mesothelioma are palliation of symptoms and debulking of tumor with therapeutic intent. Many believe that therapy should follow the paradigm of treatment developed for ovarian cancer because of the similarities in biologic behavior of the cancer and similar embryologic origin of the cells of the primary tumor.[130] In both diseases, surgical resection alone does not prevent disease recurrence. However, the approach of surgical debulking followed by systemic chemotherapy has shown significant success for the treatment of ovarian cancer. For surgical debulking of mesotheliomas, two surgical approaches are commonly employed: pleurectomy with decortication (P/D) or extrapleural pneumonectomy (EPP). P/D removes all gross disease from all pleural surfaces and preserves the underlying lung. EPP entails en bloc removal of the lung along with surrounding parietal pleura, pericardium, and diaphragm, with the pericardium and diaphragm then replaced by synthetic grafts. These are both technically challenging procedures and should be performed only by surgeons with extensive experience. EPP is especially difficult and was originally associated with an unacceptably high morbidity of 30%. However, with advances in surgical, anesthetic, and critical care techniques, and more exacting patient selection, experienced centers now report mortality rates of less than 4%, a rate comparable with that of standard pneumonectomy.[131] Both P/D and EPP are accomplished through an extended posterolateral thoracotomy and, as mentioned previously, talc pleurodesis is not a contraindication to either procedure and may actually facilitate the separation of the pleura from the chest wall.

Preoperative evaluation of patients considered for surgery includes a thorough assessment of tumor stage, cardiac function, and pulmonary function. Most surgery is confined to those with the epithelial cell morphology. If debulking surgery is to be of benefit, it is essential that tumor is early stage and confined to one hemithorax. Chest CT or MRI is the usual first step in staging. MRI is preferred by some centers for assessment of transdiaphragmatic extension of tumor (see Fig. 75-4), and many now request PET or PET/CT as well (see Fig. 75-5). Recognition that mediastinal lymph node involvement is a poor prognostic sign has prompted centers to require either cervical mediastinoscopy or endoscopic ultrasound with biopsy of suspicious nodes prior to EPP. Even with negative imaging studies, some groups perform extensive surgical staging with mediastinosopy as well as laparoscopy because mesothelioma often spreads through the diaphragm to the peritoneum.[111]

For patients who successfully complete such extensive screening, a few large series suggest that surgical debulking procedures may provide a survival advantage. In the first studies in which both surgeries were performed, it appeared as if pleurectomy was superior, with better survival than EPP.[127,132] However, in a follow-up report, the same investigators found that there was no difference in median survival between the two surgical debulking procedures.[128] Both series showed that failure after pleurectomy is more often local, whereas failure after EPP is more often extrathoracic. These results underscore the difficulty in eradicating mesothelioma with surgery alone.

Based on such studies showing that surgery alone is insufficient to cure mesothelioma, Sugarbaker and colleagues[131] at the Brigham and Women's Hospital have developed a strategy of tumor debulking using EPP followed by chemotherapy and high-dose radiation therapy to destroy residual tumor cells. This strategy was reported to yield a median survival of 19 months and a 5-year survival of 15%. However, patients with all three positive variables (an epithelial cell type, clean margins after resection, and negative lymph nodes) had a median survival of 51 months and a 5-year survival of 46%. Of note, patients with sarcomatous cell type did especially poorly. These results, although exciting, have been criticized for selection bias. Given the lack of prospective, randomized studies comparing surgery with or without adjuvant therapy with medical management or supportive care, the therapeutic or even palliative benefit of surgical debulking followed by chemotherapy and radiation therapy remains unknown. Some critics point out that there are some long-term survivors without treatment and that surgery may actually harm patients without improving survival.[133] For example, in one unrandomized, prospective study, 52 patients receiving surgery and other treatments (chemotherapy or radiotherapy) were compared with 64 patients without treatment. Although the treatments were felt to provide palliation, there was no significant difference in survival between treated and untreated patients.[134] Until randomized studies are performed, the best treatment plan for patients with mesothelioma will remain unknown.

Surgical debulking has been combined with a variety of other cytoreductive approaches to destroy residual tumor cells on the surface of the thoracic cavity including hyperthermia and photodynamic therapy, without convincing success. At this time, the value of surgical debulking and adjunctive measures such as hyperthermia, photodynamic therapy, intrapleural chemotherapy, immunotherapy, and radiation therapy is not known. It may be that an approach of debulking followed by some modality to eradicate residual tumor will improve outcome. However, until randomized trials are undertaken and a consensus is reached on staging, this will not be known with confidence.

Chemotherapy

Most patients with mesothelioma are not candidates for surgical or radiotherapy treatment and chemotherapy is their main option. There are two main regimens that are used in mesothelioma. The most commonly used now includes the multitargeted antifolate drug pemetrexed with a platinum drug such as cisplatinum. The use of this combination has been compared with cisplatin alone in a large phase III study of 456 patients.[135] Response rates

were significantly better in the pemetrexed/cisplatin arm than in the cisplatin-alone arm (41.3% vs. 16.7%), and survival was significantly better as well (median survival 12.1 mo vs. 9.3 mo). Importantly, the addition of folic acid and vitamin B_{12} significantly reduced toxicity without reducing the survival benefit.[135] The other regimen used commonly is the false nucleotide gemcitabine with a platinum agent. Nearly half of the patients on this doublet regimen noted symptom improvement, 33% had a partial response, and 60% had stable disease; no survival benefit was demonstrated compared with historical controls.[136] Similarly, treatment with the combination of gemcitabine and oxaliplatin has been reported to improve symptoms, but not to significantly improve survival (median survival of 13 mo).[137]

Newer Agents under Study. Studies of the molecular biology of mesothelioma and the cellular mechanisms leading to a malignant phenotype have led to the identification of several possible therapeutic targets for treatment of this disease. Some of these are already under investigation in clinical trials (see www.clinicaltrials.gov). For example, several receptor tyrosine kinases are aberrantly expressed in these tumors, including the EGFR.[138] Inhibitors of these proteins are now available in oral form and are being evaluated in patients with mesothelioma. However, so far, drugs blocking EGFR or platelet-derived growth factor (PDGF) receptor signaling, such as gefitinib and imatinib, have not proved to be of benefit when used as single agents. Other novel agents targeting growth factors found to be overexpressed in mesothelioma (e.g., VEGF and its receptor) are under investigation. Other agents under study include antiangiogenic agents (e.g., AZD2171, thalidomide, and PTK/ZK787), inhibitors of histone deacetylase superoylanilide and hydroxamic acid (SAHA), proteasome inhibitors, and histone deacetylase inhibitors (PXD101). Monoclonal antibodies labeled with toxins targeted to the mesothelioma cells are also being studied in immunotoxin trials.[139]

Radiation Therapy

Although in vitro studies suggest that mesothelioma is more sensitive to radiation than non–small cell lung cancer,[140] the clinical experience reported by radiation oncologists suggests that it is an especially radioresistant tumor. In addition, radiation of the involved chest is limited by the presence of radiosensitive organs and the extensive nature of the tumor. As a consequence, its use appears limited to adjunctive therapy for patients who have undergone EPP and to palliative treatment of painful chest wall lesions. Prophylactic chest wall irradiation may reduce the incidence of chest wall recurrences at incision sites, but there is no consensus on its use and randomized, controlled trials are needed.[141] An area of active ongoing research is the role of high-dose hemithorax irradiation after EPP for early-stage disease. In carefully staged patients, this approach has resulted in a marked reduction in local tumor recurrences, although nearly one half of patients subsequently developed isolated distant metastases.[142]

Immunotherapy

It is known that an immune response is induced by mesothelioma, but it is weak.[143] This knowledge has prompted a number of investigators to study different ways of strengthening that response. The intrapleural instillation of cytokines is limited by the short half-life of most cytokines, necessitating repeated injections or continuous infusion via a pleural catheter. Intrapleural interferon-γ twice weekly for 2 months was reported to induce response rate of 56% in early-stage disease.[144] A continuous intrapleural infusion of interleukin-2 induced a partial response in four of 21 patients and an overall survival of 16 months.[145] In both cases, side effects were minimal and consisted primarily of fever and constitutional symptoms. Studies in animals suggest that interferons have an antiproliferative effect on mesothelioma cells and enhance the cytotoxic effect of cisplatin. The results from these studies led to the development of a phase II trial of cisplatin-doxorubicin and interferon alfa-2b in advanced malignant mesothelioma.[146] The overall response rate was 29% and the median survival was 9.3 months with a 1-year survival of 45% and 2-year of 34%. However, severe myelosuppression was seen in 60% of patients, limiting the application of this treatment.[146]

Gene Therapy

Gene therapy strategies that have been investigated for the treatment of mesothelioma include mutation compensation, molecular chemotherapy, and genetic immunopotentiation. Mutation compensation attempts to block or replace abnormally expressed genes. The best example of this in mesothelioma is compensation for the absence of p16 gene expression, a consistent abnormality in mesothelioma. Reexpression of p16INK using an adenoviral vector improved survival in a murine model of mesothelioma.[147] Molecular chemotherapy is a technique of genetically modifying cancer cells to make them susceptible to a drug. For example, an adenoviral vector containing the herpes simplex thymidine kinase (HSVtk) gene has been injected into the pleural space of patients; the virus is taken up by mesothelioma cells and the HSVtk gene product makes the cells metabolize ganciclovir to a toxic by-product. In humans, such approaches have been limited by patchy viral uptake and the development of immunity to the virus.[148] Genetic immunopotentiation employs the genetic induction of an inflammatory antitumor response. For example, vaccinia virus carrying the gene for interleukin-2 has been studied in patients to determine toxicity.[149] Intratumoral injection was not only well tolerated but 50% of tumors were found to have T-cell infiltration. However, no tumor regression was seen. Recent gene therapy trials are focusing on the use of the interferon-beta gene to enhance immunity.[150]

Palliative Therapy

Pain is common and often disabling. Invasion of the chest wall can cause localized somatic pain, intercostal

nerve invasion or vertebral invasion can cause neuropathic pain, and lung invasion may cause diffuse visceral pain. Opioids, such as liquid morphine plus sustained release morphine, are the mainstay of pain control. Somatic pain responds to nonsteroidal anti-inflammatory drugs, and neuropathic pain requires an anticonvulsant such as carbamazepine or sodium valproate. Some patients require procedural pain relief as from intrathecal analgesia or nerve block.

Dyspnea and cough are often due to large pleural effusions or from tumor spread. The approach to palliation has been described for malignant pleural effusions earlier in this chapter, and some of these options are applicable to the effusions due to mesothelioma as well (see Table 75-3). Effusions due to mesothelioma can usually be controlled with pleurodesis or placement of an indwelling tunneled catheter. Pleurodesis with talc is an option if a patent pleural space is not needed later, as it would be for intrapleural therapy within clinical trials. Talc pleurodesis is reasonably effective and relatively inexpensive for this task. As described earlier, talc can be administered as a slurry through a chest tube or as an aerosol during thoracoscopy with equal effect. Regardless, with either technique, the affected lung must be capable of expanding so that the visceral and parietal pleura are in contact. Placement of a tunneled pleural catheter for chronic pleural drainage is another option for these patients, as described for "Malignant Pleural Effusions," earlier.

Psychosocial care is also very important in palliation given the fear, anger, and suffering associated with the disease.[151,152]

Chemoprevention and Screening

The existence of populations with known exposure to asbestos suggests that an effective chemoprevention strategy could reduce the incidence of mesothelioma. In one such study, former workers of the Wittenoom asbestos mines of Australia were assigned randomly to daily use of vitamin A (retinol) or β-carotene, without a placebo group.[153] Although not definitive, studies of retinol are continuing because of some early promising data. Such approaches have the potential of preventing a disease for which curative therapies do not yet exist.

Screening of high-risk populations has the potential of detecting early lesions that could respond better to therapy. Screening trials of high-risk populations are ongoing to determine the value of routine low-dose CT scanning.[154] The sensitivity of serum mesothelin is not sufficient for use as a marker for early-stage mesothelioma; biomarkers with greater sensitivity are needed.[114]

Additional information on clinical and basic research concerning mesothelioma can be found in reports of biannual meetings plus the website of the IMIG[155] (www.imig.org). Other independent websites are the National Cancer Institute (www.nci.nih.gov), Oncolink (Abramson Cancer Center, University of Pennsylvania) (www.oncolink.com), and for referral of patients for ongoing National Institutes of Health (NIH)-sponsored studies (www.clinicaltrials.gov).

SOLITARY FIBROUS TUMOR OF THE PLEURA

Solitary fibrous tumors are mesenchymal tumors that can arise not only in the pleura but also throughout the body.[156] The term "solitary fibrous tumor" is now used in preference to earlier terms such as "benign mesothelioma" or "localized mesothelioma" for several reasons: to distinguish it clearly from malignant mesothelioma, to acknowledge that it may contain malignancy within it, and also to recognize that its cellular origin is more likely from pleuripotential fibroblasts than from mesothelial cells.[1,157] These localized tumors of the pleura are more rare than malignant mesotheliomas, accounting for 8% of all benign pathologies of the chest and 10% of all pleural neoplasms.[158] More than 50% cause no symptoms and are identified as an incidental finding on radiographic examination.[159] When symptoms do occur, they are usually chronic and related to the mechanical effects of the tumor. Most commonly noted are cough, dyspnea, and chest pain.[157,160]

Paraneoplastic syndromes are associated with this tumor. Hypertrophic osteoarthropathy has been described in 14%[160] to 19%[157] and usually resolves over a few months following resection of the tumor.[157] Hypoglycemia has been described in between 4%[157] and 14%[160] of patients with solitary fibrous tumors, although the percentage may be elevated because the hypoglycemia may bring the patient to medical attention. The hypoglycemia arises from the production by the tumor of insulin-like growth factor II (IGF-II), which has insulin activity peripherally and at the liver.[161] As for other non–islet cell tumors associated with hypoglycemia, the hypoglycemia can be treated best by full resection of the tumor.[162] If this is not possible or while awaiting surgical resection, patients have been treated successfully with corticosteroids, which can suppress IGF-II production.[162]

Most solitary fibrous tumors arise from the visceral pleura, but some arise from the parietal.[160] In cases in which they appear within the lung parenchyma, the tumor border may be attached to the pleura via a pedicle or stalk. They are usually round and firm with clear borders and can grow to be several centimeters in diameter. On cut section, the tumor has a fibrous whorled appearance with occasional calcification, hemorrhage, and central necrosis. Cells are elongated and spindle-shaped on histologic examination. By immunohistochemistry, the solitary fibrous tumor can be distinguished from malignant mesothelioma by its staining for vimentin and CD34 (a hematopoietic progenitor cell antigen) and its lack of staining for keratin.[160,163]

Radiographic evaluation usually reveals a solitary circumscribed lesion (Fig. 75-6). It rarely may occupy the entire hemothorax, but the average size is about 6 cm. In one study, most of the masses appeared to have an atypical appearance for pleural-based tumors in that they appeared to form an acute angle with the chest wall on radiographic examinations.[164] This may be due to the size of the lesions and the tendency for them to hang from a pedicle into the lung.[164] In some cases, the mass

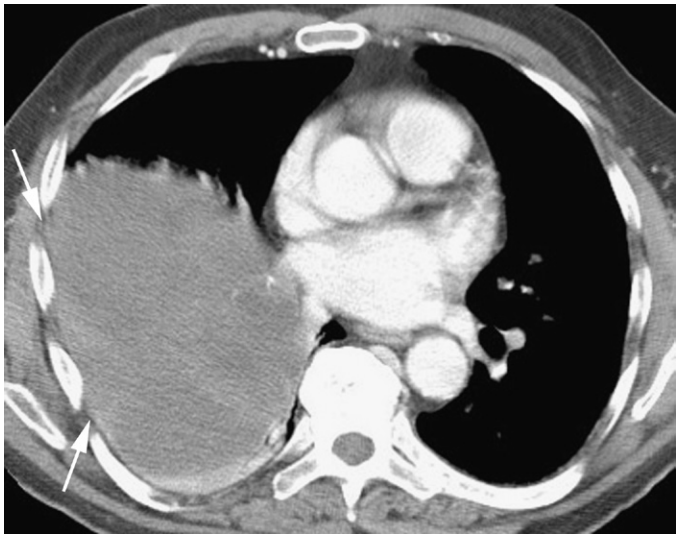

FIGURE 75-6 ■ Solitary fibrous tumor of the pleura. Axial CT image shows a large, somewhat heterogeneous mass in the right lower chest with extensive chest wall contact (*arrows*). (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

may be mobile due to the pedicle and occasionally movement can be documented using decubitus views. CT scans may reveal heterogeneous areas of enhancement in some larger tumors that correlate pathologically with areas of cystic necrosis and hemorrhage. All have contours that are smooth and lobulated without evidence of invasion into underlying tissues. Occasionally, dense calcification is seen.[165] MRI findings are consistent with a fibrous tumor with low signal on T1- and T2-weighted images.[166] There is little information about the use of PET to differentiate solitary fibrous tumors from malignant mesothelioma. However, the few cases in the literature support the finding of low or absent uptake of fluorodeoxyglucose on PET imaging of the solitary fibrous tumor.[167]

The diagnosis is strongly suggested by the chest radiograph and CT scan. If a paraneoplastic syndrome is present together with a large tumor of the pleural space, the diagnosis of solitary fibrous tumor is likely. Needle biopsy may be unhelpful and, even if malignancy is present within a portion of the tumor, may miss the areas of concern. Surgery is advised in most cases both for diagnosis by excision and for definitive treatment.

Surgical resection will be curative in most cases. When the tumor arises from the visceral pleura, surgical resection may involve wedge resection or lobectomy. Recurrences do occur and have been documented many years after resection, sometimes with malignant transformation.[157,168] Yearly chest radiographs are recommended to follow these patients after resection. Sometimes, return of a paraneoplastic syndrome can accompany a recurrence of the solitary fibrous tumor.[160]

Treatment of recurrent tumors can be difficult if reresection is not possible. Current approaches targeting VEGF and angiogenesis pathways have shown promise.[156]

PRIMARY EFFUSION LYMPHOMA

Primary effusion lymphoma (PEL) is a type of high-grade B-cell lymphoma that grows within the serous body cavities (pleural, peritoneal, and pericardial) without a detectable tumor mass (Fig. 75-7). Because of its tropism for serosal spaces, it is considered one of the entities within the group of body cavity lymphomas.[169] PEL is a body cavity lymphoma caused by the human herpes virus 8 (HHV8),[169] the same virus that is the etiologic cause of Kaposi's sarcoma. Most cases of PEL are found in homosexual men with advanced human immunodeficiency virus (HIV) disease. In a few cases, PEL has also been described in HIV-negative patients, usually elderly persons of Eastern European/Mediterranean descent, in an epidemiologic pattern similar to that of HIV-negative, classic Kaposi's sarcoma.[169] Many primary effusion lymphomas in HIV-positive patients are coinfected by Epstein-Barr virus (EBV),[169] suggesting a cooperative etiologic role between HHV8 and EBV. Nonetheless, the HHV8 is thought to be the primary etiologic factor and the identification of HHV8 is required for the diagnosis of PEL.[169]

PEL tends to occur as a late manifestation of HIV infection. Therefore, PEL should be considered in patients with advanced HIV disease with large exudative lymphocytic effusions. CT scan will show a small degree of pleural thickening, without any tumor mass or mediastinal adenopathy[170] (see Fig. 75-7). Pleural fluid may have a very elevated LDH level.[1] Cytologic examination will show pleomorphic large lymphocytes and suggest the diagnosis. The lymphocytes stain negatively for B- and T-cell antigens. Identification of HHV8 can be performed by extracting DNA from involved tissues followed by Southern blot analysis, by in situ hybridization of slides from paraffin-embedded samples, and by in situ reverse transcriptase polymerase chain reaction of cytologic smears or cell blocks.[171]

Treatment is usually attempted with a CHOP-like regimen (cyclophosphamide, doxorubicin, vincristine, and prednisone) and, if the patient is HIV-positive, antiretroviral therapy.[172] Some patients have shown benefit from antiretroviral therapy alone, suggesting that the immune reconstitution can be effective against the lymphoma.[172] Nonetheless, prognosis is poor, with a median survival of around 6 months. As more is learned

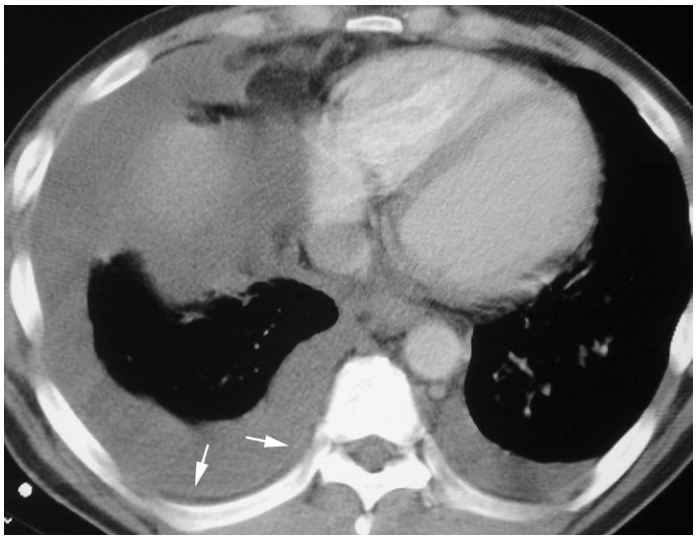

FIGURE 75-7 ■ Primary effusion lymphoma. On axial CT, the malignancy is manifest by bilateral effusions. *Arrows* indicate a minimally thickened parietal pleura, without nodularity. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

of the life cycle of HHV8, there is hope for specific therapy targeting the causative virus.

PYOTHORAX-ASSOCIATED LYMPHOMA

Pyothorax-associated lymphoma (PAL) is an HHV8-negative body cavity lymphoma, associated with EBV.[169] It is a high-grade non-Hodgkin lymphoma occurring as a mass in the pleural space of patients with long-standing chronic pleural inflammation usually following artificial pneumothorax for pleuropulmonary tuberculosis.[173] This entity is mainly seen in Japan but has also been reported in Western countries.[173,174] The few series available report a strong association with EBV, with 70% of tumors having evidence of EBV in one study.[175] The cell type is usually B-cell with frequent plasmacytoid features, but occasionally an aberrant dual B/T phenotype may be seen.[174] As opposed to PEL, which is associated with systemic immunodeficiency as from HIV or old age, PAL is associated with a local pleural immunosuppression and antigenic stimulation.[169]

A relatively large review of 106 patients with PAL in Japan showed the median age at the time of diagnosis to be 64 years (range, 46–82 yr).[175] In these patients, there was at least a 20-year history of pyothorax (mean, 37 yr; maximum, 64 yr), and patients were predominately male (12:1). All had a history of chronic inflammation of the pleura, due to either artificial pneumothorax for treatment of pulmonary tuberculosis (80%) or tuberculous pleuritis (17%). Fever and/or back pain were the common symptoms on presentation, and chest radiograph or CT scan showed a localized pleural mass in an area of chronic pleural disease. There are no large series evaluating specific treatments for this disease. In some reports, it appears that patients may do better with radiotherapy than with chemotherapy.[176,177] In the review of 106 patient records, patients underwent a variety of treatments including surgical resection, chemotherapy with CHOP-like regimen or radiotherapy.[175] Patients appeared to respond initially to chemotherapy, but clinical outcome was poor with a 5-year survival of 22%.[175] In one patient undergoing treatment, the serum EBV load measured by a quantitative real-time polymerase chain reaction correlated well with tumor size, suggesting that monitoring of the serum EBV load might be helpful in the management of EBV-positive patients with this disease.[177] Recognition of the development of a pleural soft-tissue mass adjacent to a longstanding empyema cavity may allow earlier diagnosis and potentially better response to treatment.[178]

KEY POINTS

- Malignant effusions are most commonly due to lung cancer, followed by breast cancer and lymphoma.
- Malignant effusions are often diagnosed by cytology (60% of cases), which has a high yield for adenocarcinoma and a low yield for squamous cell carcinoma. If cytology is negative, image-guided biopsy and VATS have a high yield (80%–100%) for diagnosis.
- Malignancy may involve the pleural space without formation of an effusion. In the 7th edition of TNM staging for lung cancer, pleural malignancy with or without effusion is now classified as a metastatic lesion (M1a, intrathoracic metastasis).
- Palliation of malignant pleural effusions may include repeated taps, talc pleurodesis, indwelling catheter drainage, and even thoracotomy with pleurectomy, with the choice depending on the life expectancy of the patient and whether the lung can reexpand. Indwelling catheter drainage can lead to symphysis and catheter removal in many patients.
- Pleural mesothelioma should be considered in any patient with a persistent undiagnosed exudate, especially if there is a history of exposure to asbestos, chest pain, a rindlike nodular thickening of the pleura, and involvement of the mediastinal pleura. Diagnosis may be suggested by an elevated mesothelin in serum or pleural fluid but will require biopsy, often by VATS, for adequate tissue for panels of immunohistochemical stains.
- Pleural mesothelioma has been shown in a large prospective, randomized trial to respond to cisplatin plus pemetrexed; although not studied in a randomized trial, surgery may play a role in debulking and as a part of multimodality therapy including chemotherapy and radiotherapy.
- Solitary fibrous tumors are mesenchymal tumors that can involve the visceral pleura and are usually treated successfully with resection. If the tumors recur and cannot be resected again, targeted therapy is being used against VEGF and angiogenic pathways.
- Primary effusion lymphoma (PEL) and pyothorax-associated lymphoma (PAL) are both mostly B-cell body cavity lymphomas, the first presenting without a mass and the second as a mass. PEL is associated with systemic immunosuppression from HIV and is caused by HHV8; PAL is associated with long-standing pleural inflammation and with EBV.

CHAPTER 76

TUMORS AND CYSTS OF THE MEDIASTINUM

David R. Park, MD • Eric Vallières, MD

INTRODUCTION

THE NORMAL MEDIASTINUM

CLINICAL SETTINGS AND PRESENTATIONS OF MEDIASTINAL DISEASE
Asymptomatic Mass
Effects of Compression or Invasion of Adjacent Tissues
Systemic Symptoms and Syndromes
Investigation of the Mediastinum in Patients with Malignancy

TECHNIQUES FOR VISUALIZING THE MEDIASTINUM AND ITS CONTENTS
Conventional Radiographic Techniques
Computed Tomography
Magnetic Resonance Imaging
Ultrasonography
Radionuclide Imaging

TECHNIQUES FOR OBTAINING MEDIASTINAL TISSUE
Needle Aspiration and Biopsy
Mediastinoscopy, Anterior Mediastinotomy, and Thoracoscopy

THE MEDIASTINAL MASS
Definition
Classification and Incidence

SPECIFIC MEDIASTINAL TUMORS AND CYSTS
Lesions Typically in the Anterior Mediastinum
Lesions Typically in the Middle Mediastinum
Lesions Typically in the Posterior Mediastinum
Miscellaneous Mediastinal Masses

GENERAL APPROACH TO DIAGNOSTIC INVESTIGATION
Evaluation of a Mediastinal Mass
Mediastinal Evaluation to Stage Bronchogenic Carcinoma

INTRODUCTION

The mediastinum is the region in the chest between the pleural cavities that contains the heart and other thoracic viscera except for the lungs. Interest in the mediastinum as a separate body region stems from the diversity and vital importance of the structures it contains, and the multiplicity of disease processes by which it can be affected. The nonspecific clinical manifestations of most of these disorders and the mediastinum's relative inaccessibility for diagnostic examination result in considerable challenges to the clinician evaluating mediastinal disease. This chapter begins by describing the normal anatomy and contents of the mediastinum, the clinical manifestations produced by mediastinal disease, and the means available for diagnostic investigation. It then describes the features of specific mediastinal tumors and cysts and outlines an overall clinical approach to the evaluation of mediastinal disease.

THE NORMAL MEDIASTINUM

The anatomy of the mediastinum can be described in several ways. Most clinicians simply divide the mediastinum into anterior, middle, and posterior compartments, as seen on the lateral chest radiograph (Fig. 76-1).[1]

The anterior compartment consists of everything lying forward of and superior to the heart shadow; its boundaries are the sternum, the first rib, and an imaginary curved line following the anterior heart border and brachiocephalic vessels from the thoracic inlet to

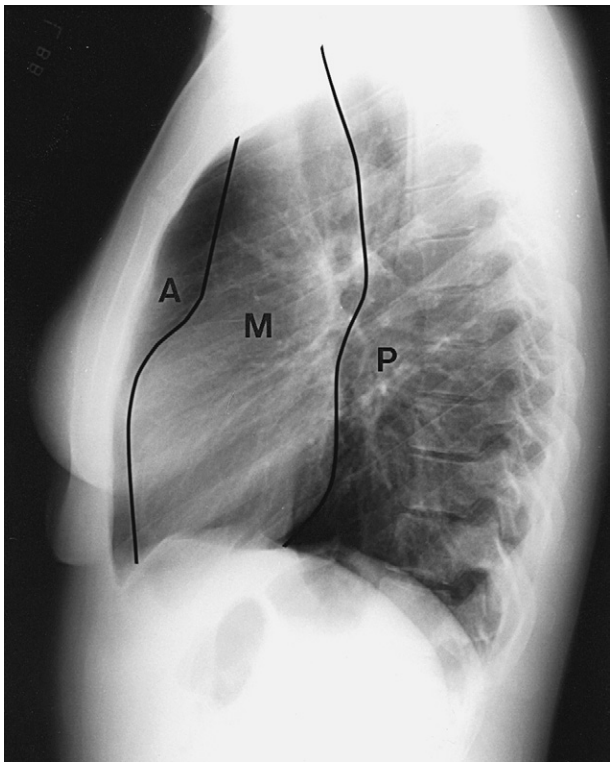

FIGURE 76-1 ■ By convention, the mediastinum is divided into anterior (A), middle (M), and posterior (P) compartments, according to its appearance on lateral chest radiograph. Although other more complex subdivisions exist, this one is most helpful to the clinician.

TABLE 76-1. Normal Mediastinal Contents

ANTERIOR COMPARTMENT
Thymus gland
Substernal extensions of thyroid and parathyroid glands
Lymphatic vessels and lymph nodes
Connective tissue
MIDDLE COMPARTMENT
Heart
Pericardium
Aortic arch and great vessels

the diaphragm. Within the anterior compartment lie the thymus gland, any substernal extensions of the thyroid and parathyroid glands, and lymphatic tissue (Table 76-1).

The middle compartment, dorsal to the anterior mediastinum, extends from the lower edge of the anterior heart border along the diaphragm and then cephalad along the posterior heart border and posterior wall of the trachea. It contains the heart, the pericardium, the aortic arch and its major branches, the innominate veins and superior vena cava, the pulmonary arteries and hila, the trachea, and several groups of lymph nodes. In addition, the phrenic and upper vagus nerves course through the middle mediastinal compartment.

The posterior compartment occupies the space between the back of the heart and trachea and the front of the posterior ribs and paravertebral gutters. It extends from the diaphragm cephalad to the first rib. In it are the esophagus, descending aorta, azygous and hemiazygous veins, paravertebral lymph nodes, and thoracic duct. The lower portions of the vagus nerve and sympathetic chains also lie within the posterior mediastinum.

This three-compartment model is consistent with embryonic development of the region and also with the characteristic distribution of individual disorders encountered clinically. Separation of mediastinal structures into anterior, middle, and posterior compartments follows logically from the appearance of the chest on conventional radiography. And, because evaluation of a mediastinal abnormality nearly always starts with a conventional chest radiograph, these compartments will likely remain the fundamental anatomic units of the mediastinum. However, other classifications exist. One, based on surgical landmarks, is used for the mapping of lymph node locations during mediastinal staging of bronchogenic carcinoma.[2] Many of the anatomic relationships of the mediastinal viscera and tissue planes are best appreciated on axial images such as shown schematically in Figure 77-1.[3]

CLINICAL SETTINGS AND PRESENTATIONS OF MEDIASTINAL DISEASE

Asymptomatic Mass

The incidental discovery of a mediastinal mass that has produced no symptoms is the most common presentation of primary mediastinal disease. At least half of all mediastinal masses are asymptomatic and detected by chest radiography performed for unrelated reasons. About 80% of such asymptomatic masses are benign, whereas more than half of those that produce symptoms are malignant.[4-6]

Effects of Compression or Invasion of Adjacent Tissues

Symptoms in patients with mediastinal mass lesions are usually due to compression by mass effect, or invasion of adjacent intrathoracic structures.[4,5] Chest pain, from traction on mediastinal tissues, tissue invasion, or bone erosion, is common. Cough also occurs frequently because of extrinsic compression of the trachea or bronchi, erosion into the airway, and sometimes post-obstructive pneumonia. Hemoptysis, hoarseness, or stridor also may be part of the clinical presentation. Invasion or irritation of the pleural surface may produce a pleural effusion, and can cause pain and dyspnea. Compression or direct invasion of the esophagus may lead to dysphagia. Rarely, anterior mediastinal tumors can cause pericarditis or pericardial tamponade, and masses in the middle mediastinum can produce right ventricular outflow obstruction and cor pulmonale.

The superior vena cava is especially vulnerable to extrinsic compression and obstruction because it is thin walled, its intravascular pressure is low, and it is relatively confined by lymph nodes and other more rigid structures. A "superior vena cava syndrome" results from increased venous pressure in the upper thorax, head, and neck,[7] and is characterized by dilation of collateral veins in the upper portion of the thorax and neck; edema and plethora of the face, neck, and upper torso; suffusion and edema of the conjunctiva; and cerebral symptoms, such as headache, disturbance of consciousness, and visual distortion (see Fig. 47-5 in Chapter 47). Tinnitus and epistaxis also may occur. All symptoms are exacerbated in the supine position. Numerous benign causes of superior vena cava syndrome are described,[8] but bronchogenic carcinoma and lymphoma are now the most common etiologies,[9,10] and fewer than 20% of cases are due to nonmalignant disease.[9,10]

Mediastinal masses can produce a variety of symptoms by invading or compressing nerves. These include hoarseness from recurrent laryngeal nerve involvement, Horner's syndrome from involvement of sympathetic ganglia, dyspnea from phrenic nerve involvement causing diaphragmatic paralysis, tachycardia secondary to vagus nerve involvement, and clinical manifestations of spinal cord compression.

Systemic Symptoms and Syndromes

Fever, anorexia, weight loss, and other systemic symptoms are nonspecific features of malignancy and inflammation that occur frequently in patients with mediastinal disease. In addition, primary mediastinal tumors are associated with a wide array of distinctive systemic syndromes (Table 76-2).[4,5,11–13] Some typically have endocrine activity, such as thyrotoxicosis sometimes seen with intrathoracic goiter; Cushing's syndrome, associated with thymomas and carcinoid tumors; gynecomastia, seen in patients with human chorionic gonadotropin–secreting germ cell tumors; hypertension, typical in patients with pheochromocytoma; and hypercalcemia, observed in patients with parathyroid adenoma and lymphoma. Hypoglycemia in patients with certain pleural tumors, teratomas, fibrosarcomas, and neurosarcomas is also believed to be the result of tumor products with endocrine activity.

TABLE 76-2. Systemic Syndromes Associated with Mediastinal Masses

Syndrome	Associated Conditions
ENDOCRINE EFFECTS	
Hypothyroidism or hyperthyroidism	Mediastinal goiter
Hypercalcemia	Parathyroid adenoma, lymphoma
Hypertension	Pheochromocytoma, ganglioneuroma, chemodectoma
Cushing's syndrome	Carcinoid, thymoma
Hypoglycemia	Mesenchymal tumor
Gynecomastia	Germ cell tumor
Diarrhea	Ganglioneuroma, neuroblastoma
AUTOIMMUNE EFFECTS	
Opsomyoclonus	Neuroblastoma
Myasthenia gravis	Thymoma
Red cell aplasia	Thymoma
Myocarditis	Thymoma
Hypogammaglobulinemia	Thymoma
CONGENITAL SYNDROMES	
Neurofibromatosis	Neurofibroma
Multiple endocrine neoplasia	Parathyroid adenoma, pheochromocytoma
UNKNOWN CAUSES	
Alcohol-induced pain	Hodgkin's disease
Fever and night sweats	Lymphoma

Thymomas are associated with numerous systemic syndromes, most of which appear to be autoimmune in origin.[4,5,12] The most familiar of these is myasthenia gravis; others include pure red blood cell aplasia, myocarditis, and hypogammaglobulinemia. Patients with thymoma also have an increased incidence of collagen vascular disease, Whipple's disease, and malignancy elsewhere in the body.

Other mediastinal tumors associated with systemic syndromes or diseases include carcinoid and parathyroid adenomas (multiple endocrine neoplasia), neurofibromas (neurofibromatosis), and lymphomas (fever of unknown origin and alcohol-induced pain). Osteoarthropathy is a known feature of primary pleural tumors, neurofibroma, and neurilemoma.

Investigation of the Mediastinum in Patients with Malignancy

The most common reason that clinicians evaluate the mediastinum is in the staging of patients with lung cancer. Whether and to what extent the mediastinum is involved is crucial to the management of patients with non–small cell lung cancer.[14] Although metastatic

involvement of the mediastinal lymph nodes has traditionally been considered a contraindication to surgical resection, increasing attention is being focused on multimodality treatment approaches for these patients, and treatment options are rapidly evolving. Regardless of the latest treatment options, careful preoperative evaluation of the mediastinum is crucial to the decision-making process.[15,16]

Nonthoracic malignancies also may metastasize to the mediastinum. This is particularly common with tumors originating in the head and neck, the esophagus, the genitourinary tract, the breasts, and the skin (malignant melanoma).

TECHNIQUES FOR VISUALIZING THE MEDIASTINUM AND ITS CONTENTS

The diagnostic evaluation of disorders of the mediastinum may be divided into two phases: noninvasive investigations via imaging, and invasive procedures to obtain tissue samples. The mediastinum is relatively inaccessible for examination or exploration. Accordingly, imaging studies play an important role in the initial evaluation of mediastinal disease. These include conventional radiographic studies, computed tomography (CT), magnetic resonance (MR) imaging, transthoracic and endoscopic ultrasonography, and various radionuclide studies.

Conventional Radiographic Techniques

Standard posteroanterior and lateral chest radiographs are the means by which most mediastinal abnormalities are first detected, and certain mediastinal mass lesions have characteristic findings (Table 76-3). For example, teratomas are usually anterior and may contain areas of calcium (sometimes teeth or bone), fat, and soft tissue. Neural tumors are usually far posterior, with sharply delineated margins. Pericardial cysts usually lie against the pericardium, on the diaphragm, or against the anterior chest wall. Bronchogenic cysts tend to lie against the trachea, carina, or main bronchus. These findings give clues to the possible origin of a mediastinal mass, but further imaging evaluation is usually required.

In the appropriate clinical settings, contrast studies remain important diagnostic tools in mediastinal disease. Barium esophagrams can demonstrate extrinsic compression, esophageal diverticulum, tumor invasion, or fistula formation.[4] Angiography can identify vascular compression or invasion, can define the vascular supply of tumors, and can sample blood for hormonal localization of certain tumors. Myelography may help to delineate intraspinal extension of posterior mediastinal tumors and to differentiate neurogenic neoplasms from meningoceles. For the most part, these techniques have been supplanted by CT and MR.

Computed Tomography

Evaluation of mediastinal disease is greatly facilitated by CT imaging. The transaxial plane of CT is well suited for assessment of mediastinal structures, most of which are oriented perpendicularly to this plane. Certain patterns and densities on CT images are virtually pathognomonic. These include the high density of calcified tissue, contrast-enhanced blood vessels, and the characteristic low

TABLE 76-3. Some Characteristic Imaging Findings in Mediastinal Disease

Feature	Likely Etiology
Huge mass on initial presentation	Neurogenic tumor Meningocele Mesenchymal tumor
Teardrop-shaped mass within interlobar fissure	Pericardial or bronchogenic cyst
Fat density on computed tomography scan	Mediastinal lipomatosis or lipoma
Calcification in mass	In rim of mass Cystic thymoma or thyroid adenoma Aneurysm Silicosis ("eggshell" calcification) In center of mass Thyroid adenoma Teratoma
Teeth or bone	Teratoma
Phleboliths	Hemangioma
Air-fluid level in mass	Esophageal disease Diaphragmatic hernia Developmental cyst Cystic teratoma Abscess
Mass with associated parenchymal infiltrate	Granulomatous infection Metastatic bronchogenic carcinoma Lymphoma with direct extension into lung Esophageal abnormality with aspiration pneumonitis Bronchial compression by primary mediastinal mass
Mass with associated pleural effusion	Metastatic malignancy with pleural involvement Granulomatous inflammation of lymph nodes
Superior vena cava obstruction	Recent onset Bronchogenic carcinoma Lymphoma Catheter-associated thrombosis Long-standing Mediastinal fibrosis
Erosion or destruction of bone	Arterial aneurysm Tumors of peripheral nerves or sympathetic ganglia Meningocele
Spine or rib deformity	Enteric cyst

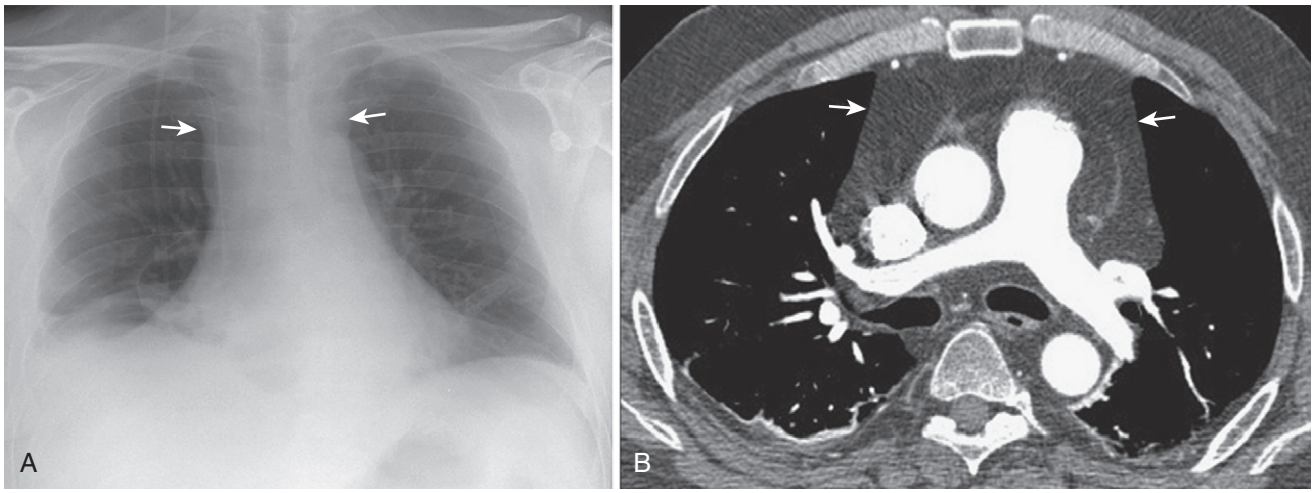

FIGURE 76-2 ■ Chest radiograph **(A)** showing diffuse mediastinal widening (*arrows*) and computed tomography (CT) scan **(B)** showing extensive fat deposition (*arrows*) in the anterior mediastinum in a patient with mediastinal lipomatosis. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

density of fat (Fig. 76-2).[17] Normal anatomic variations and fluid-filled cysts can be distinguished confidently from other processes, and the site of origin of mediastinal masses can be better identified.[18] Characteristic CT findings in a variety of mediastinal disorders have now been described (see Table 76-3). A recent report described 100% specificity for the CT appearance of teratomas, thymolipomas, and omental fat herniation, but the overall accuracy of CT for predicting the diagnosis of all mediastinal masses was only 48%.[17]

Lymph nodes are readily identifiable on CT scan and can be categorized as normal in size and shape, enlarged, coalescent, or grossly replaced by tumor mass. Mediastinal lymph nodes greater than 1.0 cm in diameter in the short axis are considered to be abnormally enlarged. However, in numerous studies of the use of CT in mediastinal staging of lung cancer, the sensitivity of the 1.0-cm cutoff for detecting cancerous nodes by CT has ranged from 18% to 94% (reviewed in Gould and coworkers[19]). The specificity of the 1.0-cm cutoff in these studies ranged from 43% to 100%, although it was usually under 90%. Mediastinal lymph nodes greater than 2.0 cm in diameter are virtually always abnormal, and most nodes greater than 2.0 cm in diameter in patients with lung cancer contain metastatic disease. However, even in series of patients with proven bronchogenic carcinoma, benign findings were present in 10% of lymph nodes either larger than 2.0 cm in diameter or with evidence of central necrosis.[20] In another study, no cancer was found in 37% of lymph nodes 2 to 4 cm in diameter.[21] Thus normal-appearing nodes often contain metastatic cancer, while even markedly enlarged nodes with abnormal appearance may not.

Nevertheless, CT has become the initial imaging procedure of choice for the evaluation of the mediastinum in patients with a primary mediastinal mass[11-13] or with suspected lung cancer.[22] In the majority of patients, CT cannot establish a diagnosis with certainty. However, CT can precisely define the mediastinal anatomy and guide subsequent invasive diagnostic and staging procedures, or can confirm a clinical suspicion of extensive mediastinal involvement or visceral organ invasion that precludes curative resection.

Magnetic Resonance Imaging

MR assesses tissues by measuring radiofrequency-induced nuclear resonance emissions and is better suited than CT to evaluating vertically oriented structures and tissue boundaries[23,24] (Fig. 76-3). In addition, MR images of blood vessels are identifiable without the need for contrast enhancement (Fig. 76-4). Finally, metallic objects that cause artifact on CT scans do not interfere with MR, although some metallic devices may be subjected to magnetic forces.[25]

MR has use in evaluation of the mediastinum, both in general applications in chest disease[18,23,24] and in more specific circumstances such as bronchogenic carcinoma.[22] A large multicenter study comparing CT and MR in patients with lung cancer found similar accuracy for the detection of mediastinal node involvement, but MR was superior for detecting direct mediastinal tumor invasion.[26] Most authorities now recommend CT for routine staging purposes, and MR for defining anatomy in special circumstances such as prior to surgical resection of superior sulcus tumors or those invading the mediastinum, chest wall, or diaphragm.[15,22]

Both CT and MR have limitations. Both imaging techniques distinguish poorly between hilar masses and adjacent collapsed or consolidated lung. Both can also show displacement or compression of the esophagus or trachea by tumor, but often are unable to indicate whether there is also invasion of these structures. Most importantly, neither technique reliably distinguishes between benign and malignant causes for mediastinal lymph node enlargement.

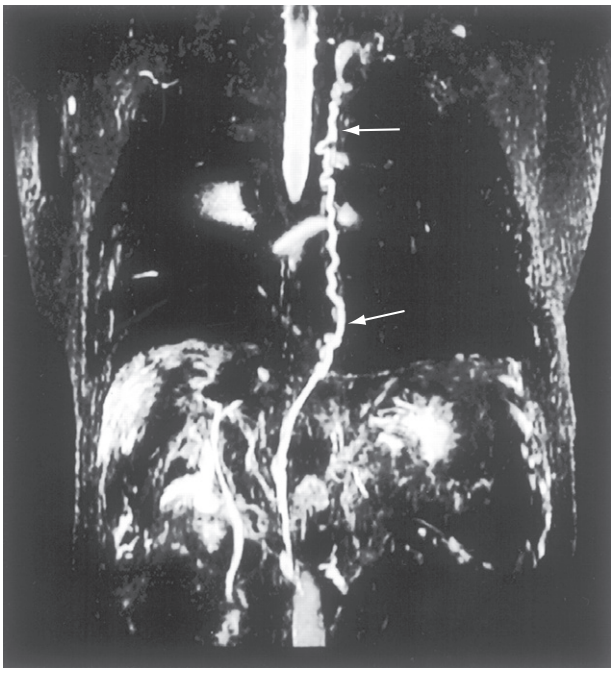

FIGURE 76-3 ■ Magnetic resonance lymphogram of the thoracic duct. The normal course of the thoracic duct can be seen crossing diagonally through the lower mediastinum from the patient's right to left and then ascending along the left mediastinum to reach the subclavian vein. In this case the duct is somewhat more dilated and tortuous than normal due to the presence of hepatic cirrhosis. (From Takahashi H, Kuboyama S, Abe H, et al: Clinical feasibility of noncontrast-enhanced magnetic resonance lymphography of the thoracic duct. Chest 124:2136–2142, 2003.)

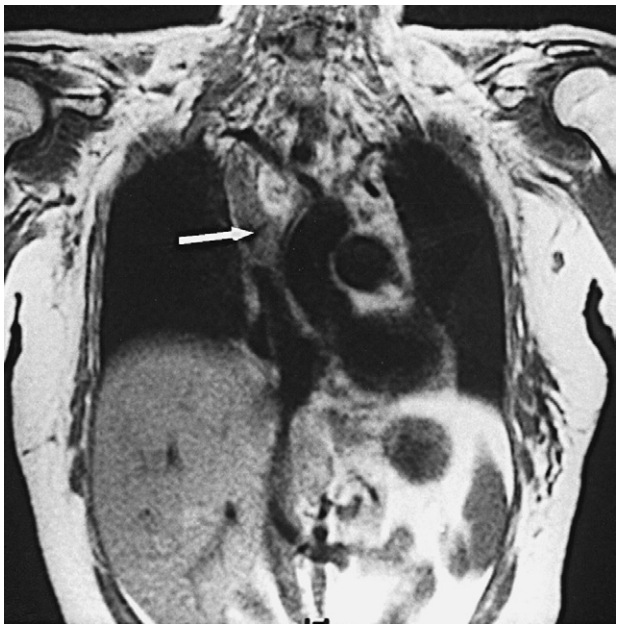

FIGURE 76-4 ■ Magnetic resonance imaging of a 52-year-old woman with multiple myeloma, experiencing symptoms of superior vena cava (SVC) obstruction following placement of an indwelling central venous catheter in preparation for bone marrow transplantation. Vertically oriented structures are clearly discernible, and black "flow void" is present within the heart and great vessels. The SVC is completely obstructed by thrombus (*arrow*).

Ultrasonography

Ultrasonography may be useful in confirming the cystic nature of mediastinal masses, although it cannot readily distinguish between benign and malignant cystic lesions. Both transthoracic and endoscopic ultrasound probes may be useful in the evaluation of mediastinal disease.[27] Ultrasound may be most useful in guiding endoscopic biopsy techniques, as discussed later in this chapter.[28]

Radionuclide Imaging

Radionuclide imaging studies rely on the localization of markers based on specific metabolic or immunologic properties of the target tissue. The spatial resolution of radionuclide scans is relatively poor, but the overall diagnostic accuracy may be good if a sufficiently specific probe is available. An additional appeal is the potential ability to stage a malignancy and identify distant metastases with a single scan of the entire body.

Planar imaging with gallium-67 (^{67}Ga) has been used in the evaluation of patients with sarcoidosis. Characteristic "lambda" and "panda" signs result from uptake in the lacrimal and salivary glands and the mediastinal lymph nodes.[29] However, the lack of specificity has relegated the use of ^{67}Ga scans to selected cases with high pretest probability, or to detect subclinical extrathoracic sites of involvement. ^{67}Ga scans are less accurate than CT for evaluating mediastinal spread of lung cancer.[30] Radioiodine scanning may detect ectopic thyroid tissue; a positive result is pathognomonic for that condition.[4] Various radionuclide studies used to characterize specific primary mediastinal masses are discussed later in this chapter.

Single-photon emission computed tomography (SPECT) permits imaging of standard gamma-emitting probes in an axial fashion similar to that of conventional CT. The accuracy of ^{201}Tl-SPECT for determining mediastinal node involvement by lung cancer compares favorably with CT, but is not sensitive or specific enough to supplant surgical staging.

Positron emission tomography (PET) is perhaps the most promising imaging technique available for use in the evaluation of the mediastinum.[19,31] PET technology relies on high-energy photon–emitting probes such as [^{18}F]fluorodeoxyglucose (FDG), which are chemically trapped within metabolically active cells. The result is a high signal-to-background ratio, excellent spatial resolution, and good accuracy (Fig. 76-5). PET is demonstrating increasing versatility in the evaluation of many forms of mediastinal disease.[32] Unfortunately, PET technology is costly and not universally available, and false-positive results can be caused by inflammatory conditions.

The role of PET in the mediastinal staging of lung cancer remains to be determined. Early experience found that PET detected mediastinal metastases with sensitivity and specificity ranging from 50% to 100% and 63% to 100%, respectively.[19] The American College of Surgeons Oncology Group reported the results of a prospective multicenter evaluation of PET in staging resectable non–small cell lung cancer[33]; in this realistic setting,

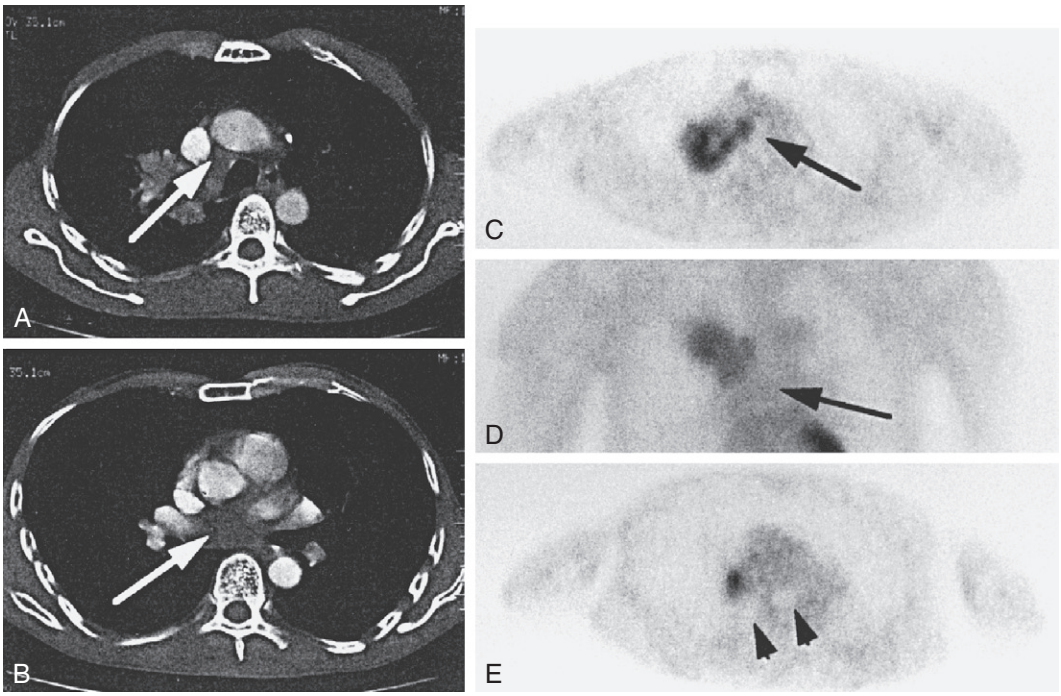

FIGURE 76-5 ■ Computed tomography (CT) and positron emission tomography (PET) scans of a patient with right upper lobe squamous cell carcinoma. The primary tumor and right paratracheal adenopathy **(A)** and subcarinal adenopathy **(B)** are evident on the standard CT images (*arrows*). PET images reveal probe uptake in the primary tumor and right paratracheal nodes on axial **(C)** (*arrow*) and coronal **(D)** views, but not in the subcarinal node on coronal **(D)** (*arrow*) and axial **(E)** views. The *arrowheads* in **E** point to the main bronchi. At mediastinoscopy, the right paratracheal nodes were found to be malignant, and the subcarinal nodes were enlarged but benign. (From Vansteenkiste JF, Stroobants SG, De Leyn PR, et al: Mediastinal lymph node staging with FDG-PET scan in patients with potentially operable non-small cell lung cancer: A prospective analysis of 50 cases. Leuven Lung Cancer Group. Chest 112:1480–1486, 1997.)

the sensitivity of PET in determining mediastinal nodal involvement was 61%, its specificity was 84%, the negative predictive value was 87%, and the positive predictive value was only 56%. PET may provide other helpful information. In a series from our institution, FDG-PET scans failed to detect mediastinal metastases in 8 of 118 patients with surgically established nodal stage, but identified unsuspected sites of distant metastasis and prevented unnecessary operations in 17% of patients.[34]

Technological advances such as co-registration of PET and CT images have improved the sensitivity of PET,[35] but at the cost of lower specificity and increased false-positive results.[36] Based on these experiences, it seems prudent to confirm both positive and negative FDG-PET findings if the findings of mediastinal involvement would alter the subsequent surgical approach (see also Chapters 21 and 47).

TECHNIQUES FOR OBTAINING MEDIASTINAL TISSUE

Definitive diagnosis of most mediastinal masses requires the evaluation of a tissue sample. Available approaches for biopsy of mediastinal lesions include needle aspiration and biopsy via transbronchial, percutaneous, or transesophageal approaches; and surgical biopsies obtained by more invasive procedures including mediastinoscopy, mediastinotomy, and thoracoscopy.

Needle Aspiration and Biopsy

Transbronchial Needle Aspiration

Transbronchial needle aspiration (TBNA) via the fiberoptic bronchoscope can yield definitive proof of the presence of malignancy in the mediastinum using a procedure less hazardous and costly than mediastinoscopy. Despite the proximity of major vessels and lung parenchyma to the areas routinely biopsied, TBNA appears to be a relatively safe procedure. Few significant complications (pneumothorax and hemomediastinum) have been reported in over 1500 reported procedures. Although experience with TBNA in patients receiving mechanical ventilation is limited, no complications were reported in a series of 8 patients.[37]

In the setting of bronchogenic carcinoma, a careful prospective study found that only 15% of patients with the established diagnosis of lung cancer had a positive result from TBNA but, in 69% of these, the TBNA specimen was the only preoperative evidence for mediastinal metastasis.[38] The true sensitivity and specificity of TBNA appear to range from 14% to 50% and 96% to 100%, respectively.[39,40] Thus, negative results require definitive operative confirmation, but the risk of false-positive TBNA results appears to be quite low. Nonetheless, to avoid generating false-positive results by aspirating malignant cells stirred up from elsewhere in the tracheobronchial tree, TBNA should be performed prior to

bronchial exploration or biopsy of any endobronchial lesions.[38,41]

The yield of TBNA is improved in patients with visible endobronchial lesions, with widening or erythema of the carina,[38,41] or with mediastinal adenopathy on plain radiographs and subcarinal adenopathy on CT.[42] The yield of TBNA can be improved by guidance of the biopsy needle using CT or especially using real-time endobronchial ultrasound (EBUS).[43–45] In addition, diagnostic algorithms combining EBUS-guided TBNA with PET scan identification of specific areas of concern may lead to improved diagnostic yields.[46,47]

Finally, TBNA may have utility in other clinical situations such as in the diagnosis of a variety of primary mediastinal masses and cysts, metastases from extrathoracic malignancies, and miscellaneous benign conditions,[48,49] and in the evaluation of mediastinal adenopathy associated with human immunodeficiency virus (HIV) infection.[50]

Percutaneous Needle Aspiration and Biopsy

Percutaneous needle aspiration and biopsy of mediastinal masses can be performed using ultrasound or, more often, CT guidance[51] (Fig. 76-6). Percutaneous needle aspiration of the mediastinum has acceptable morbidity and yields comparable to those from percutaneous biopsy of pulmonary lesions. As with TBNA, serious bleeding is seldom encountered,[51] and accurate diagnosis of a wide variety of lesions has been reported. Accuracy is enhanced when immediate cytopathologic examination is used to determine whether or not an adequate sample has been obtained.

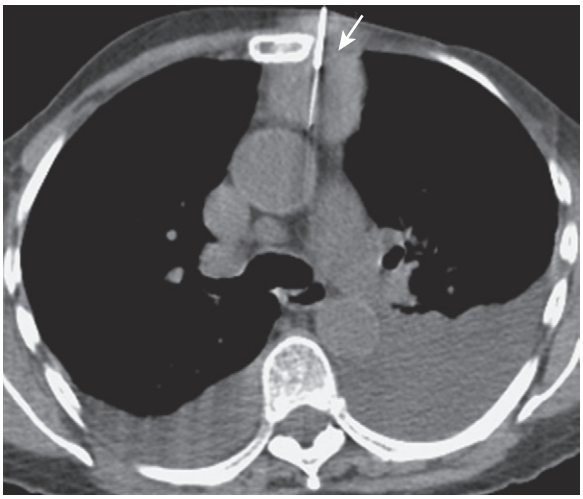

FIGURE 76-6 ■ Computed tomography–guided needle aspiration of an anterior mediastinal mass. The image shows the needle entering the mass by passing lateral to the sternum and medial to the internal mammary vessels (*arrow* = left internal mammary artery). Associated findings include a pretracheal lymph node and bilateral pleural effusions. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

Endoscopic Ultrasound-Guided Needle Aspiration and Biopsy

Endoscopic ultrasound (EUS)–guided sampling relies on the placement of biopsy needles that are passed through the working channel of a gastroscope.[52] The proximity of the esophagus to areas of the mediastinum relatively inaccessible to mediastinoscopy, such as the posterior subcarinal lymph nodes, make this approach particularly useful in selected cases. Preliminary studies suggest that it is highly accurate and well tolerated.[28,53] EUS-guided biopsy has similar sensitivity compared to PET for lung cancer, and superior specificity (100%).[54] In selected cases, it can confirm the presence of mediastinal metastases and obviate the need for surgical staging procedures.[55] By combining EUS-guided biopsy and EBUS-guided TBNA, the mediastinum can be thoroughly sampled.[56]

Mediastinoscopy, Anterior Mediastinotomy, and Thoracoscopy

Mediastinoscopy allows direct inspection and biopsy of lymph nodes or other masses in the superior portion of the anterior mediastinum.[57] Although more invasive than any of the techniques discussed previously in this chapter, mediastinoscopy can provide large specimens for histologic examination, including entire lymph nodes, rather than the cellular aspirates or small tissue fragments produced by needle biopsy techniques.

Mediastinal anatomy from the mediastinoscopist's perspective is different from that based on the lateral chest radiograph as described earlier: for mediastinoscopy; structures are considered according to whether they lie anterior, posterior, or immediately to the right or left of the trachea.[2] Not all mediastinal lymph nodes can be reached by the mediastinoscope. Those readily accessible include the right paratracheal nodes to the level of the tracheal bifurcation, the left paratracheal nodes as far as the aortic arch, and the anterior subcarinal nodes.[18] Mediastinoscopy usually requires general anesthesia, but may be performed as an outpatient procedure when subsequent thoracotomy is not planned to follow immediately.[58]

Mediastinoscopy has utility in evaluating mediastinal adenopathy or mass lesions in a variety of settings, including the evaluation of complications of HIV infection.[59] However, its most frequent application is in the staging of bronchogenic carcinoma.[60] Either frozen section or imprint cytology methods can provide rapid, accurate results and facilitate immediate decisions about the feasibility of curative resection.[61,62]

Mediastinoscopy does have potential complications, including pneumothorax, hemorrhage, recurrent laryngeal nerve or phrenic nerve paralysis, injury to the trachea, esophageal perforation, thoracic duct laceration, air embolism, and mediastinitis. A recent retrospective review of 2137 consecutive mediastinoscopies in one center reported only one death attributable to the procedure (0.05%) and 12 complications (0.6%).[63] In a nearly

identical experience of 2145 procedures at another center, there were 23 complications (1.07%), one death (0.05%), and a 5.5% false-negative rate (mostly attributable to nodes not accessible at mediastinoscopy).[64]

The precise indications for mediastinoscopy in non–small cell lung cancer are controversial. The presence of enlarged nodes is an important indication for mediastinoscopy, so that patients with resectable tumors are not incorrectly assumed to have inoperable mediastinal spread (Fig. 76-7). Some advocate the routine use of mediastinoscopy in the evaluation of all cases of potentially resectable disease.[63,65] Others use mediastinoscopy more selectively and omit the procedure if all nodes are less than 1.0 cm or 1.5 cm in diameter by CT scan,[18] or if the primary tumor is small, peripheral, or located in either of the lower lobes.[66] Despite these guidelines, the decision to perform mediastinoscopy or anterior mediastinotomy for lung cancer staging remains a variable one that depends on local resources, personal experience, institutional biases, and treatment preferences for patients with minimal mediastinal nodal involvement.[67]

Video-assisted thoracoscopic surgery, usually considered a tool for the evaluation of pleural and lung abnormalities, can also be helpful in the management of mediastinal diseases. After dissection through the mediastinal pleura, mediastinal lymph nodes can be sampled to aid in the staging of malignancies such as esophageal carcinoma and for the diagnosis and resection of primary mediastinal tumors and cysts.[68-71]

FIGURE 76-7 ■ Axial computed tomographic image through the lower trachea shows a squamous cell carcinoma in the posterior right upper lobe (*) and right paratracheal lymphadenopathy (*arrow*). The right paratracheal lymph node, which was more than 2.0 cm in short-axis diameter, did not show abnormal tracer accumulation on positron emission tomography. It was surgically sampled and proven to be free of tumor. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

THE MEDIASTINAL MASS

Definition

The next part of this chapter discusses the specific lesions that present as a mass in the mediastinum. Several of the conditions mentioned, such as thyroid and fat, are not tumors but are instead aberrantly located or overabundant normal tissues. Justification for their inclusion comes from their similar presentation to that of mediastinal tumors and the fact that in most instances they require the same evaluation as any other mediastinal mass. The clinical problem is a "mediastinal mass," and this discussion focuses on the main disease processes that are the cause of this presentation.

Classification and Incidence

Primary mediastinal masses are not uncommon, but their true incidence is difficult to ascertain. An overall incidence of one case per 100,000 population per year may be a reasonable estimation. The tumors and cysts that account for this incidence are individually much less frequent. Table 76-4 estimates the relative frequencies of the most common mediastinal tumors and cysts, based on the collection by Silverman and Sabiston of nearly 2400 cases from the literature.[4] More recent series suggest a similar pattern,[6,72] although Cohen and associates[6] have observed a rising incidence of mediastinal masses in general and an increasing proportion of

TABLE 76-4. Relative Frequencies of Mediastinal Masses in Adults and Children*

Lesion	Adults (%)	Children (%)
Thymoma	19	—
Developmental cysts	21	18
Bronchogenic	7	8
Pericardial	7	<1
Enteric	3	8
Other cysts	4	2
Neurogenic tumors	21	40
Lymphoma	13	18
Germ cell tumors	11	11
Endocrine (thyroid, parathyroid, carcinoid)	6	—
Mesenchymal tumors	7	9
Primary carcinoma	—	—
Other malignancies	3	4

*Based on Silverman and Sabiston's review of reported mediastinal masses in 1950 adults and 437 children. Data from Silverman NA, Sabiston DC Jr: Mediastinal masses. Surg Clin North Am 60:757–777, 1980.

lymphoma and malignant neurogenic tumors over the course of their 45-year survey. In general, neurogenic tumors, thymomas, and developmental cysts account for about 60% of all mediastinal masses. Lymphomas and germ cell tumors such as teratoma and seminoma account for about 25%, and a large number of other lesions, both benign and malignant, constitute the remaining 15%.

There are some differences in the incidence of mediastinal masses between adults and children: thymoma and thyroid masses rarely occur in infants and children, whereas neurogenic tumors are less common in adults. The likelihood of malignancy is higher in infants and children than in adults: in adults, about one fourth of all mediastinal mass lesions are malignant, whereas in children, the percentage is 40% to 45%.[4] In addition, HIV infection substantially alters the spectrum of mediastinal disease. In the HIV-positive population, mediastinal masses are most often due to granulomatous inflammation from mycobacterial and other infections, lymphoma, and other opportunistic processes; in addition, multiple diseases may be present simultaneously.[59] Finally, surgical case series are likely to underrepresent causes of mediastinal masses, such as goiter, that do not routinely lead to surgical intervention.

The most practical clinical classification of mediastinal masses is by their location, grouping together lesions that are characteristically found in the anterior, middle, and posterior mediastinal compartments. Table 76-5 lists the disorders that present as a mediastinal mass and the compartments in which they characteristically arise. This simple scheme is followed in this chapter, recognizing that such a classification ignores the fact that mediastinal masses may present in atypical mediastinal compartments (Fig. 76-8).

SPECIFIC MEDIASTINAL TUMORS AND CYSTS

Lesions Typically in the Anterior Mediastinum

Thymic Neoplasms

Thymoma is the most common neoplasm arising in the anterior mediastinum[4,5,18,73] and has been recognized more often recently because of increased aggressiveness in evaluating patients with myasthenia gravis.[4] Histologically, thymoma is composed of lymphocytes and epithelial cells and is described according to predominating cell type. However, a thymoma's histologic appearance correlates poorly with its biologic behavior and, clinically, these tumors are categorized according to their local invasiveness rather than their appearance under the microscope.[5] Thus, biologically aggressive thymomas are referred to as "invasive" rather than "malignant" thymoma.

The peak incidence of thymomas is between the ages of 40 and 60 years, with equal gender predilection. Two thirds of patients are asymptomatic at the time of diagnosis. The rest of the patients typically have nonspecific chest pain, cough, or dyspnea.[74] However, from 40% to 70% have at least laboratory evidence of one or more of the two dozen systemic "parathymic" syndromes that have been recognized.[4] Myasthenia gravis is the most frequent among these, reported in 10% to 50% of patients with thymoma,[4] and thought to be due to autoantibodies to the postsynaptic acetylcholine receptor.[75,76]

Radiographically, thymomas are usually detected near the junction of the heart and great vessels; typically, they

TABLE 76-5. Disorders Presenting as a Mass in the Mediastinum

ANTERIOR MEDIASTINUM	MIDDLE MEDIASTINUM	POSTERIOR MEDIASTINUM
Thymic neoplasms	Lymphadenopathy	Neurogenic tumors
Germ cell tumors	Reactive and granulomatous inflammation	Arising from peripheral nerves
Teratoma	Metastasis	Arising from sympathetic ganglia
Seminoma	Angiofollicular lymphoid hyperplasia (Castleman's disease)	Arising from paraganglionic tissue
Nonseminomatous germ cell tumors	Lymphoma	Meningocele
Embryonal cell carcinoma	Developmental cysts	Esophageal lesions
Choriocarcinoma	Pericardial cyst	Carcinoma
Lymphoma	Foregut duplication cysts	Diverticula
Hodgkin's disease	Bronchogenic cyst	Diaphragmatic hernia (Bochdalek's)
Non-Hodgkin's lymphoma	Enteric cyst	Miscellaneous
Thyroid neoplasms	Others	
Parathyroid neoplasms	Vascular enlargements	
Mesenchymal tumors	Diaphragmatic hernia (hiatal)	
Lipoma		
Fibroma		
Lymphangioma		
Hemangioma		
Mesothelioma		
Others		
Diaphragmatic hernia (Morgagni's)		
Primary carcinoma		

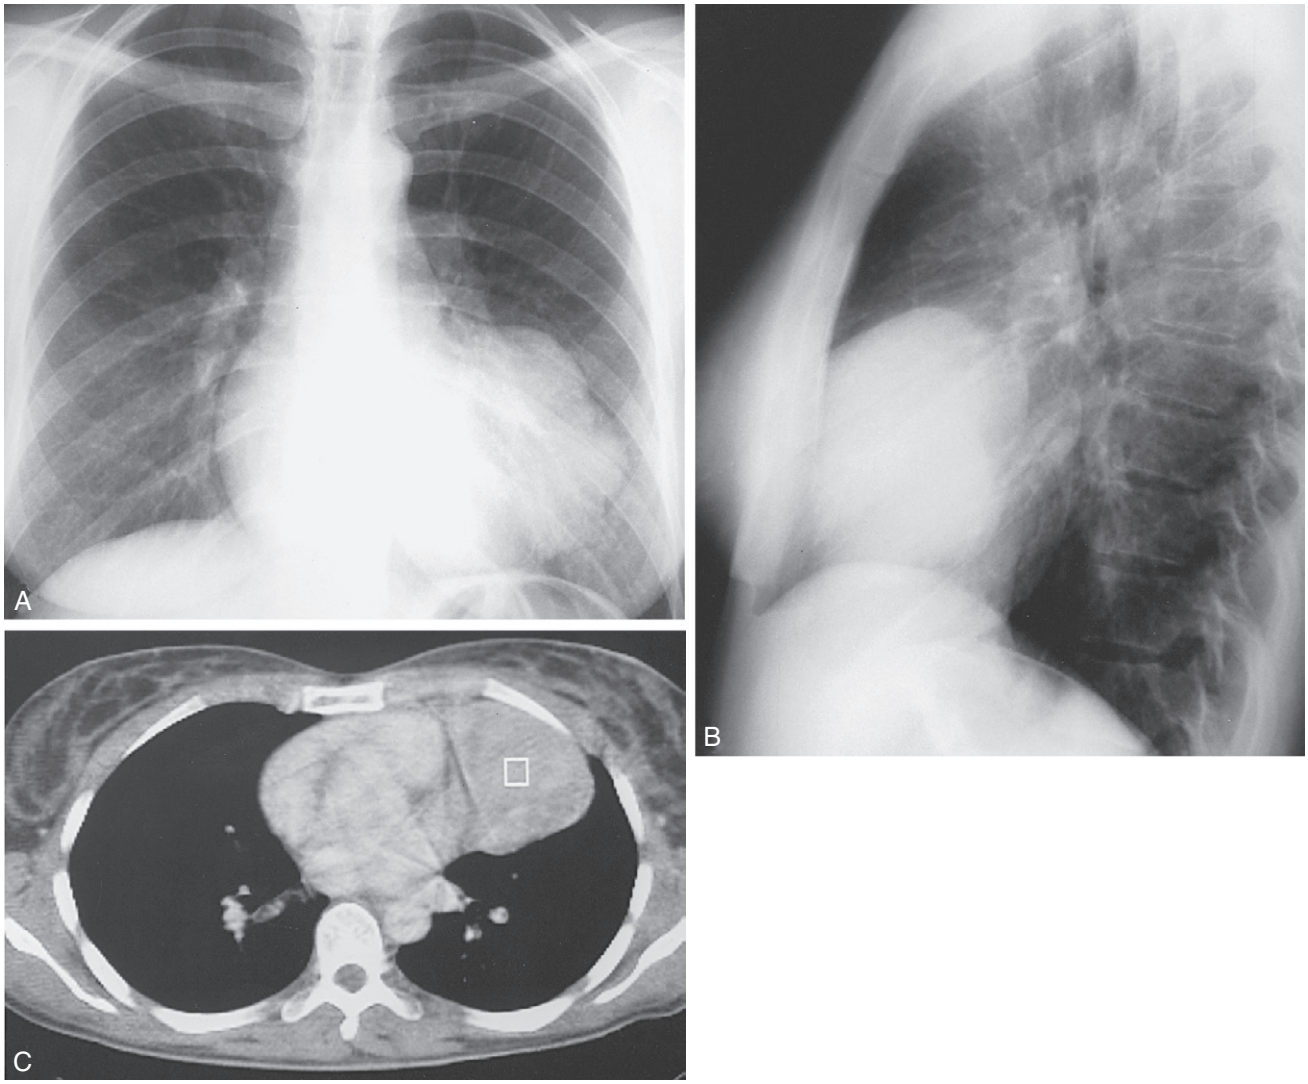

FIGURE 76-8 ■ Typical findings on chest radiographs (**A,** posteroanterior view; **B,** lateral view) and thoracic computed tomogram **(C)** showing a mass presenting in the anterior and middle mediastinum. At surgery, this mass proved to be a benign thymoma, originating in the anterior mediastinum and extending by a slender stalk into the middle radiographic compartment. (Courtesy of Dr. Robert Stevens, Wenatchee, WA.)

are round or oval and their margins are smooth or lobulated (Fig. 76-9).[77] Compared with thymic hyperplasia, which is typically symmetrical, thymoma usually distorts the gland's normal shape and extends to one side.[78] Thymoma is diagnosed with certainty only by examination of tissue. However, CT or MR can reveal gross invasion and continuity of a mediastinal mass with the thymus. Somatostatin receptor scintigraphy and FDG-PET imaging appear promising for discerning thymoma and other thymic tumors from benign thymic hyperplasia.

Thymomas are managed by resection, generally via a median sternotomy approach,[4,73] or via video-assisted thoracoscopic surgery.[70] Adjunctive treatment with postoperative radiotherapy is typically provided,[5,73,79] and the addition of preoperative or adjuvant chemotherapy appears promising for more advanced stages.[80-82]

Thymomas are neoplastic, but most have relatively benign biologic behavior. Patients whose tumors are fully encapsulated can expect survival equal to that of the general population. Invasive tumors have a poorer prognosis, with 50% to 77% 5-year and 30% to 55% 10-year survival.[83] Thymoma recurs after resection in nearly a third of patients.[83]

Other thymic mass lesions include benign conditions such as thymic hyperplasia, thymic cysts, and lipothymoma.[84] Thymic carcinoma is a histologically malignant process that invades locally and frequently metastasizes.[85,86] The prognosis depends on the histologic grade and the anatomic stage and is generally poor. Resection and combined chemoradiation therapy are advocated. Carcinoid tumors occasionally occur in the thymus.[87,88] They may cause Cushing's syndrome and be associated with multiple endocrine adenomatosis. Locally invasive carcinoids may be difficult to resect completely, but characteristically have a prolonged clinical course.[4] Interestingly, the thymus is also a common site for mediastinal Hodgkin's lymphoma, and normal thymic tissue may enlarge following chemotherapy for lymphoma (a

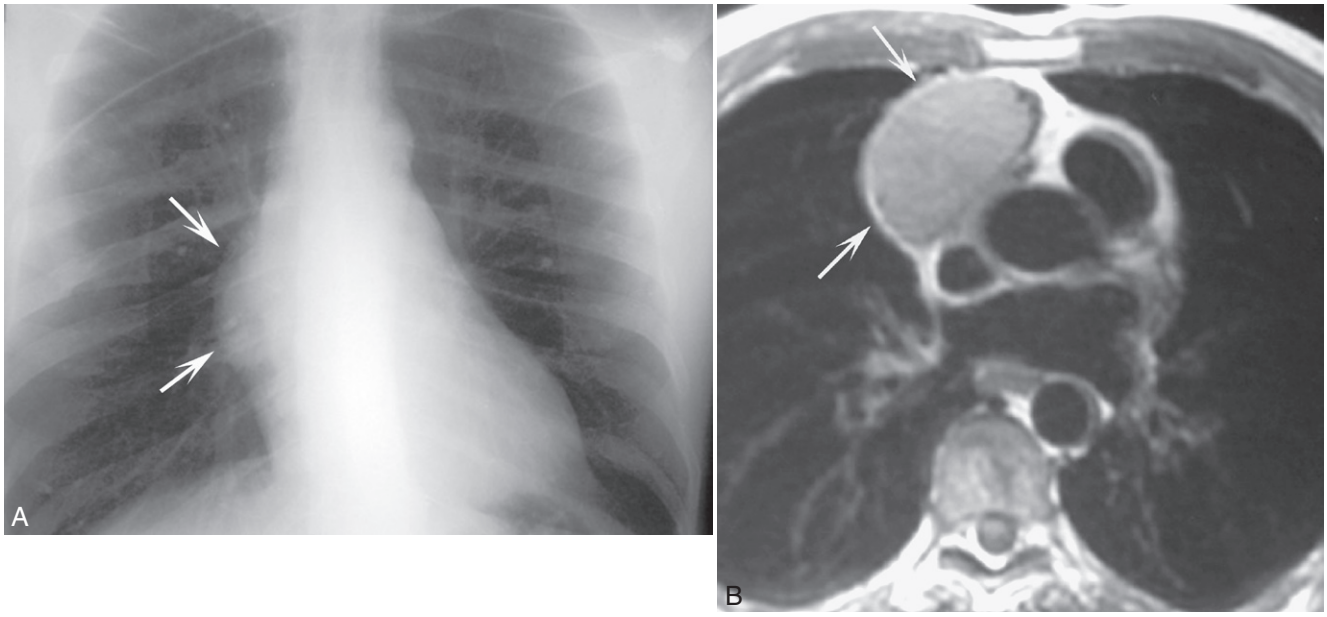

FIGURE 76-9 ■ ***A***, Frontal chest radiograph shows a smoothly marginated mass along the right side of the mediastinum (*arrows*). **B**, Axial magnetic resonance T1-weighted image through the base of the heart shows that the mass (*arrows*) is slightly hyperintense compared to the skeletal muscle and resides within the anterior mediastinum. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

process termed *thymic rebound*), mimicking recurrence of the primary disease.[89]

Germ Cell Tumors

Approximately 10% to 12% of primary mediastinal masses are derived from germinal tissues.[4,5,90] These neoplasms are classified into four main groups: teratoma and teratocarcinoma, seminoma, embryonal cell carcinoma, and choriocarcinoma. They are believed to arise from remnant multipotent germ cells that migrated abnormally during embryonic development.[91]

Teratomas are the most common germ cell tumors. By definition, they are made up of tissues foreign to the area in which they occur. Ectodermal derivatives predominate, but structures originating in all three primary germ cell layers may be found. When only the epidermis and its derivatives are present, the term *dermoid cyst* is appropriate. Teratomas arise most often in young adults, but have been reported in all age groups; men and women are affected with equal frequency. Most (80%) are benign, but teratocarcinoma, the malignant counterpart, is an aggressive, rapidly spreading neoplasm with a poor prognosis.

Most patients with teratomas have symptoms caused by the tumor; only about a third are asymptomatic.[4,92] Usual symptoms are pain, cough, and dyspnea. If the tumor erodes into a bronchus, the patient may have hemoptysis or even expectorate differentiated tissue such as hair (trichiptysis) or sebaceous material.[92] Teratomas have also ruptured into the pleural space, causing acute respiratory distress, or into the pericardium, causing pericardial tamponade.

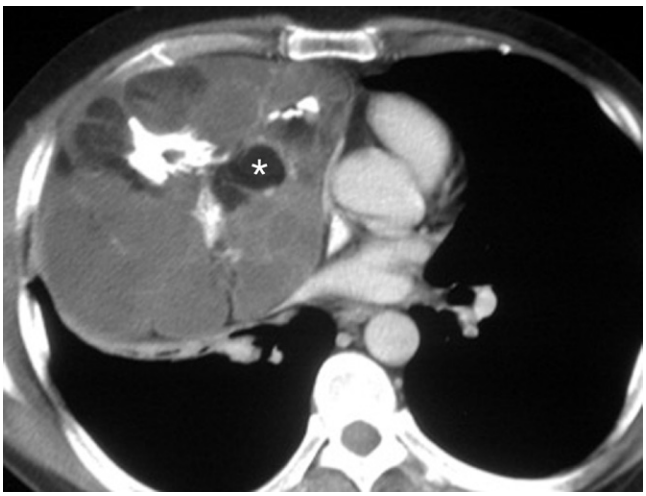

FIGURE 76-10 ■ Axial computed tomographic image through the base of the heart shows a large right-sided anterior mediastinal mass with heterogenous attenuation. Elements of calcium, soft tissue, and fat (*) are present. The presence of fat within an anterior mediastinal mass is consistent with teratoma. (Courtesy of Michael B. Gotway, MD, Scottsdale Medical Imaging and the Department of Radiology, University of California, San Francisco.)

On chest radiographs, if they are cystic, teratomas are generally smooth, rounded, and well circumscribed; if they are solid, they are more lobulated and asymmetrical. On CT scans, soft tissue, fat, and calcification (occasionally, fully-formed teeth and bone) can be identified, rendering this one of few mediastinal tumors that can be diagnosed confidently before operation[17] (Fig. 76-10). All

teratomas should be resected because they may be malignant and because, even if benign, they may enlarge and thus impinge on adjacent vital structures. In malignant teratoma, adjuvant combination chemotherapy may result in improved survival.[93]

Seminomas and nonseminomatous germ cell tumors nearly always cause symptoms and appear as a large anterior mediastinal mass on chest radiographs and CT images. PET scanning may be useful in staging these tumors, but may have greater value in identifiying residual disease and recurrence after medical treatment.[94]

Seminoma (dysgerminoma) occurs almost exclusively in men, usually in the third decade of life.[5] Most patients seek medical attention because of chest pain, dyspnea, cough, hoarseness, or dysphagia. Superior vena cava obstruction can occur. Seminomas are aggressive malignant tumors that extend locally and metastasize distantly, usually to skeletal bones. They may secrete human chorionic gonadotropin, but not alpha-fetoprotein. Factors associated with a poorer prognosis include age over 35 years; superior vena cava obstruction; supraclavicular, cervical, or hilar adenopathy; and fever.[95,96] Seminomas are extremely radiosensitive and may respond dramatically to chemotherapy even in cases with dissemination.[91,97] With aggressive cisplatin-based regimens, long-term survival for all mediastinal seminomas is approximately 80%.[91,98]

Nonseminomatous mediastinal germ cell tumors may be grouped into embryonal cell carcinoma and choriocarcinoma.[4,5,95] A nonseminomatous malignancy usually grouped with embryonal cell carcinoma is called endodermal sinus or yolk sac tumor. These highly malignant aggressive tumors often secrete human chorionic gonadotropin, alpha-fetoprotein, or carcinoembryonic antigen which may also produce clinical manifestations, such as gynecomastia, in 50% of patients.[5] Associations have been noted with Klinefelter's syndrome[99] and with hematologic malignancy.[100] Like seminoma, these tumors occur mainly in men in the third and fourth decades and are usually symptomatic. Most patients present with disseminated disease, and the prognosis has been less favorable than in seminoma.[5] Cisplatin-based treatment regimens have markedly improved the outcome, with over 50% of patients achieving long-term survival.[91,100] Long-term survival may be possible in those who undergo a complete surgical resection following chemotherapy.[101] Even disseminated and refractory malignant germ cell tumors may respond to aggressive chemotherapy[102] and salvage regimens involving bone marrow transplantation.[103,104]

Lymphoma

Lymphoma is a common cause of a mediastinal mass in both adults and children and represents between 10% and 20% of cases in most series.[4–6,72] Hodgkin's disease, or Hodgkin's lymphoma, has a bimodal distribution, arising in adolescents and young adults as well as in those over 50, whereas non-Hodgkin's lymphoma arises most commonly in older adults. Primary mediastinal B-cell lymphoma is a distinct subset of non-Hodgkin's lymphoma that shares features with nodular sclerosing Hodgkin's lymphoma.[105] Lymphoma is especially common as a thoracic complication in HIV-infected patients.[106,107] HIV-associated lymphomas are usually immunoblastic,[106] although Hodgkin's disease also is more common in patients with HIV infection than in the general population.[107,108]

Incidental discovery of a mass on a chest radiograph is a common presentation of lymphoma, although many patients have systemic symptoms or more localized complaints such as cough and chest pain. Tracheal compromise and superior vena cava obstruction are common, as are pericardial and pleural involvement, and Hodgkin's disease often involves the hilar nodes and lung parenchyma.[109] Resection is not a necessary part of therapy, but anterior thoracotomy or mediastinoscopy is usually required to confirm the diagnosis if a site outside the mediastinum is not evident for biopsy. The prognosis of Hodgkin's and other lymphomas has improved strikingly in the last 2 decades as more effective and less toxic combinations of radiotherapy and chemotherapy have evolved, and effective salvage regimens including bone marrow transplantation have been developed to treat relapsed disease.

Thyroid Lesions

In surgical series, ectopic thyroid glands account for fewer than 10% of mediastinal masses but, in clinical practice, these are probably more common. Thyroid tissue within the mediastinum is of two distinct origins. Most commonly, a cervical goiter extends substernally into the anterior mediastinum.[110] Primary intrathoracic goiter, presumably originating from an embryonic rest of heterotopic thyroid tissue, is rare. Most such goiters are in the anterior mediastinum, but they may occur in the middle or posterior mediastinum as well.[4,5] Intrathoracic goiter presents predominantly in women of middle age or older; although it is usually asymptomatic, the goiter may cause hoarseness, cough, or swelling of the face and arms. Intrathoracic thyroid tissue is easily recognized by radioactive iodine scanning,[111] and may be suspected on the basis of high radiodensity on CT scans, particularly after iodinated contrast injection.[112,113] Treatment is by resection.

Parathyroid Lesions

Mediastinal parathyroid tissue is said to account for as many as 10% of cases of hyperparathyroidism, and the mediastinum is the most common site for ectopic parathyroid adenomas in surgically-resistant hyperparathyroidism.[114] Half of ectopic parathyroid adenomas lie in the anterior mediastinum, usually near the thymus. Parathyroid cysts may enlarge sufficiently to appear as a mass on the chest radiograph and to produce symptoms.[115] Otherwise, location of aberrant functioning

parathyroid tissue can be a difficult clinical problem that may be aided preoperatively by CT, ultrasound, MR imaging and the sensitive technetium-99m sestamibi scanning.[116] Selective arteriography and venous sampling for parathormone levels have largely been supplanted by the sestamibi radionuclide scans.[116]

Technetium-99m sestamibi scans are highly accurate in the detection of aberrant parathyroid tissue.[117,118] Sestamibi, a lipophilic cationic molecule that is taken up by mitochondrial-rich cells, is accumulated and retained by hyperplastic parathyroid cells, a finding first described in 1989. The routine use of sestamibi scanning has been proposed as cost-effective because it may lessen the chance of protracted and/or failed cervical explorations in cases of primary hyperparathyroidism.[119,120] Parathyroid adenomas are cured by complete resection, and resection via video-assisted thoracoscopic surgery is increasingly advocated.[68]

Parathyroid carcinoma may be functional, resulting in varying degrees of hyperparathyroidism, but is also locally invasive and may metastasize.[121] Cure is possible with aggressive surgical management[122] that may be guided by imaging and functional localization studies.[123]

Mesenchymal Tumors

Included in this group of unusual mediastinal masses are lipomas, fibromas, mesotheliomas, and lymphangiomas, plus several other rare tumors (see Table 76-5).[4] They arise from connective tissue, fat, smooth muscle, striated muscle, blood vessels, or lymphatic channels and can occur in any region of the mediastinum. Histologically and clinically, they are not substantially different from their counterparts elsewhere in the body. Unless the lesion is very large, the presence of symptoms usually means that the lesion is malignant.[4,18]

Lipoma is the most common mesenchymal tumor of the mediastinum and is most often anterior. It may be encapsulated or unencapsulated, but in either case it is smooth and rounded with well-defined margins. The characteristic low density of lipomas on CT images (Fig. 76-11) permits a confident diagnosis unless there is associated inhomogeneity, invasion of surrounding tissues, or poor demarcation of the mass's perimeter, in which case malignancy (liposarcoma or lipoblastoma) or teratoma must be excluded.[18] Considerably more common than lipoma is mediastinal lipomatosis, or generalized overabundance of histologically normal unencapsulated fat.[124] Mediastinal lipomatosis appears on the conventional radiograph as a smooth widening or bulging of normal mediastinal contours, and its low homogeneous CT density confirms the diagnosis (see Fig. 76-2).[18] Compression or displacement of other mediastinal structures does not occur.

Sarcomas involving the mediastinum are rare but, if present, are more likely due to nerve sheath sarcoma, spindle cell sarcoma, leiomyosarcoma, or liposarcoma.[125] Prior radiation therapy appears to be a predisposing factor in some cases.[126]

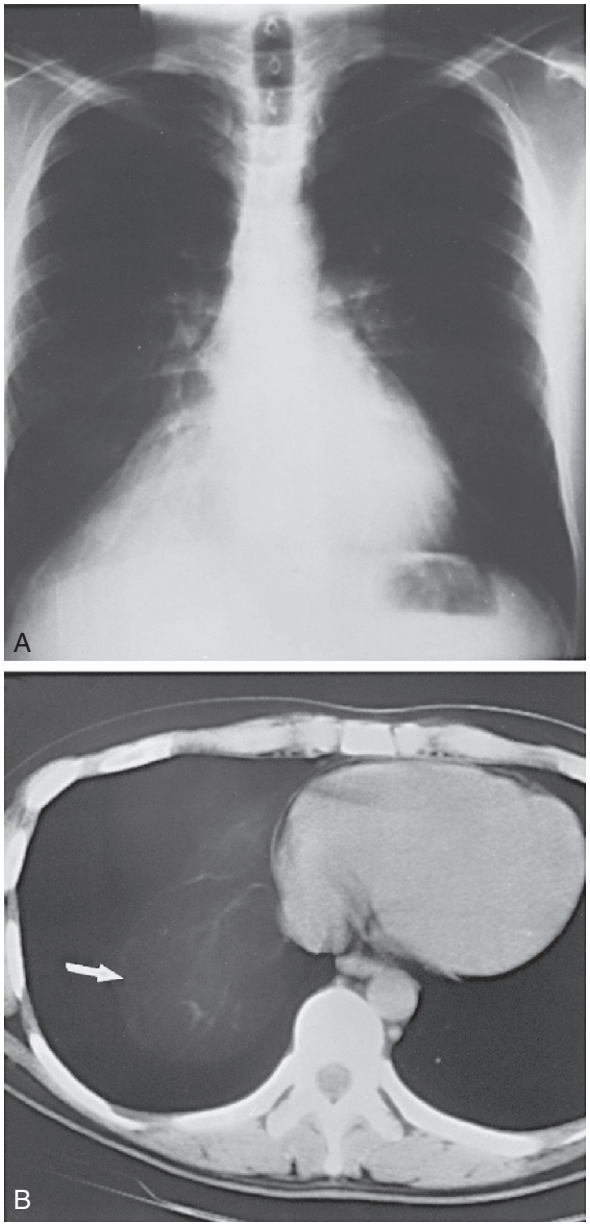

FIGURE 76-11 ■ **A**, Chest radiograph of a 31-year-old man showing an abnormality at the right cardiophrenic angle noted as an incidental finding. **B**, Computed tomogram demonstrates a well-circumscribed homogeneous fat-density mass characteristic of a mediastinal lipoma extending into the right hemithorax (*arrow*).

Lesions Typically in the Middle Mediastinum

Enlargement of Lymph Nodes

Enlargement of lymph nodes represents one of the most common causes of mediastinal abnormality on chest radiographs. Numerous classifications exist for the mediastinal lymph nodes, a comprehensive example of which is the 11-region scheme of the American Thoracic Society.[2] Figure 76-12 presents a simplified grouping of

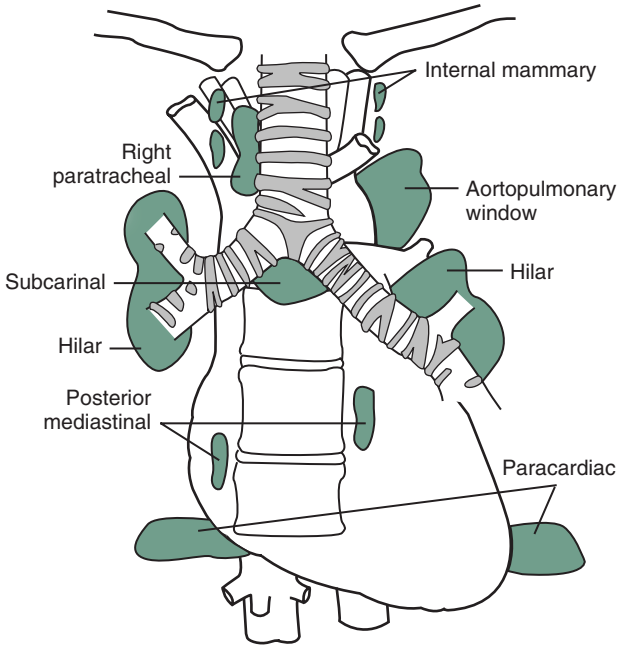

FIGURE 76-12 ■ Simplified schematic diagram depicting mediastinal lymph node groups. (Redrawn from McLoud TC, Meyer JE: Mediastinal metastases. Radiol Clin North Am 20:453–468, 1982.)

the main mediastinal nodes that corresponds to findings on conventional radiography and CT scans.[127] Nodes in the subcarinal, paratracheal, and hilar areas tend to be larger than those elsewhere,[128,129] but most authors consider 1.0-cm diameter at the short axis to be the upper limit of normal size.

Mediastinal lymph node enlargement is most often due to three general categories of disease process: lymphoma,[130] metastatic cancer,[127] and granulomatous inflammation such as that caused by sarcoidosis. Numerous less common causes are described, including Castleman's disease or angiofollicular lymphoid hyperplasia. Mediastinal adenopathy is common in HIV-infected patients and is usually induced by infection, although lymphoma, Kaposi's sarcoma, and other noninfectious processes may be responsible.[131] As discussed previously, lymph node enlargement can be detected accurately by CT and MR, but imaging studies cannot reliably distinguish between benign and malignant causes of node enlargement (see Fig. 76-7).

Developmental Cysts

Developmental cysts of various sorts comprise 10% to 20% of all mediastinal masses.[4,132] Most can be identified as pericardial, bronchogenic, or enteric on the basis of their lining tissues.[4] Bronchogenic and enteric cysts are often referred to as *foregut duplication cysts* because of their origin from aberrant portions of the ventral and dorsal foregut, respectively.

Pericardial cysts account for about one third of cystic masses in adults, but are much less common in children (see Table 76-4). They typically lie against the pericardium, diaphragm, or anterior chest wall in the right cardiophrenic angle. Rarely, pericardial cysts may communicate with the pericardial space. Although typically harmless, pericardial cysts may enlarge to cause right ventricular outflow obstruction,[133] or rupture and hemorrhage to cause pericardial tamponade[134] or sudden cardiac death.[135]

Bronchogenic cysts are typically found near the large airways, often just posterior to the carina, although they may be attached to the esophagus or even inside the pericardial space.[4] The cyst wall often contains cartilage and respiratory epithelium. Most are discovered incidentally and cause no symptoms; however, they may communicate with the tracheobronchial tree and become infected[136]; enlarge to cause airway obstruction,[137] pulmonary artery compression,[138] or hemodynamic collapse[139]; or rupture with disastrous consequences.[140] Spillage of cyst contents into the airway during anesthesia also has been reported.[141]

Enteric or enterogenous cysts are similar in location and appearance to bronchogenic cysts, but have digestive tract epithelium. They are relatively uncommon in adults, but are the most common cysts found in infants and children, in whom they may be associated with spinal extension and malformations of the vertebral column (called "neurenteric" cysts). Enteric cysts can occasionally be multiple and associated with duplications of other portions of the gastrointestinal tract.

Developmental cysts can usually be identified by CT or ultrasonography, and the diagnosis may be confirmed by aspiration cytology. MR imaging is valuable for confirming the cystic nature of these lesions and for evaluating possible spinal extension. In the appropriate clinical setting, benign cysts need not be resected unless they cause symptoms.[142] However, most authorities favor resection because of diagnostic uncertainties and the potential for development of complications.[136,140] Alternatives to thoracotomy include therapeutic aspiration[143,144] and thoracoscopic or mediastinoscopic excision.[69,145,146]

Vascular Masses and Enlargements

Although not technically masses, a variety of vascular lesions must be considered in the differential diagnosis of what appears to be a mediastinal mass seen on the chest radiograph.[5,147] These include poststenotic aortic dilation, aneurysms or tortuosity of the aorta and great vessels, aortic coarctation, innominate vein and superior vena cava aneurysm, persistent left vena cava, azygos and hemiazygos vein enlargement, anomalous pulmonary venous return, pulmonary venous varix, and cardiophrenic angle varices associated with portal hypertension.[148] Idiopathic dilation of the pulmonary trunk and pulmonary arterial hypertension of any cause may appear as a mediastinal mass, and traumatic aortic transection or more subtle vascular injuries may result in mediastinal hematoma.

Angiography has been the traditional means of diagnosing mediastinal masses of vascular origin but, in most cases today, CT imaging with intravenous contrast injection provides a more convenient diagnosis.[149,150] MR

imaging may permit definitive diagnosis without radiation or contrast exposure.

Diaphragmatic Hernia

Omental fat or other abdominal contents may protrude through the diaphragm via several potential routes, producing mediastinal mass lesions in any compartment.[18] A hernia through the foramen of Morgagni produces a cardiophrenic angle mass, usually on the right side in the anterior mediastinum. Bochdalek's hernia, in the posterior mediastinum, generally appears on the left side, presumably because the liver prevents herniation on the right. Herniation of fat around the esophagus is believed to precede hiatal hernia formation; either may appear as a mediastinal mass. In the latter instance, an air-fluid level is intermittently seen on horizontal beam films. Fine linear densities are often demonstrable in diaphragmatic fat herniations on CT imaging. These are thought to represent omental vessels within the hernia, and they may help differentiate a hernia from a lipoma.[18]

Lesions Typically in the Posterior Mediastinum

Neurogenic Tumors

Neoplasms arising from neural tissues constitute the largest single group of mediastinal masses,[4,5] accounting for about 20% of adult cases and twice that proportion in children (see Table 76-4). They are classified into those arising from peripheral nerves, from sympathetic ganglia, and from paraganglionic (chemoreceptor) tissue (Table 76-6). As a group, neurogenic tumors usually appear radiographically as a unilateral paravertebral mass.[4,151,152] Clinical manifestations include chest pain from nerve or bone erosion, dyspnea secondary to tracheal compression, and neurologic deficits resulting from spinal cord compression by intraspinal tumor extension. In addition, many neurogenic tumors are hormonally active.

TABLE 76-6. Neurogenic Tumors of the Mediastinum

Ganglioneuroblastoma
Neuroblastoma
Sympathicoblastoma
Neoplasms Arising from Paraganglionic Tissue
Pheochromocytoma
Paraganglioma (chemodectoma)

Tumors arising from peripheral nerves include neurofibromas, neurilemomas (also called schwannomas), and neurosarcomas. Neurofibromas contain both nerve sheath cells and nerve elements and are the most common tumor of this group. They are incompletely encapsulated and may grow quite large, producing symptoms by nerve compression or space occupation. Mediastinal neurofibroma may be one manifestation of von Recklinghausen's disease (neurofibromatosis). As with these tumors elsewhere, malignant degeneration into neurosarcoma eventually occurs in 10% to 15% of patients with von Reckinghausen's disease.[5]

Neurilemoma, or schwannoma, is another common neurogenic tumor that arises from the neural sheath. Most often seen in the third to fifth decade of life, neurilemoma usually causes no symptoms and appears as a well-circumscribed, homogeneous density on chest radiograph (Fig. 76-13A).[4,5] It is always completely encapsulated and does not invade surrounding tissues, although neurilemomas may extend into intervertebral foramina (see Fig. 76-13B and C). Treatment of both neurilemoma and solitary neurofibroma is resection.

Malignant tumors of nerve sheath origin are also known as malignant neurofibroma, malignant schwannoma, or neurogenic fibrosarcoma. These tumors behave aggressively, with both local invasion and distant metastasis. Half occur in patients with neurofibromatosis.[13] Treatment requires wide excision and usually adjuvant radiation.[13]

Tumors arising from nerve cells in sympathetic ganglia display a spectrum of neoplastic behavior ranging from ganglioneuroma, a benign tumor occurring mainly in children, to the malignant tumors ganglioneuroblastoma and neuroblastoma. Ganglioneuromas cause symptoms merely by mass effect, and are usually cured by surgical excision. Ganglioneuroblastomas have intermediate behavior and can invade locally but are less likely to metastasize.[5] Neuroblastoma rapidly displaces and invades adjacent structures and may be widely metastatic at the time of presentation.[153,154] These tumors often elaborate endocrine peptides and catecholamines, and are associated with diarrhea, fever, anorexia, and weight loss.[4] The propensity to produce catecholamines is used to advantage by imaging tumor uptake of the catecholamine precursor [^{123}I]-metaiodobenzylguanine (MIBG) for purposes of diagnosis, identification of distant tumor metastases and treatment.[155,155a] Treatment of neuroblastoma involves risk-based strategies that guide multimodality therapy.[156]

Neoplasms arising from paraganglionic or chemoreceptor tissue include pheochromocytomas, which are rare in the mediastinum and indistinguishable clinically or histologically from their counterparts in the abdomen, and paragangliomas (chemodectomas). Paragangliomas may secrete catecholamines just as do pheochromocytomas and thus may also be detected and perhaps treated with MIBG.[156a] They appear benign under the microscope and seldom metastasize, but spread locally in an aggressive fashion and thus have high morbidity and mortality rates.[4]

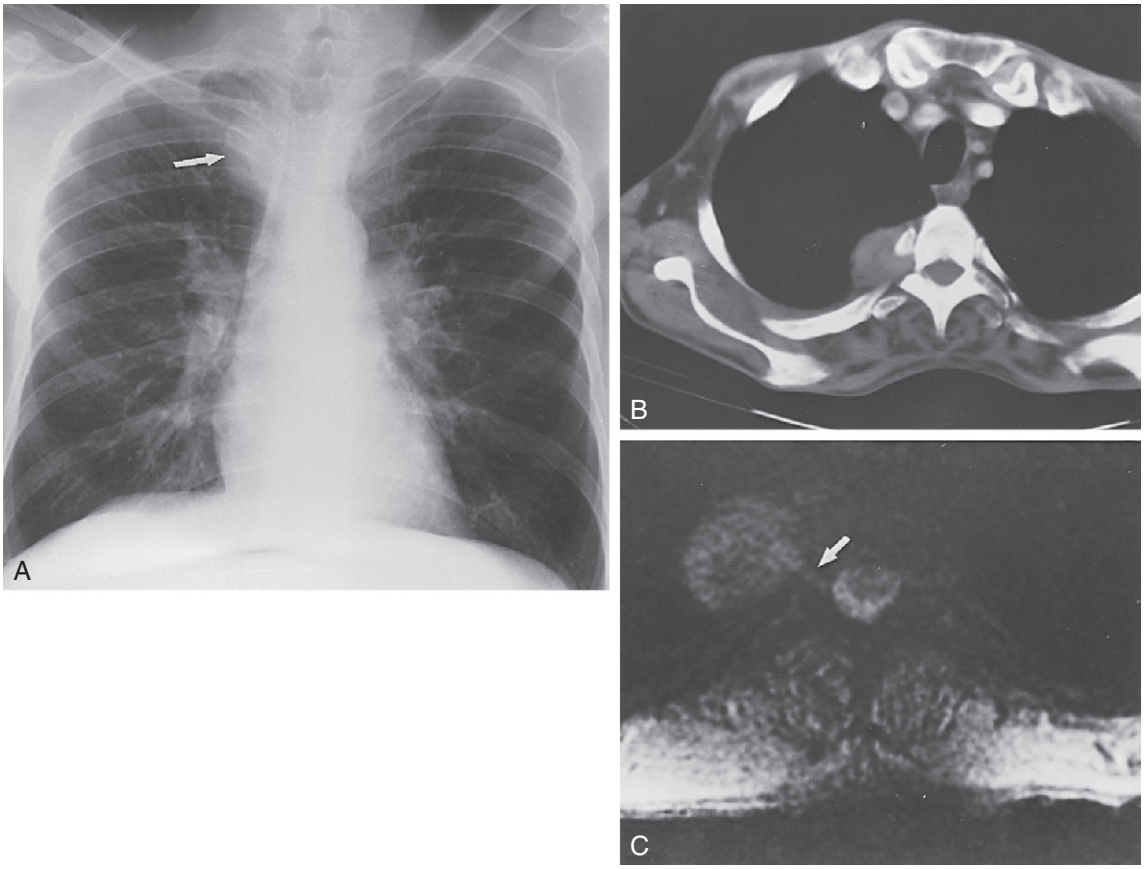

FIGURE 76-13 ■ Series of imaging studies of a 64-year-old asymptomatic man with a surgically proved neurilemoma, or schwannoma. **A**, Posteroanterior chest radiograph showing an incidental finding of a discrete mass behind the right clavicular head (*arrow*). **B**, Computed tomogram showing homogeneous, well-circumscribed appearance and posterior location adjacent to the vertebral column. **C**, Magnetic resonance image showing extension of the tumor into the intervertebral foramen (*arrow*).

Miscellaneous Mediastinal Masses

Numerous rare causes of mass lesions in the mediastinum have been described.[5] These include malignancies known as primary carcinoma and sarcoma of the mediastinum.[4] Primary carcinoma usually occurs in the anterior or middle mediastinum and is believed to be distinct from bronchogenic carcinoma and from other primary mediastinal neoplasms. It occurs primarily in adults, usually in men, and has an aggressive, rapidly fatal course with little response to therapy. Primary mediastinal sarcoma is a rare lesion of children, which otherwise clinically resembles primary carcinoma. Poorly differentiated carcinoma of the mediastinum ("Adkins tumor"[157]) is a rare neoplasm whose histology does not permit identification of a likely tissue or site of origin.

Miscellaneous benign causes of a mediastinal mass have been described. Pancreatic pseudocysts may extend into the mediastinum, usually through the aortic or esophageal hiatus.[5,158,159] They have been reported in all three mediastinal compartments. Hydatid cysts also rarely occur in the mediastinum.[5] The posterior mediastinum is occasionally the site of a thoracic duct cyst.[4,72] Also, extramedullary hematopoiesis in patients with chronic hemolytic anemia may appear as a mediastinal mass, often in a posterior location. Meningoceles, outgrowths of spinal meninges that protrude along the course of a spinal nerve, produce posterior mediastinal masses.

Finally, it must be remembered that masses found within any of the mediastinal compartments may be due to lesions more commonly found in another mediastinal compartment or due to those which have extended from another area in the mediastinum (see Fig. 76-8).

GENERAL APPROACH TO DIAGNOSTIC INVESTIGATION

Evaluation of a Mediastinal Mass

Occasionally, mass lesions in the mediastinum can be diagnosed based on clinical information and noninvasive test results alone, without need for a biopsy. Only a few masses fall into this category. These include mediastinal thyroid tissue, which can be identified by radioactive iodine scans, certain calcified lesions that have remained unchanged on serial radiographs, and mediastinal lipomatosis with typical CT findings. Determining that a mass is cystic does not unequivocally establish it as benign: solid tumors may become cystic (especially thymomas and degenerating nerve sheath tumors), and teratomas may be solid, cystic, or a combination of these. In addi-

tion, some cystic lesions become so densely packed with secreted material and detritus that they appear solid on CT. Lymphoma or other malignancy diagnosed by biopsy of tissues outside the thorax does not require separate demonstration that it is also the cause of a mediastinal mass. Confirmed active pulmonary tuberculosis or sarcoidosis usually warrants a trial of therapy and period of observation before invasive approaches are used to evaluate coexistent mediastinal abnormalities. However, for the large majority of mediastinal masses, thorough diagnostic evaluation must lead to examination of tissue obtained from the lesion.

Primary mediastinal tumors usually require biopsy in order to determine the cause. However, because most primary mediastinal masses should be removed regardless of the cause, consideration should be given to surgical resection as the initial invasive diagnostic approach. In general, even benign lesions should be removed because they may subsequently enlarge, compress vital mediastinal structures, hemorrhage, rupture, become infected, or, with varying degrees of likelihood, undergo malignant degeneration. In light of these factors, the basic focus of the diagnostic evaluation of a mediastinal mass is an orderly preparation for obtaining a tissue diagnosis or a complete resection. The goals should be to assess the patient's general health and suitability for operation, and clinical syndromes and laboratory clues suggesting a specific diagnosis (Table 76-7).

Conventional chest radiographs are the first diagnostic tool in all cases, and certain mediastinal mass lesions have characteristic appearances (see Table 76-3). A stable appearance, in comparison to older films, can obviate the need for further investigation in selected patients. Imaging by CT or MR will more completely depict the mass's size, location, density, homogeneity, and gross involvement of surrounding tissues than standard chest radiographs and will also help guide the surgeon. The need for specialized studies such as a thyroid scan, a sestamibi scan, or ^{123}I-MIBG will be dictated by the clinical setting and by suspicion of a specific diagnosis. Sometimes a more accessible site for biopsy is discovered on general evaluation of the patient, as in cases of lymphoma with extrathoracic lymphadenopathy. However, in most cases, tissue from the mediastinal mass must be obtained, and the optimal management of mediastinal tumors and cysts usually includes complete resection of the mass. Therefore, if the patient is a candidate for potentially curative surgical resection, surgery should be the next step in most cases. Surgery and anesthesia can be challenging, and approaches should be individualized.[160]

TABLE 76-7. Diagnostic Approach to the Primary Mediastinal Mass

History
Symptoms of local effects or complications
Systemic syndromes as clues to diagnosis (see Table 76-2)
Physical Examination
Physiologic compromise
Extrathoracic manifestations as clues to diagnosis (see Table 76-2)
Potential extrathoracic biopsy sites
General condition and candidacy for surgery
Chest Radiography and Computed Tomography
Anatomic location (see Table 76-5)
Appearance (size, shape, density, invasion)
Characteristic imaging features (see Table 76-3)
Special Imaging Studies
Thyroid scan (suspected goiter, abnormal thyroid function tests)
^{67}Gallium scan (suspected sarcoidosis)
Somatostatin receptor scintigraphy (suspected thymoma)
^{99m}Technetium sestamibi scan (suspected parathyroid adenoma)
^{123}I-MIBG scintigraphy (suspected catecholamine-producing neurogenic tumors)
Positron emission tomography (suspected lung cancer)
Laboratory Studies
Complete blood count
Routine chemistries (hypercalcemia, hypoglycemia)
Thyroid function tests (suspected goiter)
Anti–acetylcholine receptor antibody (myasthenic symptoms or mass contiguous with thymus)
Alpha-fetoprotein and β-human chorionic gonadotropin (suspected germ cell tumor)
Catecholamine levels (suspected neurogenic tumor)
Tissue Biopsy
Transbronchial needle biopsy (especially if bronchoscopy is already indicated)
Transthoracic or transesophageal needle biopsy (for accessible lesions when primary resection is not feasible)
Mediastinoscopy or mediastinotomy (for accessible lesions, if less invasive approaches are unsuccessful)
Primary Surgical Resection
Appropriate diagnostic approach when ultimate goal is resection and no evidence precludes therapeutic resection

Mediastinal Evaluation to Stage Bronchogenic Carcinoma

Mediastinal tissue sampling is central to the management of bronchogenic carcinoma because noninvasive assessment of the mediastinum usually cannot definitively confirm or exclude the presence of metastases, and because findings of mediastinal metastases may drastically alter the surgical and other therapeutic options. Thus, in patients who appear to be candidates for surgical resection, staging should consist of a deliberate search for metastases in the mediastinal lymph nodes.[16] To deny surgery to a patient with curable disease is a greater loss than to perform mediastinoscopy or even thoracotomy on a patient who is then found to be unresectable. It seems logical to progress through the staging process from diagnosis, to imaging of the mediastinum, to examination of nodal tissue, to surgical exploration, stopping the sequence on the confident discovery of metastatic disease but otherwise proceeding to resection. Which imaging procedures to employ, how to obtain diagnostic tissue, and what constitutes the confident identification of metastases that contraindicate surgery are decisions that must be made but have no absolute answers.

Finally, the general condition and wishes of the patient with lung cancer must enter into the clinical staging process. A systematic extrathoracic assessment may indicate that curative resection is not an option, either because the patient has obvious signs of distant metastases or because severe chronic pulmonary, cardiac, or other systemic disease precludes curative therapy.

ACKNOWLEDGMENTS

The authors wish to acknowledge the contributions of David J. Pierson, MD, who wrote this chapter for the first and second editions, and coauthored this chapter with DRP for the third edition. These earlier chapters contain more extensive and historical references.

KEY POINTS

- The mediastinum is the space in the center of the chest, between the lungs, that contains all of the other thoracic viscera.
- The mediastinum contains numerous vital organs within a confined space that is surrounded by the bony thorax and is relatively inaccessible for examination.
- The mediastinum can be divided into three compartments based on anatomic boundaries that can be seen on a lateral chest radiograph.
- The *anterior* compartment lies between the sternum and the anterior border of the heart and great vessels. Anterior mediastinal masses include thymoma, germ cell tumors, lymphoma, and thyroid and parathyroid tumors.
- The *middle* compartment contains the heart and most of the great vessels, the trachea, and the phrenic and upper vagus nerves. Middle mediastinal masses include lymphadenopathy and developmental cysts.
- The *posterior* compartment lies between the posterior wall of the heart and trachea and the posterior chest wall. It contains the esophagus, thoracic duct, descending aorta and azygos/hemiazygos veins, and the sympathetic chains and lower vagus nerves. Posterior mediastinal masses are generally neurogenic tumors.
- Benign mediastinal tumors and cysts may cause problems due to compression of adjacent organs and structures, hemorrhage, infection, or rupture.
- Malignant mediastinal lesions can invade locally and can metastasize distantly.
- Whether benign or malignant, most mediastinal tumors and cysts should be resected either because they may be malignant or because even benign masses may enlarge and impinge on vital structures.

Clinical Settings and Syndromes

Clinical Manifestations and Diagnosis

Approach to Management

MEDIASTINITIS

Acute Mediastinitis

Chronic "Granulomatous" Mediastinitis and Mediastinal Fibrosis

INTRODUCTION

Pneumomediastinum (air in the mediastinum) and mediastinitis (infection or inflammation in the mediastinum) are disorders that involve the potential spaces and tissues of the mediastinum. Although both may occur together, as following esophageal rupture, the term *pneumomediastinum* usually refers to the presence of aberrant air in the mediastinum without accompanying infection and *mediastinitis* refers to infection or inflammation regardless of the presence of air. These conditions are seen in a variety of unique clinical circumstances. However, both tend to result either from breaches in the integrity of mediastinal structures or from spread to mediastinal structures from elsewhere in the body. Thus, anatomic considerations are similar for the two processes and are considered at the beginning of this chapter. The pathophysiology, clinical settings, management approaches, and clinical impact of pneumomediastinum and mediastinitis are quite different and are discussed separately.

GENERAL ANATOMIC CONSIDERATIONS

The mediastinum is traversed by air-filled structures (the trachea and esophagus) which may contain colonizing microorganisms. In addition, mediastinal lymph nodes drain the airways and lung parenchyma where inhaled organisms, antigens, and dusts are encountered. Consequently, entry of air or inflammatory and infectious materials into the mediastinum is readily accomplished by breaches in the integrity of these mediastinal structures or when materials deposited in the airways or distal lung are transported through the lymphatic system.

How air enters and moves through the mediastinum can be understood by referring to the soft tissue compartments of the neck, thorax, and abdomen, as illustrated in Figure 77-1. The visceral space surrounding the trachea, esophagus, and great vessels in the neck continues into the chest to envelop the mediastinal viscera and passes through the diaphragm with the esophagus to communicate with the retroperitoneal space. A continuum thus connects the viscera-containing spaces of the neck, chest, and retroperitoneum. This same space extends along the vessels and airways of the pulmonary hilum to merge with the distal bronchovascular sheaths (see Fig. 77-1).[1] Thus, it is possible for air that enters these tissue planes, or inflammation originating at any site in the mediastinum, to dissect and spread to involve any of the mediastinal structures.

In the remainder of this chapter, pneumomediastinum and the various forms of mediastinitis are discussed in turn.

PNEUMOMEDIASTINUM

Pneumomediastinum consists of air or other gas in the mediastinum. Also known as *mediastinal emphysema*, it is one of several forms of aberrant extra-alveolar air, or air outside the confines of the respiratory and gastrointestinal tracts. The others include subcutaneous emphysema, pulmonary interstitial emphysema,

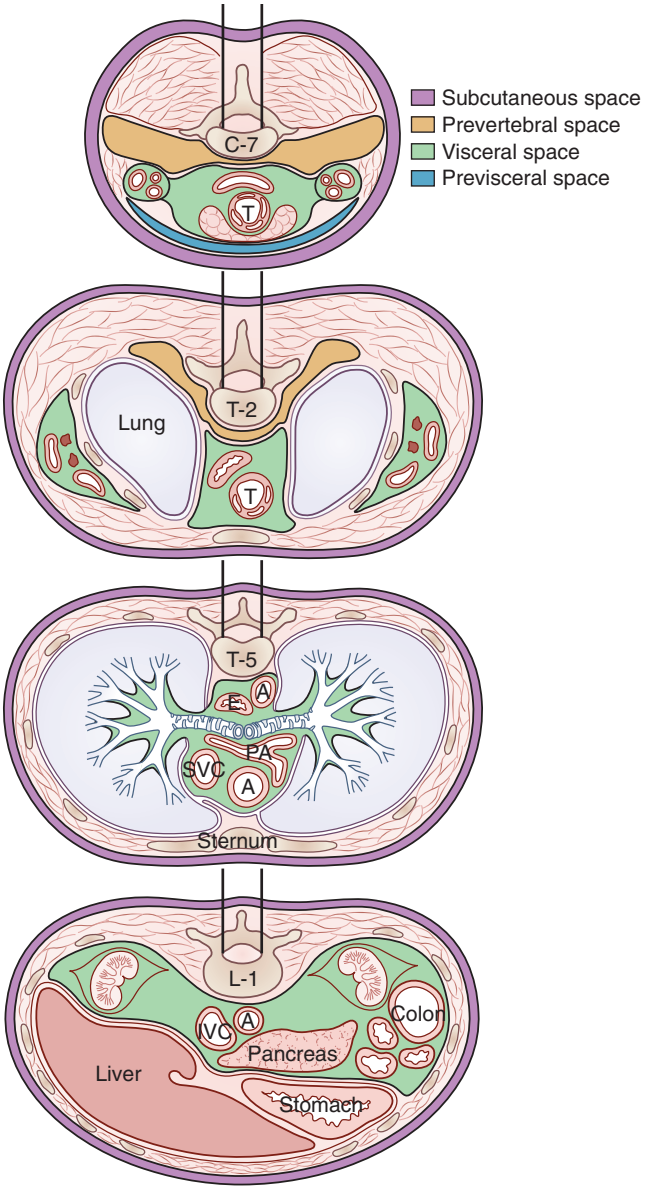

FIGURE 77-1 ■ Soft tissue compartments of the mediastinum (at levels of T2 and T5) in relation to those of the neck (at level of C7) and the upper abdomen (at level of L1) demonstrate continuity of the visceral space. (Redrawn from Maunder RJ, Pierson DJ, Hudson LD: Subcutaneous and mediastinal emphysema: Pathophysiology, diagnosis, and management. Arch Intern Med 144:1447–1453, 1984.)

pneumopericardium, pneumoperitoneum, pneumoretroperitoneum, pneumocephalus, and pneumorachis (air in the spinal canal). Pneumothorax, the most common life-threatening form of extra-alveolar air, is discussed elsewhere and mentioned only briefly here (see Chapter 74).

Extra-alveolar air in the form of pneumomediastinum and subcutaneous emphysema arises in a wide variety of clinical settings; the earliest to be recognized was during childbirth. In her "Observations" of 1617 (as cited by Gordon[2]), Louise Bourgeois, midwife to the queen of France, wrote, "I saw that she tried to stop crying out, and I implored her not to stop, for fear that her throat might swell." The first formal medical documentation of pneumomediastinum and subcutaneous emphysema during labor was by Simmons in 1784, and this association was reported in over 130 patients by 1927.[2] Within 2 decades thereafter, Hamman[3,4] had thoroughly established the clinical features of spontaneous pneumomediastinum and Macklin and Macklin[5] had elegantly elucidated its pathophysiology (see later). Little has been added to the pioneering descriptions of these investigators, but pneumomediastinum and other forms of extra-alveolar air occur today in a greater variety of clinical circumstances. In addition to childbirth, these include mechanical ventilation and other aspects of critical care, decompression in diving and other settings, chest trauma, asthma, and numerous other situations.[1]

Pathophysiology

The pathophysiology of pneumomediastinum depends on the clinical circumstances in which it is encountered. Pneumomediastinum most commonly results from alveolar rupture but can also result from air escaping from the upper respiratory tract, intrathoracic airways, or gastrointestinal tract. Gas can be generated by certain infections, and outside air can reach the mediastinum after trauma or surgery. These potential sources for mediastinal emphysema are summarized in Table 77-1 and discussed in the following sections.

Air Originating in the Upper Respiratory Tract

Mediastinal air dissecting downward from the head and neck can originate in several ways. Retropharyngeal abscess is a long-established cause of gas in the neck, but other infections including dental abscess, cervical adenitis, salivary gland infection, tonsillitis, and osteomyelitis of the facial bones can also produce this finding.[1,6] Odontogenic infections are said to be the most common of these.[7]

Dental extractions or drilling can be followed by pneumomediastinum. Passage of air into the soft tissues from the socket of an extracted tooth can be increased dramatically if positive pressure is applied at the mouth—as illustrated by the case of a soldier whose neck swelled on resumption of his duties as a bugler immediately after a tooth extraction.[8]

Injury to the paranasal sinuses, orbit, mandible, and other facial bones adjacent to the upper airways can provide access of air to the fascial planes of the neck, especially following nose blowing. Surgical procedures involving the upper respiratory tract may produce air in the neck via breaches in either the oropharyngeal mucosa or the trachea and skin. For instance, pneumomediastinum and subcutaneous emphysema are common after tracheotomy: these findings were noted in 13% of cases in one prospective series in adults.[9]

TABLE 77-1. Possible Origins of Air in the Mediastinum

UPPER RESPIRATORY TRACT
- Head and neck infection (odontogenic, salivary glands, cervical adenitis, tonsillitis, peritonsillar abscess, osteomyelitis of facial bones)
- Fractures (involving paranasal sinuses, orbit, mandibles, other facial bones)
- Other mucosal disruption (trauma, surgery, attempted endotracheal intubation)
- Dental procedures (extractions, air-turbine drilling)

INTRATHORACIC AIRWAYS
- Blunt or penetrating chest trauma
- Foreign body
- Iatrogenic (bronchoscopy, bronchial brushing, transbronchial biopsy, needle aspiration)
- Neoplasm

LUNG PARENCHYMA
- Direct disruption of alveoli (penetrating trauma, surgery, transbronchial biopsy, needle aspiration)
- "Spontaneous" alveolar rupture (between alveolus and adjacent bronchovascular sheath)*

GASTROINTESTINAL TRACT
- Esophageal perforation
- Via pneumoperitoneum or pneumoretroperitoneum (gastric or intestinal perforation, diverticulitis, pneumatosis cystoides intestinalis, endoscopy, biopsy, infection)

EXTERNAL TO THE BODY
- Penetrating trauma to neck or chest
- Surgical procedures (tracheotomy, mediastinoscopy, sternotomy)
- Via subcutaneous emphysema in association with chest tube insertion
- Artificial pneumothorax
- Artificial pneumoperitoneum

INFECTION WITH GAS-PRODUCING ORGANISMS
- Acute bacterial mediastinitis
- Head and neck infections

*See Table 77-2 for clinical settings.

Pneumomediastinum can also occur following attempts at endotracheal intubation or after overinflation of the endotracheal tube cuff when the hypopharyngeal mucosa or membranous trachea is injured.[10] Tracheal injury and esophageal rupture leading to pneumomediastinum can happen also when air is forced into the open mouth.[11,12]

Air Originating in the Intrathoracic Airways

Blunt thoracic trauma, particularly deceleration injury as sustained in motor vehicle crashes, may lacerate or fracture the trachea or main bronchi and allow air to enter the mediastinum.[13] Although this may occur in the proximal trachea, the majority of such injuries are within 3 cm of the carina, probably owing to the relative fixation of the airway at the carina and the development of a shearing force when the more mobile parts are displaced by the sudden impact.

Other potential sources of mediastinal air from the major intrathoracic airways include perforation by an aspirated foreign body and erosion by bronchogenic or esophageal neoplasm. Visceral perforation is associated with bronchoscopy much less frequently than with esophagoscopy. However, the increasing use of bronchoscopic biopsy techniques and endobronchial therapies for bronchial obstruction render this source for mediastinal air increasingly likely.

Air Originating in the Lung Parenchyma

Most instances of pneumomediastinum are the result of alveolar disruption. This may occur after direct injury to the lung parenchyma, which allows air to escape from torn alveoli and terminal bronchioles after penetrating thoracic trauma or from cut surfaces during surgery. The lung may be nicked in the course of tracheotomy or central venous access procedures, and this mechanism may also be the source of extra-alveolar air after percutaneous or transbronchial lung biopsy. The majority of cases of pneumomediastinum, however, follow "spontaneous" alveolar rupture.

Mechanism of Alveolar Rupture. Disruption of alveolar walls and entry of air into the bronchovascular sheath can result when a pressure gradient becomes sufficient to disrupt the alveolar walls at their bases and force air into the pulmonary interstitium, as depicted in Figure 77-2.[1,5,14] Although it has been speculated that a increase in intra-alveolar pressure was capable of producing alveolar rupture, animal experiments have demonstrated that an increase in alveolar volume, due to increased transpulmonary pressure, is a more important determinant of disruption of the alveolar walls.[15] This finding may explain the rarity of alveolar rupture following coughing and sneezing; contraction of muscles of the chest and abdominal walls counter the transient high intra-alveolar pressures.[16]

High alveolar volumes undoubtedly contribute to alveolar rupture after decompression due to decreases in external pressure.[16,17] The mechanism of alveolar rupture presumably relates to overdistention due to the expansion of gas trapped in the lungs during ascent.[18,19]

Pneumomediastinum and other forms of extra-alveolar air arising from the lung are almost always associated with parenchymal abnormalities in the affected lung both during mechanical ventilation[16,20] and during spontaneous ventilation.[1,5]

Spread of Air following Alveolar Rupture. Entry of air into the bronchovascular sheath, as depicted schematically in Figure 77-2, produces pulmonary interstitial emphysema. This is the initial consequence of alveolar rupture and may be the only overt manifestation of extra-alveolar air. According to Munsell,[21] Laennec called this condition "interlobular emphysema." Because the mean pressure in the mediastinum, like that in the pleural space, is always somewhat negative with respect to the

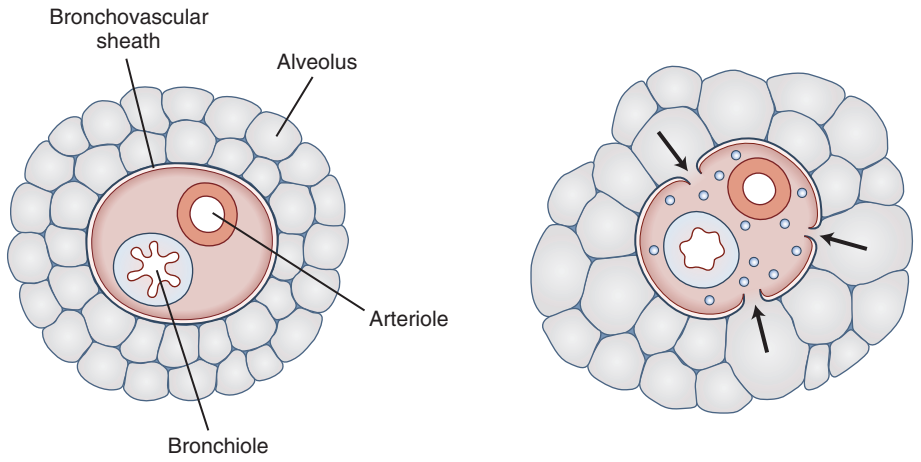

FIGURE 77-2 ■ Schematic diagram shows the mechanism of alveolar rupture into the bronchovascular sheath resulting from a momentary pressure gradient between them. (Redrawn from Maunder RJ, Pierson DJ, Hudson LD: Subcutaneous and mediastinal emphysema: Pathophysiology, diagnosis, and management. Arch Intern Med 144:1447–1453, 1984.)

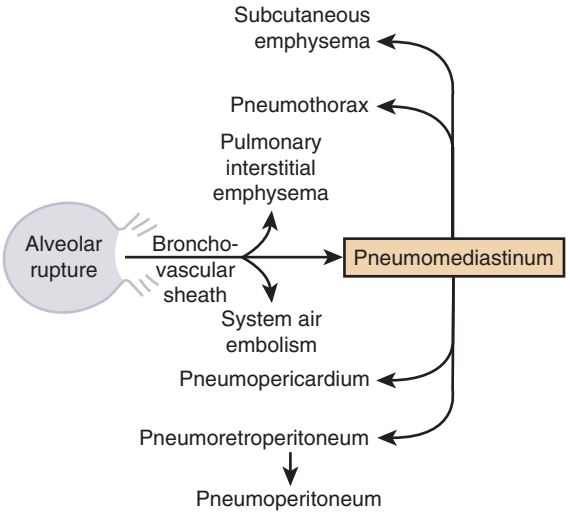

FIGURE 77-3 ■ The pathogenesis of the different forms of extra-alveolar air resulting from alveolar rupture.

pressure in the pulmonary parenchyma, the pressure difference causes air to move toward the mediastinum.[22] This is illustrated in Figure 77-3 and convincingly described in the 1944 paper by Macklin and Macklin,[5] which first confirmed the sequence in experimental animals:

> The first step … was air passing through numerous minute ruptures in the strained bases of the alveoli of the overinflated region into the underlying vascular sheaths. The air bubbles, at the very first minute, moved along the vascular sheaths, coalescing and gaining in size. This streaming of air through the pulmonic interstitium reminded one of the flow of a river that ever increases in size by addition of new tributaries as it proceeds on its course. Reaching the root of the lung, the train of air bubbles passed into and distended the mediastinum. With continued insufflation an actual overflow into the retroperitoneum, anterior mediastinum and subcutaneous tissues of the root of the neck and axillae occurred. In extreme cases the mediastinal wall ruptured, producing a pneumothorax.

These classic observations have since been confirmed in other studies but, conceptually, little has been added.

Entry of Air into the Pleural Space. Once in the mediastinum, air follows the path of least resistance and may rupture through the delicate mediastinal fascia and overlying pleura into the pleural space. This model is supported by observations that, in animal experiments, lower sustained inflation-hold pressures were required to produce pulmonary interstitial emphysema than to create a pneumomediastinum or pneumothorax and that, in most mechanically-ventilated patients in one clinical series, pneumomediastinum preceded pneumothorax.[23] Another mechanism for pneumothorax following alveolar rupture has been proposed, in which air dissects toward the periphery of the lung rather than toward the mediastinum and ruptures via subpleural blebs through the visceral surface of the lung. Which of these mechanisms most often accounts for "spontaneous" pneumothorax is uncertain.

Entry of Air into the Abdomen. Extra-alveolar air originating from disrupted alveoli may appear below the diaphragm as either *pneumoperitoneum* or *pneumoretroperitoneum*.[24] To reach the retroperitoneal space, air from the mediastinum usually travels via the loosely packed paraesophageal connective tissue across the diaphragm. The retroperitoneal air may then break through the peritoneum to enter the peritoneal space.

Entry of Air into the Vasculature. Extra-alveolar air also may enter pulmonary blood vessels resulting in *arterial air embolism*.[17,25] This complication is particularly common in the setting of decompression illness,[25] yet is relatively rare as a complication of mechanical ventilation, despite a high incidence of alveolar rupture and other forms of aberrant air.[26] The more common recognition of air embolism in decompression illness than in barotrauma due to mechanical ventilation may

relate to a larger volume of air entering the circulation, to a greater injury to the pulmonary venules and veins, to the relative ease in recognizing subtle forms of air embolism in otherwise healthy patients, or to the upright posture of ascending divers favoring clinically overt cerebral embolization of any air entering the systemic circulation. Also, during decompression, bubbles may form directly within systemic circulation, leading to arterial air embolism in the absence of pulmonary barotrauma.

Although commonly associated with cardiac septal defects or pulmonary arteriovenous shunts,[27] systemic air embolism can follow introduction of air into the venous system without the obvious presence of such right-to-left shunts.[28]

Air Originating in the Gastrointestinal Tract

Mediastinal air can originate from the gastrointestinal tract, either above or below the diaphragm. In *Boerhaave's syndrome*, rupture of the esophagus allows air and other material to enter the mediastinum.[29] In this circumstance, pneumomediastinum is accompanied by acute mediastinitis, as discussed later in this chapter. Pneumomediastinum can also result from esophageal perforation during upper gastrointestinal endoscopy[30] or following the ingestion of a caustic such as paraquat[31] or lye (sodium hydroxide).

Rarely, air or other gas originating in the retroperitoneal space can spread to the mediastinum.[1] Retroperitoneal causes of pneumomediastinum include perforation of a duodenal ulcer, ulcerative colitis, sigmoid diverticulitis, pneumatosis cystoides intestinalis, "rectal barotraumas,"[32] and procedures such as sigmoidoscopy, colonoscopy, and barium enema.[33]

Air Originating from External and Miscellaneous Sources

Pneumomediastinum can arise from air entering the body from external sources, particularly if positive pressure is applied at the subcutaneous tissue planes. Air can reach the mediastinum via the cervical soft tissues during tracheotomy,[9] via the chest wall during arthroscopic shoulder surgery,[34] or via the extremities as a result of industrial accidents.[35] Mediastinal air can also arise from a pneumothorax by an unusual mechanism: air in the pleural space can reach the subcutaneous tissues via the tube thoracostomy tract, can dissect to the neck, and can then penetrate down to the mediastinum. Pneumomediastinum has also been observed following the insufflation of air into the peritoneal cavity for tuberculosis treatment,[36] during the course of modern era laparoscopy,[37] and via the female genital tract during pelvic examination,[38] douche,[39] postpartum exercise,[40] or blowing into the vagina,[41–43] especially during pregnancy.[44]

Gas can form in the mediastinum during acute bacterial mediastinitis caused by gas-producing microbes. More commonly, pneumomediastinum associated with mediastinitis is due to communication with the gastrointestinal tract (as in Boerhaave's syndrome), respiratory tract (as in necrotizing pneumonia), or outside air (as in traumatic or poststernotomy mediastinitis). These conditions are described in more detail in the second part of this chapter.

Clinical Settings and Syndromes

Pneumomediastinum following alveolar rupture is encountered clinically in two general settings: "spontaneous" mediastinal emphysema and "barotrauma," or pneumomediastinum arising during positive-pressure ventilation or associated with other externally applied distending pressures (Table 77-2).

Spontaneous Pneumomediastinum

Voluntary Alterations in Breathing Pattern. Alveolar rupture can sometimes be induced by voluntary manipulations of the breathing pattern. A typical example

TABLE 77-2. Alveolar Rupture: Reported Clinical Settings

DUE TO ALTERATIONS OF SPONTANEOUS BREATHING PATTERNS

Voluntary Alteration in Breathing Pattern
- Marijuana smoking and cocaine inhalation
- Pulmonary function testing
- Mountain climbing—"voluntary pressure breathing"
- Wind instrument playing
- Yelling, shouting, and singing

Inadvertant Alteration in Breathing Pattern
- Childbirth
- Vomiting
- Seizures; status epilepticus
- Violent coughing; sneezing; hiccupping
- Heavy lifting; athletic competition
- Straining at stool

Intrinsic Airway and Lung Disease
- Asthma
- Atelectasis
- Bronchiolitis
- Pneumonia
- Influenza
- Measles
- Tuberculosis
- Silicosis
- Foreign body
- Tumor
- "Idiopathic" (Hamman's syndrome)

DUE TO RAPID CHANGES IN TRANSPULMONARY PRESSURE GRADIENT

Decrease in External Pressure from Decompression Causing Gas Expansion
- Scuba diving
- Air travel

Increase in Intrathoracic Pressure of External Origin
- Mechanical ventilation
- Continuous positive airway pressure
- Manual ventilation during resuscitation, anesthesia, or transport
- Equipment malfunction or misconnection in anesthesia or oxygen therapy
- Heimlich maneuver
- Deceleration injury

is pneumomediastinum reported after vigorous straining against a closed glottis during marijuana smoking[45] or after inhaling free-base cocaine,[46,47] during which users sometimes add additional external airway pressure by having an accomplice blow vigorously into their mouths through a cardboard tube.[48] Pneumomediastinum has also been reported in two college fraternity brothers following the recreational inhalation of nitrous oxide from disposable canisters.[49]

Mediastinal and subcutaneous emphysema occurred in a medical student after pulmonary function testing,[50] and these findings have also been observed in other healthy young individuals after dancing[51]; strenuous shouting, yelling, and singing[52]; playing the trumpet[53]; inflating a balloon[53,54]; and mountain climbing.[55] In mountaineers, alveolar rupture may be related to "voluntary pressure breathing," a practice originally proposed for fliers during World War II, that consists of slow, deep inhalations followed by forced exhalation through tightly pursed lips. This maneuver has been advocated by some climbers as a means of getting more oxygen into the blood, but it could well lead to alveolar rupture. The cases reported by Vosk and Houston[55] were members of the same climbing party and both had practiced "voluntary pressure breathing" during ascent.

Inadvertent Alteration of Breathing Pattern. Much more common than the voluntary maneuvers just discussed is the inadvertent manipulation of the breathing pattern in the course of straining or exertion such as during childbirth.[2] It has also been noted after vomiting in association with bulimia,[56] hyperemesis gravidarum,[57] diabetic ketoacidosis,[58] and other settings. Prolonged straining during convulsive seizures can be followed by mediastinal emphysema,[59] as can athletic competition,[60,61] violent coughing,[62] sneezing, hiccupping, and straining at stool.[1,5] It is reasonable to expect that any activity producing large momentary swings in intrathoracic pressure could result in alveolar rupture and pneumomediastinum.

Associated Airway and Lung Diseases. Localized airway obstruction can overdistend lung tissue, disrupt alveoli, and lead to all the reported forms of extra-alveolar air. This is easiest to visualize in the case of an obstructing foreign body,[63] but it may also explain the observation of extra-alveolar air in diffuse obstructive and parenchymal lung diseases. Pneumomediastinum is well described as a complication of acute asthma. Although chest radiographs are not routinely obtained during attacks of asthma, pneumomediastinum was noted in 5.4% of 479 radiographs of children admitted with asthma attacks.[64]

Parenchymal lung diseases associated with pneumomediastinum include atelectasis,[5] bronchiolitis,[65,66] pneumonia,[67,68] influenza,[5,21] measles,[69] and hematogenous tumor metastases.[70]

Idiopathic Pneumomediastinum. Although a history of a potential predisposing event or disease process is elicited in most patients with "spontaneous" pneumomediastinum, cases have been described without such associations and are known as *Hamman's syndrome*. Hamman's original patient was a 51-year-old physician in whom no predisposing factor could be identified.[71] Hamman later reported several additional cases of truly "idiopathic" pneumomediastinum; in modern series, patients been reported despite normal lung parenchyma as determined by chest computed tomography (CT).[3,72]

Pneumomediastinum Associated with Pressure Changes

Decreased Extrathoracic Pressure. Decreases in external pressure, such as during decompression events, may lead to alveolar overdistention and rupture. Alveolar rupture is a relatively common complication of sudden decompression.[17,25] Extra-alveolar air may develop following scuba diving,[73,74] during decompression in a hyperbaric chamber,[75] or with sudden barometric pressure changes during air travel.

Increased Intrathoracic Pressure. Externally applied positive airway pressure is another general category of clinical settings associated with extra-alveolar air. Most familiar within this category is "barotrauma" during mechanical ventilation.[16,76] Alveolar rupture during positive-pressure ventilation is thought to result from overdistention in an area with abnormal airways or lung parenchyma. Large delivered tidal volumes and high levels of positive end-expiratory pressure predispose to barotrauma, although the disease processes traditionally managed in this fashion are themselves associated with alveolar rupture.[16] Gammon and associates[23] found that the acute respiratory distress syndrome (ARDS) was the lung disease most commonly associated with barotrauma and, among ventilated patients, was the only independently associated risk factor for barotraumas.[20] Previously reported univariate associations between airway pressures and barotrauma may reflect that airway pressures serve as a marker of the severity of lung injury.[20] Further supporting this hypothesis, studies have found that the airway pressures and tidal volumes used were not different among those ARDS patients who developed and did not develop barotrauma.[77–79] In fact, it is likely that both the severity of underlying lung dysfunction and the particular styles of ventilator management that result in higher pressures and regional overdistention are responsible.[80]

Noninvasive forms of positive-pressure ventilation are associated with barotrauma less often than with conventional mechanical ventilation. This is probably because of the lower airway pressures used and the less severe lung diseases being treated. For instance, continuous positive airway pressure (CPAP) applied by mask was associated with pneumomediastinum in only 1 of 331 applications of this therapy, as cited in one review.[81]

Barotrauma is especially likely when air or oxygen is inadvertently insufflated under high pressure. Barotrauma is a well-documented complication of manual ventilation during cardiopulmonary resuscitation. Improperly connected oxygen tubing that prevented exhalation has resulted in life-threatening barotrauma,[82] as have similar errors following anesthesia and surgery.[83,84]

Extra-alveolar air can result from deceleration injury, even when there is no open chest wound or displaced rib fracture. Although such deceleration injuries most commonly result from motor vehicle accidents, they can also follow blows to the chest or falls into water with the glottis closed.[14,85] Pneumomediastinum has also been caused by resuscitation using the Heimlich maneuver.[86]

Arterial Air Embolism

Entry of aberrant air into the pulmonary vessels can result in systemic or arterial air embolism. This is particularly common in the setting of decompression illness (detectable in 3% of submarine escape trainees[87]) and is often accompanied by pneumomediastinum.[25] When a predisposing condition such as asthma is present, even ascents from the bottom of a swimming pool can cause air embolism.[88] The clinical manifestations depend on the amount and the distribution of the bubbles; cerebral air embolism is often fatal.[17,25,88]

As discussed previously, arterial air embolism is relatively rare as a complication of mechanical ventilation,[26] except after thoracotomy for penetrating lung injury. Fatal air embolism has also been reported after recreational inhalation of helium from a pressurized cylinder.[89]

Systemic air embolism may develop from circumstances other than alveolar rupture. Dramatic cases of air embolism have followed the rupture of an air-filled bronchogenic cyst during ascent in an aircraft[90] and the establishment of a bronchial–left atrial fistula due to a mediastinal abscess.[91]

Clinical Manifestations and Diagnosis

Symptoms, Physical Signs, and Laboratory Findings

Chest pain is the most common symptom reported by patients with pneumomediastinum.[1,72] It has been reported in 80% to 90% of patients with "spontaneous" mediastinal emphysema and may account for some cases of unexplained acute chest pain in otherwise healthy young people.[72,92] The pain is characteristically substernal in location and aggravated by movement, breathing, and position changes. It often radiates to the back, shoulder, or arm. Discomfort may extend into the neck, and retropharyngeal or perilaryngeal air dissection may give rise to dysphagia or dysphonia, with characteristic muffled voice. Dyspnea is present in about half of the cases.[72]

Physical examination reveals palpable crepitation in the neck and supraclavicular area in perhaps 50% of cases,[92] and cyanosis and neck vein distention have been observed.[21] The most characteristic physical finding in pneumomediastinum is Hamman's sign,[3,21] a crunching or clicking sound synchronous with the heartbeat, heard over the precordium, and increased in intensity during inspiration and in the left lateral decubitus position.[1,21,93] *Hamman's crunch* has been described as similar to the noise produced by rubbing two rubber balloons together.[21] Although considered by Hamman to be pathognomonic for mediastinal air, it can occasionally be heard in other circumstances such as pneumothorax without radiographic evidence for pneumomediastinum.[1]

Low-grade fever, along with mild to moderate leukocytosis,[1,21] likely results from reactive inflammation associated with air dissection in the mediastinum. Leukocyte counts of over 10,000/mm^3 in 16 of 23 patients and over 20,000/mm^3 in 5 of 23 were noted in one series, but returned to normal without treatment within 1 to 2 days.[21]

Electrocardiographic changes occur in some cases of pneumomediastinum without evidence of other cardiac abnormalities.[21] These may consist of diffusely low voltage, nonspecific axis shifts, ST-T wave changes, and ST segment elevation in the lateral precordial leads.[21] These changes are also observed in association with pneumothorax and may be in part related to physical displacement of mediastinal structures.

Radiographic Features

Pneumomediastinum is most often detected by standard chest radiography, and the finding of pneumomediastinum may be the first manifestation of extra-alveolar air. The diagnosis is usually made by demonstrating a thin line of radiolucency, best seen along the left heart border (Fig. 77-4).[1] Other common signs are the highlighting of the aortic knob, which is surrounded by increased radiolucency, and the "continuous diaphragm sign,"[94] an unbroken radiolucent line extending from one hemidi-

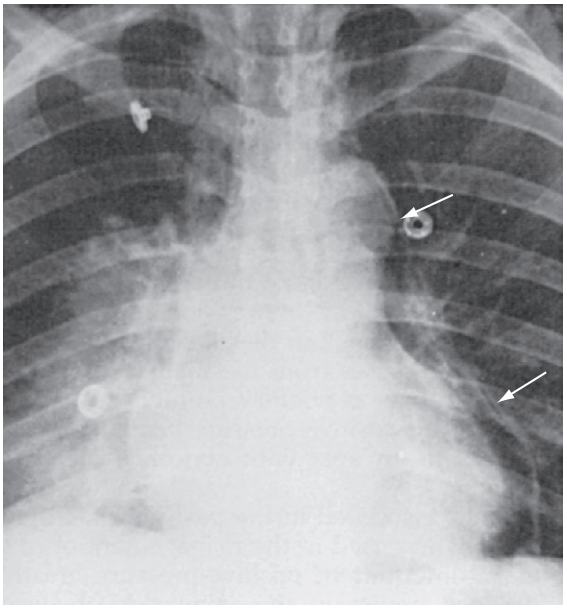

FIGURE 77-4 ■ Chest radiograph of a 47-year-old man who developed mediastinal emphysema while hospitalized for treatment of right lower lobe pneumonia shows displacement of the mediastinal pleura by air (*arrows*).

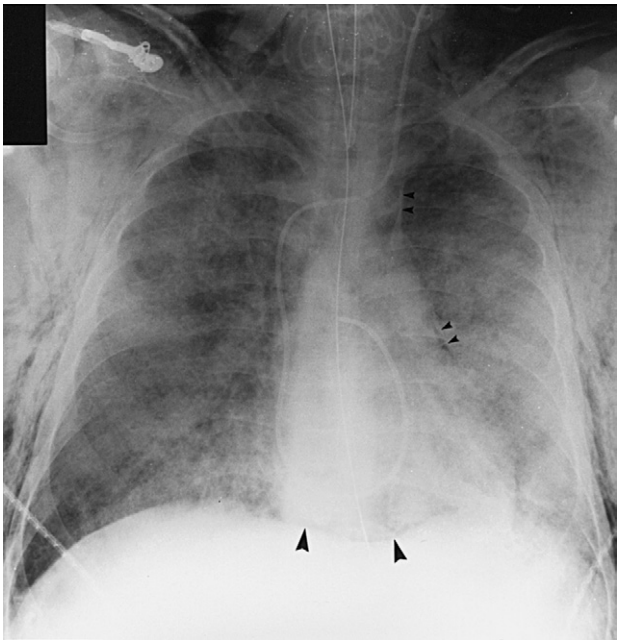

FIGURE 77-5 ■ The "continuous diaphragm sign" in a patient with pneumomediastinum that developed during mechanical ventilation for acute respiratory distress syndrome. An unbroken radiolucent line (*large arrowheads*) is visible from one hemidiaphragm to the other, rendering the inferior heart border clearly visible. Air is also present in the mediastinum (*small arrowheads*) and in the soft tissues of the shoulders, neck and chest wall.

aphragm to the other beneath the heart (Fig. 77-5). Mediastinal air may be easier to see on films taken in lateral projection, which may demonstrate retrosternal air or vertical lucent streaks outlining the aorta, pulmonary artery, or other mediastinal structures.[1] A variety of more subtle findings may be present.[95] Distinguishing between mediastinal emphysema and a small pneumothorax may be difficult. A film taken in the lateral decubitus position may show air rising to the most elevated portion of the thorax if it is free to move in the pleural space, whereas mediastinal air moves little with changes in position.[95]

Subcutaneous emphysema is readily detected as streaks or pockets of air outlining the visceral planes in the neck or within subcutaneous tissues. It often outlines the tissue compartments of the chest wall, clearly identifying the pectoral muscles. Both subcutaneous emphysema and pneumomediastinum are common findings in patients on mechanical ventilators,[96,97] being present in 7% of cases in one early series (Fig. 77-6).[96] These signs of alveolar rupture during positive-pressure ventilation are important clinical danger signals, because half or more will go on to pneumothorax.[23,97]

Chest CT is more accurate than plain radiographs for detecting aberrant air in all its forms and should be considered when important management decisions rest on a given distinction or when the underlying cause is not evident.[95] This is especially true in patients with pneumomediastinum due to blunt trauma, in which only 15% could be detected by plain chest radiographs.[98]

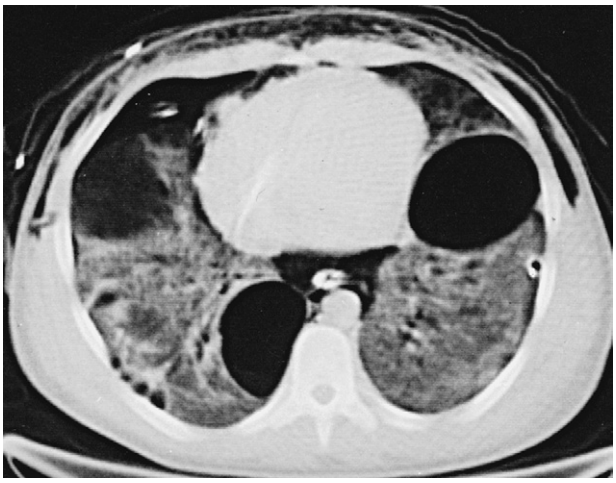

FIGURE 77-6 ■ Computed tomography (CT) scan of the chest shows pneumomediastinum associated with extensive subcutaneous emphysema in a patient undergoing mechanical ventilation for acute respiratory distress syndrome. Mediastinal air is seen in both the middle and the posterior mediastinal compartments.

Approach to Management

Natural History of Pneumomediastinum

In most cases of pneumomediastinum, the air tends to spread throughout the mediastinum and to vent out of the thorax into the subcutaneous tissue planes.[1] Subcutaneous emphysema can become massive and prove distressing to both patient and physician, but it is seldom dangerous in itself. Subcutaneous air collections will resolve spontaneously without surgical decompression once the primary air leak has sealed.

Management of Spontaneous Pneumomediastinum

Most cases of spontaneous pneumomediastinum can be linked to one or more predisposing factors such as bronchospasm, infection, or foreign body, and treatment or removal of these is followed by gradual resolution of the aberrant air. Pain and other symptoms should be alleviated and supplemental oxygen may hasten reabsorption, but specific therapy for pneumomediastinum is rarely needed. Most cases resolve with conservative management alone.[99] In fact, beyond the radiographs necessary to confirm the diagnosis, rarely is clinically useful information obtained from further diagnostic evaluation.[100]

Nonetheless, although pneumomediastinum rarely becomes physiologically significant, it can produce life-threatening cardiovascular collapse.[2,5,101] An early, well-documented incident was described by Laennec more than 150 years ago, as related by Munsell.[21] The great French clinician was called to see a small boy who had been run over by a dung cart: Laennec describes how his 4-year-old patient was placed in a tent with a candle for light. With the boy in extremis, Laennec inserted sharp sticks into the boy's neck, supraclavicular areas,

and anterior portion of the chest; a rapid, large outpouring of air extinguished the candle and the boy recovered. Modern medicine can add little more to this emergency decompression regimen except for the substitution of needles for sticks.

Other equally convincing, if less eloquently described, instances of life-threatening pneumomediastinum and its immediate surgical relief have been recorded.[101] Although surgical treatment of massive or symptomatic subcutaneous emphysema has been advocated, a careful examination of the literature reveals very few instances in which this has actually been carried out. Most experienced clinicians reserve invasive therapy for cases of increasing airway impingement or cardiovascular compromise. In these instances, small infraclavicular venting incisions seem to be the most prudent initial approach.[102]

Management of Pneumomediastinum during Positive-Pressure Ventilation

The appearance of mediastinal or subcutaneous air in a patient receiving positive-pressure ventilation is always a cause for concern. Discontinuation of positive-pressure ventilation, if possible, would seem advantageous for patients with ventilator-related extra-alveolar air in any form. Short of this, several adjustments should theoretically diminish the tendency of air to enter the mediastinum. Delivered tidal volumes and distending pressures should be reduced if possible. Positive end-expiratory pressure should be reduced or discontinued, and mean intrathoracic pressure should be minimized by adjusting inspiratory flow and timing. Patient-triggered pressure-limited ventilation (e.g., inspiratory pressure support) or low-rate intermittent mandatory ventilation would probably be preferable to mandatory volume-limited ventilation if clinically feasible.[103] Cough suppression should be considered.

Occult positive end-expiratory pressure, or "auto-PEEP," can augment air leakage. If present, auto-PEEP should be reduced[104] as, for example, by reducing minute ventilation and maximizing expiratory time. Finally, bronchospasm and other potentially reversible contributors to air trapping during mechanical ventilation should be treated vigorously.

Tracheobronchial disruption causing extra-alveolar air requires prompt diagnosis and surgical repair.[13] This condition should be considered in a patient with blunt thoracic trauma in the presence of extensive soft tissue emphysema, airway bleeding, or nonresolving pneumothorax[1,14] especially if, on chest radiography, the collapsed lung tissue appears to have fallen away from the hilum.[105] When these findings are present, emergent bronchoscopy should be carried out to establish the diagnosis.[1]

MEDIASTINITIS

The term *mediastinitis* encompasses a number of loosely related processes that induce inflammation of mediastinal structures. Most forms of mediastinitis are infectious, and variations in their clinical presentation depend largely on the chronicity of the underlying process rather than on the specific microbial cause. Thus, it seems logical to classify this family of disorders according to "acute" and "chronic" forms rather than into more specific etiologic categories. Acute mediastinitis is a distinct, usually catastrophic, disorder. The chronic forms of mediastinal inflammation cover a spectrum of disease, defined usually by radiographic or histologic features, that ranges from active granulomatous inflammation to "burned-out" mediastinal fibrosis.

Acute Mediastinitis

Acute mediastinitis was once a rare, dramatic, and usually fatal condition seen after rupture of the esophagus from forceful vomiting or in conjunction with penetrating trauma. With the proliferation of endoscopic procedures and the rise of cardiac surgery via median sternotomy, acute mediastinitis has become both more common and more varied in its clinical presentation. Because of this clinical variation, which may include relatively indolent infections, the term "suppurative mediastinitis" has been proposed as more accurate than "acute." In either case, a distinction is drawn between these disorders and chronic "granulomatous" and "fibrosing" mediastinitis.

Typical Clinical Features of Acute Mediastinitis

In the classic clinical description of acute mediastinitis, the onset is sudden and dramatic, with chills, high fever, and prostration. Patients are restless and irritable, with a sense of impending doom. Tachycardia, tachypnea, and signs of systemic toxicity are prominent. Most patients complain of severe substernal chest pain, worsened by breathing or coughing, and unrelieved by opiates. With involvement of the superior mediastinum, the pain may be referred into the neck and ear, whereas, with involvement of the posterior or inferior mediastinum, the pain may be radicular and radiate around the chest and between the scapulae. Examination may reveal supraclavicular fullness, tenderness over the sternum or sternoclavicular joints, and crepitus and other signs of mediastinal and subcutaneous emphysema. Hamman's sign (a crunching sound synchronous with cardiac systole, heard over the anterior thorax) is characteristic but not always present. Later, tracheal deviation, jugular venous distention, and other signs of compression of mediastinal structures may appear. These features are typical after spontaneous esophageal rupture as seen in Boerhaave's syndrome, but the presentation varies considerably in other settings.

Clinical Classification of Acute Mediastinitis

Involvement of different mediastinal regions tends to be associated with characteristic causes: superior mediastinal infection is most often the result of direct extension from neck infection; anterior mediastinal infection is

typical after surgery or penetrating wounds to the anterior thorax; and posterior mediastinal infection can arise from tuberculous or pyogenic spinal infections. The following discussion characterizes the clinical picture and management of acute mediastinitis in different settings classified according to the mechanism of mediastinal entry (Table 77-3).

Mediastinitis Resulting from Visceral Perforation

Boerhaave's syndrome refers to esophageal rupture associated with forceful vomiting, classically after overeating or excessive drinking. It is the most familiar example of acute mediastinitis,[106,107] although no longer the most common. Unilateral or bilateral hydropneumothorax is common and quickly progresses to empyema (Fig. 77-7). Spontaneous esophageal rupture can be difficult to diagnose, especially in the patient with altered sensorium who may delay seeking medical attention and who may not be able to relate a clear history. Adding to the clinician's confusion is the fact that lower esophageal rupture may be mistaken for an abdominal catastrophe.

The mechanism of esophageal rupture involves hydrostatic forces that overcome the tensile strength of the normal esophageal wall. A momentary rise in intragastric pressure, as in vomiting, trauma, seizure, or other straining, accompanied by relaxation of the lower esophageal sphincter, permits gastric contents to enter and distend

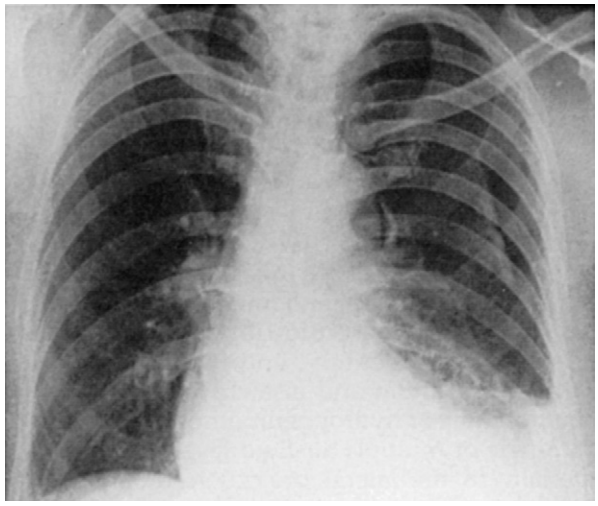

FIGURE 77-7 ■ Chest radiograph of a 64-year-old woman taken 16 hours after traumatic perforation of the esophagus. The classic features of pneumomediastinum and left-sided pneumothorax and pleural effusion are evident.

the lower esophagus. If the upper sphincter does not open to allow regurgitation of esophageal contents, hydrostatic pressure in the esophagus may rise to the point that its wall gives way at its weakest point. This is usually in the lower left posterolateral wall, where the muscle bundles in the longitudinal layer of the esophagus separate, allowing a bubble of mucosa to protrude into the mediastinum and burst. This mechanism may be similar to that in pneumatic esophageal rupture, which follows exposure of the esophagus to air under high pressure as, for example, after biting and puncturing an automobile tire inner tube or closing the mouth around the leaking valve of an automobile tire.[108] Rarely, rupture can occur even above the upper esophageal sphincter.[109]

In the present era, the most common cause of acute mediastinitis is esophageal perforation during diagnostic or therapeutic endoscopic procedures.[110] In a review of 54 esophageal perforations related to endoscopy or instrumentation, 35 instances were in patients with inoperable esophageal malignancy and 19 were in patients with benign disease. Most followed stent placement or dilation procedures.[111] The diagnosis was made within 2 hours in 94% of these patients. Of the 19 patients with benign disease, 14 were treated conservatively and 5 underwent surgical repair; there were no deaths among these patients, probably reflecting the influences of an empty gut lumen, prompt recognition of the complication, and immediate treatment.

Endoscopic injection sclerotherapy is associated with mediastinal complications.[110,112] Frank perforation, associated with necrosis of the esophageal wall and usually occurring 2 to 14 days after the procedure, has been reported in approximately 6% of patients. More common is pleural effusion, presumably associated with subclinical chemical mediastinitis without actual perforation, which has been noted in up to 14% of patients.[110,113] In most instances, this complication is benign and self-limited, responding to conservative therapy in this chronically ill patient population.[113]

Other reported causes of traumatic esophageal perforation include the use of the esophageal obturator airway and swallowed foreign bodies, particularly if the aim is to induce injury. One series describes six prison inmates who swallowed hypodermic needles fashioned in the shape of "stars" to win temporary reprieves from incarceration.[114] Unfortunately, all required surgical management and one patient experienced a lengthy and complicated hospital course. Accidental or intentional ingestion of caustic solutions such as paraquat or lye also can lead to esophageal perforation.[31]

The diagnosis of esophageal perforation depends on an appropriate degree of clinical suspicion. On the chest radiograph, the hallmarks are diffuse mediastinal widening and the presence of air in the mediastinum and elsewhere in soft tissues. Mediastinal air-fluid levels may be seen, and pneumothorax or hydropneumothorax may be present. CT can delineate these abnormalities clearly. Passage of ingested contrast material into the periesophageal or pleural space may be observed.[115,116]

Successful management of frank uncontained esophageal perforation requires early surgical repair, drainage of the mediastinum and often the pleural space, and administration of appropriate antibiotics.[117,118] Percutaneous catheter aspiration of mediastinal abscesses, under CT guidance, has been used when the infection is localized and the clinical setting is less urgent. Of 51 patients in a recent series, 3 died before intervention could be accomplished, 31 underwent standard thoracotomy and repair leading to 11 deaths, and 17 highly selected patients with minimal contamination were managed successfully with targeted drainage and antibiotic therapy.[119] In selected cases, esophageal perforation can be contained using endoscopically placed stents. Stenting appears to be most successful for the management of anastomotic leaks after esophageal surgery and may be less effective at controlling leaks after spontaneous esophageal rupture.[120,121]

Complications of acute mediastinitis after esophageal rupture may include localized abscess formation, extensive pleural empyema, and persistent esophagocutaneous fistulas. A prolonged stormy course is usual, and reexploration may be necessary to ensure adequate drainage. Reported mortality has varied due to differences in patient selection and management approaches. Timing of surgical drainage has been of prime importance in determining the clinical outcome. Modern series reporting the use of consistently aggressive surgical management cite 89% to 90% survival after spontaneous esophageal rupture.[122,123]

Other potential iatrogenic causes of mediastinitis include bronchoscopic airway perforation and migration of indwelling central venous catheters. Bronchoscopy is a much less frequently reported cause of mediastinitis than esophagoscopy. However, increasing use of laser and mechanical endobronchial procedures, often performed in the setting of malignancy with chronic airway colonization or postobstructive pneumonia, add to the likelihood of potential mediastinal complications. Intravascular catheters may be another source of acute mediastinitis when the catheter tip erodes through the vessel wall into the mediastinum. Instillation of hyperosmotic,[124] vessicant, or vasoactive substances via these catheters may induce a chemical, rather than an infectious, inflammation (Fig. 77-8).

Direct Extension of Infection from Other Sites

Infection can extend directly into the mediastinum from elsewhere.[125] Infection originating in periodontal tissues, in the tonsillar region, or after pharyngeal perforation may extend to the mediastinum via the prevertebral, visceral, or pretracheal spaces or carotid sheaths,[6,126] although the usual route is via the retropharyngeal space to the posterior mediastinum (Fig. 77-9).[127,128] Mediastinal infection of this type, which has been given the name *descending necrotizing mediastinitis*, is perhaps the most clinically devastating form of the disorder.[127–129]

Odontogenic infection is consistently the most common source of descending necrotizing mediastinitis.[125,130] Most infections are mixed, with both aerobic and anaerobic organisms; purulent pleural and pericardial involvement is common.[125]

In addition to the clinical signs described previously for acute mediastinitis after esophageal perforation, patients with this form of the disease may have widening of the retropharyngeal space, with or without associated air-fluid levels, anterior displacement of the tracheal air column, and loss of the normal cervical spine lordosis on lateral films of the neck. CT scans of the neck and chest are usually definitive (Fig. 77-10).[127]

Treatment of descending necrotizing mediastinitis requires aggressive surgical drainage, usually via a cervical approach.[125,125a] Whether or not to explore the mediastinum via a thoracic approach in addition depends on the imaging findings. Some authors have suggested that thoracic exploration be reserved for cases in which the infection extends below the level of the fourth vertebral body or the tracheal bifurcation.[125a] Others have argued that any evidence of mediastinal involvement should prompt transthoracic exploration and drainage.[125,130] This more aggressive approach is supported by findings of Corsten and coworkers[127] that the mortality rate of patients treated with cervical drainage alone was 47% compared with 19% when thoracic mediastinal drainage was added. Routine serial postoperative cervicothoracic CT imaging and aggressive reexploration and drainage guided by these imaging findings appear to reduce the mortality of this condition even further.[128] Although thoracoscopic and other percutaneous drainage procedures have been described and may be appropriate in selected patients, open surgical drainage and irrigation remains the standard approach.

Direct extension of infection from elsewhere in the chest is a rare cause of acute mediastinitis. Such extension can be associated with eroding neoplasms, with anterior chest wall and neck infections in injection drug users, or as a complication of vertebral or costal tuberculous infection. Penetrating chest injuries may result in acute mediastinitis, especially if the wound causes visceral perforation or is grossly contaminated, or if there

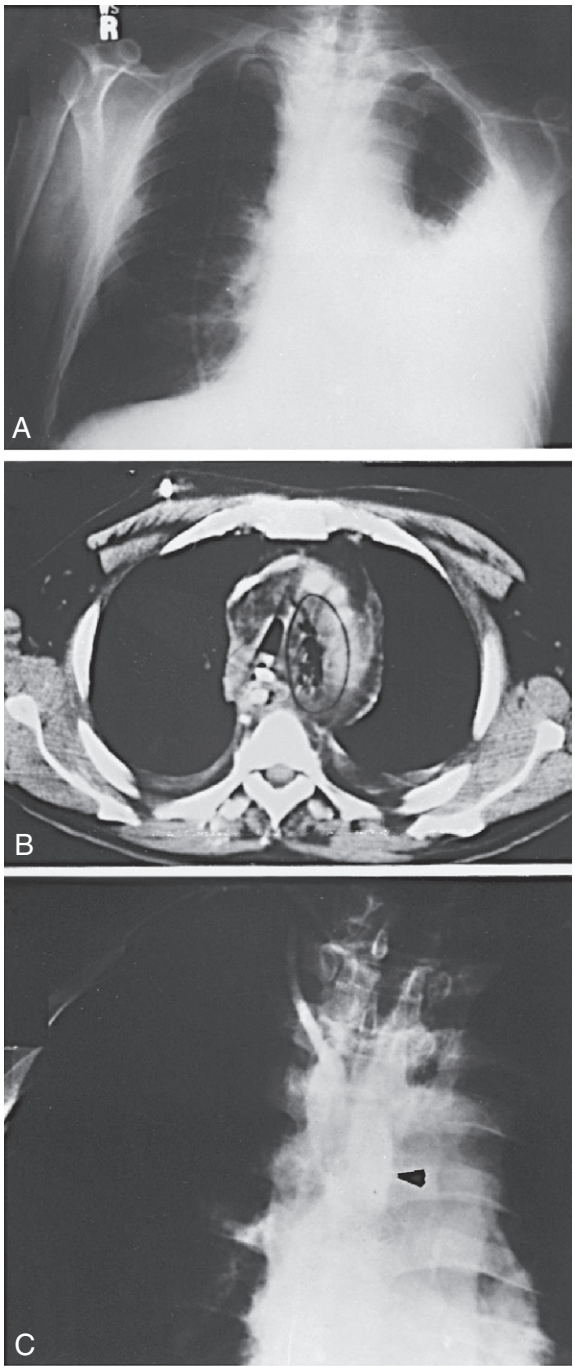

FIGURE 77-8 ■ Films of a 74-year-old man with mediastinitis due to erosion of an indwelling central venous catheter tip into the mediastinum. **A,** The chest radiograph shows mediastinal widening, radiolucency in the left upper mediastinum, left pleural effusion, and medial deviation of the catheter tip. **B,** The chest CT scan shows a gas-containing mediastinal abscess between the trachea and the contrast-enhanced great vessels (an indelible elliptical line was drawn around the area on the original film). **C,** Although blood could be aspirated from the catheter, contrast material injected through the catheter passed directly into the mediastinum (*arrowhead*).

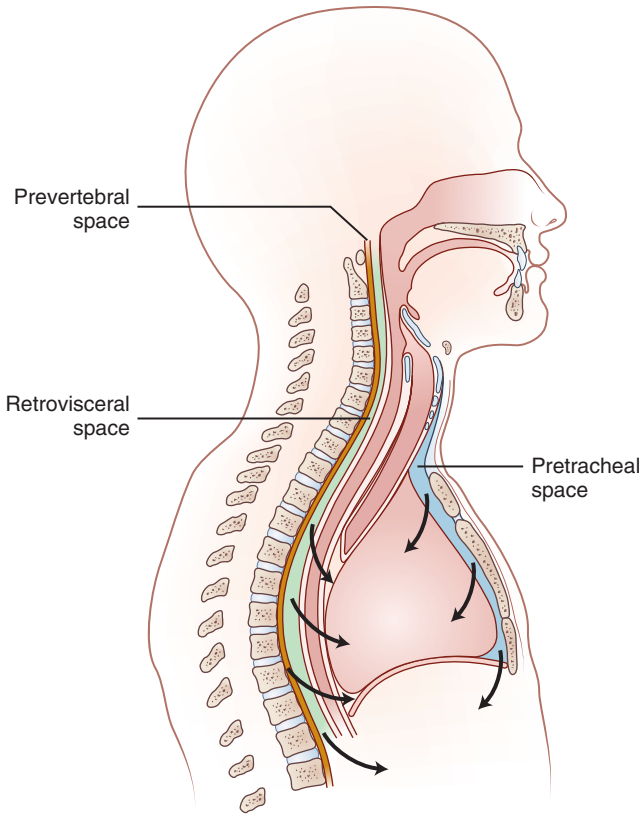

FIGURE 77-9 ■ The three deep spaces of the neck and their communication with the mediastinum. (Redrawn from Freeman RK, Vallières E, Verrier ED, et al: Descending necrotizing mediastinitis: An analysis of the effects of serial surgical débridement on patient mortality. J Thorac Cardiovasc Surg 119:260–267, 2000.)

has been a delay in reaching medical attention. In such instances, the diagnosis of acute mediastinitis may not be apparent if the patient has other serious injuries.

Pancreatitis has been reported to extend into the mediastinum, presenting as mediastinal widening with the clinical picture of acute mediastinitis. Spread in such a circumstance is presumably via the aortic and esophageal hiatuses. Both gastric and esophageal ulcers have been reported as causes of mediastinitis, sometimes eroding directly into the pericardium.

Mediastinitis after Cardiac Surgery

Whereas some forms of acute mediastinitis have been decreasing in frequency, mediastinitis after cardiac surgery has become an increasingly important entity.[131,132] Several cases of acute bacterial mediastinitis have occurred after heart and heart-lung transplantation.[133–135] Along with mediastinitis as a complication of endoscopy, this form illustrates the predominantly iatrogenic character of acute mediastinitis in the present era.

The incidence of mediastinal infection after cardiac surgery has been variously reported at 0.4% to 5.0%, but a more recent series reported rates of less than 1%.[136] Post-sternotomy mediastinitis has become a substantial

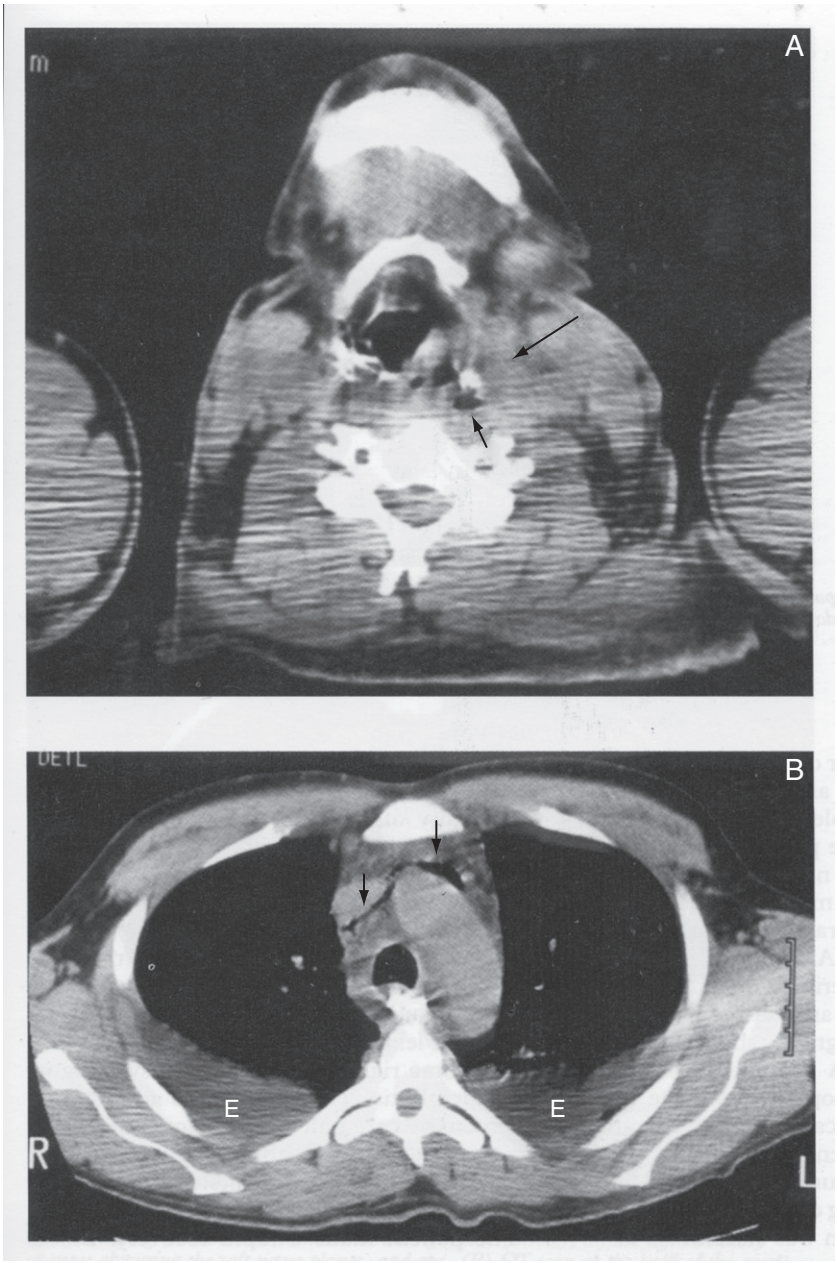

FIGURE 77-10 ■ CT scans of a 35-year-old man with descending necrotizing mediastinitis. **A,** At the level of the hyoid bone in the neck, there is gas in the retropharyngeal soft tissues (*short arrow*) and inflammatory changes in the parapharyngeal space (*long arrow*). **B,** At the level of the aortic arch in the chest, there is gas outlining the great vessels (*arrows*). There are inflammatory changes in the paratracheal tissues, and bilateral pleural effusions (empyema). (From Corsten MJ, Shamji FM, Odell PF, et al: Optimal treatment of descending necrotizing mediastinitis. Thorax 52:702–708, 1997.)

clinical problem not because of a high case incidence but because cardiac surgery via median sternotomy has become such a widely used procedure.

Risk factors that appear to predispose to development of mediastinitis after cardiac surgery have been reported in a myriad of case series.[136,137] Preoperative risk factors include advanced age and male gender, diabetes mellitus, obesity, the need for immunosuppressive therapy, smoking, obstructive lung disease, a history of previous sternotomy or mediastinal irradiation, and poor preoperative cardiac dysfunction and New York Heart Association functional class. Perioperative risk factors include shaving rather than clipping for hair removal, the use of bilateral internal mammary artery grafts, a longer duration of the surgical procedure and of perfusion time, greater use of cautery or bone wax, a low cardiac output state in the early postoperative period, and greater amounts of postoperative bleeding. The incidence of postoperative mediastinitis appears to be increased further if reoperation is required to control bleeding, if multiple valve replacement accompanies coronary artery bypass, or if the patient requires more than 48 hours of mechanical ventilation postoperatively.

The pathogenesis of mediastinitis following sternotomy is debated. Three possible routes of infection are postulated. Some authorities suspect that primary sternal instability leads to failure of the skin closure and subsequent penetration of bacteria through the wound.[138] Others suspect that a focus of sternal osteomyelitis is the initial site of infection, leading to secondary sternal instability and deeper penetration of the infection.[139,140] A third postulated mechanism is bacterial seeding of an

undrained mediastinal fluid collection.[136] In the acute stages, the mediastinal structures are enveloped with pliable fibrinous exudates; osteomyelitis, if present, is confined to the wound margins. Subacute infections are characterized by increasingly dense adhesions entrapping the visceral organs, sinus track formation, and more extensive sternal bone involvement.[136]

The epidemiology of cases within an institution suggests that sound infection control measures and careful asepsis in the operating room remain the most effective means of prevention.[136] Although definitive proof of their efficacy is still lacking, prophylactic antibiotics are widely used in the perioperative management of cardiac surgery patients.[136] The prophylactic intranasal application of mupirocin ointment has been shown to reduce by 50% the rate of *Staphylococcus aureus* nosocomial infections in carriers who undergo major surgery,[141] and there is a suggestion that its general use in cardiac surgery may significantly decrease the rates of post-sternotomy wound infections and osteomyelitis,[142] but there have been no confirmatory randomized, controlled trials.

The bacteriology of postoperative mediastinitis parallels that of early prosthetic valve endocarditis. *Staphylococcus epidermidis* and *S. aureus* have been the most frequent organisms in several series,[143,144] and as many as 40% of cases have mixed infections.[143] Methicillin-resistant *Staphylococcus aureus* (MRSA) is a relatively uncommon but virulent cause.[145] Rare organisms include anaerobes and Gram-negative bacilli,[143,146] *Candida* species,[143,147] and atypical mycobacteria (especially *Mycobacterium chelonei* and *Mycobacterium fortuitum*).[131] Infection with the last two groups tends to be more indolent and more likely to involve the sternum or costochondral tissues. Presentation within the first postoperative week is more often associated with gram-negative infection and also more likely to be accompanied by bacteremia, whereas presentation after the second week increases the likelihood that *Staphylococcus* is the infecting agent.[148]

Acute mediastinitis presenting after cardiac surgery tends to be less devastating than that seen in the settings described previously, perhaps because it remains relatively localized longer and tends to be recognized earlier. Typically, the clinical course consists of fever and systemic signs, followed by bacteremia and local signs of wound infection.[148] Drainage from the sternotomy incision and other localizing findings are present in the great majority of patients.[139,143,148]

The diagnosis is usually made at the time of reexploration of the sternotomy wound and rests on a high clinical suspicion in the appropriate setting. Distinguishing between superficial and deep wound infections may be difficult, especially if the clinical signs of infection are modest. CT is particularly helpful in identifying and discerning soft tissue swelling, fluid collections, and sternal erosion or dehiscence.[149] However, because swelling and fluid collections are common in the early postoperative period, their significance is much more clear when they persist or develop after 14 days.[149,150] Some authors use subxiphoid[151] or transsternotomy[140] needle aspiration in suspected cases, although, as with the other tests mentioned, such diagnostic maneuvers may delay treatment in a condition that can progress rapidly. Patients with fever, positive blood cultures, and wound abnormalities in the post-sternotomy period should probably be explored surgically.

As in other settings, therapy for post-sternotomy mediastinitis consists of early surgical exploration, débridement and drainage, irrigation, and administration of systemic antibiotics.[136,143,152,153] There has been disagreement in the past as to whether the incision should be left open or closed around drains for irrigation. Most authors now advocate early closure, even though reexploration may be necessary. This approach avoids both the respiratory and the cardiovascular compromises from the open chest wound and the longer hospital stay associated with open wounds.[136,143,153,154] A variety of surgical options exist for the débridement, establishment of irrigation, and buttressing and closure of sternal wounds.[153]

Reported mortality from mediastinitis after cardiac surgery varies considerably. Currently, most patients survive, with mortality rates of 20% to 40%.[136,148] Hospitalization of survivors is usually prolonged by this complication.[155]

"Primary Mediastinitis": Inhalational Anthrax

Anthrax, caused by infection with *Bacillus anthracis*, is primarily a disease of cattle, sheep, and goats and is most prevalent in the Middle East, although it is now recognized as an important disease of bioterrorism (see later). The most common form of anthrax is the cutaneous form, which is contracted by direct inoculation usually from handling hides or hair from infected animals. The less common form, inhalational anthrax, or *woolsorter's disease*, is contracted by inhaling *B. anthracis* spores from animal sources. Anthrax spores inhaled into the distal air spaces are ingested by alveolar macrophages and transported to the mediastinal lymph nodes, where they induce a hemorrhagic mediastinitis, followed by bacteremia, overwhelming sepsis, and usually death.[156–158]

Clinically, patients typically experience a biphasic illness with an initial insidious flulike illness lasting 2 to 4 days and characterized by fever, malaise, myalgias, and nonproductive cough. This is followed by a fulminant phase of acute mediastinitis, with respiratory distress, chest pain, cyanosis, and prostration.[157–160] The chest radiograph and CT typically show mediastinal widening and pleural effusions (Fig. 77-11).[161] The diagnosis is established by demonstration of gram-positive, boxcar-shaped bacilli in tissue or body fluid specimens or in the blood buffy coat. A direct fluorescent antibody test, polymerase chain reaction, and serologic tests are available for confirmation.

Sporadic anthrax is fortunately rare, with one report documenting only two confirmed cases in this country in 25 years.[162] However, anthrax has remained a very real concern because of its devastating clinical effects and its ominous potential as an agent of biologic warfare and

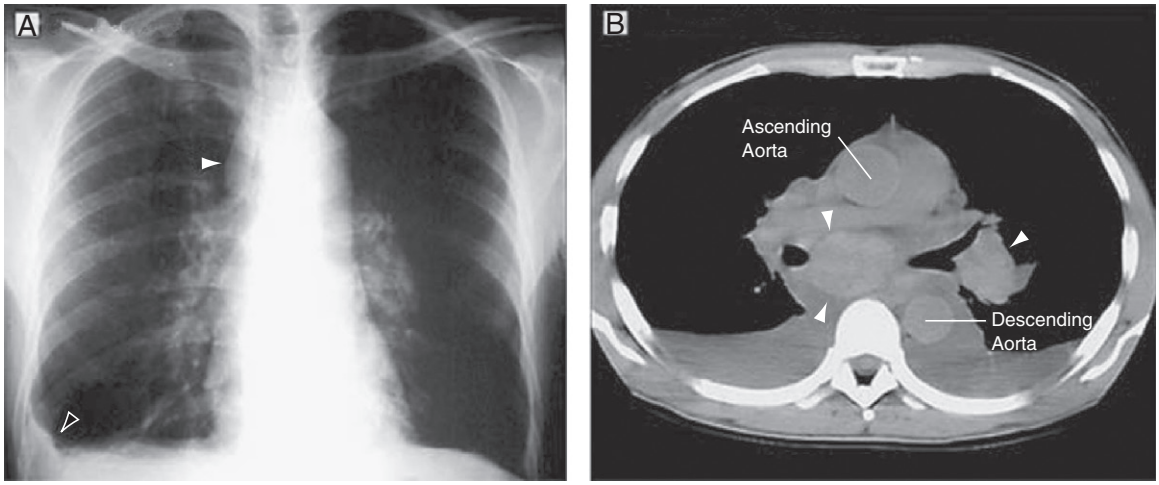

FIGURE 77-11 ■ Films from a 56-year-old man with inhalational anthrax. **A,** The chest radiograph shows a widened mediastinum (*white arrowhead*), perihilar infiltrates, and right pleural effusion (*dark arrowhead*). **B,** The noncontrast chest CT confirms mediastinal edema, mediastinal and hilar adenopathy, and bilateral pleural effusions. Note the large hyperattenuated, dense lymph nodes (*arrowheads*) in the subcarinal space and left hilum; such dense nodes are described with anthrax mediastinal adenitis and, in the setting of acute respiratory illness, can raise the suspicion for anthrax. (From Mayer TA, Bersoff-Matcha S, Murphy C, et al: Clinical presentation of inhalational anthrax following bioterrorism exposure. JAMA 286:2549–2553, 2001.)

bioterrorism.[157,158,163,164] In the fall of 2001, this potential was realized when *B. anthracis* spores were intentionally dispersed through the U.S. postal system. An outbreak followed, with many cases of cutaneous anthrax and at least 10 cases of inhalational anthrax identified by astute local physicians, local public health officers, and an investigative team headed by the U.S. Centers for Disease Control and Prevention.[159,160] All patients became ill within 4 to 6 days of presumed exposure, presented within 2 to 5 days of symptom onset, and had abnormal chest radiographs. Most had evidence of bacteremia.[159,160]

Inhalational anthrax has historically been a devastating disease even with appropriate treatment: 12 of 13 well-documented sporadic cases in the United States had fatal outcomes.[156] However, in the bioterrorism outbreak, prompt diagnosis and initiation of antibiotic therapy plus aggressive drainage of mediastinal and pleural collections resulted in the survival of 6 of the 10 patients.[159] High-dose intravenous penicillin has traditionally been the treatment of choice,[156] although penicillin-resistant strains have been reported.[165] Cephalosporin resistance is typical, and most patients in the bioterrorism outbreak were treated with multiple agents including a fluoroquinolone.[159] Future treatment will likely include passive immunization with anti-toxin antibodies.[165a]

Granulomatous Mediastinitis and Mediastinal Fibrosis

Mediastinal disease that is chronic in nature may be considered in the broad categories of granulomatous mediastinitis and mediastinal fibrosis. These conditions are not so much separate disease processes, however, as they are two ends of a spectrum of chronic inflammation and fibrosis. This pathophysiologic continuum is not evident in most of the literature, which mainly reports groups of cases at one or another end of the spectrum. Among the larger series, some have been based on pathologic material, selected according to the presence of granulomas or fibrosis; others have reported only cases of proved etiology, with mediastinal widening or mass on the chest radiograph, or who presented with superior vena cava (SVC) obstruction. Attempts to garner large numbers of cases from the literature[166,167] have necessarily been hampered by this lack of uniformity in selection. Further, because nearly all published series are retrospective, the clinical descriptions of chronic mediastinitis are incomplete and biased toward especially prominent or commonly recorded features.
