Arterial-arterial embolization (atheroembolism) usually is observed as one of two types, spontaneous or iatrogenic. Patients with spontaneous atheroembolism present with painful, cyanotic digits of acute onset. Occasionally, the majority of the forefoot is involved. Bilateral findings indicate an aortic source; unilateral findings suggest an iliac or femoral source. Aneurysms of the aorta, femoral, or popliteal arteries are also potential causes of distal emboli. Unless the entire foot is involved, the patient typically has a palpable pedal pulse and a normal or only slightly diminished ABI because the circulation from the digital arteries to the embolic source remains relatively uninterrupted.

Iatrogenic atheroembolism may complicate aortic catheterization procedures. The clinical picture of limb atheroembolism in this setting can vary from mild livedo reticularis that slowly resolves, to severe limb pain and cyanosis and eventual tissue loss, with concurrent elevated plasma muscle enzyme levels and myoglobinuria. Peripheral pulses are usually unaffected, as the atheroemboli lodge distal to the dorsalis pedis or posterior tibial arteries. Atheroembolism frequently includes cholesterol emboli, which can be confirmed by skin biopsy of peripheral lesions demonstrating cholesterol crystals in the capillaries. Rising creatinine, oliguria, and urine eosinophils are often present in patients with emboli involving the renal circulation. The diagnosis is usually not difficult if the lower extremities are also involved. Severe abdominal pain (indicating intestinal ischemia) following arteriography is a recognized indication for laparotomy. Direct surgical treatment of arteries occluded by atheroembolic material is usually not possible, given the small particle and vessel size. Because of the nonthrombotic nature of the embolus, anticoagulation and thrombolytic therapy are also relatively ineffective and may even be deleterious, and are thus not recommended for the management of the ischemic limb. Statins, by causing plaque stabilization, may reduce the risk

of recurrent atheroemboli in affected patients who recover from an acute embolic event. Most patients with catheter-induced atheroembolism have diffuse aortic disease not amenable to surgical treatment. An exception occurs if catheter-induced atheroembolism calls attention to an arterial aneurysm as the suspected source of the embolic material.

In situ arterial thrombosis occurs in two common scenarios. First, patients with a hypercoagulable state (Chapter 98), often previously unrecognized, may have an acutely occluded native artery (frequently with previous subclinical thromboses of small arteries). Second, patients with severe aortoiliac occlusive disease may develop iliac artery thrombosis secondary to catheter trauma from coronary angiography (resulting either from dissection of the iliac artery from the catheter or overzealous compression and occlusion of the groin postcatheterization).

In acute ischemia, the extremity is often pale and cool to palpation; pulses are often absent. It is particularly important to palpate the femoral as well as pedal pulses because a reduced femoral pulse indicates obstruction of the inflow vessels (aorto-iliac) that may be amenable to angioplasty. In contrast, a relatively normal femoral pulse with absent pedal pulses indicates occlusive disease distal to the inguinal ligament; in these patients, relief of limb ischemia typically requires a bypass operation to the distal vessels (popliteal or tibial). Doppler studies are critical and can be used to calculate an ABI. Determination of limb viability is made primarily based on physical examination and the judgment of the surgeon; thus, early vascular surgery consultation is required for all patients with suspected limb ischemia.

Differential Diagnosis and Initial Evaluation

The initial evaluation of the patient with suspected acute limb ischemia is directed toward confirming the ischemia and assessing limb viability. Paralyzed, insensate extremities with fixed skin mottling, and especially extremities with hard calf musculature, are not salvageable and require primary amputation as soon as the patient is medically prepared for the procedure and the margin of viability is clearly determined. However, the majority of acutely ischemic limbs are salvageable, because skeletal muscle generally can tolerate warm ischemia for 6 hours, or even longer in patients with chronic arterial occlusive disease, prior to irreversible loss. The decision about whether to proceed with limb salvage in marginal cases usually relies on the judgment of the vascular surgeon.

Acute limb ischemia rarely is confused with other processes. Infections (particularly necrotizing fasciitis), trauma, or conditions such as Raynaud's disease occasionally may cause initial diagnostic confusion. Once the diagnosis of acute arterial insufficiency is made, the differential diagnosis principally involves distinguishing embolic from thrombotic occlusion. Patients with emboli in normal

arteries typically present with sudden onset of clinical symptoms, without a preceding history of claudication, and may have a known embolic source; the unaffected extremity has normal pulses and Doppler signals. Patients with arterial emboli to the limb also should be carefully evaluated for emboli in other arterial beds. In contrast, patients with thrombotic occlusions typically have an antecedent history of claudication or rest pain, prior vascular grafts, and clinical and laboratory evidence of occlusive disease in both lower extremities.

Differential diagnosis of acute ischemia includes emboli from a cardiac source or atheroemboli from large vessel atherosclerosis or aneurysm (Table 51.1). *In situ* thrombosis of native vessels or in bypass grafts also are recognized causes of acute arterial ischemia. Cardiac emboli associated with acute limb ischemia typically affect proximal vessels and lead to the sudden loss of a femoral pulse and a pale, cool extremity. In contrast, atheroemboli typically affect the most distal vessels and result in blue, intensely painful toes (*blue toe syndrome*).

Atrial fibrillation as a potential cause of cardiac emboli may be diagnosed from the electrocardiogram. Identification of mitral stenosis, left-atrial enlargement, or mural thrombus by echocardiography also may indicate a proximal source for the emboli. In addition, ultrasound or computed tomographic imaging of the aorta and femoral or popliteal vessels may identify aneurysms as a source of atheroemboli. However, although these options are useful in individual clinical situations, angiography provides more definitive diagnosis; an acute embolic source typically is identified by a "meniscus sign," and *in situ* thrombosis usually is accompanied by extensive atherosclerosis. Additionally, angiography provides vascular access for either angioplasty or thrombolysis, if indicated.

Additional laboratory evaluation is typically not necessary, except as required for pre-operative evaluation (Chapter 30). A sedimentation rate or ultra-sensitive C-reactive protein may be obtained if the clinical presentation is consistent with arteritis (Chapter 111), and an evaluation for hypercoagulable states (Chapter 98) is indicated in selective cases of unusual *in situ* thrombosis in otherwise healthy individuals.

Indications for Hospitalization or Intensive Care Unit Admission

The majority of patients presenting with acute limb ischemia need hospital admission. Occasionally patients with mild ischemia may be managed with oral analgesia and elective admission or nonoperative outpatient management. Most patients require hospital admission for pain control, rapid anticoagulation with heparin, and evaluation directed at either revascularization or amputation.

Most patients can be managed in a non-ICU setting. Considerations for ICU admission include requirements for management of comorbid conditions, level and severity of

ischemic pain, and rapidity of planned interventions. For example, if high-dose analgesia, rapid central venous access, or urgent heparinization or fluid resuscitation are needed prior to surgery or angiography, the ICU is often a more practical place to perform these interventions quickly. Post-procedural monitoring usually is performed in the ICU, as these patients have a high risk of needing other interventions and of developing hemorrhage at the operative site because of the frequent concomitant anticoagulation. In addition, the incidence of postintervention myocardial infarction is high in this group of vascular patients. Complications of myoglobinuria and limb reperfusion require careful acid-base monitoring and hydration and are also best managed in the ICU (Chapters 100 and 105).

Initial Therapy and Issues During Hospitalization

Initial therapy for all patients with acute limb ischemia (Figure 51.1) includes prompt heparinization (unless contraindicated) and administration of oxygen. Heparin therapy may be associated with rapid improvement of symptoms and helps stabilize the patient prior to more definitive management. Other systemic factors that may contribute to poor limb perfusion and oxygenation need to be optimized as indicated in individual patients. For example, patients with hypotension or heart failure should be stabilized hemodynamically to maximize limb perfusion. Patients with evidence of secondary bacterial infection should receive appropriate antibiotic therapy (Chapter 69). Most patients need diagnostic or therapeutic arteriography and thus should have an urgent evaluation of their renal function and receive hydration in preparation for this procedure. In patients with diabetes and renal insufficiency, use of N-acetylcysteine may reduce the risk of contrast-induced renal failure. Definitive therapy of the patient with acute limb ischemia requires re-establishment of arterial perfusion. Thus, all patients with acute peripheral ischemic syndromes should receive emergent consultation from a vascular surgeon.

The priorities in early management of the patient with graft occlusion include assessment of limb viability and current circulatory status, determination of the nature of previous operations (patients frequently have undergone multiple procedures at different institutions, and operative reports are often critical), and achievement of rapid, therapeutic heparin anticoagulation to prevent propagation of thrombus. Also important are decisions concerning timing of arteriography (emergent or next day), timing of exploration and graft thrombectomy (unusually emergent), and management of comorbid diseases or risks (hydration to prepare for arteriography, evaluation and therapy of associated cardiac arrhythmias or ischemia). Another practical issue is obtaining central venous access. These patients frequently need repeat vascular reconstructions, often using arm veins for the conduit (because the leg veins have

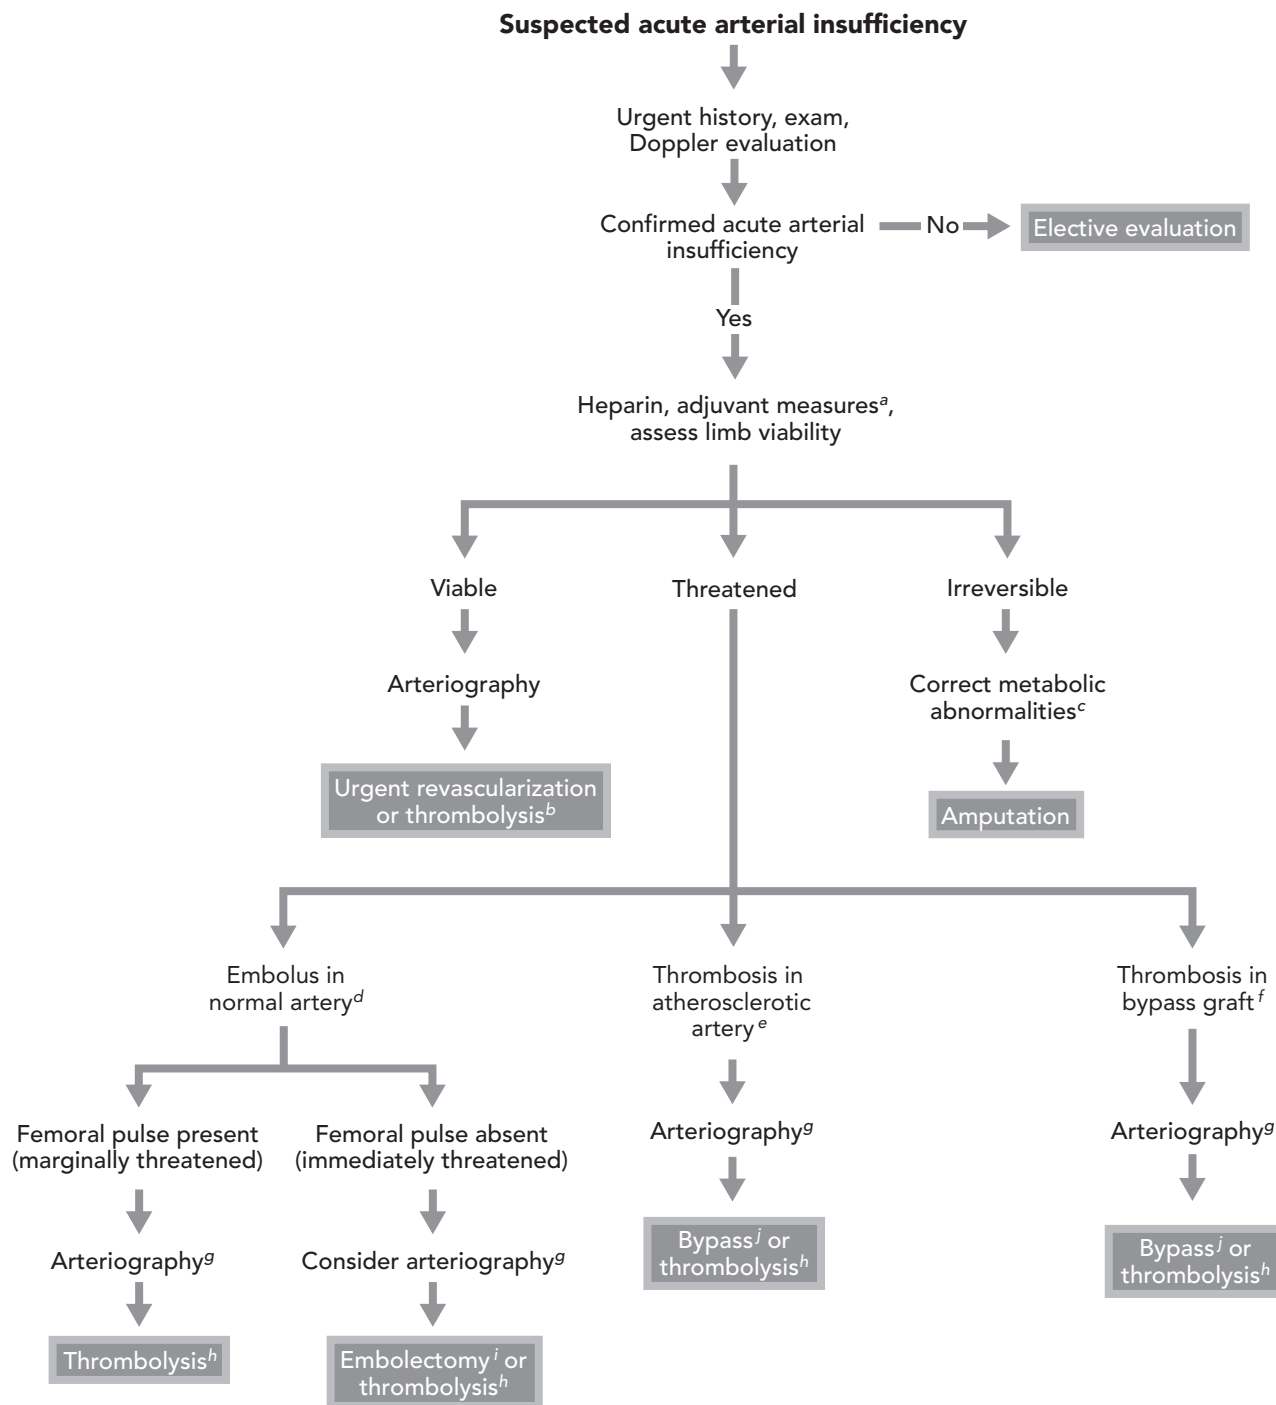

Figure 51.1 Algorithm for management of acute arterial insufficiency. ^aAdjuvant measures include antibiotics for infection and wound care if appropriate. ^bIn a viable limb, there is usually time to attempt a course of thrombolysis. ^cPotential metabolic abnormalities include acidosis, hyperkalemia, and creatinine kinase elevations with myoglobinuria. ^dThe acute occlusion of a primarily normal artery is usually caused by an embolus. In this situation, collateral vessels are usually not well developed, so there is a high risk for rapid progression to irreversible ischemia. ^eThe acute occlusion of a previously atherosclerotic artery is usually because of a thrombosis. Typically these vessels have extensive collaterals that partially protect the leg from progression to irreversible ischemia. ^fMost graft occlusions are caused by thrombosis. ^gThe decision to perform arteriography is based, in part, on time constraints in obtaining the procedure before irreversible changes occur. Duplex imaging of the leg may provide anatomic information more rapidly than arteriography. However, an arteriogram is always required for catheter-directed thrombolysis. ^hThrombolysis is most useful for (a) embolic occlusion of a marginally threatened leg (these patients usually have a palpable femoral pulse); (b) lack of angiographically defined outflow (in this situation, there is no target for a bypass graft); (c) thrombosis of a new inflow graft; (d) lack of definitive surgical options; and (e) hypercoagulable states. ⁱEmbolectomy is usually performed for (a) proximal embolus (absent femoral pulse) in a leg that is immediately threatened; and (b) failure of lysis or contraindications for lysis. ^jBypass grafting is performed for (a) outflow (leg) graft occlusion and (b) old inflow graft occlusion.

frequently been used for previous bypass operations); central venous access allows these veins to be preserved.

Patients with mild ischemia may undergo elective arteriography to plan the most suitable procedure. Patients presenting with fixed nonviable extremities ultimately come to amputation. Therefore, these patients are evaluated and managed primarily to determine the timing and the level of amputation. All other patients need urgent evaluation and therapy to restore perfusion rapidly to a potentially viable limb. In patients with acute peripheral arterial emboli, the decision of whether to proceed directly to operation for embolectomy (almost always involving a groin and popliteal approach) or to proceed with angiography and regional catheter-directed thrombolysis depends on the severity of the ischemia. Thrombolysis relieves the occlusion more slowly but offers the advantages of more complete resolution of the thrombus and avoiding catheter-induced endothelial trauma, which often leads to later fibrointimal hyperplasia and branch stenosis or occlusion of the involved arteries. If the limb is moderately threatened but time is available, angiography can be performed, followed by catheter-directed thrombolysis of the emboli. In contrast, if profound limb ischemia is present (often the case if the femoral pulse is absent and an embolus is present at or above the inguinal ligament), patients are best treated with operative embolectomy.

In patients with suspected *in situ* arterial thrombosis, arteriography is usually critical in decision making. The physical examination helps to localize the problem but offers insufficient anatomic information to plan needed surgery.

In patients with acute occlusion of an arterial graft, the location of the graft is important to subsequent management. If the graft is an inflow conduit (aortofemoral, axillofemoral, iliofemoral, or femorofemoral), then often the surgeon can proceed directly to graft thrombectomy and revision of the graft. The vast majority of inflow graft stenoses are located at the distal anastomosis, and a simple groin approach allows access to the graft. The primary problem with this approach is exposure of the prosthetic bypass material to potential infections. If the inflow graft cannot be opened with thrombolysis or surgery, an alternative option is an extra-anatomic bypass. Some surgeons believe occluded infrainguinal bypass grafts should be replaced with a new graft. Additional studies are required to define the necessity of this approach.

Several randomized trials have evaluated the efficacy of approaches for managing acute ischemia. In one study, 114 patients with acute arterial occlusions (thrombotic/embolic) or graft occlusions were randomized to either surgery or thrombolysis followed by angioplasty or surgery if needed (3). At 1 year, the limb salvage rate was equal (82%) in both groups. However, patient survival at 1 year was 84% in the thrombolytic group compared with 58% in the surgical group. Thus, this series would suggest that thrombolytic therapy may be associated with a lower 1-year mortality rate (the mechanism of this observed benefit remains unexplained). Two larger randomized trials, Surgery versus Thrombolysis for Ischemia of the Lower Extremity (STILE)

and Thrombolysis or Peripheral Artery Surgery (TOPAS), did not show any differences in 1-year mortality rates between thrombolytic and surgical management (4, 5). The amputation rate was greater in the thrombolytic group compared with the surgical group at one year in STILE (6), but there was no difference in TOPAS. Importantly, catheter-directed thrombolysis, which is superior to systemic administration of thrombolytic agents, is required. Currently, the question of optimal management using thrombolytic therapy or operation in acute limb ischemia remains unsettled (7, 8).

CHRONIC LIMB ISCHEMIA

Issues at the Time of Presentation

Clinical Presentation

Patients presenting with chronic limb ischemia as defined here typically do not present emergently for revascularization. Rather, the typical history is that of a patient with longstanding severe claudication who develops rest pain, a traumatic injury to the foot or digit, or an ischemic ulcer. The rest pain commonly occurs at night and is relieved with dependency or short ambulation.

Ischemic ulcers usually are found at the toes and distal points of the foot and are usually painful. However, chronic diabetic malperforans ulcers (sole of the foot at metatarsal heads) and venous ulcers (medial malleolus area) can be seen in patients with concomitant arterial ischemia. These conditions must be excluded in patients with refractory lesions. In general, any patient with an open foot wound needs to have adequate arterial circulation confirmed by careful hemodynamic assessment or Duplex ultrasound imaging (including ABI measurement) of the affected limb. Failure to do so is a common error that occasionally leads to delays in appropriate therapy and to unnecessary limb loss.

Differential Diagnosis and Initial Evaluation

Confirmation of the diagnosis of arterial insufficiency requires hemodynamic assessment of the critical components of the arterial tree. In the absence of previously documented atherosclerotic PAD, hemodynamics can be assessed noninvasively by measuring the ABI, the toe:brachial index, or segmental pressures in the affected limb. Initial evaluation also must exclude other causes of acute deterioration, such as hypotension. Patients with arteritis present with a typical clinical syndrome including systemic manifestations of their disease, an elevated sedimentation rate, and loss of pulses in the upper or lower extremity. Patients with Buerger's disease (*thromboangiitis obliterans*) have histories of substantial tobacco use; the arteriogram often shows corkscrew collaterals around an occluded medium-sized vessel. Biopsy is rarely necessary to

confirm this diagnosis. Viability of the tissue should be addressed as discussed previously.

The differential diagnosis in these patients includes several entities in addition to atherosclerotic disease. Patients with diabetic neuropathy may present with symptoms consistent with ischemic pain and with nonhealing neuropathic ulcers, but their pedal pulses are normal, unless there is coexistent PAD. Reflex sympathetic dystrophy, which may develop after surgical or other forms of trauma, leads to a painful, discolored, swollen extremity; although this disorder typically is an autonomic neuropathy, arterial perfusion may be maintained. Patients with arteritis, particularly those with Buerger's disease and a strong smoking history, may present with ischemic limbs (Chapter 111). Acute limb ischemia, discussed above, must also be considered.

Indications for Hospitalization or Intensive Care Unit Admission

Admission to the hospital is guided primarily by the associated analgesic requirements to control pain, the need for intravenous antibiotics for associated infection, or the presence of comorbid conditions. In the absence of these considerations, revascularization usually can be planned in an elective manner.

Initial Therapy and Issues During Hospitalization

Initial management of these patients involves pain relief (Chapter 18). Although nonsteroidal anti-inflammatory drugs may work initially, most patients with ischemic rest pain require opiates for relief.

Patients with more severe disease including ischemic ulceration or gangrene also need wound care and prevention of further trauma to the extremity. Heel protection is critical to prevent pressure necrosis to the Achilles area. Hospitalized patients should not be allowed to bear weight on the affected limb. Patients with an infected ulcer must be treated with antibiotics. The empiric antibiotic selected should have broad Gram-positive and Gram-negative coverage, and the specific antibiotic regimen selected should be based on local microbial resistance patterns, the presence of comorbid conditions such as diabetes, and local formulary considerations.

Numerous trials of drugs of the prostaglandin class (including analogs of prostacyclin and PGE) in critical leg ischemia have shown only marginal success. Antiplatelet therapy may be necessary not only to attempt to preserve graft patency but also to reduce the systemic risk of myocardial infarction and stroke. Aspirin (325 mg/day) promotes the patency of peripheral bypass grafts and angioplasty procedures. Clopidogrel (75 mg/day) has been shown to reduce the risk of cardiovascular events in patients with PAD.

Anticoagulation is often used in the perioperative period to maintain graft patency after peripheral bypass proce-

dures. The use of unfractionated or low-molecular-weight heparin in the immediate postoperative period may improve the patency of infrainguinal bypass grafts, but with the tradeoff of an increased risk of bleeding. In contrast, there is less evidence to support long-term anticoagulation to prevent graft occlusion. The largest experience suggests that anticoagulation (with warfarin to an INR of 2–3) may improve patency of vein grafts. Finally, several ongoing clinical trials are evaluating the use of growth factors to promote revascularization in chronic severe leg ischemia.

Definitive evaluation and management requires arterial imaging to localize the lesions, followed by revascularization or primary amputation (Figure 51.2). The choice between angioplasty and bypass surgery is complex and is based on the specific vascular anatomy, availability of appropriate conduit, previous revascularizations, and local expertise. Currently, the patient's own veins (greater saphenous, lesser saphenous, and arm veins) provide the optimal bypass vessels. Current 5-year patency rates for tibial bypass grafts are 60%–70% (9–12), with limb salvage rates of 80% or more. Operative mortality is less than 5% in most series, but may reach 10% in patients older than 80 years (13). The decision to amputate, and at what level to perform the amputation, remains largely one of clinical judgment.

Despite successful revascularization, post-operative recovery may be problematic (14, 15). Leg incisions or ischemic ulcers heal poorly, with mean healing times of 2 and 4 months, respectively. During this time, the wounds should be kept clean and inspected for infection and breakdown. Use of topical agents or growth factors applied directly to the wound have not been shown to offer any clinical benefit over usual local wound care. About 20%–30% of bypasses require operative revision, usually within the first year, to repair a stenotic lesion in the vein graft (15). Up to 20% of patients require at least one readmission for wound care issues, usually associated with an operative incision. The majority of patients develop significant ipsilateral lymphedema, which, if left uncontrolled, retards incisional wound healing.

The vast majority of patients with salvaged limbs walk on them, in contrast to the poor postamputation mobility in the elderly (16). Early consultation with a vascular surgeon helps prevent progression to a necrotic forefoot lesion too advanced to heal despite revascularization and aggressive debridement. Such unfortunate delays are a common cause of limb loss.

Discharge Issues

Patients who survive an episode of acute limb ischemia are almost always suffering from a systemic, chronic disease. Patients with PAD are at high risk for cardiac and cerebrovascular events; they require aggressive cardiovascular risk factor modification programs and long-term antiplatelet therapy as for patients who have angina or who have survived a myocardial infarction (Chapters 37 and 38). In patients with

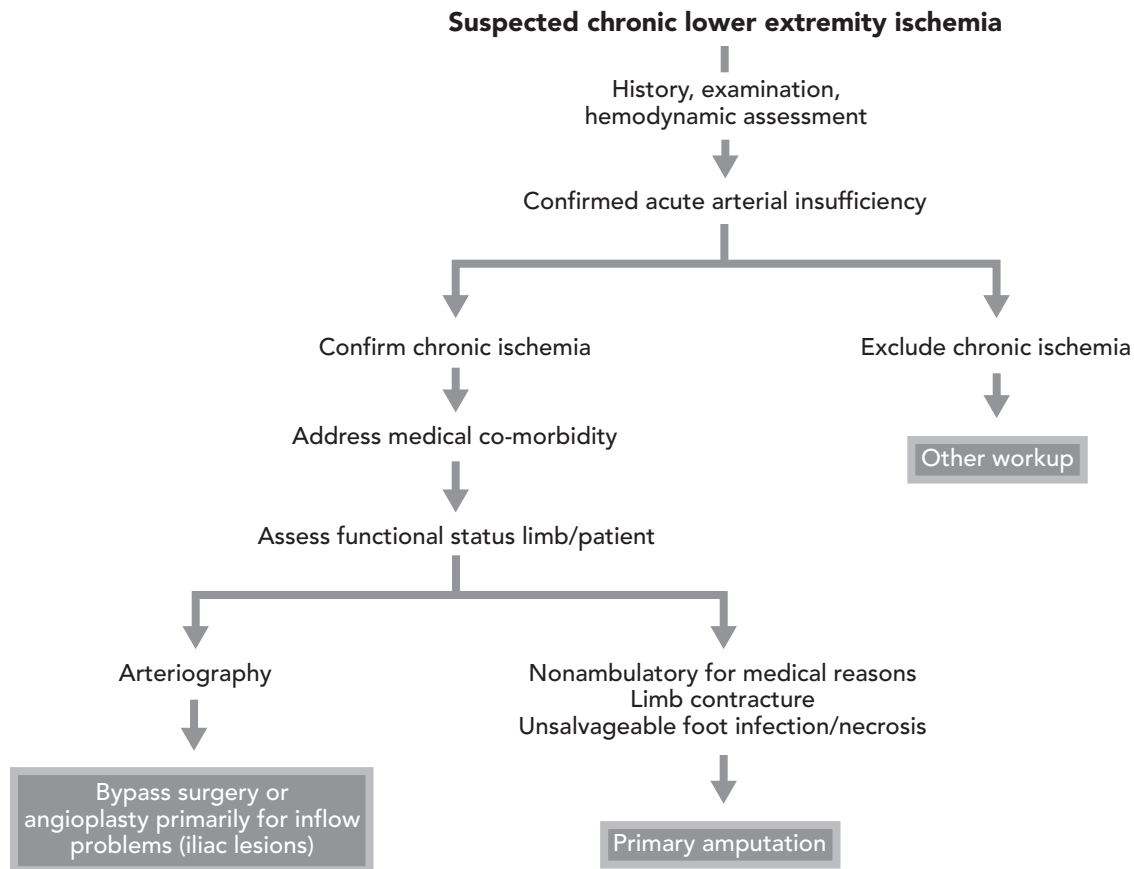

Figure 51.2. Algorithm for management of ischemic complications of peripheral arterial disease.

PAD who also have a history of myocardial infarction, acute coronary syndrome, or stroke, either aspirin or clopidogrel would be appropriate antiplatelet therapy. However, in patients with PAD who do not have other clinically evident cardiovascular disease, evidence supports clopidogrel as first-line therapy. Aggressive therapy of hyperlipidemia with statins is mandatory and can improve walking distance (17). Participation in a supervised exercise rehabilitation program is effective in improving claudication-limited exercise capacity. Management of any residual wounds, including amputation sites, is an important factor in long-term outcome. Referral to specialized wound care clinics may assist in management. Despite optimal care, however, the long-term prognosis for this population remains poor (2).

KEY POINTS

- PAD presenting as critical leg ischemia may be the result of acute arterial ischemia or progression of chronic atherosclerotic PAD.
- Initial management is focused on emergent vascular surgery consultation, identifying the level and type of arterial obstruction, assessing limb viability, and optimization of other comorbid disease processes (i.e., infection, congestive heart failure).

- The goal of therapy is to preserve the affected limb and the patient's functional status.
- Definitive therapy currently is guided primarily by the vascular surgeon's judgment and assessment because of the limited evidence from clinical trials.
- Discharge planning must recognize the chronic nature of the underlying disease processes, and their impact on long-term morbidity and mortality rates.
- Long-term outcome is critically dependent on treatment of the underlying systemic arterial pathophysiology, because most patients with PAD die from cardiac or cerebral events.

Deep Venous Thrombosis

52

David A. Garcia *Mark A. Crowther*

INTRODUCTION

Recent advances in the management of acute deep venous thrombosis (DVT) and pulmonary embolism (PE) have revolutionized the treatment of these common clinical problems. Two such advances are the demonstration that more than 90% of patients with acute venous thrombosis can be managed safely and effectively as outpatients (1) and the development and validation of diagnostic algorithms, which reduce practice variations and eliminate unnecessary diagnostic testing.

Traditionally, patients with acute venous thrombosis (including DVT and PE) have been admitted to the hospital for treatment with intravenous unfractionated heparin (UFH) for two reasons. First, it was felt that these patients required careful clinical monitoring to allow immediate treatment of PE, which could be fatal. Second, intravenous UFH requires laboratory monitoring. Outpatient treatment of DVT was made possible by the realization that most patients with acute DVT do not require in-hospital clinical monitoring and by the introduction of the low-molecular-weight heparins, which do not require laboratory monitoring of their anticoagulant effect.

The primary concerns of the physician treating patients with proven, acute proximal DVT are to triage those patients who require hospital admission and to arrange outpatient treatment for those who do not. DVT should no longer be the sole reason for admission to the hospital, except in selected circumstances (Table 52.1).

Although there is considerable overlap between the syndromes of DVT and PE, this chapter focuses on the diagnosis and treatment of patients with proximal DVT. PE is covered in Chapter 53.

WHEN THE DISEASE PRESENTS ON ADMISSION

Issues at the Time of Admission

In all cases, the diagnosis of acute DVT should be verified by an objective test. Although the gold standard for diagnosis remains contrast venography, this test is rarely needed. Rather, the diagnosis can usually be made with ultrasonography. In many symptomatic patients, compression ultrasound of the proximal venous system of the leg (or arm) reveals noncompressibility of a venous segment. This finding, in the setting of typical clinical signs and symptoms, has a specificity of 97% for acute DVT. A variety of other noninvasive testing methods, such as impedance plethysmography (IPG), thermography, and hand-held Doppler flow meters, lack sufficient sensitivity to reliably diagnose acute DVT. The use of contrast CT scanning to examine the legs for DVT ("CT venography") is generally confined to situations in which a spiral CT of the chest is being performed for suspected PE. It is further described in Chapter 53.

Recently, the use of both whole-blood and plasma D-dimer assays has been studied as an aid to the diagnosis of acute DVT (2, 3). D-dimer, which is a byproduct of fibrinolysis, is elevated in patients with active thrombosis. However, D-dimer levels also are elevated in the postoperative period, and in patients with malignancy, pregnancy, or septicemia. D-dimer levels can be assayed using a variety of techniques: plasma-based latex or enzyme-linked immunosorbent assays (ELISA), which quantify D-dimer levels, and whole-blood (bedside) assays, which are semiquantitative. Large prospective clinical evaluations have shown that a whole-blood D-dimer assay (the

TABLE 52.1

- renal insufficiency (calculated creatinine clearance <30 ml/min)
- hemodynamically apparent pulmonary embolism
- severe pain requiring parenteral opiates
- increased risk of bleeding

A system to monitor INR every 2–3 days is not available.

SimpliRED D-dimer) has a sensitivity of about 93% and a negative predictive value of 98% for proximal DVT. The specificity of the test, however, is only about 77%, because disorders other than acute DVT and PE can cause elevated D-dimer levels. Quantifying D-dimer levels using ELISA-based assays increases the sensitivity of the test but, in most cases, decreases its specificity (4). Clinicians must become familiar with the characteristics of the particular assay available at their institution, since reliance on an insensitive D-dimer could result in the inappropriate exclusion of deep vein thrombosis, placing patients at risk for pulmonary embolism (see also Chapter 53).

When evaluating a patient with possible acute DVT, the use of a clinical decision model can help determine which diagnostic tests to perform. Based on the history and clinical examination, the pretest probability of DVT can be reliably determined (Table 52.2). In a study by Wells et al., patients presenting with suspected DVT were evaluated using a validated pretest probability model. Subsequently, DVT was objectively confirmed in 5% of patients with a low pretest probability, 33% of patients with an intermediate probability, and 85% of those with a high pretest probability.

Translation of the study results into clinical practice will simplify the approach to patients with suspected DVT (Figure 52.1). Patients with a *low pretest probability* can be screened with a clinically tested D-dimer assay. A negative result rules out the diagnosis of proximal DVT (negative predictive value >99%) (5). Patients with an *intermediate* or *high pretest probability* should undergo an objective test, either a compression ultrasound or, if that is unavailable, a venogram. If the patient has a moderate or high pretest probability of DVT and negative compression ultrasound, a validated D-dimer assay should then be performed to rule out the possibility of extending calf vein thrombosis not detected by the ultrasound. If the D-dimer test is also negative, DVT can be excluded and anticoagulation safely withheld. If the D-dimer is positive, further testing with either serial compression ultrasonography or venography must be performed.

Once the diagnosis of acute DVT has been confirmed objectively, a decision regarding hospital admission should be made. Patients with evidence of a hemodynamically significant PE should be admitted to the hospital. All patients

should be assessed for bleeding risk. Initial laboratory investigations should include a hemoglobin and platelet count. Although routinely performed, an activated partial thromboplastin time (aPTT) or international normalized ratio (INR) value is not required in otherwise well patients without a history of clinically significant bleeding. Patients who are admitted with acute DVT should be treated with

TABLE 52.2
ASSESSING THE PROBABILITY OF DEEP VENOUS THROMBOSIS BASED ON THE CLINICAL PRESENTATION

Major points

- Active cancer
- Paralysis, paresis, or recent plaster cast immobilization of the lower limb
- Recently bed-ridden >3 d or major surgery within 4 wk
- Localized tenderness along the distribution of the deep venous system
- Thigh and calf swollen
- Calf swelling 3 cm >symptomless side
- More than two 1st-degree relatives with history of objectively documented deep venous thrombosis

Minor points

- History of trauma (within 60 d) to the affected leg
- Pitting edema in the symptomatic leg only
- Dilated superficial veins in the symptomatic leg only
- Hospitalization within the previous 6 mo
- Erythema

Clinical probability

Modified from Wells PS, Hirsh J, Anderson DR, et al. Accuracy of clinical assessment of deep-vein thrombosis. *Lancet* 1995;345:1326–1330, with permission.

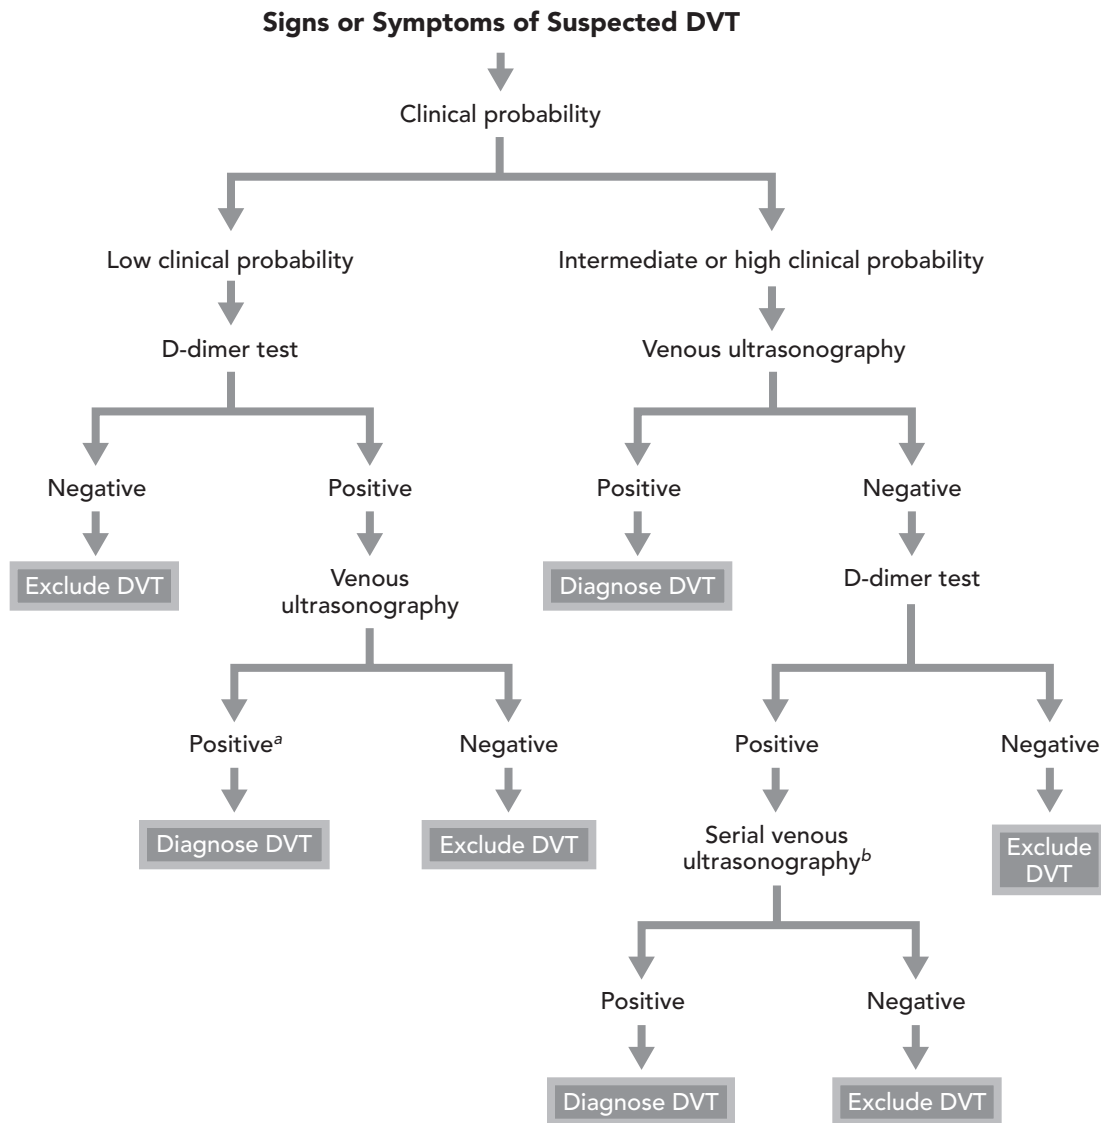

Figure 52.1 Algorithm for patient with suspected deep venous thrombosis. DVT, deep venous thrombosis. Clinical probabilities are drawn from Table 52.2. ^aRe-evaluate history and review ultrasound for features suggestive of old rather than new thrombosis. If ultrasound findings are inconclusive, venography should be considered. ^bIn patients with a high clinical probability or those who cannot return for serial ultrasonography, venography is recommended. Venography can also be considered in patients with cardiorespiratory compromise. (Reproduced from Hirsh J, Lee AY. How we diagnose and treat deep vein thrombosis. *Blood* 2002; 99:3102–3110, with permission.)

either unmonitored, weight-adjusted subcutaneous low-molecular-weight heparin or intravenous UFH monitored using the aPTT. Intravenous UFH is preferred in patients with acute DVT or PE at high risk for bleeding because once the infusion of UFH is discontinued, the majority of its anticoagulant effect is lost within 2 hours, whereas the anticoagulant effect of subcutaneous low-molecular-weight heparin persists for up to 24 hours. Furthermore, the anticoagulant effect of unfractionated heparin can be rapidly reversed with protamine sulfate; protamine sulfate cannot neutralize all of the anticoagulant effect of low-molecular-weight heparin.

If the patient is younger than 65 and does not have a risk factor for DVT (e.g., recent surgery, immobilization, or malignancy), screening for a hypercoagulable state should be considered (see Table 98.6 for a standard laboratory workup). This can be done either before anticoagulation is initiated or after it is completed. Testing for a hypercoagulable state while the patient is receiving therapy is problematic: heparin lowers antithrombin levels and may interfere with testing for both activated protein C resistance and the lupus anticoagulant; warfarin lowers the plasma levels of proteins C and S and may interfere with testing for both activated protein C resistance and the lupus anticoagulant.

Appropriate screening tests are discussed subsequently, and a more extensive discussion of hypercoagulable states is found in Chapter 98.

Issues During the Course of Hospitalization

All patients who are proven to have acute DVT and who do not have a contraindication to anticoagulation should be treated with therapeutic unfractionated or low-molecular-weight heparin beginning at diagnosis. Hospitalized patients should receive an initial bolus of UFH followed by a continuous infusion of UFH adjusted to maintain the anti-Xa heparin level in a range of 0.35–0.70 units/mL. Because heparin levels are not widely available, most laboratories have published aPTT values that correspond to this anti-Xa range. Studies have demonstrated that the use of a weight-based heparin nomogram improves outcomes and decreases complications (Table 53.2). Outpatients or inpatients at low risk for bleeding may be treated with one of the commercially available low-molecular-weight heparins. Monitoring of the anticoagulant effect of low-molecular-weight heparins is unnecessary in the majority of patients with acute DVT or PE. Dose adjustment or monitoring of anti-Xa levels may be advisable in patients with renal failure, those with significant obesity (>150 kg), and pregnant patients. The published experience using low-molecular-weight heparins for such patients is limited

because they have been excluded from most clinical trials evaluating low-molecular-weight heparins (6).

Warfarin should be initiated on the day of diagnosis, after heparin has been started. Warfarin “loading doses” (e.g., 10 mg on the first 2 days of treatment) can be associated with early overanticoagulation. For most patients (including the elderly or those with significant co-morbidities), warfarin is best initiated at a dose likely to be required for maintenance (usually around 5 mg/d) (7). (Chapter 53 for a warfarin nomogram [Table 53.3] and a list of warfarin drug interactions [Table 53.5].) A higher initial warfarin dose may be appropriate for otherwise healthy, young outpatients (8). The heparin should not be discontinued until the INR has stabilized between 2.0 and 3.0 on 2 consecutive days, and heparin has been administered for a minimum of 4–5 days.

Patients may present with, or develop, unusual manifestations of thromboembolism. Patients with DVT of the renal veins, inferior vena cava, cerebral veins, portal vein, or in the upper venous circulation should be treated similarly to those with proximal DVT in the leg. Patients with mesenteric vein thrombosis often have associated ischemic bowel, which may require surgical removal. Hepatic vein thrombosis (*Budd–Chiari syndrome*) is a potentially life-threatening condition for which optimal therapy is unknown. All patients with these unusual thrombi should be screened for a hypercoagulable state (Chapter 98). Occasionally, pa-

TABLE 52.3
OPTIMAL DURATION OF WARFARIN ANTICOAGULATION IN PATIENTS WITH DEEP VEIN THROMBOSIS

	Target INR	Duration
Calf DVT (i.e. does not involve veins proximal to the popliteal fossa)	2.0–3.0	Minimum: 6 wk; maximum: 12wk ^a
Transient risk factor that now is resolved, e.g., thrombosis after arthroscopy	2.0–3.0	Minimum: 6 wk; maximum: 12wk
Transient risk factor that is persistent, e.g., thrombosis with current plaster-cast immobilization, pregnancy	2.0–3.0	Continue for 6 wk after risk factor resolved
Thrombosis with malignancy	2.0–3.0	Indefinite anticoagulation ^b
Idiopathic thrombosis, i.e. thrombosis with no identified precipitant	2.0–3.0	≥6months anticoagulation Discuss risks and benefits of extended anticoagulation with patient
Recurrent idiopathic thrombosis occurring off anticoagulants, e.g., thrombosis in patient with previous episode of DVT/PE	2.0–3.0	Life-long anticoagulation
Recurrent thrombosis occurring while on anticoagulants, e.g. new DVT or PE in patient therapeutically anticoagulated with warfarin	LMWH, or warfarin with target INR >3.0	Life-long anticoagulation; consider placement of IVC filter

^a If anticoagulation withheld, serial noninvasive studies should be performed over 7–14 days to ensure thrombus has not extended to involve proximal veins.

^b Consider prolonged monotherapy with LMWH instead of warfarin (9).

DVT, deep venous thrombosis; INR, international normalized ratio; IVC, inferior vena cava; LMWH, low-molecular-weight heparin; PE, pulmonary embolism.

tients present with venous gangrene caused by a large proximal DVT. In such cases, thrombolytic therapy or catheter-directed therapy may be used to acutely reduce the venous outflow obstruction. There is no high quality evidence, however, that thrombolytics or catheter-directed techniques provide long-term benefit beyond those obtained with heparin (either low-molecular-weight or unfractionated) and warfarin.

The management of patients with a contraindication to anticoagulant therapy is more difficult. Patients with acute DVT of the leg and such a contraindication should have an inferior vena cava (IVC) filter placed, because IVC filters substantially reduce the short-term risk of PE. However, a randomized controlled trial found that IVC filters do not improve long-term survival, and that permanent IVC filters increase the risk of recurrent thrombosis nearly twofold in the 2 years following their placement (10). Patients with IVC filters frequently experience worsening of their leg symptoms, secondary to proximal extension of their thrombus. Therefore, if the contraindication to anticoagulation is transient (such as temporary thrombocytopenia secondary to chemotherapy or gastrointestinal bleeding from a reversible lesion), patients with filters should be anticoagulated as soon as possible to reduce the severity of their leg symptoms. "Temporary" removeable IVC filter devices may offer short-term protection from pulmonary embolism without increasing the long-term risk of recurrent DVT. Although not well studied, such devices are now available in many centers.

It is controversial whether *upper-circulation deep vein thrombi* can cause clinically important PE; traditional teaching is that they cannot. It is clear, however, that children with upper-extremity thrombosis do suffer PE and other complications such as post-phlebotic syndrome (Figure 52.2). The rate of these complications in adults is unknown but sufficiently high that patients should be treated as for lower-extremity DVT. In our opinion, extended duration therapeutic anticoagulation should be given to patients with involvement of deep, proximal (e.g. axillary, subclavian, internal jugular) veins. The optimal management of patients with upper-circulation DVT and a contraindication to anticoagulation (a scenario found frequently in oncology patients with indwelling central venous catheters) is unclear. Our practice is to either simply observe the patient closely without treatment or treat with prophylactic doses of low-molecular-weight heparin after discussing the risks of thromboembolism and hemorrhage with the patient.

During the course of hospitalization, the patient should be monitored for bleeding and for the development of *heparin-induced thrombocytopenia* (HIT). HIT is a potentially devastating complication and should be considered if the platelet count drops below normal (or by more than 50% from baseline), or if the patient develops recurrent thrombosis (arterial or venous) despite heparin therapy. The management of HIT is discussed in Chapter 98.

Figure 52.2 This upper-extremity thrombosis was associated with an AV fistula used for hemodialysis. While hospitalized and receiving IV unfractionated heparin, this patient died suddenly, seconds after reporting that his fistula had started working again. Autopsy showed the cause of death to be pulmonary embolism.

Bleeding is a common complication of anticoagulant therapy, occurring in 2%–5% of patients who are therapeutically anticoagulated. The risk of bleeding is highest during the initial days of heparin therapy. Bleeding can be managed by withdrawing heparin and, if acute neutralization is required, by the use of protamine sulfate. Bleeding in patients receiving warfarin usually can be controlled by mechanical means (such as pressure). If rapid reversal of warfarin's anticoagulant effect is required, intravenous vitamin K (1 or 2 mg) is effective. If immediate reversal is required, frozen human plasma or coagulation factor concentrates should be administered in concert with intravenous vitamin K. Recombinant factor VIIa may stop bleeding in patients receiving warfarin who present with major or life-threatening hemorrhage. However, this therapy is expensive and has not been well studied (11).

Discharge Issues

At the time of discharge, the patient should be advised to avoid situations that might precipitate bleeding. In addition, arrangements should be made for outpatient monitoring of the INR. Initially this should be performed frequently (i.e., every 2–4 days). The interval can be increased to as little as once per month once the patient has stable INR values. The target INR value for all patients with acute DVT or PE should be 2.0–3.0. The optimal duration of anticoagulant therapy varies as a function of the suspected cause of the DVT; common scenarios are shown in Table 52.3.

For patients who present with DVT without an identified precipitant, the ideal duration of anticoagulant therapy is controversial. These patients have a high risk of recurrent thrombosis (15%–30% 2-year risk of recurrence) if their

warfarin is stopped after 3 months of treatment. Although warfarin is very effective at preventing a DVT while patients are taking the drug, prolonged warfarin therapy does not appear to confer any long-term protection against recurrent DVT after anticoagulation is discontinued (12). It has been proposed that patients with an unprovoked DVT will benefit from lowering the target INR range (to 1.5–2.0) after 3–6 months of “full-dose” anticoagulation. There are now two randomized, controlled studies confirming that “low-intensity” warfarin provides substantial protection against recurrent venous thromboembolism (13, 14). Surprisingly, there is no evidence from these trials to support the hypothesis that reducing the target INR will decrease the risk of major hemorrhage among chronically anticoagulated patients. For now, it is our recommendation that all patients who have a DVT without an identified precipitant should be maintained on warfarin (target INR range 2.0–3.0) for at least 6 months. Patients who have had more than one DVT without an identified precipitant should likely receive indefinite conventional-intensity (target INR 2.0–3.0) anticoagulation. In many cases, a discussion with the patient about the risks and benefits of anticoagulation is invaluable.

The most common acquired conditions that predispose to DVT are antiphospholipid antibodies (lupus anticoagulant or anticardiolipin antibody) and malignancy. Current evidence suggests that patients with DVT and convincing evidence of antiphospholipid antibodies are best treated with indefinite duration warfarin administered to achieve an INR of 2.0–3.0 (15). One in 10 patients presenting with idiopathic DVT is found to have a malignancy within 12–18 months of follow-up. Although some authors have recommended aggressive investigation for malignancy in patients presenting with a single, acute idiopathic DVT or PE, there is no evidence that such investigations improve the outcome of these patients. For patients who present with recurrent thrombosis, particularly in the face of therapeutic anticoagulation, the clinician should perform a thorough review of systems and physical exam, with special attention to signs and symptoms that could be attributed to malignancy. Classically, carcinoma of the pancreas, breast, prostate, or bowel are associated with DVT, although DVT (and unusual complications such as migratory superficial thrombophlebitis) can accompany any type of malignancy.

The decision to screen a patient for an inherited or acquired hypercoagulable state (Table 98.5) should be made only if it is clear that the results of the testing will influence clinical management. Because the presence of a hypercoagulable state might influence the duration of anticoagulant therapy and subsequent decisions about medication use, screening of patients with idiopathic DVT is often indicated, although screening of asymptomatic populations and patients with known risk factors is not. Evidence-based strategies for screening and counseling are currently being developed.

The major long-term complication of DVT is the *post-phlebotic syndrome*. This syndrome, which is caused by ele-

vated venous pressure in the deep veins of the leg as a result of destruction of the venous valves by the thrombus, is associated with leg pain and swelling (particularly after prolonged standing) and, occasionally, venous stasis ulceration. Graduated compression stockings improve patient symptoms and may reduce the risk of ulcers (16). Physical activity improves symptoms in many patients, presumably by increasing venous outflow from the leg. Although the risk of post-phlebotic syndrome was once thought to be as high as 30%–50%, evidence now suggests the risk of severe post-phlebotic syndrome is less than 10%.

WHEN THE DISEASE PRESENTS DURING HOSPITALIZATION

Acute DVT is frequently found in already-hospitalized patients. Typically, inpatients with new DVTs present with leg (or arm) swelling that cannot be explained by their clinical conditions. Risk factors include immobilization, recent surgery (particularly orthopedic surgery), the presence of malignancy, major trauma, chemotherapy, or overwhelming infections. The incidence of DVT among hospitalized patients may be reduced if clinicians employ one of a variety of effective prevention strategies (17) (Table 52.4). For patients undergoing major orthopedic surgery, an indirect factor Xa inhibitor, fondaparinux, has been recently added to the options for thromboprophylaxis (18).

Certain groups of hospital patients are at such high risk of DVT that routine surveillance for DVT has been recommended; for example, in some centers patients who undergo orthopedic surgery on the legs are screened routinely at discharge for DVT. These patients do not require pre-discharge screening if they receive adequate antithrombotic prophylaxis (Table 52.4). Recent studies suggest that 28–35 days of thromboprophylaxis (with either low-molecular-weight heparin, fondaparinux, or therapeutic dose warfarin) is more effective in reducing the risk of VTE than 7–10 days of prophylaxis in patients with high risk of DVT, such as those who have had total joint arthroplasty or repair of a fractured hip (19–22).

Diagnostic testing options in symptomatic inpatients are similar to those available for outpatients. Compression ultrasound is the diagnostic test of choice. If the clinical suspicion is high and the ultrasound is normal, either serial ultrasonography or venography should be performed. The D-dimer (previously discussed) has not been well studied in inpatients. This test is likely to be less useful in this population because many inpatients have conditions that elevate plasma D-dimer levels (e.g., recent surgery, malignancy, infection).

Issues During the Course of Hospitalization

The clinical course of patients who have acute DVT that develops during hospitalization is primarily dependent upon their underlying conditions. Treatment with unfractionated or low-molecular-weight heparin should be initi-

TABLE 52.4**EVIDENCE-BASED STRATEGIES TO PREVENT DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM IN HOSPITALIZED PATIENTS**

Group	Subgroup	Level of risk	Effective strategies ^a
Surgical patients	General surgery ^b	Low risk (<40 y of age, minor operations, no clinical risk factors)	No prophylaxis other than early ambulation and possibly compression stockings
	General surgery	Moderate (>40 y of age, major surgery, but no additional clinical risk factors for DVT/PE)	LDUH, LMWH, IPC, or ES
	General surgery	Higher risk (>40 y of age, major surgery, and with additional clinical risk factors for DVT/PE)	LDUH or higher-dose LMWH; if prone to wound complications (e.g., hematoma or infection), IPC is a good alternative
	General surgery	Very high risk ^c (multiple risk factors for DVT/PE)	LDUH or LMWH and IPC; in selected patients postoperative warfarin (target INR of 2–3)
	Elective hip replacement ^c		Fondaparinux (started 8–10 h after surgery), LMWH (started 12–24 h after surgery) or warfarin (INR 2–3; started preoperatively or immediately after surgery) ^d , or adjusted-dose heparin started preoperatively; adjuvant prophylaxis with ES or IPC may provide additional efficacy
	Elective knee replacement		Fondaparinux (started 8–10 hours after surgery), LMWH or warfarin or IPC
	Hip-fracture surgery ^c		Fondaparinux (started 8–10 hours after surgery), preoperative LMWH, or warfarin (INR 2–3, started perioperatively or immediately after surgery)
	Intracranial neurosurgery		IPC with or without ES; LMWH or LDUH may be acceptable alternatives; in high-risk patients, combining a physical modality (IPC or ES) and pharmacologic modality (LMWH or LDUH) may be more effective
	Acute spinal-cord injury		LMWH; ES and IPC may be added to LMWH; note that LDUH, ES, and IPC are ineffective if used alone
	Trauma	With risk factors for DVT/PE	LMWH if no contraindication; consider IPC if LMWH delayed or contraindicated; consider IVC filter if patient at high risk for DVT/PE and unable to receive optimal prophylaxis
Medical conditions	Myocardial infarction		LDUH (full anticoagulation is also effective); IPC and possibly ES may be useful if heparin contraindicated
	Ischemic stroke and lower-extremity paralysis		LDUH or LMWH are effective; IPC and ES are probably effective
	General medical patients	With risk factors for DVT/PE (especially congestive heart failure or pulmonary infection)	LDUH or LMWH (Fondaparinux may be effective but has not been approved for this indication by regulatory bodies)

^a In patients having a spinal puncture or an epidural catheter placed, LMWH should be used with caution.

^b Aspirin is not recommended for prophylaxis in general surgery patients because other methods (shown in table) are more effective.

^c Consider extended anticoagulation (29- to 35-d) based on studies demonstrating a reduced risk of thrombosis.

^d Optimal duration of LMWH or warfarin prophylaxis is uncertain. At least 7–10 d is mandatory; emerging data suggest that a 29- to 35-d duration of LMWH offers additional protection.

adjusted-dose heparin, 3,500 U unfractionated heparin given subcutaneously q8 h, with postoperative dose adjustments by ± 500 U to maintain aPTT at high-normal values; *aPTT*, activated partial thromboplastin time; *ES*, elastic stockings; *higher-dose LMWH*, enoxaparin 4,000 U qd or 3,000 U bid, or its equivalent; *INR*, international normalized ratio; *IPC*, intermittent pneumatic compression; *IVC*, inferior vena cava; *LDUH*, low-dose unfractionated heparin (5,000 U q8–12 h); *LMWH*, low-molecular-weight heparin at standard doses (e.g., enoxaparin 2,000 U qd or its equivalent.)

ated, and the patient should be started on warfarin the same day. Heparin (or low-molecular-weight heparin) then should be discontinued 48 hours after the INR has risen to a level between 2.0 and 3.0, provided the patient has received heparin for a minimum of 4 days. Patients

usually begin to notice reduced pain and swelling in their leg within 48 hours of starting the intravenous heparin. Some patients, however, have prolonged symptoms that may persist for months after the diagnosis of DVT. Occasionally patients (particularly those with malignancy or

those who develop heparin-induced thrombocytopenia) develop severely impaired venous outflow from the leg with associated venous gangrene. A variety of different interventional techniques have been employed in these patients, including venous angioplasty and catheter-directed clot lysis. However, none of these interventions has been studied in a methodologically rigorous manner. Some patients, particularly those with malignancy and those with disseminated intravascular coagulation, may develop DVT in the setting of thrombocytopenia. In such cases, it generally is safe to anticoagulate the patient if his or her platelet count is more than 50,000/mL. Patients with DVT and platelet counts less than 30,000/mL should have a removable IVC filter placed if possible. Occasionally patients are found to have an asymptomatic DVT discovered during an ultrasound performed for other reasons. In general, all deep vein thrombi proximal to the knee or involving the deep circulation of the arm should be treated, irrespective of whether they produce symptoms. The incidentally discovered calf vein thrombosis is more problematic; either serial evaluation for proximal extension using ultrasonography or treatment with heparin and an abbreviated course of warfarin is probably adequate. Patients who develop DVT or PE as inpatients, but who are otherwise eligible for discharge, can be discharged on outpatient low-molecular-weight heparin and treated as described previously.

Superficial phlebitis is a commonly encountered clinical problem. Although it can occur in any superficial vein, it is most commonly encountered in the long saphenous vein of the leg. Superficial phlebitis is usually a self-limiting disease responding to conservative treatment with anti-inflammatory medications. Up to 15% of patients with extensive superficial phlebitis have a DVT on objective testing. Such patients should be treated for their DVTs, as discussed previously. Patients who have less extensive superficial phlebitis, or those with extensive phlebitis who do not have DVT on objective testing, often benefit from a short course (5–7 days) of low-dose subcutaneous UFH (5,000–12,500 units subcutaneously twice daily), which the patient can self-administer at home. Subsequently, patients can be managed in most cases with anti-inflammatory medications. Recalcitrant or recurrent superficial phlebitis (particularly superficial phlebitis that recurs in patients who are therapeutically anticoagulated) can be a manifestation of underlying malignancy.

Catheter-related thrombosis is encountered with increasing frequency. Most commonly encountered in the upper extremity, catheter-related thrombosis presents with either arm or neck swelling, signs of impaired venous outflow, or catheter occlusion. Treatment is controversial; in particular, it is unknown whether a functioning catheter should be removed. Treatment with UFH or low-molecular-weight heparin and warfarin is usually administered to prevent proximal extension of the clot, superior vena cava syndrome, PE, and worsening of clinical symptoms. If the thrombus is not causing clinical symptoms but is associ-

ated with dysfunction of the catheter, it can be cleared in some cases with the local installation of thrombolytic medication. If the catheter cannot be removed, treatment with therapeutic doses of UFH or low-molecular-weight heparin and warfarin may reduce symptoms. Although systemic thrombolytic therapy has been employed in such patients (Chapter 98), its use cannot be recommended, because there are no rigorous studies demonstrating its utility. At least one systematic review suggests the risk of catheter-associated thrombosis can be reduced by either prophylactic dose low-molecular-weight heparin or warfarin. However, the quality of available evidence is “fair” at best.

Septic thrombophlebitis is an uncommon clinical problem, and there is no consensus regarding its management. When deep veins are involved, treatment with therapeutic doses of low-molecular-weight heparin or UFH followed by warfarin is appropriate. Antibiotics should be administered, and the patient followed for evidence of septic embolization. Although both surgical removal of thrombus and thrombolytic therapy have been used in selected patients, their use as initial therapy in uncomplicated cases cannot be endorsed in the absence of appropriate studies demonstrating benefit.

Discharge Issues

All patients with symptomatic DVT should be discharged on warfarin unless they have completed a full treatment course in the hospital. The INR value should be maintained between 2.0 and 3.0, and arrangements should be made for monitoring as often as every 2–3 days for a short time after hospital discharge. Patients should be educated at the time of discharge (or soon thereafter) about precautions relevant to warfarin therapy and signs of bleeding or recurrent thrombosis. The optimal duration of anticoagulation is described in Table 52.3.

COST CONSIDERATIONS AND RESOURCE USE

Outpatient treatment of acute DVT substantially reduces the cost of treating this disorder. The vast majority of patients (more than 90% in our experience) can be successfully treated as outpatients. Further cost savings, without compromised patient care, could be realized by judicious use of a diagnostic strategy employing clinically tested D-dimer assays in patients who have a low pretest probability of DVT.

The treatment course of heparin should not be shortened to less than 4 days. However, patients frequently require heparin therapy for more than 5 days because of difficulties achieving adequate initial anticoagulation with warfarin. The proportion of patients who achieve a therapeutic aPTT within 2 days and a therapeutic INR value within 5 days can be increased with the use of validated heparin and warfarin initiation nomograms, respectively (Chapter 53).

KEY POINTS

- Patients presenting with suspected acute DVT should have the diagnosis confirmed by objective testing.
- Once the diagnosis of DVT has been confirmed, the majority of patients can be treated as outpatients with low molecular weight heparin, although patients with comorbid conditions or those with symptomatic PE should be admitted to the hospital.
- Inpatients should be treated with intravenous UFH with frequent monitoring of the aPTT, or with unmonitored, weight-adjusted subcutaneous low molecular weight heparin.
- The duration of anticoagulant therapy should be individualized based on the cause of the patient's DVT.
- The anticoagulant effect of warfarin should be monitored closely throughout the treatment course (see Chapter 53 for drug interactions).
- Patients who have had a previous DVT or PE have a life-long increased risk of having a second event and should thus monitor themselves closely for symptoms suggesting recurrence.
- Hospitalized patients, particularly those with hip fractures or who have undergone orthopedic surgery, are at high risk for acute DVT and PE. Patients at risk should receive prophylaxis with one of several effective pharmacologic or nonpharmacologic modalities (Table 52.4).
- Extending prophylaxis for 3–6 weeks after surgery should be considered in all patients who have undergone major orthopedic surgery on their legs.

Pulmonary Embolism

53

Thomas M. Hyers

INTRODUCTION

Pulmonary embolism is a common disease, with an incidence of 205 per 100,000 person-years. It accounts for as many as 250,000 hospitalizations and 50,000 deaths annually in the United States. Diagnosing pulmonary embolism remains one of the most challenging problems in hospital medicine. Clinical signs and symptoms are nonspecific, and treatment involves significant risk for bleeding. Even when pulmonary embolism is diagnosed and treated, the 1-year mortality rate approaches 25% (1). It is essential that every physician caring for hospitalized adult patients be proficient in diagnosing and treating this disorder. This chapter focuses specifically on the diagnosis and management of pulmonary embolism. The prevention, diagnosis, and treatment of deep venous thrombosis are covered in Chapter 52.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

The symptoms and signs of pulmonary embolism are nonspecific and are present in similar proportions of patients with and without pulmonary embolism. However, 97% of patients with pulmonary embolism have at least one symptom of the following: dyspnea, pleuritic chest pain, or tachypnea (2). Hemoptysis is uncommon. Chest wall tenderness suggests a musculoskeletal etiology for chest pain. Unilateral leg tenderness or edema may be signs of deep venous thrombosis. In severely ill or postoperative patients, signs and symptoms may be particularly subtle.

Given the lack of specificity of signs and symptoms, one's index of suspicion for pulmonary embolism often depends on whether a patient has predisposing factors for the disease. Patients at greatest risk for pulmonary embolism are those with a history of venous thromboembolism and those with cancer, congestive heart failure, recent surgery, or immobilization. Other risk factors include use of oral contraceptives

or postmenopausal estrogen, pregnancy, and inherited or acquired hypercoagulable disorders (Table 98.5).

INITIAL EVALUATION AND DIFFERENTIAL DIAGNOSIS

The goal of the initial laboratory evaluation is to exclude other diseases in the differential diagnosis and to refine the clinical probability of disease. The initial laboratory evaluation includes an arterial blood gas determination, chest radiograph, and electrocardiogram. Eighty-one percent of patients with pulmonary embolism have an arterial oxygen tension (PaO_2) < 80 mm Hg and 89% have an alveolar-arterial gradient > 20 mm Hg. However, hypoxia is common in patients with illnesses that mimic pulmonary embolism. The main value of the arterial blood gas is, therefore, to recognize and treat hypoxia rather than to rule in or rule out pulmonary embolism.

A chest radiograph is essential for excluding conditions such as pneumonia, pneumothorax, aortic dissection, and cancer, and for aiding in interpretation of the lung scan. The most common radiographic findings in pulmonary embolism (atelectasis, parenchymal infiltrates, and pleural effusions) are commonly seen with other diseases. Normal chest radiographic findings occur in only 12% of patients with pulmonary embolism.

The electrocardiographic findings are also frequently unhelpful. The "classic" finding of $S_1-Q_3-T_3$ is both rare and nonspecific. The primary value of the electrocardiogram is, then, to exclude the diagnoses of myocardial infarction and pericarditis.

After completing the history, physical examination, and simple laboratory tests, the clinician should estimate the probability of pulmonary embolism. Although research has not identified precisely how to estimate this probability, studies indicate that experienced clinicians can do so reproducibly. The probability of pulmonary embolism is low in the absence of a predisposing factor, when the

history or physical findings suggest another disease, or when the arterial blood gas values are normal. When patients have a predisposing factor or when their history or physical examination findings are consistent with pulmonary embolism without an alternative diagnosis, the probability of pulmonary embolism is high. Other patients (the majority) fall into the intermediate clinical probability group.

DIAGNOSTIC STUDIES

A New Diagnostic Strategy Using Spiral Computed Tomography (CT) Scanning

Although the literature has traditionally used the ventilation-perfusion scan as the lynchpin of the diagnostic algorithm, a number of recent prospective studies using spiral contrast chest CT scanning as the principal or only screening study for pulmonary embolism (PE) have shown that a negative spiral CT identifies a population at very low risk (<2%) for subsequent venous thromboembolism (VTE) (3–5). In a few studies, the venous phase of the contrast has also been used to produce an image of the deep veins of the legs following imaging of the pulmonary vasculature. The venous CT of the legs appears to have similar sensitivity and specificity to that of duplex ultrasound of the legs (6) (see Chapter 52). Moreover, the test is readily available and

can also identify other pathology that may mimic PE. Because of these virtues, in many centers spiral contrast chest CT has replaced ventilation-perfusion lung scanning as the initial screening test for PE. The major drawback of the study is the risk of contrast-induced renal injury in patients with borderline renal function, especially in diabetics. In this setting, the ventilation-perfusion lung scanning continues to be the initial test of choice.

If spiral CT scanning is used as the initial diagnostic test, an effective algorithm should incorporate both a clinical probability estimate and the use of leg ultrasound or leg venous CT. The rationale behind leg testing is the relatively low sensitivity of the chest spiral CT when pulmonary emboli involve subsegmental or smaller pulmonary arteries. As advanced multidetector CT scanners come into use, the current sensitivity of spiral CT (around 80%) for PE will likely improve, which may influence the algorithm. For now, the combination of chest spiral CT scan and a leg study improves the overall sensitivity for detecting VTE to greater than 90%. A positive result for either the chest CT scan or leg study mandates anticoagulation. If both chest and leg studies are negative and the clinical probability estimate is low or intermediate, anticoagulation can reasonably be withheld. If both tests are negative but the clinical probability estimate is high, the physician should perform pulmonary angiography. Figure 53.1 shows an algorithm for utilizing spiral contrast chest CT in diagnosing PE. This approach has recently been reviewed in greater detail (7).

Other Tests for Pulmonary Embolism

Ventilation-Perfusion Lung Scanning

The ventilation-perfusion lung scan result is classified as normal, low probability, intermediate probability, or high probability. A normal perfusion lung scan excludes pulmonary embolism. Pulmonary embolism is present in 86%–87% of patients with a high-probability scan and in 30%–34% of patients with an intermediate-probability scan. In two prospective series, patients with a low-probability scan had a 14%–31% incidence of pulmonary embolism (8). Looking at it another way, only 41% of patients with angiographically proven pulmonary embolism have a high-probability scan; an intermediate-probability scan is present in 42%, and a low-probability scan in 16%.

As in CT-scan based algorithms, an estimate of the clinical probability of pulmonary embolism should be combined with the lung scan interpretation to further refine the diagnostic probabilities (see Table 53.1). In patients for whom the lung scan and clinical probability agree (high-probability lung scan and high clinical probability, or low-probability lung scan and low clinical probability), the lung scan is highly accurate, and clinicians will generally assume (high-probability scan) or exclude (low-probability scan) the diagnosis of pulmonary embolus without further testing. When the lung scan probability and clinical probability are discordant, the probability of disease is about 40%–56%, which suggests that additional studies are needed. Additional studies are also needed when the scan is read as intermediate probability because *an intermediate-probability scan has a likelihood ratio of 1* (meaning that the posttest probability is the same as the pretest probability of pulmonary embolism; see Chapter 6).

Venous Studies

Pulmonary embolism and deep venous thrombosis are two manifestations of one illness, VTE. Because patients with pulmonary embolism frequently have deep venous

thrombosis, a commonly used adjunct to the ventilation-perfusion diagnostic algorithm is evaluation of the legs for deep venous thrombosis. In this strategy, duplex ultrasonography is performed in patients with low- or intermediate-probability lung scans. Patients with high-probability lung scans or positive findings on venous studies are treated with anticoagulation therapy. Patients with low- or intermediate-probability lung scans (“nondiagnostic”) and negative initial results on leg ultrasonography undergo a second venous study 4–7 days later. The purpose of this follow-up is to detect the proximal migration of a distal deep venous thrombosis, which may not have been evident on the initial duplex ultrasonogram. If the venous study does not show deep venous thrombosis, the patients are followed. In large studies of patients with normal or nondiagnostic lung scans and negative results on venous studies, the incidence of deep venous thrombosis or pulmonary embolism at 3-month follow-up was approximately 2% (9). Patients with poor cardiovascular reserve were excluded from these studies because of fear that they might not tolerate emboli missed by this diagnostic strategy.

Conventional Pulmonary Angiogram

The demonstration of an intraluminal filling defect by pulmonary angiogram is the “gold standard” diagnostic test for pulmonary embolism. A negative result on pulmonary angiography excludes acute pulmonary embolism in 99.4% of patients. Pulmonary angiography is indicated when (a) the diagnosis is uncertain after CT or lung scanning *and* leg studies, (b) the patient has a high-probability lung scan but is at high risk for bleeding from anticoagulation, and (c) thrombolytic therapy is anticipated.

Complications of pulmonary angiography are uncommon. Death attributable to the procedure occurs in 0.5% of patients. Major complications occur in 1% and include renal failure, bleeding at the puncture site that requires transfusion, and respiratory distress leading to intubation or cardiopulmonary resuscitation. Complications appear to be more common in patients with pulmonary hypertension. Minor complications occur in 5% of patients and include urticaria, pruritus, and mild renal insufficiency.

New Diagnostic Tests

Several new tests are being used to diagnose pulmonary embolism. *Magnetic resonance angiography* appears to be a promising new test for pulmonary embolism. In comparison with standard angiography, its sensitivity ranges from 75%–100% and its specificity from 95%–100% (10). Additional studies in larger numbers of patients from different centers are needed to fully assess the performance of this test. Studies using a whole blood-based assay or a rapid enzyme-linked immunosorbent assay

(ELISA) for D-dimer demonstrate a high negative predictive value of a low or normal D-dimer level. D-dimer assays are most useful in low- to moderate-risk outpatients (11). D-dimer assays are not particularly useful for excluding venous thromboembolism in higher-risk hospital inpatients because the great majority of these patients will have elevated D-dimer levels for nonspecific reasons. In general, a negative D-dimer assay in an outpatient with a low clinical probability of PE is as useful as a normal lung scan (12). The test is further described in Chapter 52.

Diagnostic Strategy Using Ventilation-Perfusion Lung Scanning

Figure 53.2 outlines a widely recommended, more traditional diagnostic strategy based on ventilation-perfusion lung scanning. It begins with a careful history to identify predisposing factors, a physical examination, and initial laboratory tests to determine the pretest probability of disease. A ventilation-perfusion scan is performed next and interpreted in the context of the clinical suspicion of disease. Patients with a high clinical pretest probability and a high-probability ventilation-perfusion scan have a 96% likelihood of disease, and should be treated without further tests. Patients with a high-probability lung scan and a low clinical probability of disease have a 56% likelihood of disease. Patients with a high-probability lung scan and a prior

history of pulmonary embolism have a 75% likelihood of disease (3). These latter two groups of patients should undergo either duplex ultrasonography, CT scanning, or pulmonary angiography to confirm the presence of thromboembolism. If ultrasonography is chosen first and the result is negative, CT scanning or angiography should be performed.

Low- or intermediate-probability scans are best thought of as nondiagnostic. The exception is in those patients with low-probability scans and a low clinical probability of disease, in whom the probability of pulmonary embolism is sufficiently low (2%) that other diagnoses can be pursued. In all other cases of nondiagnostic scans, duplex ultrasonography, CT scanning, or pulmonary angiography should be performed. Because the research evaluating the use of serial negative venous studies excluded patients with significant cardiopulmonary disease, such patients should either go directly to pulmonary angiography or undergo duplex ultrasonography first and then pulmonary angiography if the results of ultrasonography are negative. In patients without cardiopulmonary disease, strategies employing serial duplex ultrasonography or pulmonary angiography are both reasonable. Finally, the diagnostic strategy should be modified in patients who are at high risk for bleeding from anticoagulation or in whom thrombolytic therapy will be used. Pulmonary angiography should be performed on these patients.

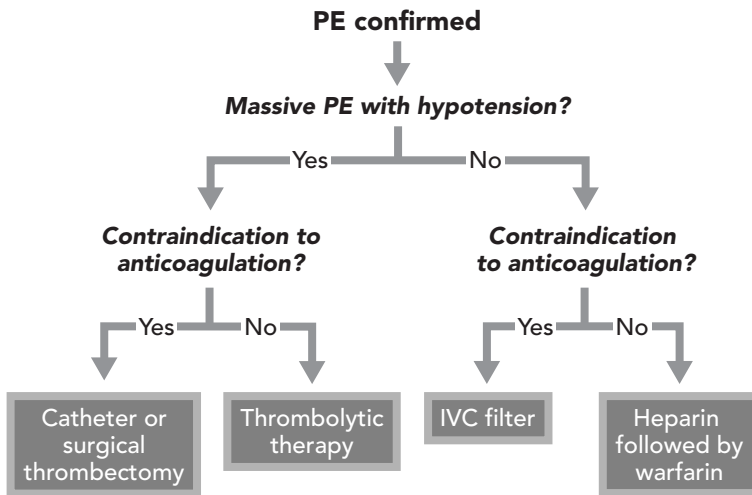

Figure 53.3 Treatment algorithm for pulmonary embolism.

INDICATIONS FOR INTENSIVE CARE UNIT ADMISSION AND CONSULTATION

Patients with hemodynamic instability or severe hypoxia, particularly in the presence of comorbid conditions, should be monitored in the ICU. A pulmonary consultation may be helpful, particularly if ventilatory or vasopressor support is anticipated.

INITIAL THERAPY

Intravenous (IV) heparin should be started immediately, even before a definitive diagnosis is made, if there is no contraindication to anticoagulation. The goal of heparin therapy is to prevent the recurrence or continued growth of thrombi. Heparin does not prevent embolism or promote thrombus resolution. Thrombolytic therapy is reserved for patients with hemodynamic compromise resulting from

massive pulmonary emboli. A vena cava filter is indicated when anticoagulation is contraindicated or unsuccessful (Figure 53.3).

Unfractionated heparin is administered by continuous IV infusion after an initial bolus of 80 units/kg. The activated partial thromboplastin time (aPTT) is measured 6 hours later, and the heparin dose is adjusted to maintain the aPTT at 1.5 to 2 times normal. A weight-based nomogram (Table 53.2) should be used to choose the dose because studies demonstrate that using the old standard dose of 1,000 units/h usually results in subtherapeutic aPTT values (13). Moreover, because aPTT values vary from site to site, every laboratory should establish target aPTT values that correspond to therapeutic anti-Xa heparin levels (Chapter 98). If the aPTT is subtherapeutic after the initial heparin bolus and infusion, the infusion is increased after a repeated bolus. *Heparin-induced thrombocytopenia* occurs in approximately 3% of patients who receive heparin for at least 7 days and can lead to arterial and venous thrombosis. The

TABLE 53.2
WEIGHT-BASED NOMOGRAM FOR UNFRACTIONATED HEPARIN ADMINISTRATION

	Dose change (U/kg per hour)	Additional action
Initial dose	18 U/kg per hour	Bolus 80 U/kg
aPTT results after 4–6 hours:		
<35 (<1.2 × control)	Increase 4 U/kg	Repeat bolus 80 U/kg
35–45 (1.2–1.5 × control)	Increase 2 U/kg	Repeat bolus 40 U/kg
46–70 (1.5–2.3 × control)	No change	None
71–90 (2.3–3.0 × control)	Decrease 2 U/kg	None
>90 (>3 × control)	Decrease 3 U/kg	Hold infusion for 1 hour

aPTT, activated partial thromboplastin time.
From Raschke RA, Reilly BM, Guidry JR, Fontana JR, Srinivas S. The weight-based heparin dosing nomogram compared with a “standard care” nomogram. *Ann Intern Med* 1993;119:874–881, with permission.

thrombocytopenia usually appears between days 5 and 9 of therapy, but a delayed-onset variant can appear after heparin has been discontinued (14). Heparin is associated with mild liver enzyme elevations after 5–10 days of treatment. Long-term use of heparin can lead to osteoporosis and can rarely cause hyperkalemia from hypoaldosteronism.

Warfarin should be started on the day of diagnosis. Warfarin reduces protein C levels (an inhibitor of coagulation) more quickly than it reduces factors II, IX, and X and may create a relative hypercoagulable state for the first 4 days. For this reason, warfarin should not be started until after heparin has been administered (although it is not necessary to wait for a therapeutic aPTT), and heparin is continued at least for 5 days, even if the prothrombin time is within the therapeutic range sooner. A 5-mg loading dose of warfarin should generally be used instead of 10 mg because 5 mg produces less excess anticoagulation (15). Heparin is discontinued when the prothrombin time has been in the therapeutic range (international normalized ratio [INR] of 2 to 3) for 2 days. Table 53.3 provides a warfarin dosing protocol.

Recent evidence suggests that *low-molecular-weight heparin* is an effective and safe alternative to unfractionated IV heparin in the treatment of pulmonary embolism (16,17).

TABLE 53.3
ORAL ANTICOAGULATION WITH WARFARIN

Day	INR	Warfarin dose
1		5.0 mg
2	<1.5	5.0 mg
	1.5–1.9	2.5 mg
	2.0–2.5	1.0–2.5 mg
	>2.5	0.0
3	<1.5	5.0–10.0 mg
	1.5–1.9	2.5–5.0 mg
	2.0–3.0	0.0–2.5 mg
	>3.0	0.0
4	<1.5	10.0 mg
	1.5–1.9	5.0–7.5 mg
	2.0–3.0	0.0–5.0 mg
	>3.0	0.0
5	<1.5	10.0 mg
	1.5–1.9	7.5–10.0 mg
	2.0–3.0	0.0–5.0 mg
	>3.0	0.0
6	<1.5	7.5–12.5 mg
	1.5–1.9	5.0–10.0 mg
	2.0–3.0	0.0–7.5 mg
	>3.0	0.0

Initial dose is 5 mg (7.5 mg for patients >85 kg). For inpatients, INR should be monitored daily; any increase >0.3–0.4 U/d should result in warfarin dose reduction.

INR, international normalized ratio.

From Harrison L, Johnston M, Massicotte MP, Crowther M, Moffat K, Hirsh J. Comparison of 5 mg and 10 mg loading doses in initiation of warfarin therapy. *Ann Intern Med* 1997;126:133–136; and Crowther MA, Harrison L, Hirsh J. Warfarin: less may be better. *Ann Intern Med* 1997;127:332–333, with permission.

This class of drugs has the advantages of not requiring aPTT monitoring and of being administered by subcutaneous injection once or twice per day. However, it costs more and has a longer half-life, and its effects cannot be completely reversed by protamine, features which make it less attractive than unfractionated heparin for routine use in hospitalized patients with complicated disease. Whether stable patients with pulmonary embolism can be managed as outpatients on low-molecular-weight heparin has not yet been clearly demonstrated, and at this time patients with pulmonary embolism are nearly always hospitalized. However, an outpatient treatment strategy (if proved safe and effective) would save considerable resources and is used in low-risk patients in some settings (18). The risks for bleeding, recurrent disease, and death are comparable to those of unfractionated heparin. Thrombocytopenia occurs less frequently with low-molecular-weight than with unfractionated heparin, but low-molecular-weight heparin is contraindicated in patients with thrombocytopenia caused by unfractionated heparin because of cross-reactivity between the two types of heparin. There are limited data contrasting the various low-molecular-weight heparin preparations (Chapter 98).

Thrombolytic therapy should be considered (in the absence of contraindications) for patients with massive pulmonary embolism complicated by hypotension. Efforts to enlarge the indications for thrombolytic therapy in pulmonary embolism have been hampered by the higher incidence of major bleeding associated with lytic therapy and the lack of a proven survival benefit. A recent study that proposed wider indications for thrombolytic therapy in PE reported a very low bleeding rate that has not generally been matched in the clinical use of alteplase (19). If possible, patients should first undergo pulmonary angiography to document the presence of disease even though bleeding often occurs at the puncture site. Thrombolytics reduce pulmonary artery pressure and improve pulmonary artery perfusion within 2 hours. Within 5 days of treatment, however, the perfusion of patients receiving heparin (as measured by lung scan) is equal to the perfusion of patients receiving thrombolytic treatment. The studies evaluating thrombolytics have been too small to demonstrate reduced mortality, and there are limited data comparing different drugs and doses (Table 53.4).

Absolute contraindications to thrombolytics include active internal bleeding, stroke or other active intracranial process within 2 months, and surgery within 10 days. Although a number of other relative contraindications exist, thrombolytic therapy is a potentially life-saving measure in the context of a massive pulmonary embolism and hypotension. In this setting, if thrombolytics are contraindicated, transvenous catheter embolectomy should be tried (20). Surgical embolectomy is indicated only as a last resort, and even then only if the clot is located in a surgically accessible site.

TABLE 53.4
ANTICOAGULANTS USED TO TREAT PULMONARY EMBOLISM

Drug	Dose	Cost ^a
Unfractionated heparin	Weight-based (Table 53.2)	\$5–\$7 daily
Low-molecular-weight heparin		
Dalteparin (Fragmin)	100 U/kg twice daily	\$51 daily
Enoxaparin (Lovenox)	1 mg/kg twice daily	\$55 daily
Nadroparin (Fraxiparin)	90 U/kg twice daily	NA
Tinzaparin (Logiparin)	175 U/kg once daily	\$41 daily
Thrombolytic agents		
Streptokinase (Streptase)	250,000 IU loading dose 100,000 IU/h for 24 h	\$904–\$1,228 per course
Urokinase (Abbokinase)	4,400 IU/kg loading dose 4,400 IU/kg/h for 12 h	\$5,460 per course
Alteplase/tissue plasminogen activator (Activase)	100 mg over 2 h or 40 mg over 2 min	\$2,750 per course \$1,100 per course
Warfarin sodium (Coumadin)	5 mg loading dose (Table 53.3) Maintenance dose varies	\$0.57 daily

^a Cost based on average wholesale price, May 1998.
 NA, not approved in the United States.

Inferior vena cava filters are indicated for patients with (a) deep venous thrombosis or pulmonary embolism when anticoagulation is contraindicated, (b) recurrent thromboembolism despite adequate anticoagulant therapy, and (c) deep venous thrombosis or pulmonary embolism and such severe concomitant cardiopulmonary disease that a subsequent embolus might be fatal.

Several types of inferior vena cava filters are available; the best known are the Greenfield and the Bird's Nest. Both are placed IV into the inferior vena cava to prevent a clot from passing from the lower-extremity venous system into the pulmonary circulation. Mortality from filter insertion is rare. Complications are unusual; they include misplacement, air embolism, hematoma, infection, pneumothorax, filter migration, and deep venous thrombosis. In one clinical trial, prophylactic insertion of filters in patients with proximal deep venous thrombosis reduced the risk for pulmonary embolism but nearly doubled the risk for recurrent deep vein thrombosis (21). Therefore, in the absence of a contraindication, anticoagulation therapy should be initiated after insertion of the filter.

ISSUES DURING THE COURSE OF HOSPITALIZATION

The first few hours after presentation are the most critical. Diagnostic tests should be promptly conducted and anticoagulation initiated without delay. Patients with massive pulmonary embolism may die within hours of the onset of

symptoms; the overall in-hospital mortality rate is about 10% (1). Pulmonary embolism recurs in about 8% of patients within 1 year of diagnosis and is associated with a 45% mortality rate. Only 2.5% of patients with pulmonary embolism die of the embolism itself; most deaths occur in patients with recurrent disease and are caused by underlying diseases such as cancer and infection (1).

Although they vary a great deal depending on size and location, pulmonary emboli begin to resolve within 24 hours on average, and by 2 weeks 50% of perfusion has returned. Clinical improvement should parallel the perfusion changes, with significant improvement seen by day 2 or 3. The symptoms and signs in a patient not improving include continued or worsening dyspnea, new chest pain, fever, tachycardia, and hypoxia. Failure to improve after 2 to 3 days of therapy suggests the possibility of recurrent pulmonary embolism, worsening of the underlying disorder (i.e., congestive heart failure), bleeding, or development of a new problem, such as pneumonia or myocardial infarction. Arterial blood gases, hemoglobin level, and aPTT should be determined, and a chest radiograph and electrocardiogram should be obtained. The diagnosis of recurrent pulmonary embolism is demonstrated by the finding of a new perfusion defect on lung scan or a new intraluminal filling defect on pulmonary angiogram or chest CT scan. It is important to diagnose recurrent pulmonary embolism promptly because the insertion of an inferior vena cava filter is indicated in patients who have failed anticoagulation. Even in the absence of a recurrence, the condition of a patient who was initially hemodynamically stable may

deteriorate so that the patient becomes a candidate for thrombolytic therapy.

There is an increased incidence of cancer in the first 6 months after the diagnosis of VTE (with 40% of cancers having distant metastases) (22). Such cancers can usually be identified by a thorough history, physical examination, and routine laboratory studies. See Chapter 98 for a fuller discussion of hypercoagulable states.

DEVELOPMENT OF PULMONARY EMBOLISM IN THE HOSPITAL

The presentation of pulmonary embolism may be quite subtle in the postoperative or hospitalized patient; as a result, the diagnosis will be missed unless consciously considered. The majority of patients in whom an embolism develops during their hospital stay are not receiving adequate thromboembolic prophylaxis. A typical patient presents several days after orthopedic, oncologic, or neurologic surgery or after admission for congestive heart failure, stroke, or pneumonia. The diagnostic workup and treatment are identical to those for patients presenting to the hospital. However, thrombolytic therapy is contraindicated in patients who have recently undergone surgery.

General issues regarding prophylaxis for deep venous thrombosis and pulmonary embolism are covered in Chapter 52.

DISCHARGE ISSUES

Stable patients can be discharged from the hospital on warfarin therapy once the INR is 2 to 3, or 48 hours after an inferior vena cava filter has been placed. The patient should be seen in the office within 2 weeks to evaluate clinical status, review current medications, emphasize the need for regular measurement of the INR, and reinforce that new medications must not be taken without speaking to the doctor. Patients and physicians should be aware of the many medications that can interact with warfarin (Table 53.5). The duration of warfarin therapy varies, depending on the presence of ongoing predisposing factors and whether the thromboembolic event was the first or recurrent; however, recent research supports longer treatment courses for many patients (23) (Chapter 52).

Two strategies designed to shorten hospital stay can be considered in stable patients who are otherwise healthy. First, a patient might be transferred to a subacute facility to continue IV unfractionated heparin therapy until the prothrombin time is therapeutic. Alternatively, some patients can be discharged home after a switch from IV unfractionated heparin to low-molecular-weight heparin a few days into the hospitalization, or even treated completely on an

TABLE 53.5

DRUGS THAT ALTER ANTICOAGULANT RESPONSE TO WARFARIN^a

Prothrombin time increased by

Antimicrobials

- Ciprofloxacin
- Erythromycin
- Isoniazid
- Metronidazole
- Fluconazole
- Itraconazole
- Ketoconazole

Analgesics

- Piroxicam

HMG CoA reductase inhibitors

- Any "statin" (e.g., lovastatin or simvastatin)

Antiarrhythmics

- Amiodarone
- Propafenone

Sulfa agents

- Disulfiram
- TMP/SMX

Miscellaneous

- Omeprazole
- Cimetidine
- Clofibrate

Prothrombin time decreased by

Agents that induce cytochrome P-450

- Barbiturates
- Carbamazepine
- Rifampin

Vitamin K

- Polyvitamin preparations

Miscellaneous

- Griseofulvin
- Nafcillin
- Bile resins (e.g., cholestyramine)
- Sucralfate
- Dicloxacillin

Warfarin interacts with coagulation factors that are dependent on vitamin K. Any disease state or drug therapy that affects vitamin K will also affect warfarin response.

Drugs that affect platelet function (e.g., aspirin, ticlopidine, NSAIDs, and the anti-GP IIb/IIIa inhibitors) may increase the risk for bleeding when used in conjunction with warfarin.

Warfarin should not be administered during pregnancy.

^a This list is not all-inclusive. It is recommended that the INR be

checked after any drug therapy is initiated or modified.

GP, glycoprotein; INR, international normalized ratio; TMP/SMX, trimethoprim/sulfamethoxazole.

Table courtesy of Steve Kayser, Pharm.D., and Julie Hambleton, M.D., with permission.

outpatient basis. In either case, low-molecular-weight heparin is discontinued once the prothrombin time is therapeutic on warfarin. Preliminary evidence suggests that some patients with both deep venous thrombosis and pulmonary embolism can be safely treated at home with low-molecular-weight heparin (24), but more research is needed before outpatient therapy can be recommended as standard treatment for pulmonary embolism (18).

The long-term prognosis depends on the patient's underlying medical problems. The 1-year mortality rate is about 24% (1). The conditions associated with increased 1-year mortality in patients with pulmonary embolism are malignancy, left-sided congestive heart failure, and chronic lung disease.

COST CONSIDERATIONS

The drug costs of low-molecular-weight heparin are 10 times those of unfractionated heparin. The early-discharge strategies previously described (to a subacute facility for continued IV heparin or to home for low-molecular-weight heparin) are relatively untested but have the potential to reduce both hospital length of stay and cost. It is important to determine whether the patient's insurance plan will pay for outpatient treatment with low-molecular-weight heparin or for subacute rehabilitation.

KEY POINTS

- The signs and symptoms of pulmonary embolism are nonspecific. However, 97% of patients with pulmonary embolism have one or more of the following symptoms: dyspnea, pleuritic chest pain, or tachypnea.
- Normal findings on a perfusion lung scan effectively exclude important pulmonary embolism. Pulmonary embolism is present in 86%–87% of patients with a high-probability scan and in 14%–31% of patients with a low-probability scan.
- Only 41% of patients with pulmonary embolism have a high-probability ventilation-perfusion lung scan. An intermediate-probability scan is present in 42%, and a low-probability scan in 16%.
- A negative spiral CT scan coupled with a negative leg study (either duplex ultrasound or “CT venogram”) identifies a patient at low risk for venous thromboembolism. It appears that anticoagulation can be withheld in these patients.
- Pulmonary embolism and deep venous thrombosis are two manifestations of one illness, venous thromboembolism, and a commonly used diagnostic strategy includes evaluation of the legs for deep venous thrombosis.
- A weight-based algorithm should be used to choose the dose of intravenous heparin because studies demonstrate that using a fixed dose of 1,000 U/h usually results in a subtherapeutic activated partial thromboplastin time. The role of low-molecular-weight heparin in the treatment of pulmonary embolism is still being defined.
- A 5–10 mg loading dose of warfarin should be used instead of higher doses because the 5–10 mg dose produces less excess anticoagulation.

- Chest Radiograph 527

INTRODUCTION

Technology has drastically transformed the evaluation and diagnosis of pulmonary disease. During the past 20 years, bronchoscopy, computed tomography (CT), and nuclear medicine studies have greatly advanced our ability to see within the chest. More recently, spiral CT has become an important tool in the diagnosis of pulmonary embolism (Chapter 53), and high-resolution CT has enhanced our ability to assess interstitial lung disease (Chapter 57). Positron emission tomography (PET) is

becoming an important noninvasive method of staging mediastinal lymph nodes in lung cancer and is having an impact on the evaluation of solitary pulmonary nodules (Chapter 61).

Despite these advances, excellence in history taking and physical examination remains extremely important in pulmonary medicine. Like the skin and gastrointestinal tract, the lungs function mainly to interface with the environment. This fact makes the occupational, substance abuse, and travel history vital parts of the initial patient assessment. The control of respiration during sleep has a great effect on daily life and activity, and disorders of sleep and obstructive apnea are extremely common and increasingly recognized. This chapter describes several basic signs, symptoms, and laboratory abnormalities in pulmonary disease and provides a general framework for their evaluation.

SIGNS

The physical examination of the chest is an important element in diagnosing respiratory disease. Signs elicited on examination, such as crackles or dullness to percussion, when combined with other findings, can be invaluable in

assessing a patient with respiratory symptoms. Given the nonspecific nature of the signs discussed in this chapter, the approach to most signs is the same whether they are present on admission or emerge during a hospitalization. Therefore, we focus on differential diagnosis rather than on the timing of presentation. Various disease entities present with a pattern of individual signs (see Table 54.1).

Crackles

When Crackles Are Present at the Time of Admission

Description and Differential Diagnosis

The American Thoracic Society has adopted the term *crackles* to describe what was previously referred to as *rales* or *crepitations* (1). Crackles are adventitious lung sounds that are discontinuous in nature. They are often described as short, explosive sounds that are nonmusical in quality. When fluid is present inside an airway and there is distal collapse of the alveoli, a crackle can be generated from the sudden opening of many small airways with the equalization of pressure that occurs during normal breathing (2). Crackles can be fine or coarse, early or late, and inspiratory or expiratory. Coarse crackles are produced from larger airways and finer crackles from smaller ones. Crackles are present in a variety of disorders, including bronchitis, pneumonia, pulmonary edema, atelectasis, and fibrosis. Pulmonary edema resulting from congestive heart failure (CHF) often yields early, fine crackles, whereas pulmonary fibrosis produces late, fine crackles. Late, coarse crackles are a common feature of pneumonia.

Evaluation

A thorough history and physical examination, in addition to a chest radiograph, can be helpful in determining the etiology of crackles heard on auscultation. Fevers, productive cough, dyspnea, and leukocytosis in conjunction with a chest radiograph demonstrating parenchymal consolidation are consistent with pneumonia. Orthopnea, elevated

jugular venous pressures, a third heart sound (S_3), and pedal edema in the face of a chest radiograph revealing perihilar interstitial infiltrates suggest pulmonary edema. When the diagnosis is not clear, further evaluation may be required to establish the etiology of crackles. For example, pulmonary function tests and high-resolution CT may be needed to diagnose pulmonary fibrosis (Chapter 57).

Management

Management depends on the etiology of the process generating the abnormality.

When Crackles Appear During Hospitalization

The differential diagnosis for crackles appearing during the course of hospitalization is identical to that for crackles present on admission. Nosocomial or aspiration pneumonia and fluid overload resulting in pulmonary edema are common complications during hospitalization that can give rise to crackles. The evaluation of the patient with crackles that develop during hospitalization is also similar to the admission evaluation. Attention should be paid to possible iatrogenic causes of crackles (e.g., fluid overload, inadequate diuresis, or oversedation leading to aspiration). Depending on the diagnosis, therapy may entail diuresis or antibiotics (the latter directed toward gram-negative organisms for nosocomial pneumonias or mixed aerobic and anaerobic organisms for aspiration pneumonias).

Wheezes

When Wheezes Are Present at the Time of Admission

Description and Differential Diagnosis

Wheezes are produced when airways are narrowed to the point of closure and the opposing walls begin to vibrate (3). The pitch of the sound depends on rate of flow of air and is independent of the length or caliber of the airway.

TABLE 54.1
PHYSICAL SIGNS OF COMMON PULMONARY DISEASES

Disease	Tracheal deviation	Percussion	Tactile fremitus	Crackles
Pneumothorax	Away or none	Hyperresonant	Decreased	None
Asthma	None	Normal (or hyperresonant if severe air trapping)	Normal or decreased	None
Atelectasis	Toward or none	Dull	Increased	None or few
Pneumonia	None	Dull	Increased	Present
Pleural effusion	Away or none	Dull	Decreased	None

Wheezing is indicative of bronchospasm. Although asthma is the most common cause of wheezing, *“all that wheezes is not asthma.”* Generalized wheezing on examination can indicate exacerbation of chronic obstructive pulmonary disease (COPD), aspiration, pulmonary edema, pulmonary embolism (transient bronchospasm caused by release of local mediators of inflammation), or anaphylaxis. Upper airway wheezing, or stridor, can be caused by laryngospasm, a laryngeal or tracheal tumor, epiglottitis, foreign body aspiration, or vocal cord dysfunction. Localized wheezing can result from airway tumors, mucous plugging, or foreign body aspiration.

Evaluation

The degree of respiratory distress accompanying the wheezing guides the pace of the evaluation. If the patient presents with respiratory failure, it is necessary to proceed urgently with intubation (Chapter 24). Establishing adequate oxygenation and ventilation is paramount. A chest radiograph can help determine the cause of generalized wheezing if it shows consolidation or pulmonary edema. The presence of an aspirated foreign body may explain a unilateral wheeze. A patient with localized wheezing and negative chest radiographic findings may benefit from a chest CT, which can better visualize the area in question. Bronchoscopy may be necessary to rule out an airway lesion. If stridor is present, an ear, nose, and throat (ENT) consultation is recommended to evaluate the upper airway; if the patient is clinically stable, pulmonary function tests with flow-volume loops can be obtained to determine the presence of intrathoracic or extrathoracic obstruction, which may be the cause of upper airway wheezing.

Management

Again, the management of wheezing depends on the etiology of the wheeze. If stridor is present and the patient shows signs of respiratory compromise, immediate treatment with intravenous (IV) methylprednisolone, nebulized racemic epinephrine, and possible intubation is vital. ENT consultation should be obtained. If the wheezing is caused by an exacerbation of obstructive lung diseases such as asthma or emphysema, β_2 -agonist nebulizers and steroids, if necessary, can be administered (Chapters 55 and 56). Pulmonary edema can be treated with diuretics and afterload reduction (Chapter 39). If foreign body aspiration is the suspected etiology of the wheeze, the method of retrieval depends on where the object is lodged. A pulmonary consultant can assist with extraction.

When Wheezes Appear During Hospitalization

Exacerbations of COPD can develop in patients who are hospitalized for other reasons. Anaphylaxis is important to consider, and foreign body aspiration may occur, especially after oral instrumentation (e.g., endoscopy or bron-

choscopy). Pulmonary embolism should always be included in the differential diagnosis. Evaluation of wheezing is similar whether it presents during hospitalization or at the time of admission; therefore, the etiology of the wheeze should guide the management.

Dullness

When Dullness Is Present at the Time of Admission

Description and Differential Diagnosis

Percussion over normal lung should produce a resonant, high-amplitude, low-pitched sound. Dullness may normally be elicited between the third and fifth intercostal spaces to the left of the sternum, an area that correlates with the position of the heart anteriorly. Dullness to percussion elsewhere indicates a barrier of the lung's ability to transmit sound from the alveoli, either because the alveoli are filled with something other than air or the alveolar units are compressed. Dullness usually indicates pneumonia, pleural effusion, atelectasis, a large intrathoracic mass, or an elevated hemidiaphragm.

Evaluation

A chest radiograph is the most helpful way to evaluate dullness uncovered on physical examination, as it can reveal consolidation, elevation of the hemidiaphragm, or pleural effusion. A chest CT is standard in the evaluation of an intrathoracic mass. Diaphragm movement can be elicited by checking for dullness during a respiratory cycle. During inspiration, the diaphragm moves downward, allowing for resonance on percussion in the lower lung fields. On expiration, the diaphragm and liver move upward, resulting in dullness to percussion in the previously resonant areas. Normal diaphragmatic movement is approximately 4 cm. Failure of hemidiaphragm movement can be confirmed with a *“sniff” test*. Patients are asked to sniff deeply while their diaphragmatic movement is visualized under fluoroscopy. Absence of movement indicates diaphragmatic paralysis, which is most often a consequence of phrenic nerve palsy. Causes of unilateral diaphragmatic paralysis include direct trauma, postoperative complications, mechanical compression (substernal thyroid, vascular aneurysm), sequelae of mediastinal infection (bacterial, viral, syphilitic, or tuberculous), malignancy, or neuropathy. Quite often, the cause is idiopathic.

Management

The management of dullness to percussion elicited on physical examination depends on the underlying cause. If a pleural effusion is present, bilateral decubitus films should be obtained to determine whether the effusion is free flowing and to evaluate the parenchyma that is obscured by the effusion. Thoracentesis should be performed if there are no

relative contraindications (such as if the effusion is very small or an underlying bleeding disorder is present) (Chapter 60). If unilateral diaphragmatic paralysis is present and malignancy is not the etiology, the patient may be referred for plication of the hemidiaphragm. If bilateral diaphragmatic paralysis is present, therapy depends on the underlying cause. If an injury has occurred in the cervical region, diaphragmatic pacing may be an option. Nocturnal ventilation may be considered in those with neuromuscular disease.

When Dullness Appears During Hospitalization

The diagnoses to be considered for dullness noted on physical examination during hospitalization are the same as for dullness present on admission. Evaluation and management should be the same as described earlier.

Tactile Fremitus

When Abnormal Tactile Fremitus Is Present at the Time of Admission

Description and Differential Diagnosis

Sound from the larynx creates vibrations that are conducted through the bronchi to the lung parenchyma and chest wall. These palpable vibrations are known as tactile fremitus (3). Tactile fremitus is elicited by placing the ulnar side of the hand against the chest wall and having the patient say “ninety-nine” as the entire chest wall is examined. Conditions such as pneumonia or atelectasis increase lung density and increase the transmission of sound waves, thereby increasing tactile fremitus. Pneumothorax, pleural effusion, bronchial obstruction, or chest wall thickening (from muscle or fat) decrease sound wave transmission, thus reducing tactile fremitus.

Evaluation

The finding of increased or decreased tactile fremitus can help distinguish consolidation from pneumothorax or pleural effusion (see Table 54.1). The signs can be misleading, however, so examination findings should be confirmed with a chest radiograph. Although decreased tactile fremitus can represent pleural effusion, there may be a small area of increased tactile fremitus at the top limit of the effusion that represents atelectatic lung. Tactile fremitus, along with dullness to percussion, can therefore allow approximation of the level of the effusion.

Management

If a pneumothorax is small (<15% of the hemithorax) and the patient is not short of breath, then a chest tube is not indicated. Further management is described in Chapter 60. Often, if a pleural effusion is present and free flowing (as demonstrated by decubitus films), both tactile

fremitus and dullness to percussion can establish the fluid level so that a thoracentesis can be performed. If there is any evidence of loculation or a question regarding the size of the effusion, either ultrasonography or CT of the chest should be obtained before any invasive procedure is performed.

Cyanosis

When Cyanosis Is Present at the Time of Admission

Description and Differential Diagnosis

Cyanosis can occur when blood is inadequately oxygenated or when it becomes deoxygenated in areas of venous stasis. The blue-gray discoloration of cyanosis in the lips, buccal mucosa, nail beds, ears, malar regions, and skin is *central cyanosis*. This finding indicates insufficient oxygenation from any of various causes: transbronchial obstruction, alveolar barriers (asthma, atelectasis, pulmonary edema), defective alveoli (emphysema, pulmonary fibrosis, pneumonia), inefficient circulation (pulmonic stenosis, right-to-left shunts, arteriovenous malformations), nonoxygenated hemoglobin (methemoglobinemia, hemoglobinopathies), and hypoventilation resulting from conditions such as the obesity-hypoventilation syndrome. *Peripheral cyanosis*, in which cyanosis is found in an extremity, is predominantly caused by an increased circulatory time of deoxygenated blood secondary to low cardiac output or vasoconstriction. In central cyanosis, the skin is warm and oxygen corrects the cyanosis. In peripheral cyanosis, the skin is cool and supplemental oxygen may only marginally improve cyanosis. If the patient appears to have central cyanosis and supplemental oxygen does not correct the cyanosis, methemoglobinemia should be considered.

Evaluation

Because cyanosis is not a reliable indicator of hypoxemia, arterial blood gases should be measured, and oxygen should be administered. Cyanosis can be seen when the arterial oxygen pressure (PaO₂) drops below 60 mm Hg, but it may be nearly impossible to detect in dark-skinned patients. Evaluation should be directed toward uncovering the cause of the hypoxemia. The history and constellation of other findings noted on examination can help distinguish inadequate oxygenation from pneumonia, atelectasis, or pulmonary fibrosis from nonpulmonary causes. An echocardiogram can detect valvular abnormalities or the presence of right-to-left shunts (Chapter 36). A history of daytime somnolence, lethargy, and apnea during sleep with polycythemia or CHF suggests a hypoventilation syndrome. Polysomnography is indicated to make the diagnosis. Patients with methemoglobinemia typically have pulse oximetry readings of about 85%. Arterial blood gas testing can detect the percentage of methemoglobinemia.

Management

Oxygen therapy should be the first step in managing the cyanotic patient. However, if the patient has *obstructive sleep apnea*, oxygen should be supplied with caution because it can aggravate the degree of nocturnal hypoventilation and further elevate carbon dioxide levels by removing hypoxic ventilatory drive. If a patient becomes more somnolent after supplemental oxygen therapy, blood gases should be measured to assess the level of hypercapnia. Patients may have compensated for hypoxemia during the course of months and may suddenly decompensate on oxygen therapy. In these cases, the target oxygen saturation may be only 90%. The use of continuous positive airway pressure, most often nocturnally, can help decrease carbon dioxide levels, daytime somnolence, morning headache, and polycythemia and pulmonary hypertension.

If *methemoglobinemia* is present, offending drugs should be eliminated. These include nitrates, nitroprusside, chlorates, sulfonamides, antimalarials, and dapsone. High levels of oxygen therapy should be instituted. In addition, 1 to 2 mg of methylene blue per kilogram should be given IV over 5 minutes if hypoxia is present or if the level of methemoglobinemia is above 30%. The dose can be repeated in 1 hour and then every 4 hours for a total dose of 7 mg/kg.

When Cyanosis Appears During Hospitalization

Cyanosis arising during hospitalization is often a consequence of inadequate gas transfer secondary to a pulmonary process that develops or worsens, such as pneumonia. It also is caused by conditions that can decrease cardiac output and increase vasoconstriction, such as cardiogenic shock. A blood gas determination, chest radiograph, and echocardiogram can be used to evaluate pulmonary and cardiac disease. Again, oxygen administration is key if cyanosis is detected.

SYMPTOMS

Cough

When Cough Is Present at the Time of Admission

Description and Differential Diagnosis

Cough is a common complaint. It is caused by activation of a series of reflexes mediated between receptors in the larynx and tracheobronchial tree and the medullary cough center (4). This reflex complex, transmitted by the vagus nerve, is designed to expel foreign bodies or excessive secretions and occurs after inspiration with a sudden contraction of the respiratory musculature and opening of a closed glottis. Cough can signify allergic, pulmonary, laryngeal, or cardiac

processes. Although the differential diagnosis is broad, multiple studies have shown that approximately 95% of chronic cough cases are caused by postnasal drip syndromes, asthma, gastroesophageal reflux disease, chronic bronchitis, bronchiectasis, eosinophilic bronchitis, or angiotensin-converting enzyme inhibitor use. The remaining 5% of cases are caused by other diseases such as bronchogenic cancer, sarcoidosis, left-ventricular failure, and aspiration secondary to pharyngeal dysfunction. Causes for chronic cough can be established in 88%–100% of cases, and specific therapies are successful in 84%–98% of these cases (5).

The character of the cough may help elucidate its etiology. A dry, nonproductive cough may suggest an alveolar process without central mucous production and is typical of hypersensitivity pneumonitis, connective tissue disease with pulmonary involvement, or interstitial lung disease. Pink, frothy sputum classically suggests decompensated CHF. Thick, green sputum can signify infection, inflammation, or both. Cough in the setting of wheezing suggests obstructive disease, but the combination of cough and wheeze is not specific for COPD; cardiac asthma and pulmonary embolus should be considered. Rarely, tympanic membrane irritation can trigger cough.

Chronic cough *per se* will rarely be a reason for hospital admission. However, cough can have several side effects, some of which may necessitate admission (e.g., syncope or hemoptysis). Recurrent paroxysms can occasionally fracture ribs in debilitated patients or in those with metastatic cancer. Prolonged paroxysms interrupt normal ventilation and can lead to desaturation in patients with poor pulmonary reserve.

Evaluation

Abnormal vital signs, such as fever with hypoxia, point to the diagnosis of pneumonia, and tachypnea suggests compensation for a primary pulmonary process. Physical examination of the ears, nose, and throat should be performed to assess for any abnormalities to suggest sinus disease or tympanic membrane irritation as a cause of cough. Absence of a gag reflex may suggest increased susceptibility to aspiration. Examination of the neck to determine jugular venous distention, tracheal shift, or thyroid enlargement is important. Full cardiac and pulmonary examinations should be performed on all patients to look for consolidation (egophony, fremitus), obstruction, or effusion. A chest radiograph should be obtained in most patients with persistent cough, and determination of oxygen saturation is routine. Evidence of bronchospasm should be followed with peak flow measurements and bedside spirometry, with serial repetitions of peak flow measurement performed to chart a trend if the findings are initially abnormal.

Patient demographics are important in the evaluation of a cough. Patients with risk factors for and associated symptoms of tuberculosis (weight loss, hemoptysis, night sweats, fatigue) should be identified; such patients should

be isolated pending the return of three sputum smears for acid-fast bacilli (Chapter 67). If patients are producing sputum, it is important to acquire an adequate sample before antibiotics are administered, as the yield for detecting a dominant organism drops dramatically afterward. Standard criteria for an adequate specimen (>25 polymorphonuclear leukocytes, <10 epithelial cells per low-power field) should be followed before sending a specimen for bacterial culture. A suspicion of *Pneumocystis jirovecii* pneumonia (HIV risk factors, dyspnea, interstitial process on chest radiograph, hypoxia) should prompt sputum induction and a search for organisms. Other special tests in the evaluation of cough may include esophageal pH monitoring (to look for reflux, which can induce bronchospasm and cough), chest CT to rule out bronchiectasis, or sinus CT to rule out sinusitis. The decision to perform these tests is based on clinical suspicion, which rises when a diagnosis is not determined through initial studies.

Management

Cough should be aggressively treated because it is extremely uncomfortable for hospitalized patients and can interfere with eating and sleeping. Cough after abdominal or thoracic surgery is particularly painful and, if excessive, can threaten suture lines. Nocturnal cough may signal postnasal drip, and decongestants can provide relief if sinus disease is the culprit. Similarly, esophageal reflux disease can be relieved by elevating the head of the bed and administering antacids, histamine₂ blockers, or proton pump inhibitors (Chapter 79). Suspicion of cough induced by angiotensin-converting enzyme inhibitors should prompt discontinuation or replacement. Cardiogenic cough is frequently relieved quickly with diuresis, oxygen, and low-dose morphine. For other coughs, the standard combination of dextromethorphan and guaifenesin is adequate for mild symptoms. All opiates are effective antitussives, but sedation, constipation, or nausea may ensue. Many patients, even those without a history of asthma, have temporary bronchoconstriction during an acute infection, and bronchodilators will often provide relief from cough. Suspicion of bronchospasm should be confirmed with peak flow measurement. Smoking cessation should be discussed and may decrease cough from tobacco-related diseases.

When Cough Appears During Hospitalization

Description and Differential Diagnosis

Cough as a new symptom in the inpatient setting is cause for concern. Nosocomial pneumonia is a constant threat (Chapter 66). Drug reactions, aspiration after administration of sedatives, and precipitation of CHF by volume overload are all common scenarios. Nasal cannulae for administration of oxygen and nasogastric or nasogastric tubes can be irritating to the sinuses and precipitate nasotracheal secretions and cough.

Of particular concern is cough that develops or worsens after procedures such as central line placement, chest tube placement or withdrawal, bronchoscopy, and extubation. In all these situations, one must be concerned about and exclude an iatrogenic complication.

Evaluation

Pneumothorax or new infiltrates should be ruled out with a chest radiograph, and a history of associated pleuritic chest pain, dyspnea, or fever should be noted. Postextubation stridor and cough warrant evaluation for tracheal stenosis, an uncommon side effect of endotracheal tube placement. As in the patient presenting with cough, a complete examination with determination of oxygen saturation and performance of chest radiography are warranted.

Management

Management is the same as for cough at admission, with therapy directed at the primary etiology. Treating cough without understanding the primary etiology may mask an important precipitant, such as pulmonary embolism or volume overload.

Dyspnea

When Dyspnea Is Present at the Time of Admission

Description and Differential Diagnosis

Dyspnea is a general sense of breathlessness, inadequate ventilation, or “discomfort” during breathing. The neurologic pathways that are activated to produce dyspnea are poorly understood, but they link the cortex and brainstem respiratory complex and chemoreceptors (peripheral and medullary) with lung and cardiovascular receptors (6). Dyspnea may be caused by acute or chronic obstructive pulmonary disease, pneumonia, pleural effusion, atelectasis, cardiac dysfunction (CHF, valvular anomalies, intracardiac shunts), pulmonary embolism, or restrictive defects—in short, any abnormality of pulmonary or cardiac function. Acidosis is a metabolic cause of dyspnea, as in diabetic ketoacidosis, aspirin overdose, sepsis, or renal tubular acidosis. The resultant compensatory respiratory alkalosis with increased minute ventilation often causes patients to notice deep breathing at rest or to feel that they are unable to catch their breath. Orthopnea classically suggests left-ventricular failure, but it may also be caused by diaphragmatic paralysis or abdominal masses. Platypnea (increased dyspnea in the upright position) may be a consequence of orthodeoxia (decreased oxygenation associated with positional change) resulting from basilar arteriovenous malformations, hepatopulmonary syndrome, or atrial septal defects. Nocturnal dyspnea may be caused by asthma, CHF, gastroesophageal reflux, or nasal congestion. Dyspnea is frequently associated with anxiety, but it should not be considered psychogenic until medical etiologies have been excluded.

Evaluation

A history of the precipitants of dyspnea, aggravating or relieving factors, orthopnea, infectious symptoms (fever, purulent sputum), recurrent dyspnea, and renal or hepatic dysfunction are all important. Examination findings of tachypnea or desaturation are also important. Cyanosis suggests an emergently low oxygen level and should prompt immediate oxygen use and a blood gas determination. A chest radiograph should be obtained, and negative findings in the setting of hypoxia should immediately suggest pulmonary vascular abnormalities, such as pulmonary embolism or pulmonary hypertension. Given the potential metabolic causes, an arterial blood gas determination should be obtained. A patient with dyspnea and any degree of respiratory acidosis or unexpected hypercarbia must be observed carefully because of the possibility of muscle fatigue and respiratory arrest. Pulmonary embolism is a life-threatening diagnosis that is frequently missed, and clinical suspicion (hypoxia, tachypnea, tachycardia, respiratory alkalosis) should prompt a workup (Chapter 53). A complete blood cell count, chemistry panel, and blood urea nitrogen and creatinine determinations should be obtained, and an electrocardiogram should be performed if the patient is over the age of 40. Patients who show any evidence of alveolar hypoventilation or muscle weakness should be evaluated for neurogenic disorders, such as Guillain-Barré syndrome or myasthenia gravis. Parameters of pulmonary mechanics, such as the maximum inspiratory force and vital capacity, should be measured in this setting, and if uncertainty remains, electromyographic and nerve conduction studies should be performed. Other special tests may include exercise testing, methacholine challenge, and echocardiography.

Management

Hypoxia should be corrected to maintain adequate saturation (>92%), and, if it is difficult to correct or is associated with hypercarbia, the patient should be monitored in the ICU. If pulmonary embolism is a possibility, patients without contraindications should immediately be started on anticoagulation with IV heparin while arrangements are made for nuclear medicine studies or spiral CT. Bronchodilators and generally corticosteroids should be used if obstructive disease is present in the hospitalized patient.

When Dyspnea Appears During Hospitalization

Dyspnea may be caused by iatrogenic volume overload or problems with oxygen delivery. Dyspnea is frequently seen in patients who become deconditioned after a critical illness. Such patients have a high dead space fraction (normal <30%) and are prone to development of atelectasis. Incentive spirometry should be encouraged, and patients should sit up in bed or transfer to chairs as soon as possible to unload the diaphragm, which performs 70%–90% of the work of breathing. The classic critical care scenario for pul-

monary embolism is a sudden increase in minute ventilation with associated tachycardia. Patients in the postoperative period are especially vulnerable to volume overload, new infections, and embolic disease. Evaluation is the same as at admission, as is management, although tests can be performed more rapidly and empiric therapy started more quickly in the inpatient setting. Such speed is particularly important when embolic disease is suspected.

Hemoptysis

When Hemoptysis Is Present at the Time of Admission

Description and Differential Diagnosis

Hemoptysis is an important initial complaint and is very alarming to patients. The differential diagnosis for this symptom covers a range of inflammatory, infectious, and malignant etiologies (Table 54.2). *Pseudo-hemoptysis* is important to recognize early; the patient coughs up blood that does not originate in the tracheobronchial system. Hemoptysis is often characterized as “ordinary” (<200 mL/24 h) or “massive” (>600 mL/24 h). The precise volume history is difficult to obtain in many cases, as patients often describe hemoptysis in terms of tablespoons of a mixture of blood and sputum. Certainly any bleeding that

compromises oxygenation or is increasing in volume should be considered life threatening, even if it fails to meet the arbitrary volume cutoff (7).

Physicians are taught that the most common cause of hemoptysis is bronchitis, and although true, this catechism may falsely lead them to discount its importance. The vast majority of patients hospitalized for hemoptysis should undergo bronchoscopy, which may rapidly identify the location and cause of bleeding, provide diagnostic and prognostic information, and correctly determine the best approach to further testing or intervention.

Evaluation

Initial tests should include a chest radiograph, determination of oxygen saturation, complete blood cell count, electrolytes and renal function, and a coagulation panel. The chest radiograph may localize the source of bleeding, but it can be misleading. For example, a patient may have a tracheal source yet present with a right lower lobe infiltrate from dependent flow of blood into this region. Both tracheal and main bronchial bleeding can be rapidly fatal because blood can be distributed to both lungs quickly, but this is true of any source that bleeds rapidly. Hypoxia in the setting of hemoptysis is an ominous sign and suggests significant compromise of a large surface area of the lung. A purified protein derivative of tuberculin (PPD) should be placed and respiratory precautions observed if tuberculosis is suspected. Hemoptysis with anemia may also provide clues about the chronicity or severity of the symptom. An elevated white cell count might suggest a primary cavitary pneumonia, eosinophilia might suggest a fungal etiology (aspergillosis), and lymphocytosis or monocytosis could suggest a more indolent bronchiectasis associated with tuberculosis. Renal function should be checked to determine whether the patient has a pulmonary–renal syndrome, such as Wegener granulomatosis or Goodpasture syndrome, both of which can present with hemoptysis. Abnormal renal function is a separate risk factor for diffuse alveolar hemorrhage, as are advanced age and a compromised immune system. In addition, a low platelet count or abnormal prothrombin time or partial thromboplastin time suggests a bleeding diathesis, which should be rapidly corrected.

The initial examination must include a complete survey of the entire body for clues to extrapulmonary causes. The conjunctivae should be checked for pallor and the sclerae for icterus or signs of liver disease and coagulopathy. The nose and throat must be inspected for evidence of bleeding or inflammation, and a history of epistaxis should be pursued. Poor dentition might suggest a lung abscess. Cervical or other adenopathy might suggest tuberculosis or malignancy. A recent history of tracheostomy might suggest that cuff- or suture-related inflammation has eroded into a blood vessel—a condition that can be rapidly fatal. The presence of a rash may suggest an underlying collagen vascular disorder such as Wegener granulomatosis or lupus. Careful observation of the extremities may reveal clubbing

or cyanosis resulting from hypoxia, or edema resulting from renal or cardiac dysfunction. The pulmonary and cardiac examinations may localize sources of risk. Isolated crackles may suggest alveolar blood, whereas wheezing may be stimulating cough, which can be relieved with bronchodilators. An apical diastolic murmur may suggest the diagnosis of mitral stenosis, most commonly seen in patients with a history of rheumatic heart disease. Fever can be caused by pulmonary hemorrhage alone; the fever is typically low grade. Tachypnea, in the setting of even mild hypoxia, should immediately prompt consideration of intubation with a relatively large (outer diameter >7.5 mm) endotracheal tube for rapid bronchoscopy and immediate suctioning if hemoptysis suddenly worsens.

Management

If the airway is compromised or threatened, immediate pulmonary and thoracic surgical consultations are mandatory. Any doubt about a patient's airway should trigger transfer to the ICU for careful monitoring while definitive therapy is planned. Patients intubated in the emergency department for hemoptysis may be best served by being sent directly to the operating room for *rigid bronchoscopy*, which allows for superior suctioning. In these cases of very rapid bleeding, flexible bronchoscopy may not only be futile (because all that is visualized is blood) but also actually delay surgical intervention. *Embolization* of the involved bronchial arteries can be accomplished in the interventional radiology suite and is effective in up to 90% of cases. If this approach fails to control bleeding, *surgical resection* of the involved lobe may be the only recourse. Temporizing measures before embolization or surgery can include intubation with a double-lumen tube, placement of a bronchial blocker (Fogarty catheter), or even temporary intubation of the main bronchus of the uninvolved lung (8).

For the awake patient with brisk hemoptysis and no evidence of airway compromise, several specific rules are worth following. First, always have suction set up and immediately available at the bedside. Second, continuous or frequent pulse oximetry should be used to highlight any trends that should hasten intervention. Third, it is important to try to identify the location of bleeding and, if it is unilateral, to place the “*bad side*” down to deter aspiration of blood into the unaffected lung. Fourth, cough suppressants are useful because cough can stimulate further bleeding. Finally, because the status of patients with hemoptysis can change rapidly, consultants should be called quickly and updated frequently.

When Hemoptysis Appears During Hospitalization

Description and Differential Diagnosis

Hemoptysis during hospitalization is common and usually mild in nature. Bloody secretions may be caused by frequent

endotracheal suctioning in the ICU. Patients who have been hospitalized for thoracic or ENT surgery may have hemoptysis in the immediate postoperative period, but this is typically very short lived. In patients who have received chemotherapy with resultant neutropenia, several etiologies for hemoptysis might be possible: thrombocytopenia, nosocomial pneumonia, recrudescence of a prior fungal disease, or diffuse alveolar hemorrhage.

Evaluation

As on admission, a full examination, determination of oxygen saturation, chest radiograph, and history (looking for recent nasal, oral, or tracheal instrumentation) should be obtained. If the patient is immunocompromised and the chest radiographic findings are abnormal, bronchoscopy should be considered early to diagnose immediately treatable diseases and narrow antibiotic coverage. Bronchoalveolar lavage findings of increasingly bloody lavage return or hemosiderin-laden alveolar macrophages support the diagnosis of diffuse alveolar hemorrhage (Chapter 57).

Management

There are few differences between the management of hemoptysis present at admission and hemoptysis developing during hospitalization. The inpatient setting may allow for more immediate bedside consultation with other services (i.e., thoracic surgery, ENT, interventional radiology). Correction of abnormal coagulation parameters is important, and this intervention, along with cough suppression and removal of inciting trauma, may be adequate to control the bleeding. Hemoptysis in any setting can be life threatening, and careful attention must be paid to changes in oxygen saturation, examination findings, and the extent of bleeding.

LABORATORY STUDIES

Oxygen Saturation

Oxygen saturation has become the fifth vital sign (9), and, because of the noninvasive way in which it is measured and its relatively close correlation with PaO₂, it is a highly useful parameter. The pulse oximeter emits two frequencies of light that are differentially absorbed by oxygenated hemoglobin (HbO₂) and reduced hemoglobin (Hb). The oxygen saturation is then determined by the ratio of HbO₂ to Hb (10). Soft tissue, bone, skin, and venous and arterial blood absorb most of the light. At each arterial pulse, the amounts of absorption are calculated to produce an oxygen saturation (SaO₂). To ensure an accurate reading of the SaO₂, it is important that the pulse oximeter is simultaneously able to capture an adequate waveform. Readings are confounded by nail polish, intravascular dyes or pigments (bilirubin, methylene blue), motion artifact, severe anemia, external light sources, and poor distal perfusion.

Normal SaO₂ is 95%–99% on room air. The SaO₂ and PaO₂ are related by the oxygen dissociation curve. When the SaO₂ is between 50% and 90%, the relationship is linear, with the estimated PaO₂ equal to the SaO₂ minus 30. The accuracy of most oximeters is $\pm 4\%$ and drops significantly when the SaO₂ is less than 70% (11). The oximeter will overestimate saturations in the presence of elevated levels of carbon monoxide (smoke inhalation, smoking) because the absorption wavelengths of HbO₂ and HbCO are very similar.

If difficulty is encountered in obtaining a saturation level, decreasing patient movement, warming the extremity, applying a vasodilator such as nitropaste, or using an ear oximeter may prove beneficial. In any case, an arterial blood gas determination is indicated if questions of accuracy remain.

Pulmonary Function Testing

Pulmonary function testing allows for the evaluation of the mechanics of airway function and gas exchange. By measuring lung volumes, the rates of airflow, and the diffusing capacity, various lung diseases can be diagnosed. Pulmonary function testing can also be employed as a tool to estimate the severity of disease, monitor disease progression, and assess response to therapy. Other indications for pulmonary function testing include monitoring of patients treated with pulmonary toxins (amiodarone, bleomycin, radiation therapy), assessment of disability, and preoperative testing. Contraindications include active airborne infection, recent massive hemoptysis, and pneumothorax. Although pulmonary function may not return to baseline for a few months after an insult, interval measures of lung function can be a helpful adjunct to observation of symptoms in assessing the speed and course of recovery.

Spirometry

Spirometry is used to differentiate between *obstructive* and *restrictive* lung disease. Maximum expiratory flow rates and certain lung volumes can be measured with simple spirometry. The forced vital capacity (FVC) is the maximal volume of air that can be exhaled after a maximal inhalation. The FEV₁ is the volume of air forcibly exhaled after 1 second. The values obtained are generally reported as a percentage of those predicted; “normal” values have been obtained from healthy, nonsmoking adults and adjusted for age, height, and race. Degrees of impairment can be assigned according to the guidelines put forth by the American Thoracic Society (see Table 54.3).

Obstructive lung disease is defined as a decrease in the FEV₁ to below 80%, a reduced or normal FVC, and a ratio of FEV₁ to FVC below 70% of that predicted. *Restrictive* lung disease is defined as a decrease in the FVC to below 80% of that predicted but with a ratio of FEV₁ to FVC that is normal or higher than predicted. Although spirometry can suggest

TABLE 54.3**TYPICAL PULMONARY FUNCTION TEST FINDINGS**

	FVC ^a	FEV ₁ ^a	FEV ₁ /FVC ^b	FEF _{25%-75%} ^a	TLC ^a

^a Percentage of predicted value.

^b Ratio, expressed as a percentage of absolute values.

^c Patients with moderate obstruction/restriction have values between those of mild and severe states.

FEV₁, forced expiratory volume in 1 second; FEF_{25%-75%}, forced expiratory flow, mid-expiratory phase; FVC, forced vital capacity; TLC, total lung capacity.

restrictive disease, a reduced total lung capacity (TLC) is definitive for a restrictive process. Restriction cannot be diagnosed by spirometry if moderate to severe airflow obstruction is present. The FEF_{25%-75%} is the volume expired between 25% and 75% of the FVC. This measurement is more sensitive to small-airway function than is the FEV₁, which is more dependent on the resistance of the larger central airways. A reduction in this value suggests small-airway disease. Increases in the FEV₁ or FVC of more than 12% along with a 200-mL increase in volumes after two inhalations of a bronchodilator are indicative of a positive bronchodilator response. A negative bronchodilator response during formal testing does not exclude the possibility of clinical benefit from bronchodilators.

Flow-volume loops are often included in spirometric measurements. Based on their shape, obstructive or restrictive disease can be inferred. More importantly, patient effort and the presence of airflow limitation secondary to upper airway obstruction can be assessed (12) (Figure 54.1). A plateau on the expiratory limb in conjunction with a reduced peak flow and a normal inspiratory limb suggests a nonfixed intrathoracic airway obstruction (intratracheal neoplasm). A plateau present on the inspiratory limb in conjunction with reduced flow suggests a nonfixed extrathoracic obstruction (vocal cord neoplasm or tracheomalacia of the extrathoracic trachea). A plateau of both the inspiratory and expiratory limbs of the flow-volume loop suggests fixed upper airway obstruction (tracheal stenosis).

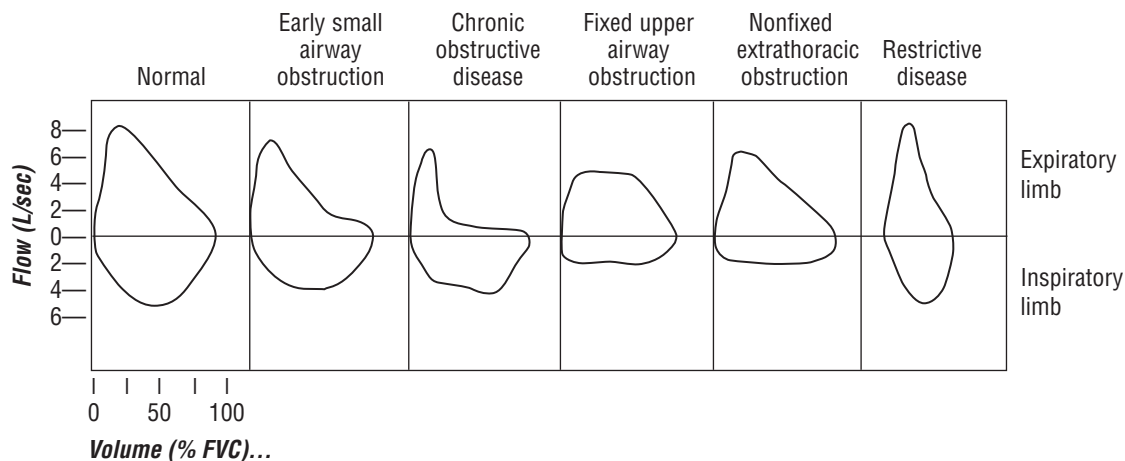

Figure 54.1 Flow-volume curves. (From Kiss GT. Pulmonary disease. In: Ferri FF, ed. *Practical Guide to the Care of the Medical Patient*. 2nd Ed. St. Louis: Mosby, 1991, with permission.)

Lung Volumes

Measurement of lung volumes can verify the presence of obstructive or restrictive lung disease. There are three ways to measure lung volumes: helium dilution, nitrogen washout, and body plethysmography. The latter is the most accurate measurement, as it measures the total volume of compressible air in the chest and is not significantly altered by air trapping.

In restrictive diseases, the TLC is reduced. In obstructive diseases, the FVC is usually normal or reduced, and the residual volume (RV) and the ratio of RV to TLC are increased. This represents air trapping caused by increased airway resistance. In some disease states, obstruction and restriction are combined (e.g., sarcoidosis, lymphangiomatosis, cystic fibrosis, hypersensitivity pneumonitis, eosinophilic granuloma).

Diffusing Capacity

The diffusing capacity (DLCO) is a measure of the ability of gases to diffuse from the alveoli into the pulmonary capillary bed. Thus, qualitative as well as quantitative differences in the status of the alveolar–capillary membrane affect the diffusing capacity. The diffusing capacity depends on age, body size, lung volume, hemoglobin concentration, the presence of carboxyhemoglobin, and changes in body position. The diffusing capacity is reduced in diseases that affect the interstitium of the lung, which can either decrease the total area of alveolar–capillary membrane available for gas diffusion or thicken the membrane, which makes diffusion more difficult. Examples of disease processes causing reduced diffusing capacity are emphysema, pulmonary vascular disease, pneumocystis pneumonia, and fibrosis. The diffusing capacity can be increased with erythrocytosis, severe liver disease, obesity, increased pulmonary blood volume (CHF, atrial septal defect), and alveolar hemorrhage.

Arterial Blood Gases

Whereas spirometry enables assessment of the mechanics of the respiratory system, determination of arterial blood gases enables assessment of the adequacy of oxygen uptake and carbon dioxide elimination. In a blood gas determination, the pH, PO₂, and PCO₂ are measured, and the bicarbonate concentration (HCO₃⁻) is calculated.

Hypoxemia is defined as a PO₂ below 80 mm Hg on room air at sea level. Causes of hypoxemia are low inspired oxygen tension (high altitude), hypoventilation (central sleep apnea and obesity hypoventilation syndrome), ventilation–perfusion (V/Q) mismatch (pneumonia, asthma, pulmonary embolus, CHF), shunt (atrial septal defect, pulmonary arteriovenous malformation), and diffusion abnormality (interstitial pulmonary fibrosis, sarcoidosis, emphysema, pneumocystis pneumonia).

The alveolar–arterial oxygen gradient [(A-a)DO₂] is normally between 10 and 15 mm Hg because everyone has a right-to-left shunt approximating 3%–5% of the right ventricular cardiac output. The (A-a)DO₂ increases with age. If the (A-a)DO₂ is greater than 15 mm Hg or greater than what is expected for a person of a particular age who is breathing room air, pulmonary disease is present and is interfering with gas exchange. If the (A-a)DO₂ fails to correct when breathing 100% oxygen, a shunt is present.

The acid–base status of the body is determined by the pH. Acidosis is present if the pH is below 7.35. Alkalosis is present if the pH is above 7.45. Determining the etiology of the acid–base abnormality first requires deciding whether the primary disturbance is metabolic or respiratory.

- Acidosis is metabolic if the serum [HCO₃⁻] is low and the PCO₂ is low.
- Acidosis is respiratory if the serum [HCO₃⁻] is high and the PCO₂ is high.
- Alkalosis is metabolic if the serum [HCO₃⁻] is high and the PCO₂ is low.
- Alkalosis is respiratory if the serum [HCO₃⁻] is normal to low and the PCO₂ is low.

Next, the duration of the primary disturbance is determined. Various rules exist to determine whether the acidosis or alkalosis is acute or chronic and whether it is compensated. In general, respiratory compensation occurs rapidly, whereas complete renal compensation takes on the order of 3–5 days. Maximum respiratory compensation reduces the PCO₂ to 12–15 mm Hg unless significant respiratory disease is present. If it is, the pH will remain low.

In acute respiratory acidosis, for each increase in the PCO₂ of 1 mm Hg, there is a fall of 0.008 in the pH. In chronic respiratory acidosis, for each elevation of 10 mm Hg in the PCO₂, the [HCO₃⁻] increases by 4 mEq/L.

In acute respiratory alkalosis, for each decrease in the PCO₂ of 1 mm Hg, there is an increase of 0.008 in the pH. In chronic respiratory acidosis, for each decline of 10 mm Hg in the PCO₂, the [HCO₃⁻] decreases by 5 mEq/L.

Many patients with COPD will have an elevated PCO₂ and respiratory acidosis, and a metabolic alkalosis will develop when they are placed on steroids or diuretics. It is important to remember that maintaining adequate oxygenation should override any concerns of hypercarbia. A low pH and lower-than-expected PCO₂ are suggestive of the combination of metabolic acidosis and respiratory alkalosis, as is seen with salicylate overdose and sepsis. Further discussion of acid–base abnormalities is found in Chapter 105.

Chest Radiograph

The chest radiograph is central to the evaluation and diagnosis of pulmonary diseases and is extremely useful for generating an overview of clinical signs and symptoms (13). As a general rule, patients with new pulmonary

symptoms should routinely undergo chest radiography. A few limited exceptions include patients with recent bronchitis outside the hospital who have normal pulmonary examination findings and patients with hemoptysis clearly determined to be of nasal origin who have a normal oxygen saturation. All patients presenting with pulmonary symptoms requiring hospitalization should have a chest radiograph, as should any patient experiencing a significant change in pulmonary status after the initial chest radiograph. Daily chest radiographs are not mandatory for stable ICU patients, but they are often performed in this rapidly changing population. It is traditional teaching that patients with endotracheal tubes, central lines, or feeding tubes warrant serial radiographs to ensure appropriate placement, although a recent study found no advantage of daily chest radiographs over performing these radiographs only when clinically indicated in mechanically ventilated ICU patients (14).

Pneumothorax

In most cases, pneumothorax (Chapter 60) is readily apparent on anteroposterior views of the chest and is predominantly apical in distribution. This finding is usually quantified as a percentage, to allow for comparison with the anticipated repeated chest radiograph taken within 6 to 8 hours after chest tube placement. Patients experiencing an iatrogenic pneumothorax after a procedure (thoracentesis, transbronchial biopsy, subclavian line placement) may not necessarily need tube thoracostomy if the chest radiographic findings remain stable. A pneumothorax in the supine ICU patient may not be readily apparent. The *sulcus sign* is noted when trapped air causes the costophrenic angle to appear lower and more radiotranslucent than expected. *Subcutaneous emphysema* should always prompt concern for undiagnosed pneumothorax or pneumomediastinum. Critically ill patients on positive pressure ventilation are susceptible to this condition, and CT is more sensitive than chest radiography for definitive diagnosis. Severe bullous disease may greatly resemble pneumothorax, and emphysematous patients frequently present with pulmonary symptoms. If the patient is clinically stable, a chest CT can prevent the inadvertent placement of a chest tube into a bullous air collection.

Interstitial Pattern

Any entity that causes fluid collection in the draining interlobular septa will cause linear densities on the chest radiograph. This fluid can be lymphatic drainage, as in CHF or Kaposi's sarcoma lesions; in these cases, Kerley B lines form at the perimeter. Lines may be inflammatory, as in fibrotic conditions, or infectious, as in pneumocystis pneumonia. Unilateral reticular changes can be seen in carcinomatosis from lung primary tumors or metastases. Reticular (linear) changes are extremely nonspecific, and the chest radio-

graph often underestimates their severity and distribution in comparison with high-resolution chest CT, the next study of choice. High-resolution CT will also help designate a site for lavage and transbronchial biopsy if indicated, and the findings can be nearly pathognomonic in some conditions (bronchiectasis, "tree and bud" pattern of inflammatory disease, nodules along bronchovascular bundles as in sarcoidosis) (Chapter 57).

Air Space (Alveolar) Disease

Infiltrates seen on chest radiographs in patients with air space disease have an indistinct edge and are "fluffy" and often confluent. Miliary disease falls within this category and can represent mycobacterial or fungal infection. Air space disease is typically caused by fluid overload, infection, inflammation, or hemorrhage. Many pulmonary processes show a combination of alveolar and interstitial changes.

Pleural Fluid

Extrapulmonary fluid is suggested by a meniscus sign, blunting of a costophrenic angle, or homogenous haziness of the lower or dependent aspects of the lungs. Pleural fluid may be free-flowing or loculated, and this important distinction is usually determined by lateral decubitus films. Tactile fremitus and chest percussion (see "Signs," earlier in this chapter) will frequently correlate accurately with the amount of fluid seen on chest radiographs. Supine films may miss a small effusion. Large effusions on supine chest radiographs, especially if unilateral, can be mistaken for infiltrates. CT is the best alternative if any confusion persists. Pleural effusions are discussed in Chapter 60.

Consolidation

Any density confined to the lobar anatomy is considered a consolidation and should be suspected of being infectious if accompanied by specific symptoms (Chapters 65 and 66). It is difficult to distinguish atelectasis from pneumonia on chest radiographs—this is a clinical and not a radiographic distinction. A greater number of involved lobes bodes a worse prognosis, particularly in community-acquired pneumonia. Upper-lobe infiltrates are more typical of recurrent tuberculosis, and middle- or lower-lobe infiltrates are more common in primary tuberculous pneumonia. Lower-lobe disease is common in aspiration pneumonia, given its dependent location. The bulging fissure sign is considered classic for *Klebsiella* pneumonia, a diagnosis more commonly seen in alcoholics and those with poor dentition. Lung cancer can mimic pneumonia or cause a postobstructive pneumonitis. For this reason, patients at risk for lung cancer (smoking history, emphysema, family history) should routinely have a repeat chest radiograph 6 weeks after discharge for pneumonia. Persistent findings after this interval are more suggestive of cancer and may need to be evaluated. Air bronchograms are commonly seen in consol-

idated lung and suggest that the proximal airways are open. Lobar collapse may mimic consolidation and has the same features on physical examination. An elevated hemidiaphragm and shift of the mediastinum toward the collapse is common.

Normal Chest Radiographic Findings

Persistent symptoms and normal chest radiographic findings do not guarantee that the patient is free of a pulmonary illness; they often demonstrate that radiography is not a very sensitive test. Diffuse abnormalities can be missed on the chest radiograph but picked up on pulmonary function tests or high-resolution CT. Cough, pleurisy, hemoptysis, and hypoxia are all classic signs of pulmonary embolism, which usually presents with normal chest radiographic findings (Chapter 53). Persistent cough may be caused by a mediastinal mass that is not well localized on a chest radiograph and can be visualized only on CT.

KEY POINTS

- Hemoptysis that impairs oxygenation is considered life threatening and should be evaluated by specialists in the ICU.
- Determination of arterial blood gases is an accurate, informative test and should be performed if there is any doubt about oxygenation or acid–base status.
- Chest radiography is a valuable test but insensitive for detecting diseases confined to the airways or pulmonary vasculature.
- Oxygen saturation does not detect alveolar hypoventilation and hypercarbia.
- All that wheezes is not asthma. Consider other causes of wheezing if initial therapy for asthma is unsuccessful.
- Pulmonary function tests can be helpful in the initial evaluation of respiratory symptoms such as cough and dyspnea.

- High-resolution computed tomography is a useful imaging test for symptoms of dyspnea and cough.

Chronic Obstructive Pulmonary Disease

55

Matthew B. Stanbrook Kenneth R. Chapman

INTRODUCTION

Chronic obstructive pulmonary disease (COPD) is the fourth most common cause of death in the United States and Canada and is a leading cause of disability. The annual U.S. health care expenditure for this condition has been estimated at \$6.6 billion in direct medical costs (1). Acute exacerbations of COPD are responsible for 9–13 hospital admissions per 1,000 population each year, with the average COPD patient experiencing 1–4 such exacerbations per year. The average length of stay for a typical COPD exacerbation is approximately twice that required for an acute exacerbation of asthma.

In the Americas and Europe, most COPD is the consequence of decades of cigarette smoking; occupational exposures to various respiratory irritants such as grain dust are thought to be cofactors of lesser importance. In large parts of Africa and Asia, COPD is more likely to result from years of exposure to cooking and heating with biomass fuels, and it affects women more commonly than men. Regardless of the source of the airway or parenchymal injury, genetic predisposition to COPD probably also has a role; clinically important disease develops in only 1 in 6 regular smokers. The only genetic predisposition to COPD that has been identified clearly is α -1-antitrypsin deficiency, which should be considered in nonsmokers or younger patients with minimally reversible airflow obstruction. Damage to the lung parenchyma in COPD is irreversible, but the rate of decline in lung function can be slowed if smoking is discontinued. In addition, some COPD patients have a component of reversible airway obstruction; this can be clinically indistinguishable from asthma and may respond to effective anti-asthma therapy, such as inhaled steroids (Chapter 56). COPD symptoms usually begin after at least

20 pack-years of tobacco exposure. For this reason, COPD usually presents in the fifth decade of life or later, so that the prevalence of COPD in a population reflects the prevalence of tobacco consumption a few decades earlier. Thus, the frequency of hospital admissions for COPD will continue to increase significantly in the near future despite recent decreases in smoking rates. In fact, current data show that women now suffer from COPD as commonly as men and tend to develop their disease at an earlier age.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

An exacerbation of COPD can best be defined as an acute and persistent worsening of the patient's respiratory symptoms, beyond that which can be attributed to normal day-to-day variations, and requiring a change in medications (2). Common symptoms include, but are not limited to, increased dyspnea, increased sputum purulence, or increased sputum volume (3). Although the COPD exacerbation is commonly viewed and treated as a respiratory tract infection that causes a worsening of airflow, an exacerbation may have many etiologies.

For the newly hospitalized patient with an apparent exacerbation of previously undiagnosed COPD, it is necessary to verify the presence of obstructive lung disease and distinguish COPD from asthma. It is also important to determine whether the precipitant of the exacerbation is primarily respiratory or nonrespiratory. Common precipitating factors are listed in Table 55.1. A typical history is that of an upper respiratory tract "infection" in the preceding days to weeks, followed by increasing dyspnea. Cough

typically becomes productive of larger volumes of yellow-green and viscous sputum, but in some breathless patients sputum production is paradoxically decreased. Chest tightness or wheezing may be present. Less commonly, fever will occur. Physical examination reveals tachypnea, suprasternal and intercostal retractions, and the use of accessory muscles of respiration. Pursed-lip breathing may be seen. Breath sounds are usually decreased, accompanied by diffuse expiratory wheezes. A “silent” chest may indicate severe obstruction. A forced expiratory maneuver that is prolonged beyond 6 seconds has moderate predictive value for obstructive lung disease but does not obviate the need to measure lung function objectively.

Differential Diagnosis

Chronic obstructive pulmonary disease must be distinguished from other acute respiratory and nonrespiratory syndromes. The presence of fever, chills, or bronchial breath sounds should alert the clinician to a possible underlying pneumonia. Pleuritic chest pain suggests pulmonary embolism, pneumothorax, or a pleural complication of pneumonia. Congestive heart failure can generally be distinguished by a history of cardiac disease, signs of volume overload, and characteristic chest radiographic features. This differentiation can be more difficult in patients with severe underlying lung disease, some of whom will ultimately develop cor pulmonale.

Initial Evaluation

The initial evaluation should be directed toward rapid assessment of the severity of respiratory compromise. Measurement of oxygen saturation via pulse oximetry is a widely available and cost-effective means of determining

the adequacy of oxygenation. In addition, arterial blood gas measurement is indicated in all patients with a COPD exacerbation to assess exacerbation severity, to identify the presence of hypercapnia, and to determine the potential need for mechanical ventilation (invasive or noninvasive).

During COPD exacerbations, chest radiographs commonly show findings not identified on physical examination but which subsequently alter management, such as new infiltrates or pulmonary edema. The chest radiograph may also be helpful in distinguishing COPD from other conditions; this is particularly true for patients not previously identified as having COPD in whom typical findings (e.g., hyperinflation, flattened diaphragm, and decreased parenchymal markings) suggest the diagnosis.

An early measurement of bedside spirometry may be useful in some circumstances. For patients without an established diagnosis of COPD, a simple flow-volume loop can distinguish other conditions with similar acute presentations (such as congestive heart failure) from obstructive lung disease and thus avoid inappropriate empiric therapy. Establishing the baseline FEV₁ at the time of admission may also be helpful subsequently for comparison in monitoring response to therapy and facilitating discharge planning. However, patients in exacerbation are often too ill initially to generate valid spirometric results. Also, unlike in asthma, spirometry and peak flow measurements have been found to correlate poorly with the severity of a COPD exacerbation. Therefore, in patients with *well-documented* COPD, such measurements may be omitted.

Electrocardiographic (ECG) features such as tall P waves and right-sided changes, although nonspecific, support the diagnosis of COPD; an ECG may be more useful in patients with previously undiagnosed disease than in those with known COPD. However, in patients with an irregular pulse, careful ECG interpretation is important to separate those with multifocal atrial tachycardia from those with atrial fibrillation; multifocal atrial tachycardia is associated with COPD and responds well only to treatment of the underlying condition (Chapter 42).

In addition to the blood gas determination, diagnostically useful blood work includes a complete blood cell count, which may reveal polycythemia resulting from chronic hypoxemia. A theophylline level should be checked in patients taking this medication.

Indications for Hospitalization

The need for management in the hospital rather than as an outpatient depends on the severity of the exacerbation and of the patient’s underlying lung disease, as well as the availability of resources for support and surveillance of a community-based treatment attempt. The likelihood of outpatient treatment failure increases in proportion to the frequency of previous exacerbations and is also higher for patients using home oxygen (4). Hospital admission is clearly indicated for patients with a decreased level of

consciousness, hypercapnia or hypoxemia representing a significant change from baseline, or severe symptoms. Hospitalization is also appropriate for patients with persistent or progressive symptoms despite an attempt at outpatient management and for those who cannot provide adequate self-care in their current environment.

Indications for Initial Intensive Care Unit Admission

The usual reason for ICU admission with a COPD exacerbation is respiratory failure currently requiring or likely to require intubation and mechanical ventilation (Chapter 24). Signs on physical examination such as cyanosis, asterixis, paradoxical abdominal movement (or other evidence of respiratory muscle fatigue), decreased level of consciousness, or hemodynamic instability should alert the clinician to this situation. Patients with persistent hypoxemia refractory to oxygen supplementation (which may suggest a secondary cause for the exacerbation, such as pneumonia or pulmonary embolism) or with severe hypercapnia also require ICU admission.

Patients with tachypnea and respiratory acidosis or severe hypoxemia are candidates for noninvasive ventilation, an intervention best monitored in an ICU or “step-down” setting. Some centers with appropriate numbers of trained personnel may be equipped to employ this modality in the medical wards.

Chronic obstructive pulmonary disease is a chronic and largely irreversible disease in which respiratory exacerbations recur frequently and baseline disability may be significant. Such patients may have issued advance directives indicating their wishes regarding mechanical ventilation or other life-sustaining therapies. It is prudent to address these issues with patients or their appropriate surrogates at the time of hospital admission in all cases, whether they appear likely to require ICU management or not (Chapter 17). Mortality after a COPD exacerbation that requires ICU admission is high. However, contrary to popular belief, mortality rates and duration of mechanical ventilation are no greater in patients with COPD than in patients suffering respiratory failure from other causes.

Initial Therapy

Hypoxemia must be corrected with an appropriate amount of *supplemental oxygen*. In patients who chronically retain carbon dioxide, a frequently expressed concern is that excessive oxygenation will lead to increased hypercapnia. Although traditionally this was attributed to depression of central respiratory drive, most of the increase in carbon dioxide pressure following oxygen administration is the consequence of altered ventilation-perfusion matching and simple biochemistry (oxygen competitively reduces the capacity of hemoglobin to carry carbon dioxide, a phenomenon known as the Haldane effect). *Oxygen therapy*

must not be withheld from a hypoxemic patient because of concerns that hypercapnia may result. Instead, it should be administered carefully and levels reassessed frequently. A target range of 88%–92% for oxygen saturation is both safe and adequate.

Noninvasive ventilation via facial or nasal mask has been demonstrated in multiple randomized trials to decrease mortality, hasten improvement of hypercapnia and acidosis, reduce respiratory rate, avoid complications associated with intubation, and decrease hospital length of stay (5). Suitable candidates are patients with moderate respiratory acidosis ($\text{pH} < 7.35$) and hypercapnia despite an increased respiratory rate. Conversely, noninvasive ventilation is unlikely to be beneficial in those with milder ($\text{pH} \geq 7.35$) exacerbations and is contraindicated in patients with decreased respiratory drive, decreased level of consciousness, hemodynamic instability, or very severe ($\text{pH} < 7.20$) exacerbations, who instead require intubation. Noninvasive ventilation is best delivered by experienced personnel able to monitor patient respiratory status, titrate pressures, and allay patient anxiety. The technique is well described in Chapter 23. Improvement should be seen within the first 4 hours; if not, intubation should be considered.

Inhaled bronchodilators are the safest, most rapid, and most effective means of improving airway caliber to the degree possible. Both β_2 -adrenergic agonists and inhaled anticholinergic agents (e.g., ipratropium bromide) improve spirometric parameters and relieve symptoms in acute COPD exacerbations. In this setting, the optimal dose of β -agonist based on dose-response studies in COPD patients, is the equivalent of 800–1,000 mg of albuterol via metered-dose inhaler (MDI) (approximately six to eight puffs), or 2.5 mg via nebulizer. Higher doses may increase bronchodilation but also cause more adverse effects, such as tachyarrhythmias and tremor. Similarly, optimal benefit from ipratropium bromide has been demonstrated at a dose of 80–120 mg (4–6 puffs) via MDI, or 0.5 mg via nebulizer. It is common practice to treat with both classes of bronchodilator together, although studies to date have been too limited to establish whether combined therapy is superior to single-agent therapy early in the acute exacerbation (6). However, in the setting of stable disease, the combination produces greater spirometric benefit than does monotherapy, making it plausible that the acutely ill COPD patient will benefit from the combination approach sometime during the recovery. In general, administration of bronchodilators via MDI with a spacer device achieves bronchodilation equal to that achieved via nebulizer but at lower cost. An added advantage of this approach is the in-hospital opportunity to assess and teach inhaler technique. Moreover, current concerns about the spread of highly contagious respiratory infections such as SARS in the hospital setting will discourage the use of nebulizers that are likely to aerosolize infectious droplets. Patients unable to hold their breath for 3 seconds may require initial nebulizer therapy with appropriate infection control procedures in place.

Systemic corticosteroids have been shown in multiple randomized trials to be effective in reducing treatment failure, hastening the recovery of lung function, and decreasing length of stay (7). Studies comparing different doses are lacking, but a dose of 0.5 mg/kg of prednisone or equivalent, given once daily either orally or intravenously, appears to be sufficient. Inhaled steroids have not been well evaluated in the management of exacerbations. The only exception is nebulized budesonide, which appears to improve lung function, but tends to be less effective overall than systemic steroids and is more expensive (8).

Antibiotics can be beneficial in COPD exacerbations, primarily in patients with productive cough and purulent-appearing sputum. For patients with mucoid sputum or no sputum, antibiotics do not appear to alter recovery (9). Acquisition of a new strain of *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Moraxella catarrhalis* (but not of *Pseudomonas aeruginosa* or *Staphylococcus aureus*) has been found to be associated with exacerbations (10), so the antibiotic chosen should cover these three pathogens, taking into account local resistance patterns. Reasonable choices include a second-generation cephalosporin, a second-generation macrolide, a tetracycline, a second-generation fluoroquinolone, or amoxicillin clavulanate.

Intravenous aminophylline appears to add little benefit, produces troublesome side effects, and interacts with multiple other medications. Its use in the setting of acute COPD exacerbation *must be considered hazardous*, and we do not recommend it. Although some argue that theophylline may be a ventilatory stimulant or may relieve fatigued respiratory muscles, these attributes are of questionable benefit in acute COPD, a disease in which most patients already have an increased drive to breathe. The best treatment for fatigued respiratory muscles is rest with supportive ventilation. Oral theophylline may be continued in patients who have been taking it before their acute illness; indeed, abrupt discontinuation during an exacerbation may be detrimental (11). The theophylline level should be checked.

Mucolytic agents such as *N*-acetylcysteine have not been shown to be useful. Long-acting bronchodilators (e.g., formoterol) and heliox have been the subject of preliminary investigations, but do not currently have a defined role in acute exacerbations.

Medications that depress the respiratory system, such as opiates and sedative/hypnotics, should be avoided or minimized. However, if patients are "end-stage" and the goal of care is comfort, their use is permissible and sometimes essential (Chapter 19).

Indications for Early Consultation

Most COPD exacerbations can be managed by the generalist without difficulty. Consultation by a specialist in pulmonary medicine should be considered in patients with severe disease, complicated disease, or atypical features. This last category might include COPD occurring before

age 50 or in the absence of a significant smoking history. Those whose FEV₁ value is better (>1 L or approximately >35% of the predicted value) than one would guess from the degree of symptoms or arterial blood gas abnormalities should receive subspecialty assessment. The markedly breathless patient with an FEV₁ value greater than 1 L may have concomitant congestive heart failure or some other condition to explain the disproportionate symptoms. The use of the B-type natriuretic peptide (BNP) can aid in the diagnosis of CHF in patients with asthma or COPD (12) (Chapter 39). The patient with hypercapnic respiratory failure despite only moderate obstruction may have a previously undiagnosed sleep apnea syndrome and should undergo formal evaluation.

ISSUES DURING THE COURSE OF HOSPITALIZATION

A critical pathway for acute exacerbations of COPD is shown in Figure 55.1.

In the period immediately following admission, bronchodilators must be given aggressively to provide symptomatic relief, and oxygen needs must be met. The respiratory therapist plays a key role at this time. β_2 -agonists may be given as often as every 20 minutes; the severity and persistence of symptoms should guide the frequency of administration. Ipratropium is commonly given initially and administration repeated every 2–4 hours, although there is little research to guide optimal dosing frequency in this setting. In patients whose clinical or blood gas findings indicate impending respiratory failure, supportive ventilation must be initiated by invasive or noninvasive means. The management of mechanical ventilation in patients with airway obstruction is reviewed in Chapter 23.

For the majority of patients who stabilize with treatment, the subsequent goal is gradual improvement in respiratory function toward baseline within the next few days. Use of oxygen and bronchodilators is guided by the same principles as before, but the patient's less precarious status allows for less frequent administration of bronchodilators and fewer assessments of blood gases. As improvement is seen, bronchodilator dose and frequency of administration can be decreased to typical maintenance regimens. Steroids and antibiotics are continued and should be given orally whenever possible unless there is concern that absorption may be impaired by a coexisting condition such as congestive heart failure. The optimal duration of steroid therapy is 5 days to 2 weeks (13); longer steroid use should be discouraged because it can lead to muscle wasting (including respiratory muscles), metabolic alkalosis, hyperglycemia, and increased risk of infections. Tapering of the steroid dose is not necessary, since adrenal suppression is not an issue with short courses of steroids in the acute setting. Patients should be encouraged to increase their activities as tolerated. Physiotherapy may be helpful

Figure 55.1 A critical pathway for the hospitalized patient with chronic obstructive pulmonary disease. ABG, arterial blood gas; ADLs, activities of daily living; CBC, complete blood count; MDI, metered dose inhaler; PFTs, pulmonary function tests; RT, respiratory therapist; SW, social worker.

to prevent deconditioning; however, traditional chest physiotherapy by means of percussion and postural drainage (which is useful in other obstructive lung diseases such as bronchiectasis) has not been shown to be of benefit in COPD and may even be detrimental.

Duration of illness varies among patients; an average hospitalization generally ranges from 5–15 days, with the median length of stay being 9 days. In some managed care markets in the United States, an average length of stay of 3 to 5 days is now seen without obvious untoward effects. In the stable patient, some of the final days can potentially be spent in a post-acute setting.

A successful treatment outcome is usually heralded by an improvement in FEV₁ within the first 2 days after admission (11). If patients fail to improve, one must search for underlying diseases or factors impeding recovery. Possi-

bilities and suitable approaches in this circumstance are outlined in Table 55.2.

The hospital admission provides a major opportunity for patient education. *Smoking cessation* is the most important intervention in COPD and has been proved to reduce the decline in lung function; a hospitalization thus represents a particularly appropriate time for counseling. *Teaching optimal inhaler technique* is a simple but often overlooked factor that can improve symptom control and reduce readmission rates.

DISCHARGE ISSUES

The patient is ready for discharge when the presenting symptoms have been substantially reduced or abolished,

TABLE 55.2**CONSIDERATIONS IN PATIENTS FAILING TO IMPROVE AFTER EMPIRIC THERAPY FOR ACUTE EXACERBATION OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE**

Reason for failure to improve	Recommended approach
Respiratory muscle fatigue	Look for physical signs. Consider mechanical ventilation.
Respiratory depression	Repeat arterial blood gases. Review medications carefully. Assess for other causes of decreased level of consciousness (delirium, sepsis). Consider mechanical ventilation (noninvasive or invasive).
Underlying precipitant not reversed	Repeat history and physical, review medications, repeat chest radiograph and basic bloodwork. Consider sputum culture for atypical mycobacteria. Consider pulmonary consult if cause remains unclear.
Pneumothorax	Repeat chest examination and chest radiograph. Suspect particularly in patients with known bullous disease or if positive pressure ventilation has been used.
Poor inhaler technique	Reassess technique and reinforce teaching as appropriate. Encourage use of spacer device.
Psychological misperception of dyspnea	Repeat objective measurements of pulmonary function. Refer for pulmonary rehabilitation incorporating breathing retraining, coping, and self-management techniques.
Lung disease at end-stage	Repeat history with focus on patient's level of function during recent months. Obtain past pulmonary function results for comparison. Consider pulmonary consultation. Consider palliative management.

requirements for oxygen and other medications have stabilized, and any precipitating causes have been reversed. Although resolution of symptoms is typically seen by day 7 on average, recovery to pre-exacerbation levels of physical function may take up to 3 months (3). In the interval between discharge and full recovery to usual self-care, patients may need assistance at home on a temporary basis.

Patients who have not previously required long-term oxygen therapy may exhibit mild persistent hypoxemia in the recovery period. Nevertheless, if they are otherwise stable, they may safely be discharged with home oxygen therapy. The criteria for home oxygen are listed in Table 55.3. Appropriate arrangements should be made before discharge. Because only about 20% of such patients will require the oxygen supplementation indefinitely, follow-up blood gas studies should be scheduled.

TABLE 55.3**CRITERIA FOR LONG-TERM OXYGEN**

Room air $PO_2 \leq 55$ mm Hg or O_2 saturation $\leq 88\%$
 Room air PO_2 56–60 mm Hg or O_2 saturation 89–90% and any of the following:
 cor pulmonale
 pulmonary hypertension
 persistent erythrocytosis

Maintenance bronchodilator therapy should be prescribed and a plan for discontinuation of oral steroids established. Several studies have reported that stable but exacerbation-prone patients with severe airflow obstruction are less likely to suffer exacerbations if inhaled corticosteroids are used regularly as maintenance therapy; these findings are reflected by current international and national COPD management guidelines. Whether such therapy should be initiated after the first COPD exacerbation or whether it is more appropriate to await a pattern of exacerbations is a matter of current debate. Some experts would currently regard a severe exacerbation requiring hospitalization to be reasonable grounds for long-term inhaled anti-inflammatory therapy. The use of long-acting bronchodilators seems to reduce the exacerbation risk, as has been reported for both tiotropium (14) and salmeterol (15). Studies are currently underway to define the role of combination therapy with inhaled long-acting bronchodilators and inhaled corticosteroids in COPD.

Advice should also be given regarding what to do if symptoms recur. For some patients, a self-management plan with instructions to start antibiotics or steroids in the face of an exacerbation may prevent a visit to the emergency department or hospitalization. Factors associated with an increased risk of readmission include the degree of baseline lung function impairment, the frequency of previous admissions for COPD, a limited capacity for self-care, and polypharmacy (16).

Follow-up should be arranged with the patient's primary care physician or pulmonary specialist. Pneumococcal and influenza vaccines are indicated in all COPD patients and may be given before discharge when appropriate. It may also be useful to repeat spirometry before discharge to provide a baseline for the outpatient return visit. Patients observed to have a sudden decrease in FEV₁, the appearance of bullae on radiographic tests, or severe respiratory disease but who otherwise have a good medical status may be appropriate candidates for surgical interventions, such as lung volume reduction surgery or bullectomy (Chapter 58). The follow-up visit also represents an appropriate opportunity for the primary physician to discuss advance directives, if these have not already been addressed.

EXACERBATIONS OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE PRESENTING DURING HOSPITALIZATION

Exacerbations of COPD frequently commence after patients are hospitalized for other reasons. As such, symptoms often go unrecognized initially or are attributed to other processes. A typical example is the postoperative patient who fails extubation or has difficulty being weaned from supplemental oxygen; commonly, underlying COPD has been previously unsuspected. In some instances, the COPD exacerbation will be triggered by the primary event responsible for the hospitalization. When a patient with COPD experiences respiratory difficulties after a cholecystectomy, for example, it is not difficult to understand how postoperative sedation, atelectasis, and an upper abdominal incision would impair gas exchange and respiratory muscle function.

Some hospital interventions may contribute more subtly to worsening COPD. A frequently overlooked culprit is β -blocker eyedrops, which may be absorbed in sufficient amounts to produce systemic effects. In exacerbations arising in the hospital, identification and treatment of the underlying precipitant is of primary importance. Management is otherwise similar to that for community-acquired cases, although empiric antibiotic treatment may not be useful. In-hospital presentations more frequently represent *de novo* diagnoses of COPD, and so more attention may need to be paid to investigation and follow-up.

COST CONSIDERATIONS AND RESOURCE USE

Although previous estimates have been higher, a population-based study found the average cost of a COPD admission in the United States to be \$2,700, using data from the early 1990s (1). A simple but often neglected way to minimize costs is to administer medications by less expensive

but equally efficacious routes. Two examples are administration of bronchodilators by MDI with spacer instead of by nebulizer, and oral (in place of IV) administration of antibiotics and steroids at the earliest appropriate juncture. Patient education can also be a simple way to decrease resource utilization: establishing self-management plans for patients to initiate during exacerbations has been shown to reduce hospitalizations and emergency room visits (17).

KEY POINTS

- Chronic obstructive pulmonary disease is a major cause of morbidity, mortality, and hospitalization, and its prevalence continues to increase.
- The initial approach to an exacerbation of chronic obstructive pulmonary disease consists of identifying obstructive lung disease, distinguishing chronic obstructive pulmonary disease from asthma and other causes of acute respiratory symptoms, and determining the precipitating factor(s).
- The severity of respiratory compromise is determined from the physical examination findings and arterial blood gas measurement.
- Hypoxemia must be corrected with appropriate and carefully monitored oxygen therapy.
- Treatment of acute exacerbations generally involves inhaled bronchodilators, systemic corticosteroids, and antibiotics.
- Noninvasive ventilation can reduce morbidity and mortality significantly in selected patients.
- Exacerbations of chronic obstructive pulmonary disease in patients hospitalized for other reasons are common, but recognition is often delayed.

Asthma

Homer A. Boushey

INTRODUCTION

The causes, pathophysiology, clinical presentation, and treatment of asthma exacerbations share many features with those of exacerbations of Chronic obstructive pulmonary disease (COPD), discussed in the previous chapter. There are, however, important differences in the presentations and treatments of the two disorders that must be understood to avoid potentially serious errors in management.

EXACERBATIONS OF ASTHMA

Asthma is the most common respiratory emergency encountered in clinical practice. About 7% of the U.S. population suffers from asthma. In 1998, asthma accounted for 13.9 million visits for outpatient care, 2 million visits for urgent care, and 423,000 hospitalizations (1). The costs for hospitalization account for over half of the more than \$6 billion in direct medical costs of asthma (2).

The incidence of asthma peaks in childhood, but new asthma may present at any age. The condition is now recognized as a chronic disorder of the airways, so the risk for attacks extends over the lifetime of most patients, especially for those with asthma in adulthood. National and international guidelines have classified asthma as “mild intermittent,” “mild persistent,” “moderate,” or “severe,” based on the frequency and severity of symptoms, the disturbance in pulmonary function, and the requirement for medications (3) (see Table 56.1). Although this classification has proved useful in providing general guidelines for therapy, it does not recognize all forms of asthma, such as “sudden asphyxic asthma” or “brittle asthma” (4). In general, the

frequency of attacks requiring urgent treatment varies with severity, but severe and even fatal attacks can occur in patients with mild forms of asthma. The risks for severe morbidity or death from attacks increase with age, probably because of the development of complicating coexistent diseases, especially of the cardiovascular system.

Acute asthma exacerbations in patients presenting to the emergency department are a common and potentially serious complication of asthma. Between 20%–30% of asthmatic patients presenting for emergency care require hospitalization (5). The most common precipitating factor—accounting for as much as 80% of exacerbations in children—is infection with one of the viruses responsible for the common cold, especially rhinovirus (6). However, infections with other respiratory pathogens, including influenza, parainfluenza, and respiratory syncytial viruses, adenoviruses, and the bacteria *Mycoplasma pneumoniae* and *Chlamydia pulmonis*, can also trigger severe attacks. Other precipitants are exposure to allergens or irritants (e.g., sulfur dioxide, particulate pollutants), use of medications (especially nonsteroidal anti-inflammatory agents or oral or topical β -blocking drugs), and medication noncompliance. Asthmatic patients with anaphylactic sensitivity to an allergen such as peanuts or insect venom have especially severe sudden attacks on encountering the allergen.

Knowing the cause of an attack can be useful for predicting the duration of treatment likely to be necessary and for educating patients about measures they should take to avoid severe attacks in the future, but it has no effect on initial management. Regardless of the cause of the attack, the first steps are to assess the severity of airflow obstruction and begin treatment. It is also necessary to identify risk factors for a poor outcome, including death, to determine

TABLE 56.1**CLASSIFICATION OF ASTHMA SEVERITY: CLINICAL FEATURES BEFORE TREATMENT**

	Days with symptoms	Nights with symptoms	PEF or FEV ₁	PEF variability
Severe persistent	Continual	Frequent	≤60%	>30%
Moderate persistent	Daily	≥5/mo	61–79%	>30%
Mild persistent	3–6/wk	3–4/mo	≥80%	20–30%
Mild intermittent	≤2/wk	≤2/mo	≥80%	<20%

Patients should be assigned to the most severe group in which any feature occurs. Clinical features for individual patients may overlap across groups. A patient's classification may change over time. Patients with chronic asthma at any level of severity can have mild, moderate, or severe exacerbations of asthma. Some patients with intermittent asthma experience severe and life-threatening exacerbations separated by long periods of normal lung function and no symptoms. Patients with two or more asthma exacerbations per week (i.e., progressively worsening symptoms that may last hours or days) tend to have moderate to severe asthma.

FEV₁, forced expiratory volume in 1 second; PEF, peak expiratory flow.

From National Asthma Education and Prevention Program, Expert Panel Report 2. *Guidelines for the diagnosis and management of asthma*. NIH publication No. 97-4051, April 1997, with permission.

whether admission to intensive care or to a hospital ward will likely be necessary, and to identify comorbid diseases that may complicate management, such as pneumothorax, pneumonia, and bacterial sinusitis.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

The cardinal symptoms of asthma are wheeze, chest tightness, and shortness of breath, often associated with cough. When a patient with a prior history of asthma presents with dyspnea and diffuse wheezes throughout the lung fields, the diagnosis is not difficult. The fundamental abnormality accounting for these features is diffuse, inhomogeneous narrowing of the airways throughout the lungs, but the signs and symptoms of asthma correlate poorly with the severity of airflow obstruction. Except for patients with an obviously severe attack, the initial assessment should therefore include some objective assessment of airflow. Simple measurements of lung function, such as forced expiratory volume in 1 second (FEV₁) or peak expiratory flow (PEF), provide quantitative, reproducible information, and serial measurements help the clinician to assess the response to therapy and avoid both unnecessary admission and premature discharge. Performing a maximal inspiratory-expiratory maneuver can itself provoke bronchoconstriction, especially in the absence of bronchodilator treatment. Therefore, in the patient suffering an obviously severe acute attack, it is prudent to wait until an hour or two after treatment has started before the first measurement of FEV₁ or peak flow.

Differential Diagnosis and Initial Evaluation

Cough, shortness of breath, and wheeze are nonspecific symptoms, and other diagnoses need to be considered, especially in patients without a prior diagnosis of asthma. In children under the age of 3 years, the most common cause of these symptoms is acute viral bronchitis/bronchiolitis, often resulting from infection with respiratory syncytial virus. Pneumonia is a cause of dyspnea, cough, and sputum production, but it is associated with localized wheezing at most. In elderly patients or in those with risk factors for cardiac disease, pulmonary edema must be considered, as acute elevations in left atrial pressure can cause airway narrowing and wheezing ("cardiac asthma"). The frequency with which acute pulmonary embolism presents with wheezing is probably overestimated, but the association is authentic. The disorder most commonly confused with an asthma exacerbation is probably acute bronchitis. Strictly speaking, the label of "acute bronchitis" may be correctly applied to the condition of asthmatic patients presenting with dyspnea and cough productive of purulent sputum, for they do indeed have an acute inflammation of the bronchial mucosa. The problem is that the diagnosis is insufficient, and the treatment prescribed, generally a broad-spectrum antibiotic, is inappropriate and ineffective. In fact, the correct diagnosis is often delayed by this error, and many patients are not given a diagnosis of asthma until they have taken multiple courses of antibiotics over several years to treat "bronchitis."

The most important mimic of asthma is *mechanical obstruction of the upper airway*. Unusual cases include laryngeal edema, an aspirated foreign body, benign or malignant tumors of the larynx or trachea, or mediastinal masses

compressing the central airways. The most common cause of upper airway obstruction is *vocal cord dysfunction*, a frequently overlooked psychophysiologic disorder in which contraction of intrinsic muscles of the larynx causes adduction of the vocal cords (7). Patients may be diagnosed with this disorder only after multiple emergency department visits and hospitalizations for asthma; many are treated (inappropriately) with high daily doses of an oral corticosteroid. Patients with vocal cord dysfunction are heterogeneous, but a substantial subgroup consists of overweight females with a history of sexual or emotional abuse. Another risk factor appears to be gastroesophageal reflux with repeated microaspiration of gastric acid. Regardless of an individual patient's demographics, upper airway obstruction should be considered when auscultation reveals monophonic wheezing over the lung fields that is loudest over the neck. Other clues include dysphonia and inspiratory stridor. The consequences can be dramatic; vocal cord dysfunction can even result in hypoventilation and carbon dioxide retention. The diagnosis may be confirmed by a flow-volume curve indicating fixed limitation of inspiratory flow (Chapter 54), but it usually requires laryngoscopy showing paradoxical adduction of the vocal cords during inspiration. The distinction of vocal cord dysfunction from asthma is important because β_2 -agonists and systemic corticosteroids are ineffective in the former, and the emergency treatment for severe attacks of vocal cord dysfunction—intravenous administration of a short-acting sedative such as midazolam—is contraindicated for asthma. Long-term management of vocal cord dysfunction often requires psychological counseling and consultation with a speech therapist.

The low mortality of asthmatics who present for emergency care is partly attributable to improved recognition of the features of potentially fatal attacks so that early transfer to an ICU is facilitated. It is sometimes easy to recognize an attack as life threatening. Obvious clues are an altered sensorium, an upright posture, diaphoresis, telegraphic speech, cyanosis, and fatigue. When any of these signs is present, objective assessment of the severity of airflow obstruction is not necessary before treatment is started (and, as noted earlier, may actually be risky). However, the absence of these signs does not exclude an attack from being potentially life threatening. Other clues are an inspiratory fall in systolic blood pressure (pulsus paradoxus) of more than 15 mm Hg, intercostal retractions, poor air movement ("silent chest"), a PEF or FEV₁ value that is below 25% of the predicted value, PEF below 100 L/min, and FEV₁ below 1.0 L. Pneumothorax is a life-threatening complication of asthma; wide swings in pleural pressure can rapidly cause progression to lung collapse and tension pneumothorax (Chapter 60).

Although a portable chest radiograph should be obtained whenever pneumothorax is suspected, chest radiography is not necessary for routine assessment of a patient with an asthma exacerbation. Bacterial pneumonia rarely

causes exacerbations, and the purulent sputum sometimes produced by asthmatic patients usually reflects inflammation of the bronchial airways caused by viral infections or allergen inhalation rather than bacterial bronchitis or pneumonia. Chest radiographs are thus reserved for the assessment of patients with fever in addition to purulent sputum, those with localized wheezing, and those in whom pneumothorax is suspected. Similarly, measurement of the white blood cell count and Gram stain of the sputum need not be performed in assessing acute attacks of asthma unless pneumonia is suspected.

Measurement of arterial blood gases is rarely necessary in the initial assessment. Patients having mild attacks usually have mild hypoxemia with normal oxygen saturation (PaO₂ 66 to 69 mm Hg), hypocapnia (PaCO₂ 33–36 mm Hg), and respiratory alkalosis. Hypoxemia can be detected by simple percutaneous oximetry and can be corrected by administering supplemental oxygen. *The practical purpose of measuring arterial blood gases is detection of carbon dioxide retention.* Respiratory drive is invariably increased in asthma exacerbations, and a normal value for PCO₂ may indicate extremely severe airflow obstruction (FEV₁ <15%–20% of predicted value) and fatigue of the muscles of respiration. However, even patients with carbon dioxide retention often respond quickly to therapy, so the important goal of initial assessment is to recognize that an attack is severe and to administer effective treatment. The information obtained from arterial blood gas measurement becomes particularly important when an attack does not respond to initial therapy, as it can help with the decision regarding the need for intubation and mechanical ventilation. In severe attacks, arterial blood gas values may also indicate the presence of acidosis, variably from metabolic and respiratory causes (lactic acidosis and alveolar hypoventilation, respectively); this rarely requires any treatment beyond effective oxygenation and relief of airflow obstruction.

Initial Treatment

Treatment should be started as soon as an asthma exacerbation is recognized and its severity assessed (Figure 56.1). While treatment is being administered, a focused history and physical examination pertinent to the exacerbation should be obtained. Lung function should be measured periodically, usually 2 hours after initial treatment and prior to hospital admission or discharge. The following are the key treatment modalities:

1. *Supplemental oxygen* (by nasal cannulae or mask) should be administered to maintain an oxygen saturation above 90% (>93% in children and pregnant women). Oxygen saturation should be monitored until a clear response to bronchodilator therapy occurs.
2. An inhaled short-acting β_2 -agonist should be administered promptly. In the emergency department, it is

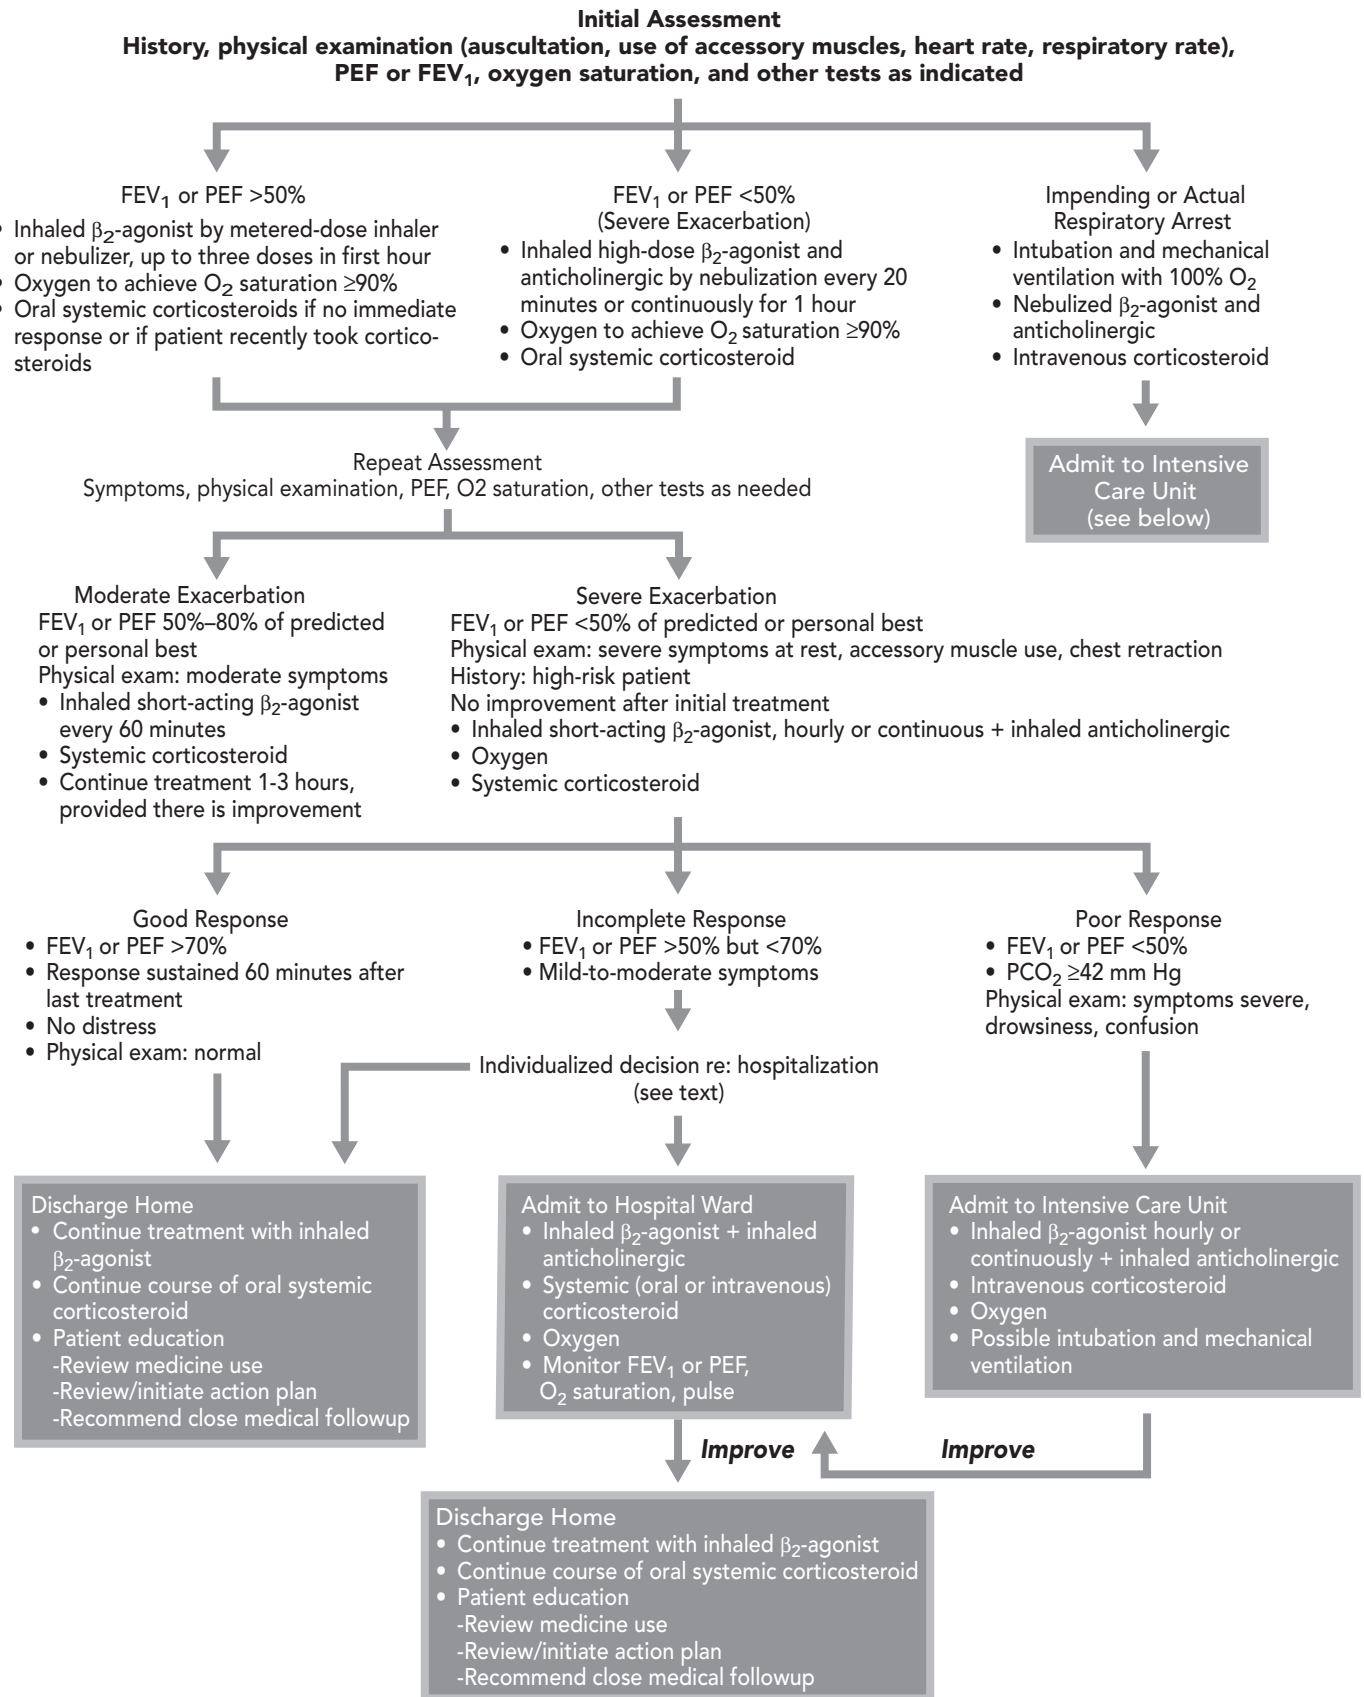

Figure 56.1 Management of asthma exacerbations: emergency department and hospital care. Adapted from the NIH guidelines for the diagnosis and management of asthma. Expert panel report 2. United States Department of Health and Human Services publication no. 97-4051.

usually given via a nebulizer (albuterol 2.5–5.0 mg in 1.5–2.0 mL isotonic saline) powered by a compressed oxygen–air mixture every 20 minutes for the first hour and hourly thereafter, or until clear improvement occurs. An alternative, but no more effective, strategy is to give the same total dose by continuous nebulization over 4–6 hours (8). Another equally effective approach for patients who can coordinate the use of a metered dose inhaler is to give albuterol by metered-dose inhaler (MDI) with a spacer, four to six puffs (90 mg per puff) every 20–30 minutes for the first hour and hourly thereafter. After this initial period of intense treatment, the frequency of administration varies according to the improvement in airflow obstruction and associated symptoms.

3. For severe exacerbations, an *anticholinergic agent* should be added to the nebulized β_2 -agonist. The addition of a high dose of ipratropium bromide (0.5 mg in adults) to an aerosolized solution of albuterol has been shown to enhance bronchodilation and reduce the rate of hospitalization in asthmatic patients with severe airflow obstruction (9).
4. For moderate to severe exacerbations, and for exacerbations incompletely responsive to initial β_2 -agonist therapy, begin an *oral corticosteroid "burst" regimen* (e.g., 40–60 mg of prednisone per day or 1–2 mg/kg per day), given in a single or divided doses for 3–7 days. Also provide supplemental doses of oral corticosteroids to patients who take them regularly, even if the exacerbation is mild. Prednisone and methylprednisolone are well absorbed when taken orally, so intravenous administration is not necessary. Systemic corticosteroids do not act immediately (the earliest demonstrable improvement is noted at 6 hours), but they have been proven to reduce the rates of hospitalization and relapse (10). In the past, treatment of patients hospitalized for severe asthma with an inhaled corticosteroid was thought to be contraindicated, for fear that the inhaled particles would irritate the airways and provoke bronchoconstriction. The opposite has been found to be the case, and some exploratory studies have suggested that early treatment with high doses of a potent inhaled corticosteroid may reduce or eliminate the need for systemic corticosteroid therapy after the third hospital day (11,12). At the least, starting patients on an inhaled corticosteroid before discharge provides an opportunity to instruct patients in their use and may reduce the risk of relapse even if oral corticosteroids are continued for 10–14 days after the attack (13,14).
5. *Methylxanthines are no longer recommended* because they appear to add no benefit to optimal inhaled β_2 -agonist therapy and may increase adverse effects. In patients currently taking a theophylline preparation, the serum level should be measured to rule out theophylline toxicity.

6. The place of antibiotics in treatment is not established. Only two prospective, blinded clinical trials have examined the question, and neither showed beneficial effect (15). Antibiotic treatment may be necessary for comorbid conditions (e.g., pneumonia, bacterial sinusitis), and it should be considered for patients with fever and purulent sputum or pulmonary infiltrates on chest radiography. The use of macrolide antibiotics has some theoretical attractiveness because they are active against the atypical bacteria *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*, which are identified in around 5% of asthma exacerbations. There is even a possibility that some asthmatic patients have a chronic, low-grade bronchial epithelial infection with these organisms (16) that flares with viral respiratory infection. This unproven hypothesis may account for the frequency with which macrolide antibiotics, especially azithromycin, are prescribed for asthma exacerbations.
7. If the response to treatment is favorable (no shortness of breath or wheezing, PEF or FEV₁ greater than 70% of predicted or "personal best" value), the patient can be discharged from the emergency department or short-stay unit with instructions to take a continued, tapering burst of oral corticosteroids and an inhaled β_2 -agonist as needed. Inhaled corticosteroid therapy should be initiated or continued, and arrangements should be made for appropriate follow-up.
8. If the response is incomplete or poor (persistence of symptoms, PEF less than 70% of baseline), an inhaled, short-acting β_2 -agonist should be given hourly and systemic corticosteroids begun. Treatment and monitoring can be continued for 1–3 hours provided improvement is noted. If the response is still incomplete (the patient remains symptomatic, PEF <70% of baseline), consider hospitalization for more intensive therapy and monitoring.

In summary, in the emergency department or hospital, the primary therapies—oxygen, inhaled β_2 -agonist, and systemic corticosteroids—are constant, but the dose and frequency of administration and the frequency of assessing the patient's response may vary.

Indications for Hospitalization

The decision to hospitalize a patient is based on several considerations: duration and severity of symptoms, severity of airflow obstruction (measurements of FEV₁ or PEF), course and severity of prior exacerbations, medication use at the time of the exacerbation, access to medical care and medications, adequacy of support and home conditions, and presence of comorbidities, especially psychiatric illness.

In general, patients with an incomplete response to therapy in the emergency department (FEV₁ or PEF >50% but <70% of predicted value or "personal best") and persistence

of mild to moderate symptoms require an individualized decision regarding hospitalization. Patients with an FEV₁ below 50% after 2 or 3 hours of initial treatment will generally require hospitalization; those who still appear fatigued or severely distressed or who still have severe airflow obstruction (FEV₁ or PEF <30% of predicted value) should be admitted to an ICU.

Identifying Patients at High Risk

Patients at high risk for asthma-related death require special monitoring and intensive education and care. The elements to consider in defining asthma severity and identifying those at risk for death are shown in Table 56.2.

It is not yet entirely resolved whether excessive use of an inhaled β -agonist is simply a marker of life-threatening asthma or in itself leads to an increased risk for death, but it is clear that the use of more than two canisters of an inhaled β -agonist per month is associated with a significant increase in the risk for death or near-death from asthma (17).

Indications for Intensive Care Unit Admission

A small subset of patients will require admission to an ICU for monitoring or for intubation and mechanical ventilation. These are patients with asthma that is unresponsive to

TABLE 56.2
RISK FACTORS FOR DEATH FROM ASTHMA

Past history of sudden severe exacerbations
Prior intubation for asthma
Prior admission for asthma to an ICU
Two or more hospitalizations for asthma in the past year
Three or more emergency care visits for asthma in the past year
Use of >2 canisters per month of inhaled short-acting β_2 agonist
Current use of systemic corticosteroids or recent withdrawal from systemic corticosteroids
Difficulty perceiving airflow obstruction or its severity
Comorbidity, such as cardiovascular diseases or chronic obstructive pulmonary disease
Serious psychiatric disease or psychosocial problems
Low socioeconomic status and urban residence
Illicit drug use
Sensitivity to <i>Alternaria</i>

the usual methods of treatment (*status asthmaticus*) or who manifest severe airway obstruction and impending respiratory arrest. Clinical features include an altered level of consciousness, obvious physical exhaustion, cyanosis or severe hypoxia (PaO₂ <60 mm Hg), pulsus paradoxus of more than 15 mm Hg, diminished breath sounds on auscultation (“silent chest”), tachycardia (>130 beats/min), and low arterial pH with a high PaCO₂. An FEV₁ value below 0.6 L or a PEF rate below 60 L/min that is unresponsive to bronchodilator therapy also heralds impending respiratory failure.

Such patients require the aggressive treatment and close monitoring that are possible only in an ICU setting. Arterial blood gases should be reassessed periodically until improvement occurs. Because of the dangers of intubation in severe asthma, additional treatments are sometimes attempted. One study found that the addition of intravenous montelukast improved FEV₁ and lessened the need for β agonist treatments but did not reduce the need for hospitalization (18). Slow (over 20–30 minutes) intravenous administration of magnesium sulfate (1–2 grams in adults) has not been proven effective but is safe, and it may be beneficial for some patients with severe acute asthma unresponsive to bronchodilators, oxygen, and corticosteroids (19). The same may be said of substitution of a mixture of helium and oxygen (“heliox”) for oxygen-enriched air. Resistance to flow is a function of gas density, and use of a 70% helium, 30% oxygen mixture does lead to transient improvements in airflow and in clinical status, but the benefits wane after about an hour, so the treatment can be regarded only as temporizing, given in the hopes that other therapy becomes effective before intubation is necessary (20). A more promising approach to forestalling the need for intubation may be to apply noninvasive mechanical ventilation (21).

The addition of these unproven therapies may prevent the need for some intubations, but *intubation should not be delayed once it is deemed clinically necessary*. The intubation and ventilation of asthmatic patients is fraught with hazard and should be performed in a controlled setting by a physician with extensive experience in intubation and airway management (Chapters 23 and 24). Because respiratory failure can develop rapidly once a patient becomes fatigued, it may be necessary to intubate the patient in the emergency department or inpatient ward and subsequently transfer the patient to an ICU.

Once intubation has been performed, mechanical ventilation is complicated by a dramatic shift in intrathoracic pressures, with wide swings from inspiration to expiration in response to a continuously positive pressure. Venous return falls sharply, and the consequent fall in arterial pressure requires aggressive IV administration of crystalloid. The general strategy in mechanically ventilating a patient with respiratory failure from asthma is to avoid dynamic hyperinflation and high airway pressures and the associ-

ated risks of barotrauma (22) (Chapter 23). Expiratory time is thus made as long as possible to allow complete exhalation, and if the ventilation necessary to maintain a normal PCO₂ cannot be achieved without excessive airway pressure, “permissive hypercapnia” is accepted. Adequate tissue oxygenation is ensured by administration of high inspired oxygen tensions. Hypercapnia is intensely uncomfortable to the patient, so profound sedation and paralysis are necessary for this strategy.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Treatment with inhaled β -agonists and oral or intravenous prednisone or methylprednisolone is almost invariably effective, but not always promptly. The rate of response roughly parallels the rate of deterioration, and the most rapid improvements occur in patients with sudden, severe attacks (e.g., after ingestion of sulfites or nonsteroidal anti-inflammatory medication, or after a food-provoking anaphylaxis). Slower responses to treatment are typically seen in attacks provoked by viral respiratory infections, especially if the attack has developed during several days and is associated with mucous hypersecretion. Clear improvement is sometimes not apparent until the third or fourth hospital day. In such cases, it is important to continue to monitor the patient closely because *improvement is not always smoothly progressive, and asthma sometimes worsens after initial improvement*. Nocturnal deterioration seems particularly common, and most respiratory arrests in hospitalized patients occur in the early hours of the morning. Monitoring FEV₁ or peak flow each morning and evening can provide useful information; wide diurnal swings suggest extreme bronchial lability and a heightened risk for respiratory arrest. Impatience with the slowness of response sometimes provokes the use of injudicious or unproven therapies, such as chest physical therapy or aerosolized mucolytic agents. Both can cause distress or fatigue, and an aerosolized mucolytic agent (e.g., acetylcysteine) can irritate the airway, thereby worsening cough and airflow obstruction.

DISCHARGE ISSUES

The criteria for discharge from the hospital resemble those for discharge from the emergency department. Discharge is appropriate when symptoms and physical findings are minimal and the PEF or FEV₁ remains above 70% of the predicted or “personal best” value for 3 or 4 hours after administration of a standard dose of an inhaled β -agonist from an MDI.

The requirement for hospitalization is a signal event, indicating an increased risk for asthma mortality during the

subsequent year and probably also an inadequate understanding of triggers to be avoided or the actions that should be taken to abort attacks once they start. Before patients are discharged from the emergency department or hospital, they should be educated (or re-educated) regarding the need for maintenance “long-term controller” therapy (e.g., with an inhaled corticosteroid), avoidance of triggers (e.g., removing allergens and irritants from the home environment), and development of self-assessment skills (e.g., monitoring symptoms and peak flow). A peak flow meter should be given to the patient, along with instructions on how to measure and record peak flow values in a diary (see Table 56.3).

Before discharge, the provider and patient should review the nature and purposes of prescribed medications, with an emphasis on the importance of correct inhaler technique. Patients given systemic corticosteroids should continue them for 7–10 days. Inhaled corticosteroids, or the combination of an inhaled corticosteroid and a long-acting β -agonist should also be started before discharge. A follow-up appointment should be scheduled at about the time the course of oral corticosteroid therapy is to be completed.

Finally, the patient should be given at least a simple plan for actions to be taken if symptoms, signs, and PEF values suggest recurrent airflow obstruction (see Figure 56.2). The plan can be based on symptoms or peak flow, but it should follow the principle that therapy must be intensified (e.g., by increasing the dose of inhaled corticosteroid fourfold) as soon as asthma begins to worsen, with even more aggressive treatment undertaken (e.g., initiating a short course of prednisone) if the attack progresses. Action plans should be coupled with instructions for early contact with a provider to prevent recurrences of severe or life-threatening episodes.

COST CONSIDERATIONS AND RESOURCE USE

The high cost of asthma is largely attributable to the costs of hospitalization, emergency department visits, and unscheduled office visits. The risks for these events increase with increasing severity of disease and can be reduced by the regular use of “long-term controller” therapies, such as an inhaled corticosteroid and a long-acting inhaled β -agonist. The logical approach to reducing costs is thus improving the care of those patients most likely to require emergency care or hospitalization—patients with moderate or severe persistent asthma. One marker of severity is the need for hospitalization, and attention to the exacerbation itself should not distract providers from the opportunity hospitalization presents for intense patient education about the principles of self-assessment and care.

The measure that most powerfully reduces the costs of treatment of individual attacks is reducing the duration of

TABLE 56.3**HOSPITAL DISCHARGE CHECKLIST FOR PATIENTS WITH ASTHMA EXACERBATIONS**

Intervention	Dose/timing	Education/advice (with M.D./R.N. initials)
Inhaled medications (MDI + spacer/holding chamber)	Select agent, dose, and frequency (e.g., albuterol)	Teach purpose Teach technique
β_2 -agonist	2–6 puffs q3–4h p.r.n.	Emphasize need for spacer/holding chamber
Corticosteroids	Medium dose	Check patient technique
Oral medications	Select agent, dose, and frequency (e.g., prednisone 20 mg b.i.d. for 3–10 days)	Teach purpose Teach side effects
Peak flow meter	Measure a.m. and p.m. PEF and record best of three tries each time	Teach purpose Teach technique Distribute peak flow diary
Follow-up visit	Make appointment for follow-up care with primary clinician or asthma specialist	Advise patient (or caregiver) of date, time, and location of appointment (should be within 7 days of hospital discharge)
Action plan	Before or at discharge	Instruct patient (or caregiver) on simple plan for actions to be taken when symptoms, signs, and PEF values suggest recurrent airflow obstruction

MDI, metered dose inhaler; PEF, peak expiratory flow.

hospitalization. Prompt initiation of patient education in self-monitoring and treatment appears to increase the comfort of the inpatient medical and nursing staff with the idea of allowing the patient to go home so that a hospital stay is shortened by about a day. Additional savings can be achieved by avoiding unnecessary laboratory tests (especially arterial blood gas determinations, chest radiographs, and blood and sputum cultures) and avoiding inappropriate administration of antibiotics. Even severe airflow obstruction responds well to β -agonist administration by MDI with a spacer device. The costs for the personnel, equipment, and medication needed to deliver nebulized therapy are much greater, so savings can be achieved by reserving nebulized therapy for patients with severe attacks and switching to treatment by MDI as soon as possible. Institution of all these measures is enhanced by institution of a “clinical pathway” for inpatient asthma (23).

KEY POINTS

- Management of patients with asthma, particularly those with acute exacerbations, should begin with a risk assessment that considers the clinical presentation, the

history, and objective measures of the severity of the attack.

- Respiratory drive is invariably increased in acute attacks of asthma, so detection of an elevated or even normal carbon dioxide tension (PCO_2) on arterial blood gas measurement indicates an attack of life-threatening severity.
- Hospital management of acute attack consists principally of oxygen supplementation, the frequent use of bronchodilators (especially inhaled β -adrenergic agonists), and systemic administration of corticosteroids.
- The place of antibiotics in the treatment of exacerbations of asthma is not established. Because viral respiratory infections are the most common precipitant of exacerbations, antibiotics should not be given routinely. There is some theoretical basis for the use of a macrolide antibiotic, but its clinical value has not been established.
- Hospitalization for asthma is a predictor of increased risk for readmission for subsequent attacks and for death from asthma. Full advantage must be taken of the opportunity presented by hospitalization to evaluate and improve the patient’s knowledge of the disease and skills for self-monitoring and treatment.

Date _____

When to Monitor Peak Flow Numbers

- In the morning soon after waking up
- Before supper
- Before bed
- Before and 5-15 minutes after inhaled treatments
- With increased respiratory symptoms
- _____

Important Peak Flow Numbers

Baseline _____
 _____ % baseline = _____
 _____ % baseline = _____

If your peak flow number drops below _____ or you notice:

- Increased use of inhaled treatments to manage asthma
- Increased asthma symptoms upon awakening
- Awakening at night with asthma symptoms

Follow these treatment steps:

- Increase inhaled steroids.
Take _____ puffs of _____ times a day.
- Begin/increase treatment with oral steroids.
Take _____ mg of _____
in the morning and/or before supper.
- Other _____

If your peak flow number drops below _____ or you continue to get worse after increasing treatment according to the directions above, follow these treatment steps:

- Begin/increase treatment with oral steroids.
Take _____ mg of _____
in the morning and/or before supper.
- Contact your health care provider.
- Other _____

Contact your health care provider if:

- Asthma symptoms worsen while you are taking oral steroids, or
- Inhaled bronchodilator treatments are not lasting 4 hours, or
- Your peak flow number falls below _____.
- If you cannot contact your health care provider go directly to the Emergency Room.

Directions for Resuming Normal Treatment:

- Continue increased treatment until symptoms and peak flow number have returned to normal; then continue increased inhaled steroids or _____ mg of oral steroids for the same number of days it took to return to normal. If your peak flow number has not returned to normal in 5 days, contact your health care provider.
- Call your health care provider for specific instructions.

If you have questions please call:

_____ After hours _____
 Name Phone Name Phone

Interstitial Lung Disease

57

Talmadge E. King, Jr.

INTRODUCTION

The interstitial lung diseases (ILDs) are a heterogeneous group of parenchymal lung disorders that are classified together because of similar clinical, roentgenographic, physiologic, or pathologic manifestations. Environmental or occupational exposures, especially to inorganic or organic dusts, are the most common known causes of ILD. Sarcoidosis, idiopathic pulmonary fibrosis (IPF), and pulmonary fibrosis associated with connective tissue diseases (CTD) are the most common ILDs of unknown etiology.

The incidence and prevalence of ILDs are unknown. Studies suggest a prevalence of 80.9 per 100,000 for men and 67.2 per 100,000 for women, with both incidence and prevalence rising with age. In 1988, an estimated 30,000 hospitalizations (compared with 665,000 hospitalizations for chronic obstructive pulmonary disease and asthma) and 4,851 deaths in the United States were attributed to pulmonary fibrosis. The death rate for pulmonary fibrosis appears to have increased during the past 20 years, but vital statistics are sparse and unreliable.

Table 57.1 outlines the major causes of ILD. In the vast majority of ILDs, the symptoms and signs unfold over months or years (e.g., IPF, sarcoidosis, and pulmonary histiocytosis X). In other ILDs, the onset may be acute (days to weeks) or subacute (weeks to months). These latter processes may be confused with community-acquired pneumonias because they often present with diffuse radiographic opacities, fever, or recurrent episodes of disease activity. Examples of acute or subacute processes include acute idiopathic interstitial pneumonia (AIP), diffuse alveolar hemorrhage syndromes (DAH), bronchiolitis obliterans with organizing pneumonia (BOOP), some drug-induced ILDs, eosinophilic pneumonias, hypersensi-

tivity pneumonitis (HSP), and the acute immunologic pneumonia that complicates CTDs (especially systemic lupus erythematosus or polymyositis). Because these acute and subacute groups most frequently lead to hospitalization, this chapter focuses on these processes.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

Patients with ILD most commonly come to clinical attention because of the insidious onset of progressive breathlessness on exertion (dyspnea), a persistent nonproductive cough, or an incidental finding associated with another disease, such as a CTD. Acute presentations are usually associated with the development of spontaneous pneumothorax, hemoptysis, wheezing, or chest pain.

Differential Diagnosis

Acute Interstitial Pneumonia (Hamman-Rich Syndrome)

Acute interstitial pneumonia is a rare fulminant form of lung injury that presents acutely (days), usually in a previously healthy person over the age of 40 (1). Fever, cough, and dyspnea are the most common clinical signs and symptoms. There is no sexual predilection. Results of routine laboratory studies are nonspecific and generally not helpful. Diffuse, bilateral opacification is seen on chest radiographs. Computed tomography (CT) shows bilateral, patchy, symmetric areas of "ground glass" attenuation. Most patients have moderate to severe hypoxemia, and in

TABLE 57.1**CLINICAL CLASSIFICATION OF INTERSTITIAL LUNG DISEASE****Environmental and occupational exposures**

-
- I. Inorganic dust
 - A. Silica
 - B. Silicates (i.e., asbestos, talc, and kaolin or “china clay”)
 - C. Hard-metal dusts (i.e., cadmium and titanium oxide)
 - D. Beryllium
 - II. Organic dusts (hypersensitivity pneumonitis or extrinsic allergic alveolitis)
 - A. Thermophilic bacteria (i.e., *Micropolyspora faeni*, *Thermoactinomyces vulgaris*, and *T. sacchari*)
 - 1. Farmer’s lung
 - 2. Grain handler’s lung
 - 3. Humidifier or air conditioner lung
 - B. Other bacteria (i.e., *Bacillus subtilis* and *B. cereus*)
 - 1. Humidifier lung
 - C. True fungi (i.e., *Aspergillus*, *Cryptostroma corticale*, *Aureobasidium pullulans*, and penicillin species)
 - III. Animal proteins (e.g., bird fancier’s disease)
 - IV. Bacterial products (byssinosis)
 - V. Chemical sources, gases, fumes, vapors, aerosols, paraquat, and radiation
-

Drug-induced lung disease (partial list)

-
- I. Acute onset
 - A. Diffuse alveolar damage (DAD): “crack” cocaine, amiodarone, nitrofurantoin, and any cytotoxic agent (e.g., bleomycin, carmustine, busulfan, mitomycin, procarbazine, methotrexate, gefitinib, and trastuzumab)
 - B. Noncardiogenic pulmonary edema (probably DAD): cytosine arabinoside, aspirin and related compound, and opiates
 - C. Diffuse alveolar hemorrhage (DAH): “crack” cocaine, penicillamine, phenytoin, anticoagulants, thrombolytic agents, and cytotoxic drugs that cause diffuse alveolar damage
 - II. Acute or subacute onset
 - A. Eosinophilic pneumonia: nonsteroidal anti-inflammatory agents and antibiotics (ampicillin, minocycline, sulfonamides, nitrofurantoin, and sulfasalazine)
 - B. Bronchiolitis obliterans organizing pneumonia (BOOP): amiodarone, methotrexate, and bleomycin
 - C. Desquamative interstitial pneumonia (DIP): nitrofurantoin and sulfasalazine

many patients, respiratory failure requiring mechanical ventilation develops.

The diagnosis of AIP requires the demonstration of organizing *diffuse alveolar damage* (DAD) on lung tissue examination. Consequently, a lung biopsy (now generally performed thoracoscopically) is required to confirm the diagnosis. DAD is a nonspecific reaction to lung injury and is therefore the underlying lesion seen in many insults, including in the acute respiratory distress syndrome and cytotoxic drug injury. The characteristic histology of DAD includes the presence of interstitial and intra-alveolar edema, capillary congestion and microthrombi, and intra-alveolar hyaline membranes.

The mortality associated with AIP is high (>60%), with the majority of patients dying within 6 months of presentation. However, those who recover usually do not have a recurrence of the disease, and many have a substantial or complete recovery of lung function. The main treatment is supportive care; corticosteroids have not been demonstrated to be beneficial.

Diffuse Alveolar Hemorrhage

Diffuse alveolar hemorrhage (DAH) is a syndrome of diffuse intra-alveolar bleeding originating from the alveolar capillaries and occasionally the precapillary arterioles and postcapillary venules (2). The most frequent underlying associated histology is *pulmonary capillaritis*, which is an infiltration of neutrophils into the interstitium of the lung. Pulmonary capillaritis has been reported with variable frequency and severity among the vasculitides (Chapter 111). A bland form of pulmonary hemorrhage *without capillaritis* can be found as a complication of anticoagulation or thrombolytic therapies, various coagulopathies, and mitral stenosis.

Patients with DAH have several days of cough, dyspnea, and (most importantly) hemoptysis. Patients presenting to the hospital with DAH may be having a first episode, a recurrent episode, or the initial manifestation of an underlying disease. DAH should be suspected if there is an acute pneumonic presentation, a chest radiograph demonstrating diffuse alveolar opacities, or an unexplained anemia. It is important to note that one can have significant alveolar bleeding without hemoptysis. The demonstration of sequential hemorrhagic bronchoalveolar lavage specimens can verify the presence of DAH if hemoptysis is absent. Although the diagnosis of pulmonary capillaritis can be made by fiberoptic bronchoscopy with transbronchial biopsy, thoracoscopic biopsy is often required to be certain of the diagnosis. In addition, certain ancillary laboratory tests, such as antineutrophil cytoplasmic antibodies, antinuclear antibodies, and antiglomerular basement membrane antibodies, may help diagnose an underlying disease (Chapters 111 and 112). Therapy depends on the underlying process that gave rise to the pulmonary capillaritis and usually includes corticosteroids and cyclophosphamide or

azathioprine. Thus, it is crucial that infection be excluded as a cause of the acute illness. In more than 50% of DAH cases, regardless of cause, mechanical ventilation is required. Furthermore, many of the causes of DAH are associated with recurrent episodes.

Cryptogenic Organizing Pneumonia

Cryptogenic organizing pneumonia (COP), or *idiopathic bronchiolitis obliterans with organizing pneumonia* (idiopathic BOOP), is a clinicopathologic syndrome of unknown etiology that is often confused with community-acquired pneumonia. The disease usually presents in the fifth and sixth decade and affects men and women equally. Almost three-fourths of the patients have their symptoms for less than 2 months, and few have symptoms for more than 6 months before diagnosis. A flulike illness, characterized by cough, fever, malaise, fatigue, and weight loss, heralds the onset of COP in two-fifths of the patients. Inspiratory crackles are found on chest examination. Results of routine laboratory studies are nonspecific. Pulmonary function is usually impaired; a restrictive defect is the most common finding. Resting or exercise arterial hypoxemia is also common. The roentgenographic manifestations are quite distinctive and include bilateral, diffuse alveolar opacities (often recurrent and migratory) in the presence of normal lung volumes. Chest CT may reveal much more extensive disease than is expected from the plain radiographic findings. Corticosteroid therapy is the most commonly used treatment and results in clinical recovery in two-thirds of these patients.

Lung biopsy (usually via thoracoscopy) is required to confirm the diagnosis. The histopathologic process is characterized by an excessive proliferation of granulation tissue within small airways (*proliferative bronchiolitis*) and alveolar ducts associated with chronic inflammation in the surrounding alveoli. This organizing pneumonia ("BOOP pattern") is a nonspecific reaction to lung injury that can occur as a secondary finding adjacent to many pathologic processes (e.g., malignancy) or as a component of other primary pulmonary disorders (e.g., cryptococcosis, Wegener's granulomatosis, lymphoma, HSP, and eosinophilic pneumonia) (3). In cases of COP, however, the "BOOP pattern" is the only lesion found.

Drug-Induced Interstitial Lung Disease

Many drugs are capable of causing interstitial lung reactions, usually during the therapeutic period or immediately thereafter (4). Pulmonary reactions can occur acutely after a single dose of a drug such as nitrofurantoin or after inhalation of "crack" cocaine. Factors that increase the likelihood of a drug-induced ILD include older age of the patient, higher initial dosing, higher cumulative dose, and the use of several cytotoxic drugs in combination. Patients who receive cytotoxic chemotherapy for underlying malignancy with either bleomycin, busulfan, or carmustine are also at

risk for the development of DAD after radiation therapy or treatment with high concentrations of oxygen. Patients being treated with amiodarone who undergo a surgical procedure in which high concentrations of oxygen are administered may also develop DAD. The diagnosis of drug toxicity is confirmed when withdrawal of the drug is followed by improvement and eventual resolution of the ILD. Further proof of a drug-related ILD is the return of the pneumonitis with reinstatement of the drug (not a recommended strategy).

Connective Tissue Diseases

Because of the systemic nature of CTDs, all components of the respiratory system can be involved. Although the pulmonary complication may occur simultaneously with the onset of the systemic disorder, it is more common for the pulmonary disorder to complicate a previously established CTD. An acute presentation, often mimicking that of community-acquired pneumonia, is most likely to occur in systemic lupus erythematosus but has also been noted in other CTDs (polymyositis–dermatomyositis, scleroderma, and mixed CTD). The possible underlying histologies for this acute pneumonitis include BOOP (usually seen with rheumatoid arthritis or polymyositis–dermatomyositis) (Figure 57.1), DAD, DAH (usually in patients with systemic lupus erythematosus and nephritis), nonspecific interstitial pneumonia, and lymphocytic interstitial pneumonia (often in patients with Sjögren syndrome, either primary or associated with rheumatoid arthritis). Pul-

monary hypertension (Chapter 59) and vasculitis (Chapter 111) can complicate the clinical course of patients with CTD. Although pulmonary complications of CTDs are not uncommon, the clinician must carefully consider infection or side effects of drug treatment as the cause of acute worsening in any patient with a CTD.

Idiopathic Pulmonary Fibrosis

The clinical manifestations of IPF are dyspnea on exertion, nonproductive cough, and “Velcro-type” inspiratory crackles on chest examination. In advanced disease, signs of cor pulmonale, digital clubbing, and cyanosis may be noted on physical examination. The chest roentgenogram and high-resolution CT typically reveal reduced lung volumes with patchy reticular opacities in the lower lung zones in a predominantly peripheral distribution. Honeycombing (small cystic lesions), traction bronchiectasis, subpleural fibrosis, and signs of pulmonary hypertension also may be present, depending on the stage of the disease. Pulmonary function studies often reveal restrictive impairment, reduced diffusing capacity for carbon monoxide, and hypoxemia.

Clinical deterioration in patients with IPF is expected. Most patients experience progressive breathlessness and decreased exercise tolerance during months to years. End-stage IPF frequently leads to incapacitating respiratory insufficiency, with patients unable to carry out activities of daily living without extreme distress. The goals of hospitalization are usually to search for a treatable cause of worsening symptoms or to provide comfort (oxygen, sedation)

Figure 57.1 Dermatomyositis. **A.** This 51-year-old woman with long-standing dermatomyositis presented with cough, fever, and dyspnea of 2 weeks duration. The chest roentgenogram shows diffuse bilateral alveolar opacities, most prominent at the left lung base. **B.** High-resolution, thin-section computed tomogram shows predominantly patchy, “ground glass” opacities and consolidation, especially in the lower lobes. Thoracoscopic lung biopsy showed the pattern of bronchiolitis obliterans with organizing pneumonia (BOOP).

to the patient at the end of life (Chapter 19). Weaning patients with IPF from mechanical ventilation is extremely difficult; therefore, a decision to start mechanical ventilation should be made with extreme caution. Death usually ensues as a result of intractable hypoxemia and respiratory failure.

Some patients have acute or rapidly progressive disease ("acute exacerbation" or "accelerated stage" of IPF). This presentation is generally characterized by severe worsening dyspnea or cough and systemic symptoms, such as fever, fatigue, and weight loss. Usually, the illness duration prior to presentation is 2–4 weeks (5). The episodes often represent the superimposition of another process, such as DAD, DAH, or BOOP. In the evaluation of subacute or acute clinical deterioration in patients with IPF, disease progression may be difficult to distinguish from disease-associated complications and adverse effects of therapy (6). The incidence of pulmonary infections is slightly increased in IPF and is a major factor in the death of 2%–4% of patients. Therapeutic interventions, especially corticosteroids and cytotoxic agents, may further increase the risk for infection and reactivation of latent infections by suppression of cell-mediated immunity. Heart failure and ischemic heart disease are common problems in patients with IPF, accounting for nearly one-third of deaths. Right ventricular failure may develop as a result of pulmonary hypertension (present in approximately 70% of patients) (5). Pneumothorax is uncommon and may be extremely difficult to treat because the lung is stiff and difficult to re-expand. Prolonged chest tube drainage, with high levels of negative pressure (20–40 mm Hg), may be necessary. Some patients may require thoracotomy, bleb resection, and pleurectomy to close the air leak. Acute pulmonary embolism may cause a sudden worsening of dyspnea, with unexplained deterioration in arterial blood gas levels. Pulmonary embolism causes 3%–7% of deaths in IPF.

Interstitial Lung Disease Associated with Respiratory Bronchiolitis

Interstitial lung disease associated with respiratory bronchiolitis is a distinct and unusual clinical syndrome found in current or former cigarette smokers in their fourth or fifth decades of life. ILD associated with respiratory bronchiolitis and desquamative interstitial pneumonia are now thought to be different stages of the same process. Most patients present with a subacute (weeks to months) illness characterized by dyspnea and cough. Diffuse, fine, reticular or nodular interstitial opacities are found on chest radiographs; lung volumes are usually normal. Other features include bronchial wall thickening, prominence of peribronchovascular interstitium, small regular and irregular opacities, and small peripheral ring shadows. High-resolution CT shows similar features with hazy opacities. A mixed obstructive–restrictive pattern is common on lung function testing. Arterial blood gas levels show mild hy-

poxemia. The clinical recognition of ILD associated with respiratory bronchiolitis and of desquamative interstitial pneumonia is important because the process is associated with a good prognosis. Smoking cessation is the main treatment. Hospitalization is generally unnecessary (when it occurs, it is usually to facilitate initial evaluation and lung biopsy). The estimated mortality rate is 5% within 5 years, and overall survival is about 70% after 10 years.

Pulmonary Langerhans' Cell Histiocytosis

Pulmonary Langerhans' Cell Histiocytosis (previously called Pulmonary Histiocytosis X) is a rare, smoking-related diffuse lung disease that primarily afflicts young adults (usually men) between the ages of 20 and 40. The clinical presentation is variable, ranging from an asymptomatic state to a rapidly progressive condition. The most common clinical findings at presentation are cough, dyspnea, chest pain, weight loss, and fever. Pneumothorax occurs in about 25% of patients and is the most common reason for hospitalization. It is occasionally the first manifestation of the illness. Hemoptysis and diabetes insipidus are other, rare manifestations. The physical examination findings are usually normal. The radiographic changes include a combination of ill-defined or stellate nodules (2 mm–10 mm in size), reticular or nodular opacities, upper zone cysts or honeycombing, preservation of lung volume, and costophrenic angle sparing. The most frequent pulmonary function abnormality is a markedly reduced diffusing capacity for carbon monoxide, although varying degrees of restrictive disease, airflow limitation, and diminished exercise capacity have been described. Discontinuance of smoking is the key treatment; it results in clinical improvement in one-third of patients. Most patients with Pulmonary Langerhans' Cell Histiocytosis suffer persistent or progressive disease, and about 10% die of respiratory failure.

Sarcoidosis

Sarcoidosis is a systemic disorder of unknown origin characterized by granulomatous inflammation in a variety of organs, most commonly the lung. This disease is usually seen in younger persons between the ages of 20 and 40. The clinical presentation is quite variable; some patients are asymptomatic, some have generalized constitutional symptoms, and others have symptoms associated with specific organ involvement. Dyspnea, cough, and chest pain are common thoracic manifestations. The lungs often seem normal on auscultation even when parenchymal abnormalities are present on the chest roentgenogram. Hypercalcemia, hypergammaglobulinemia, and abnormal serum liver chemistries are frequently found. Symmetric, bilateral hilar adenopathy is the most common chest radiographic finding, but parenchymal opacities occur in roughly half of subjects (Figure 57.2). Pulmonary function testing may show a normal, restrictive, or mixed obstructive–restrictive

Figure 57.2 Sarcoidosis. This 38-year-old man was hospitalized because of worsening cough and breathlessness of 3–4 weeks duration. Previous chest radiographic findings were normal. This film shows bilateral hilar lymphadenopathy and diffuse nodular opacities (stage II sarcoidosis).

pattern. Hypoxemia or exercise-induced desaturation and a reduced diffusing capacity for carbon monoxide may also be seen. The diagnosis is occasionally made on clinical grounds, but in most cases, examination of lung tissue obtained by transbronchial biopsy is useful in confirming a suspected diagnosis of sarcoidosis.

Life-threatening situations that require hospitalization are very uncommon. These include progressive fibrosis with development of respiratory failure; cardiac disease (which often has a relatively rapid onset and high mortality because of ventricular arrhythmias, supraventricular arrhythmias, or heart block); renal failure secondary to granulomatous interstitial nephritis and hypercalcemia with hypercalciuria; hepatic disease with development of hepatic vein occlusion or bleeding esophageal varices; and neurosarcoidosis (meningitis, space-occupying lesions, cranial nerve involvement, diabetes insipidus, seizure disorders, peripheral neuropathies). Treatment with corticosteroids is indicated for symptomatic patients and those with involvement of vital organs, such as the eyes, central nervous system, and heart. Although sarcoidosis is generally very responsive to steroids, it is unclear whether the natural history of this disease is altered by therapy.

Eosinophilic Pneumonia

Acute eosinophilic pneumonia presents as a community-acquired pneumonia causing several days of dyspnea, nonproductive cough, and low-grade fever (7). It tends to appear in young persons. A recent history of the onset of cigarette smoking is present in some patients. The chest

radiograph shows diffuse bilateral alveolar opacities. Most cases are idiopathic, but drug toxicity (particularly to nonsteroidal anti-inflammatory agents and tetracycline and its related compounds) can also be responsible. Peripheral and bronchoalveolar lavage eosinophilia is often found.

Chronic eosinophilic pneumonia is a recurrent disease, appearing intermittently during several years and, in some patients, leading to extensive lung fibrosis. Most patients are between the fifth and eighth decades, and the onset is subacute, with cough and dyspnea present for weeks to months. More than half the patients with chronic eosinophilic pneumonia have a prominent background of asthma or allergies, and wheezing with evidence of airflow obstruction on lung function studies may therefore be present. Another important finding is an increased serum level of immunoglobulin E, seen in approximately two-thirds of the patients. The chest radiograph often shows alveolar opacities that are peripherally distributed (“photographic negative of pulmonary edema”) (Figure 57.3). With recurrent disease, pulmonary fibrosis can develop, most prominently in the upper lung zones.

When patients are hospitalized with eosinophilic pneumonia, it is usually because of impending respiratory failure and the need to make a definite diagnosis. Intensive care is rarely needed if the diagnosis is made promptly and treatment initiated with corticosteroids. Both acute and chronic cases of eosinophilic pneumonia have an excellent response to corticosteroid treatment. Unfortunately, in

Figure 57.3 Idiopathic chronic eosinophilic pneumonia. This 35-year-old woman was hospitalized because of a progressive nonproductive cough, fever, malaise, and a 10-pound weight loss of 4 weeks duration. She had noted progressive breathlessness and night sweats during the week before admission. The chest roentgenogram shows bilateral diffuse peripheral opacities. There was a dramatic response to corticosteroid therapy, with complete resolution of the chest radiographic abnormalities within 1 month following discharge. She unfortunately has had multiple recurrences after withdrawal or lowering of her corticosteroids.

chronic eosinophilic pneumonia relapse frequently results when the steroids are tapered. Maintenance therapy with low doses of prednisone (5 mg–20 mg) is often required to prevent recurrence.

Inhalation Injury Secondary to Toxic Fumes, Gases, Chemicals, Aerosols, or Mists

Exposure to noxious and toxic fumes and gases is a significant industrial and environmental hazard (8). Oxides of nitrogen are the most common and best-described agents that cause acute and chronic lung injury, particularly nitrogen dioxide (NO₂). Silo filler's disease is a well-studied example, with an annual incidence of 5.0 cases per 100,000 silo-associated farm workers. Several outcomes are possible after an exposure, based on the setting, degree, and type of exposure: (a) Sudden death may occur in persons exposed to high concentrations of these substances. Death is caused by bronchiolar spasm, laryngospasm, reflex respiratory arrest, or simple asphyxiation. (b) In persons with mild exposures, symptoms may be limited to upper airway and visual disturbances. Some patients will experience cough, dyspnea, fatigue, cyanosis, vomiting, hemoptysis, arterial hypoxemia, vertigo, somnolence, headache, emotional difficulties, and loss of consciousness. These symptoms usually resolve in hours but may persist for several weeks before complete recovery occurs. (c) Pulmonary edema is a common complication at higher concentrations. Frequently, these patients have deceptively mild symptoms initially, but severe, acute DAD develops within several (3 to 30) hours. Most patients recover with no significant sequelae, but death may occur at this stage from progressive respiratory insufficiency. (d) In patients who have recovered or who suffered no acute illness after exposure, cough and dyspnea may recur or develop 2–6 weeks later.

In patients with acute lung injury, rales are usually present on auscultation of the lungs. The chest roentgenogram often demonstrates pulmonary edema. In survivors, these changes often clear rapidly. The roentgenographic pattern in the late stage can be variable, either normal or hyperinflated. Arterial hypoxemia, which is common, is caused by ventilation–perfusion mismatching resulting from altered airway dynamics and interstitial and alveolar edema. Methemoglobinemia may contribute to the arterial hypoxemia. Severe metabolic acidosis occurs when nitrogen dioxide dissolves in body fluids to form nitrous and nitric acid and tissue hypoxia leads to lactic acidosis. Decreased diffusing capacity is also common. These abnormalities gradually resolve in most patients.

Histopathologically, there may be severe pulmonary edema and evidence of DAD. Autopsy studies reveal marked intra-alveolar edema and exudation, in addition to thickening of the alveolar walls with lymphocytic cellular infiltrates. An organizing DAD with a component of proliferative bronchiolitis obliterans is seen in some patients who survive but have persistent lung injury. Widespread

constrictive bronchiolitis, obliterans or not, is found in patients in whom progressive obstructive lung disease develops.

Hospitalization for 24–48 hours is required after acute exposure, and the patient should be followed weekly or bi-weekly for 6–8 weeks. If arterial blood gas or pulmonary function test values are abnormal, treatment with corticosteroids should be started immediately. Corticosteroid therapy has been demonstrated to be useful in the management of both nitrogen dioxide-induced pulmonary edema and bronchiolitis obliterans. Treatment should be continued for a minimum of 8 weeks to avoid relapses. Bronchodilators are occasionally helpful. Antibiotics should be used only when clinically indicated and directed at a specific pathogen. The prognosis for survivors is generally good, although about one-third of persons exposed to nitrogen dioxide die acutely.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (HSP) denotes a group of diseases produced by repeated inhalation of finely dispersed organic dusts or simple chemicals in susceptible persons. Respiratory symptoms, fever, chills, and abnormal chest roentgenographic findings are often temporally related to working (*farmer's lung*) or engaging in a hobby (*pigeon breeder's disease*). Granulomatous inflammatory responses in these people produce diffuse or patchy patterns of interstitial and alveolar disease in the lungs. The list of antigens and sources or reservoirs of antigens potentially related to HSP continues to grow. Bacterial and fungal overgrowth in air conditioners, humidifiers, and evaporative coolers, in addition to bird droppings and proteins, are important causes of disease in urban settings.

The disease may present acutely, presumably after heavy or new antigen exposure, with the patient complaining of fever, chills, dyspnea, and cough. Inspiratory rales and mild hypoxemia are common. Chest radiographic findings may be normal or show fleeting reticular, nodular, or alveolar opacities, predominantly in the middle to lower lung zones (Figure 57.4). Leukocytosis is common, but eosinophilia is generally absent. Restrictive pulmonary function is seen early in the disease course, but lung function frequently is normal between exposures.

Hospitalization is rarely necessary, as the symptoms and signs usually resolve several hours after exposure has ended; symptoms often reappear on repeated exposure. In most patients who are hospitalized, the diagnosis is not suspected. Often, the patient is thought to have a community-acquired pneumonia and improves rapidly on treatment with antibiotics. After discharge, the patient commonly suffers a rapid and sometimes severe relapse when exposed again to the antigen.

HSP may present in a much less dramatic fashion. Low-level, persistent antigen exposure may cause a progressive deterioration in function associated with irreversible

Figure 57.4 Hypersensitivity pneumonitis. This 39-year-old woman was hospitalized because of severe cough, dyspnea, and hypoxemia (oxygen saturation of 83% while breathing room air). She gave a history of a recurrent illness characterized by cough, breathlessness, and low-grade fever 4–6 hours after using her hot tub. Her admission chest examination revealed bilateral basilar crackles. Her chest radiographic findings were normal. High-resolution, thin-section computed tomography (Figure) showed a diffuse increase in lung attenuation with profuse, small, poorly defined centrilobular nodules. Thoracoscopic lung biopsy showed diffuse inflammation and numerous ill-formed granulomas.

pulmonary fibrosis. Mixed obstructive and restrictive pulmonary function is present, and predominantly upper lobe fibrosis with volume loss on chest radiography is typical of late-stage disease. Lung biopsy is often required for diagnosis and commonly shows bronchiolitis obliterans, fibrosis, and honeycombing in addition to areas of persistent interstitial pneumonitis with ill-formed granulomas. The diagnosis is often made on clinical grounds, especially in the early form of the disease. Precipitating antibodies to antigens commonly associated with HSP (e.g., thermophilic actinomycetes, *Micropolyspora faeni*, avian proteins) are often not present, and when present, they are not diagnostic. Avoidance of antigen exposure is the only established therapy for HSP. Steroids are often used to treat all forms of this disorder, but there are few data to confirm that they alter the natural history.

Initial Evaluation

History

The initial evaluation of patients with ILD should include a complete history and physical examination. Key areas of focus in the past history include occupational and environmental exposures and the smoking, medication, and family history. A strict chronologic listing of the patient's lifelong

modes of employment must be sought, including specific duties and known exposures to dusts, gases, and chemicals. The degree, duration, and latency of exposure and the use of protective devices should be elicited. A review of the environment (at home and at work, and including the environments of spouse and children) is also valuable. Exposures to pets (especially any birds), air conditioners, humidifiers, hot tubs, and evaporative cooling systems (e.g., swamp coolers) and the presence of any water damage in the home or work environment is important to determine. The history of tobacco use is important because some diseases occur largely among never-smokers and former smokers (sarcoidosis and HSP) or among current and former smokers (desquamative interstitial pneumonitis, respiratory bronchiolitis, pulmonary histiocytosis X, and IPF). A detailed history of the medications taken by the patient is needed to exclude the possibility of drug-induced disease, including over-the-counter medications, oily nose drops, and amino acid supplements. Importantly, lung disease may occur weeks to years after the drug has been discontinued. The family history is occasionally helpful because familial associations have been identified in cases of IPF, sarcoidosis, tuberous sclerosis, and other rare conditions.

Physical Examination

The physical examination findings are commonly not specific but can be useful by revealing tachypnea, reduced chest expansion, and bilateral basilar end-inspiratory dry crackles. The cardiac examination findings are usually normal except in the middle or late stages of the disease, when findings of pulmonary hypertension (i.e., augmented P₂, right-sided lift, and S₃ gallop) and cor pulmonale may become evident (Chapter 59). Signs of pulmonary hypertension and cor pulmonale are generally secondary manifestations of advanced ILD, although they may be primary manifestations of a connective tissue disorder (e.g., progressive systemic sclerosis). Clubbing of the digits is common in some disorders (IPF, asbestosis) and rare in others (sarcoidosis, HSP, histiocytosis X). In most patients, clubbing is a late manifestation suggesting advanced derangement of the lung.

Laboratory Evaluation

The routine laboratory evaluation is often not helpful. Serologic studies should be obtained if clinically indicated by features suggestive of a CTD or vasculitis: sedimentation rate, antinuclear antibodies, rheumatoid factor, antineutrophil cytoplasmic antibodies, and antibasement membrane antibody (Chapters 111 and 112). A recent chest roentgenogram should be obtained, and it also is important to review all old chest roentgenograms to assess the tempo of change in disease activity. Complete lung function testing (spirometry, lung volumes, diffusing capacity) and a determination of resting arterial blood gases in room air should be obtained. Common diseases, such

as chronic obstructive pulmonary disease, anemia, heart failure, and mycobacterial or fungal disease, can mimic ILD, so they must be ruled out. Most causes of ILD will be identified by the history, physical examination, and laboratory studies.

Chest Imaging Studies

The most common radiographic abnormality is a reticular or nodular pattern; however, mixed patterns of alveolar filling and increased interstitial markings are not unusual. Most ILDs have a predilection for the lower lung zones. As the disease progresses, widespread opacities are associated with reductions in lung volume and the appearance of pulmonary hypertension. A subgroup of ILDs has a predilection for the upper lung zones, and these ILDs often produce nodular opacities that cause an upward contraction of the pulmonary hilus. With progression of the disease, small cystic structures, which represent fibrous replacement of the normal alveolar architecture, and radiographic honeycombing appear. Although the chest roentgenogram is useful in suggesting the presence of ILD, the correlation between the roentgenographic pattern and the stage of disease (clinical or histopathologic) is generally poor. Only the radiographic finding of *honeycombing* (small cystic spaces) correlates with the pathologic findings; when present, it portends a poor prognosis. High-resolution CT is well suited for the evaluation of diffuse pulmonary parenchymal disease and often reveals disease patterns that aid in the diagnosis.

Lung Function Testing

Measurement of lung volumes and spirometry are important tests in assessing the severity of lung involvement in patients with ILD. Also, the finding of an obstructive or restrictive pattern is useful in narrowing the number of possible diagnoses. Most of the interstitial disorders have a *restrictive defect*, associated with a reduced total lung capacity (TLC), functional residual capacity (FRC), and residual volume (RV). Flow rates are decreased (forced expiratory volume in 1 second—FEV₁—and forced vital capacity—FVC), but these decreases are related to the decreased lung volumes. The ratio of FEV₁ to FVC is usually normal or increased. The smoking history must be considered when the functional studies are interpreted. A few disorders are associated with interstitial opacities on the chest roentgenogram and obstructive airflow limitation on lung function testing (e.g., sarcoidosis, lymphangioleiomyomatosis, HSP, tuberous sclerosis, and chronic obstructive pulmonary disease with superimposed ILD).

A reduction in the diffusing capacity for carbon monoxide is very commonly found but is not specific for any particular type of ILD. The decrease partly represents the degree of effacement of the alveolar capillary units, but more importantly the extent of ventilation–perfusion mismatching in the alveoli.

The resting arterial blood gas values may be normal or reveal hypoxemia (secondary to ventilation–perfusion mismatching) and respiratory alkalosis. Carbon dioxide retention is rare and usually a manifestation of far-advanced, end-stage disease. A normal resting value for arterial oxygen tension (or oxygen saturation by oximetry) does not rule out significant hypoxemia during exercise or sleep. Because resting hypoxemia is not always evident and because severe exercise-induced hypoxemia may go undetected, it is important to perform exercise testing with serial measurement of arterial blood gases. There is evidence that serial assessment of gas exchange at rest and during exercise is the best method to identify disease activity and responsiveness to treatment. Lung function testing is also discussed in Chapter 54.

Lung Biopsy

Occasionally, the bronchoalveolar lavage cellular distribution (not a recommended test; see below), chest radiographic or high-resolution CT appearance, or specific laboratory results in conjunction with the clinical story may be sufficient to establish a specific diagnosis. However, in most cases, histologic examination of lung tissue is required to make the diagnosis. In some disorders, transbronchial biopsy may yield a specific diagnosis; examples include alveolar proteinosis, sarcoidosis, and lymphangitic carcinomatosis. However, a transbronchial biopsy that shows only nonspecific inflammation or fibrosis is not acceptable. In these cases, *video-assisted thoracoscopic lung biopsy* by an experienced chest surgeon is recommended to establish a specific diagnosis.

Indications for Hospitalization

Hospitalization of patients with ILD usually occurs as a result of sudden worsening of dyspnea or cough, often associated with hypoxemia. Hospitalization is usually required to determine the diagnosis (especially to rule out or treat acute pneumonia) or to manage and monitor the severe hypoxemia that complicates the course of many of these patients. When associated with pleural pain, such hypoxemia may indicate a spontaneous pneumothorax or pulmonary embolism. *Spontaneous pneumothorax* is a characteristic finding in pulmonary histiocytosis X, tuberous sclerosis, lymphangioleiomyomatosis, and neurofibromatosis.

Indications for Initial Intensive Care Unit Admission

Few patients with ILD will require admission to an ICU during the initial phase of hospitalization. Those who do require intensive care have respiratory failure that is often associated with hemodynamic instability (hypovolemia or sepsis), significant concomitant medical disease (usually cardiovascular disease or renal failure), or severe hypoxemia

requiring frequent monitoring of arterial blood gases or mechanical ventilation. The presence of hypercapnia is rare and portends a grave prognosis. Intubation and mechanical ventilation should be undertaken only after the patient's long-term prognosis has been carefully assessed. Patients with end-stage lung fibrosis of any cause are difficult to ventilate and are rarely successfully weaned from mechanical ventilation. ILD patients are rarely candidates for or tolerant of noninvasive ventilation.

Initial Therapy

The management of most ILDs is difficult, and the approach depends on the specific entity (Table 57.2) (6). Regardless of etiology, end-stage fibrosis is irreversible and untreatable. Thus, patients at this stage of illness should be spared the potential toxicity of agents such as corticosteroids. Pursuing a diagnosis and instituting appropriate therapy early in the disease course, before the development of extensive fibrosis, is likely to improve responsiveness to therapy and, it is hoped, delay or prevent the functional limitation and disability that commonly occur in these patients.

The major therapies for ILD involve the administration of corticosteroids, either alone or with a cytotoxic agent (cyclophosphamide or azathioprine). Many patients with ILD are elderly; consequently, the decision to treat them with immunosuppressive drugs should not be taken lightly, as the toxicity and side effects of these medications can be substantial. Among patients who present acutely and require hospitalization, those with underlying DAD have the worst prognosis. Conversely, patients with hypersensitivity pneumonitis, BOOP, or nonspecific interstitial pneumonia often demonstrate an excellent response to corticosteroid treatment (Table 57.2).

TABLE 57.2
LIKELIHOOD OF TREATMENT RESPONSE BASED ON HISTOLOGIC PATTERNS OF INTERSTITIAL LUNG DISEASE

Probability of response	Histologic entity
High	Bronchiolitis obliterans organizing pneumonia (BOOP) Cellular interstitial pneumonia Lymphocytic interstitial pneumonia (LIP) Eosinophilic pneumonia Pulmonary capillaritis Granulomatous pneumonitis
Medium	Diffuse alveolar damage (DAD) Desquamative interstitial pneumonia (DIP) Alveolar proteinosis
Low	Usual interstitial pneumonia (UIP) Honeycomb (end-stage) lung

Treatment of drug-induced ILD is based on recognition of the potential etiology and withdrawal of the suspected offending agent. In some cases, severe gas exchange abnormalities develop after the initiation of mechanical ventilation with high-flow oxygen. In this situation, corticosteroid medications are effective. This is especially true of drug-induced eosinophilic pneumonia, BOOP, and some cellular (nonspecific) interstitial pneumonias. In some patients with DAD secondary to cytotoxic drugs, corticosteroids can have a beneficial effect. Unfortunately, some patients with drug-induced DAD may progress to pulmonary fibrosis despite corticosteroid therapy. There is no rationale for the use of other immunosuppressive medication in cases that do not respond to corticosteroids. However, the failure to respond to both discontinuation of the drug and the addition of corticosteroid medication should raise the possibility of another cause for the interstitial pulmonary reaction.

Corticosteroid Therapy

The optimal dose of corticosteroids in the treatment of most ILDs is not known. Because most of the ILDs are chronic processes, patients who are hospitalized usually are on maintenance corticosteroid or cytotoxic therapy. It is the author's practice to treat acute exacerbations of established cases of AIP or new-onset AIPs with intravenous methylprednisolone (250–500 mg every 6 hours for up to 5 days). The patient is then placed on 40–60 mg of oral prednisone daily for 10–12 weeks, after which the dose is tapered to 20 mg and maintained for an additional 6–12 months. Intermittent, high-dose parenteral corticosteroid treatment ("pulse therapy") has also been used in patients with aggressive and severe disease. Treatment with 2 g of intravenous methylprednisolone once a week plus 0.25 mg of oral prednisone per kilogram daily suppresses the alveolitis present in many ILDs, but this treatment has not been clearly shown to improve the long-term outcome of patients with the lung disease.

The proper length of therapy in patients who respond to treatment is not known. The usual aim for a duration of therapy is at least 1 year. Rapid tapering or a shortened course of corticosteroid treatment can result in disease recurrence. Unfortunately, most patients experience declining lung function and worsening exercise tolerance despite corticosteroid therapy. If the patient's condition continues to decline on corticosteroids, a second agent is often added, and the prednisone dose is lowered to or maintained at 0.25 mg/kg/day. However, the addition of azathioprine or cyclophosphamide, particularly in patients with DAD, is of questionable benefit.

Cytotoxic Therapy

There is little experience with the use of intermittent ("pulse") intravenous cyclophosphamide therapy in patients with rapidly progressive disease. The author has used

a dose of 2 mg/kg of ideal body weight administered over 30–60 minutes once daily for 3–5 days. Following this, daily oral therapy is initiated.

Although side effects are frequently encountered when corticosteroid or cytotoxic therapy is used, they usually do not necessitate discontinuation of therapy. Patients should be carefully monitored for the development of side effects from both corticosteroids and cytotoxics (see Figure 111.2).

Indications for Early Consultation

The initial presentation of patients with ILD frequently suggests that of acute community-acquired pneumonia. Consequently, the initial evaluation should follow the critical pathway outlined for the management of this problem (Figure 65.3). If there is concern that the illness is of non-infectious etiology, then pulmonary medicine consultation is recommended. Other indications for specialized testing and referral to a pulmonologist include the following: no specific cause of dyspnea or cough can be found; symptoms exceed the physiologic or radiographic abnormalities identified; empiric management (antibiotics, bronchodilators, diuretics, smoking cessation) results in an atypical or unsatisfactory clinical outcome; specialized testing is needed for diagnostic purposes (e.g., fiberoptic bronchoscopy with bronchoalveolar lavage; transbronchial, video-assisted thoracoscopic, or open lung biopsy); and therapy with immunosuppressive or cytotoxic drug is contemplated.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Correction of the hypoxemia with appropriate levels of supplemental oxygen is the most important first step. The levels of oxygen required to maintain saturations above 90% can be much higher than those usually employed in other lung diseases. Wheezing should be managed with inhaled bronchodilators. Often, these are best delivered by nebulizer because the patient is too breathless to use a metered-dose inhaler properly (Chapter 56). Parenteral antibiotics are often given empirically because the presentation of acute exacerbations in patients with ILD is similar to that of a community-acquired pneumonia (fever with cough productive of purulent sputum). The critical pathway for community-acquired pneumonia (Figure 65.3) should be followed during the initial phases of hospitalization. The failure to improve after empiric therapy (usually by day 3 of hospitalization; Table 65.3) or the presence of other complications (pneumothorax, hemoptysis, worsening pulmonary status) prompts further pulmonary workup. Despite their often extreme breathlessness, patients should be encouraged to increase or maintain their level of activity, as tolerated, to prevent further deconditioning. Counseling regarding smoking cessation may be particularly effective during the hospital stay.

When appropriate, pneumococcal and influenza vaccination should be given before discharge.

DISCHARGE ISSUES

Patients with ILD, especially IPF, should be enrolled in a pulmonary rehabilitation program at discharge. Typically, patients are sufficiently dyspneic with exertion that they have stopped regular exercise and in fact might be frightened even to carry out normal daily activities that require physical exertion. These patients need encouragement to develop a routine conditioning program to improve muscle strength and cardiovascular efficiency. Education in energy management techniques may enable patients to perform more of their daily activities and hence improve their quality of life. For example, using labor-saving devices to simplify work, planning daily priorities, pacing physical activity, and improving breathing and body mechanics can significantly contribute to energy conservation.

Severe hypoxemia ($\text{PaO}_2 < 55$ mm Hg) at rest or during exercise should be managed with supplemental oxygen. Usually, this can be accomplished by prescribing low-flow oxygen therapy via nasal cannula at home. Often, patients with ILD need higher oxygen flow rates (4–6 L/min, especially when walking) than are commonly employed in other chronic lung disorders. This must be taken into consideration when the oxygen prescription is written.

The patient and family should receive information and education about the medications used in treatment, especially because side effects are frequently encountered during corticosteroid or cytotoxic therapy (see Figure 111.2 for sample discharge instructions). Routine follow-up with the primary care physician should be scheduled within 2–3 weeks of discharge or sooner if significant comorbidities are present.

Many cases of ILD are chronic and irreversible. Consequently, these patients should be encouraged to issue advance directives indicating their wishes regarding life-sustaining therapies (Chapter 17). This issue should be discussed with the patient and family at the time of admission or at discharge.

COST CONSIDERATIONS AND RESOURCE USE

No studies have examined resource utilization in patients with ILD. Recent data show that surgical lung biopsy substantially changes the level of diagnostic certainty and is required in the patient with ILD whose clinical evaluation fails to establish a “certain” diagnosis. Also, studies have demonstrated that some tests previously touted in the assessment of ILD are not helpful, so reducing their use will result in lower costs. One such test is bronchoalveolar lavage, which may be valuable in ruling out certain acute processes (hemorrhage

or infection) but has not proved to be clinically useful in the routine evaluation of the state of the pulmonary inflammatory response. In addition, the cellular analysis is time consuming and improperly performed by most clinical laboratories, so the data obtained can be invalid. The role and value of serial bronchoalveolar lavage in assessing the clinical progress of patients with IPF have also not been defined. Other frequently unhelpful tests include measurement of the sedimentation rate, angiotensin-converting enzyme levels, and circulating immune complex levels (none is helpful in diagnosis or follow-up) and gallium lung scanning (which is nonspecific and difficult to interpret).

Most ILD patients have progressive lung disease and cannot return to full employment after hospital discharge. The hospital or primary physician often needs to document the patient's level of impairment on an application for disability coverage. Lung transplantation may be offered to young patients with end-stage ILD but without significant comorbidities and to those with progressive, severe disease that is unresponsive to other forms of treatment. Lung transplantation is a costly procedure, and the guidelines for the selection of ILD patients are discussed elsewhere (Chapter 58).

KEY POINTS

- The interstitial lung diseases are a heterogeneous group of disorders with typical manifestations of cough, dyspnea, crackles on chest examination, diffuse interstitial opacities on chest radiograph, and a restrictive ventilatory defect.
- The vast majority of interstitial lung diseases are chronic; however, in some cases, the onset may be acute (days to weeks), subacute (weeks to months), or progressive, with the patient requiring hospitalization. These latter processes are often confused with community-acquired pneumonia.
- Important disorders to consider in hospitalized patients include acute idiopathic interstitial pneumonia, diffuse alveolar hemorrhage syndromes, bronchiolitis obliterans with organizing pneumonia, some drug-induced interstitial lung diseases, eosinophilic pneumonias, hypersensitivity pneumonitis, and the acute immunologic pneumonia that complicates connective tissue disease (especially systemic lupus erythematosus or polymyositis).
- In most cases, a specific diagnosis requires histologic examination of lung tissue. Therefore, lung biopsy (usually a video-assisted thoracoscopic lung biopsy) should be performed early in the clinical course.
- Treatment responses vary among these processes, and the likelihood of response is based mostly on the histologic patterns of the interstitial lung disease.

Lung Transplantation and Lung Volume Reduction Surgery

58

Steven G. Peters **David E. Midthun**

INTRODUCTION

Over the past decade, surgical options have emerged for patients with end-stage lung diseases that have been unresponsive to medical therapy. Lung transplantation is an established option for a subset of patients with obstructive lung diseases, restrictive diseases, and pulmonary hypertension, whereas lung volume reduction surgery has been evaluated for patients with emphysema. This chapter focuses on the evolving status of these procedures.

Patients with chronic obstructive pulmonary disease comprise the largest pool of candidates for transplantation. Chronic obstructive pulmonary disease is the fourth leading cause of death in the United States, accounting for more than 8 million physician visits, 726,000 hospitalizations, and approximately 119,000 deaths in 2000 (1). The majority of outpatient visits are for exacerbations of chronic bronchitis, and the majority of deaths are related to emphysema.

The pathophysiology of emphysema is characterized by irreversible destruction of distal air spaces with loss of alveolar walls and development of bullae. The combined effects of loss of elastic recoil and increased airway resistance lead to hyperinflation and decreased airflow. Ventilation-perfusion (V/Q) mismatching occurs, with regions of abnormally high V/Q acting as physiologic dead space, with impairment of CO₂ elimination, and areas of low V/Q contributing to venous admixture and shunting, resulting in hypoxemia. Surgical approaches may be di-

rected toward replacement or toward removal of diseased areas to improve physiologic function.

LUNG TRANSPLANTATION

History

The first human *single-lung transplant* (SLT) was reported by Hardy and colleagues in 1963. The patient died of renal failure after 18 days. During the next 20 years, approximately 38 SLT procedures were performed, with poor results (2). The majority of patients died within 2 weeks of surgery of primary graft failure, rejection, or infection. Of 12 survivors beyond 2 weeks, seven died of dehiscence of the bronchial anastomosis. Enthusiasm for this procedure increased greatly in 1986 after the report by the Toronto Lung Transplant Group of successful SLT in patients with pulmonary fibrosis in a closely supervised program of perioperative pulmonary rehabilitation, limited use of preoperative corticosteroids, use of omentum to wrap the bronchial anastomosis, and immunosuppression with cyclosporine (3).

The beginning of *double-lung transplantation* (DLT) has been attributed to Yacoub and colleagues (2). Use of a single tracheal anastomosis was complicated by a high frequency of airway ischemia and dehiscence. Subsequent success has been achieved with bilateral bronchial anastomoses. Vascular anastomoses for SLT and DLT include the

pulmonary artery and venous return via a cuff of donor left atrium. The indications for single versus double lung transplantation continue to evolve and are discussed below.

Heart–lung transplantation emerged in the early 1980s as an option for patients with pulmonary vascular diseases, especially congenital cardiac disease with Eisenmenger’s syndrome, and primary pulmonary hypertension. Early postoperative complications included graft failure, acute rejection, and infection. As experience with heart–lung transplantation grew, the late complication of obliterative bronchiolitis (OB) emerged as the major contributor to morbidity and mortality. Although it was hoped that OB would not be as prevalent a complication of SLT and DLT, current experience indicates that this life-threatening complication may occur in more than half of lung transplant recipients who survive beyond 2–3 years.

Indications and Selection Criteria

Current indications for lung transplantation are shown in Table 58.1. Contraindications include active infection, malignancy, current cigarette smoking, drug abuse, and unstable psychological status, especially if the patient is unable to understand and comply with a complicated postoperative medical program. Additional relative contraindications include diabetes, osteoporosis, obesity, prior long-term use of corticosteroids, or a current requirement of more than 5–10 mg of prednisone daily. Systemic diseases that would be expected to affect outcome or survival following transplantation are considered contraindications. The presence of a connective tissue disease such as scleroderma resulting in pulmonary fibrosis or pulmonary hypertension is a contraindication in many but not all transplant programs. Prior thoracic surgery including open lung biopsy complicates possible removal of the lung and increases the risk for serious bleeding, but usually does not represent a contraindication to transplantation. Negative serologic status for Epstein-Barr virus (EBV) greatly increases the risk for posttransplantation lymphoproliferative disorder, which is discussed further

below. Whether negative EBV serology should preclude consideration of transplantation is controversial.

Preoperative Evaluation

Patients with emphysema, pulmonary fibrosis, cystic fibrosis, or pulmonary hypertension are referred most frequently for consideration of transplantation (4). Although SLT may be adequate for many of these patients, bilateral transplantation or heart–lung transplantation has often been performed, depending on surgical recommendation, donor availability, and underlying cardiac function. Patients with suppurative lung diseases, including bronchiectasis and cystic fibrosis, are considered for bilateral lung transplantation.

Data from the 2002 Registry of the International Society for Heart and Lung Transplantation show that SLT is currently carried out for emphysema (excluding α_1 -antitrypsin deficiency) in approximately 54% of cases, α_1 -antitrypsin deficiency emphysema in 9%, idiopathic pulmonary fibrosis in 24%, and primary pulmonary hypertension in only 1% (5). DLT or bilateral transplantation is performed for cystic fibrosis in 34%, emphysema in 22%, α_1 -antitrypsin deficiency emphysema in an additional 10%, primary pulmonary hypertension in 8%, pulmonary fibrosis in 9%, and a variety of conditions in the remainder of cases.

Potential candidates are evaluated with a complete history and physical examination and by pulmonary function testing, arterial blood gas determination, and exercise testing, including 6-minute walking distance. Cardiac catheterization is carried out for assessment of right-sided pressures, and coronary angiography is performed for older adults and previous cigarette smokers. Laboratory studies include blood typing and serologic studies for cytomegalovirus (CMV), EBV, herpes viruses, *Toxoplasma*, and fungal organisms. Renal function is assessed in anticipation of impairment induced by cyclosporine, tacrolimus, or other immunosuppressive and anti-infective agents. Bone mineral density frequently is abnormal in transplant candidates because of corticosteroid therapy and prolonged inactivity. Although newer anti-resorptive agents have improved the outlook for patients with osteoporosis, measurements below the fracture threshold may represent a relative barrier to successful transplantation and rehabilitation. All candidates participate in an ongoing program of pulmonary rehabilitation, with goals of maintaining cardiorespiratory conditioning and functional status to the greatest extent possible. Because waiting periods currently exceed 2 years in most centers, management during the waiting time may have an important impact on outcome.

Outcomes

Currently, overall survival following lung transplantation is approximately 75% at 1 year, 65% at 2 years, and 50% at 4–5

TABLE 58.1
SELECTION CRITERIA FOR LUNG
TRANSPLANTATION

Age <65y
End-stage pulmonary disease despite maximal medical therapy
Limited life expectancy without transplantation
Satisfactory rehabilitation potential
Ability to comply with medical program
Satisfactory psychosocial status
No active systemic disease expected to worsen outcome
No other major organ system dysfunction

years (5). Survival for patients with emphysema is approximately 10% greater at any time after transplant than for patients with idiopathic fibrosis or pulmonary hypertension. For patients with emphysema, bilateral lung transplantation is associated with statistically improved 3- to 5-year survival compared to SLT. However, criteria for patient selection have varied, and organ supply remains limited, so that the choice of transplant procedure remains controversial. For the individual patient, survival figures must be considered in light of the existing quality of life and expected survival without further intervention. Physiologic improvement following successful lung transplantation is characterized by increased vital capacity and expiratory flows and by improved gas exchange. Maximal oxygen consumption and 6-minute walking distance typically double by 3 months after transplantation. Functional status may improve proportionally, with approximately 80% of patients performing daily activities without restriction at 1 year after surgery. Approximately 20% of patients are reported to be working full-time and 10% part-time at 1 year. The major causes of morbidity and mortality following transplantation, including infection, rejection, OB, and malignancy, are discussed below.

CARE OF THE HOSPITALIZED PATIENT FOLLOWING LUNG TRANSPLANTATION

Postoperative Care and Immunosuppression

Complications following organ transplantation usually reflect the conflict between the need to administer immunosuppressive drugs to prevent rejection and the side effects of these agents. Most current protocols for immune suppression are based on the use of a combination of *cyclosporine* or *tacrolimus (FK-506)*, *azathioprine* or *mycophenolate mofetil*, *corticosteroids*, and *antilymphocyte antibodies* (antilymphocyte globulin, antithymocyte globulin, or OKT3) (6).

In lung-transplant patients receiving regimens containing cyclosporine, close monitoring is necessary. The most common adverse effects of cyclosporine are renal insufficiency and hypertension. At maintenance dosing levels, renal clearance typically falls and serum creatinine rises to average values of 1.5–2.0 mg/dL. Within 1 year following lung transplantation, the serum creatinine level is greater than 2.5 mg/dL in approximately 8% of patients. Hypertension requiring additional treatment is present in the majority of patients at 1 year. Early studies, including both retrospective data and prospective comparisons, suggest that tacrolimus may be superior to cyclosporine for maintenance immunosuppression and for treatment of rejection episodes (7). Although no improvement in overall survival has been demonstrated, the frequency of acute rejection episodes and of late development of OB is reported to be less with tacrolimus regimens. Recent registry data indicate that approximately 40% of lung transplant recipients are receiving tacrolimus for maintenance immunosuppression (5).

Similarly, early data support a potential role for mycophenolate mofetil as an alternative to azathioprine in anti-rejection therapy for solid organ transplants. Preliminary data in lung transplant recipients suggest that this agent may also be useful in the treatment of chronic rejection and bronchiolitis obliterans. In an effort to reduce the long-term adverse effects of corticosteroids (including obesity, osteoporosis, and myopathy), many solid organ transplant programs attempt to wean from steroids stable patients who have not had recurrent rejection episodes. However, experience with steroid withdrawal in lung transplant recipients is limited, and concern remains regarding the risks for chronic rejection or OB. Finally, monoclonal OKT3 has been used in cardiothoracic transplantation for induction immunosuppression and for acute rejection.

Complications Requiring Hospitalization

In the first year following lung transplantation, approximately 55% of patients are readmitted, most frequently for infection and rejection. Common complications are listed in Table 58.2.

Early graft dysfunction may result from a variety of insults, including acute lung injury after implantation, airway ischemia, dehiscence or stenosis, and pulmonary vascular complications. Acute rejection may present with any combination of dyspnea, cough, and fever; as an asymptomatic decline in pulmonary function test values; or as radiographic pulmonary infiltrates. In addition to these complications, infections constitute the main differential diagnostic considerations in the early weeks following transplantation.

As indicated in Table 58.2, a relatively small number of organisms account for most infections following lung transplantation. Bacterial infection with gram-negative or

TABLE 58.2

CMV, cytomegalovirus; EBV, Epstein-Barr virus.

-positive organisms is common, and, although these infections are usually treated successfully, they contribute significantly to early postoperative mortality. CMV infection is a common cause of morbidity and mortality, especially if the recipient is CMV antibody-negative and receives an organ from a CMV-positive donor. Early manifestations may range from asymptomatic viral shedding identified in blood or urine to pneumonitis or extrapulmonary involvement of gastrointestinal, hepatic, neurologic, or hematologic systems. Prophylaxis for CMV-mismatched patients is commonly administered in the form of ganciclovir or valganciclovir. Prophylactic therapy also is given for fungal organisms. Although *Candida* isolates rarely result in organ injury, *Aspergillus* species can cause significant morbidity and mortality in lung transplant patients. Disease may be localized to the native or transplanted lung, and dissemination is usually a fatal late complication. Prophylaxis with itraconazole has probably decreased these complications, but controlled data are not available. *Pneumocystis jirovecii* pneumonia is generally prevented by prophylactic trimethoprim-sulfamethoxazole, but pneumonitis remains a life-threatening complication in patients who discontinue or cannot tolerate these medications.

Bronchoscopy plays an early and important role in differentiating rejection and infection. Bronchoalveolar lavage should have a yield of at least 80% for most of the pathogens listed in Table 58.2, especially CMV and pneumocystis. Transbronchoscopic lung biopsy increases the yield of infectious agents only slightly but may identify or confirm an inflammatory response (e.g., granulomas or CMV inclusions). However, the chief purpose of transbronchoscopic lung biopsy is to establish and quantify the presence of rejection. Acute rejection is characterized by perivascular lymphocytic infiltrates and is classified according to a standardized scale (grade 0, none; grade 4, severe). Acute rejection is treated by augmentation of immunosuppression, most commonly with high-dose methylprednisolone. Bronchoscopic biopsies are usually repeated after treatment to confirm resolution. Persistent rejection is often treated with further corticosteroids, anti-lymphocyte antibodies, or cytotoxic agents.

Obliterative bronchiolitis has been identified as the most common cause of late morbidity and mortality following lung transplantation. The prevalence of OB approaches 50% at 1 year, and the entity accounts for the majority of posttransplant deaths at 5 years. The onset is characterized by a gradually progressive decline in pulmonary function, most often defined as a decrease in the forced expiratory volume in 1 second (FEV₁) of more than 10% of the baseline postoperative value. Radiographic changes can include hyperinflation and loss of peripheral vascular markings, but these can be subtle on plain films. Computed tomography may show a mosaic pattern of increased lucency representing focal air trapping, especially evident on expiratory views. Histologic changes are characterized by patchy fibroproliferative occlusion of bronchioles. Al-

though the specific causes of these chronic and progressive inflammatory changes are unknown, the major risk factors appear to be recurrent acute rejection episodes and possibly prior CMV pneumonitis. Although the specific diagnosis of OB requires histologic confirmation, the yield with transbronchoscopic lung biopsy is low, and open lung biopsy is performed infrequently because other diagnoses are unlikely in the appropriate clinical setting and therapeutic options are limited. The OB syndrome can be diagnosed in the setting of a decline in FEV₁ in the absence of infection, acute rejection, or other apparent etiology. Treatment with augmented immunosuppression has been disappointing. A definition of the potential role of tacrolimus and mycophenolate mofetil in the possible prevention and treatment of OB awaits further experience, although many programs use these agents as primary immune suppression, or switch from cyclosporine and azathioprine if acute or chronic rejection is detected.

Following solid organ transplantation, malignancies develop in 5%–10% of patients, at an average interval of 4–5 years after surgery. Squamous cell carcinomas of the skin and lips are most common, accounting for nearly half of all neoplasms. *Posttransplantation lymphoproliferative disorders* (PTLD) account for 15%–20% of malignancies. The overall frequency of PTLD following solid organ transplants is approximately 3%, but the risk is higher for lung transplant recipients. Histologically, PTLD usually are identified as B-cell neoplasms of recipient origin and may be monoclonal or polyclonal. Extranodal disease is common, including lung, liver, and central nervous system nodular lesions. EBV infection following transplantation has been implicated as the major risk factor for PTLD. In a Mayo Clinic series of solid organ transplant patients, PTLD developed in 3 of 367 (0.8%) patients who were EBV-seropositive before transplant, and in 11 of 22 (50%) who were EBV-negative (8). Additional risk factors include CMV mismatch (seronegative recipient) and OKT3 immune suppression. Because the relative risk for PTLD is high in EBV-negative patients, EBV seronegative status is considered a relative contraindication for potential lung recipients at some centers. Some cases of PTLD have been observed to resolve after immunosuppression is decreased, so the current empiric approach to therapy usually includes a period of several weeks of observation after cyclosporine is reduced by approximately 50%, azathioprine is decreased or discontinued, and prednisone is reduced to approximately 5–10 mg. Combination chemotherapy protocols for lymphoma (Chapter 94) are considered if disease persists or progresses.

The hospital physician may encounter a variety of other complications of immunosuppression or of the underlying disease. These include diabetes, hypertension, complications of osteoporosis, renal failure, neurologic disease, and gastrointestinal bleeding, ulceration, or perforation. These conditions are relatively uncommon causes of late death following transplantation but are frequent contributors to major morbidity.

LUNG VOLUME REDUCTION SURGERY

History

Pulmonary resection for emphysema has been performed for more than 40 years, most commonly for localized large bullae that compress adjacent lung tissue. Physiologic improvement results from recruitment of functioning alveoli, increased elastic recoil of the lungs, and improvement in chest wall and diaphragm mechanics. The origin of lung resection for diffuse emphysema (in the absence of giant bullae) is attributed to Brantigan in 1957. Initially, high morbidity and mortality prevented widespread acceptance of the procedure. In recent years, a variety of approaches have been taken to remove or obliterate peripheral bullous disease, including wedge resections using midline sternotomy, thoracotomy or thoracoscopic techniques, and laser treatment of the lung surface. Cooper and colleagues (9) are credited with developing the current approach to lung volume reduction surgery (LVRS), in which approximately 20%–30% of each lung (usually tissue from upper zones where the severity of the emphysema is the greatest) is excised by means of a linear stapling device buttressed with strips of bovine pericardium intended to prevent air leaks. This procedure has shown better short-term outcomes than has laser bullectomy. Following bilateral LVRS, FEV₁ improves by an average of approximately 50%, residual volume falls by 28%, and symptoms of dyspnea improve. Physiologic improvement has been attributed to increased lung elastic recoil, decreased chest wall compliance, improvement in respiratory muscle function, and increased airway conductance.

The reported success of LVRS led to the widespread application of surgical procedures for emphysema, with varying results from a large number of centers and practitioners, most of which have not been reported. The value of the intervention, considerations of cost versus benefit, and the potential role of randomized, controlled trials in the assessment of surgical procedures have been debated publicly. In a new paradigm for clinical research, the Health Care Financing Administration (now called the Center for Medicare and Medicaid Services) and the National Heart,

Lung, and Blood Institute jointly sponsored the National Emphysema Treatment Trial (NETT). This study was designed to compare medical therapy, including pulmonary rehabilitation, with similar therapy plus LVRS. The hospital physician might encounter patients who are candidates for LVRS, or who have undergone this type of surgery. Less invasive methods than surgery for achieving volume reduction in emphysema are emerging. The bronchoscopic placement of one-way valves has shown the ability to reduce volume in applied segments in animals (10). Human studies in patient with emphysema are underway.

Results

Results from three small-randomized control trials of LVRS versus medical therapy showed that bilateral LVRS improved static lung function, gas exchange and quality of life compared to medical therapy and pulmonary rehabilitation alone (11–13). However, not every patient showed improvement and mortality with surgery was higher. Results of the NETT study are summarized in Table 58.3. A total of 1,218 participants with severe emphysema completed pulmonary rehabilitation and were then randomized to continued medical therapy or LVRS (14). After a mean follow-up of 29.2 months, overall mortality was the same in both arms. However, LVRS showed a significantly greater improvement at 24 months in exercise capacity, FEV₁, quality of life and dyspnea. These improvements were greatest at 6 months, but waned in follow-up at 12 and 24 months.

The NETT study found a survival benefit with surgery only in a subset of patients with predominantly upper-lobe emphysema and low exercise capacity after rehabilitation (14). A higher risk of death was demonstrated with surgery compared to medical treatment in participants with non-upper lobe disease and high exercise capacity.

Selection Criteria for Lung Volume Reduction Surgery

General criteria for LVRS have evolved with clinical experience in patients with diffuse emphysema. These include severe and disabling disease, thoracic hyperinflation, and

TABLE 58.3
NATIONAL EMPHYSEMA TREATMENT TRIAL (NETT) RESULTS

Therapy	# patients	Mortality		% with improvement in FEV ₁			% with improvement in exercise capacity	% with improvement in QOL
		90-day	overall	6 mos.	12 mos.	24 mos.	24 months	24 months
Medical	610	1.3%	26.2%	27	26	19	3	9

TABLE 58.4
SELECTION CRITERIA FOR LUNG VOLUME REDUCTION SURGERY

Severe emphysema with hyperinflation
 Maximal medical therapy, including pulmonary rehabilitation
 Age <80 years
 $FEV_1 \leq 45\%$ predicted, $TLC \geq 100\%$ predicted, $RV \geq 150\%$ predicted
 Bronchodilator response <30% improvement
 $pCO_2 \leq 55$ mm Hg, $pO_2 \geq 45$ mm Hg on room air
 High resolution chest CT showing emphysema
 Mean pulmonary artery pressure ≤ 35 mm Hg (peak ≤ 45 mm Hg)
 No smoking
 No recurrent infections, chronic bronchitis, or bronchiectasis
 No severe cachexia

CT, computed tomography; FEV_1 , forced expiratory volume in 1 second; RV, residual volume; TLC, total lung capacity.

nonhomogeneous “target areas” for resection. Commonly accepted indications are listed in Table 58.4 (15).

The intent of these selection criteria is to identify candidates whose disease is severe enough to warrant this intervention and who are most likely to benefit, given the data available. Prior to consideration of LVRS, patients requiring steroids are weaned to the lowest possible level, typically a dose of prednisone of less than 10–20 mg daily. Patients are also expected to complete at least a 6-week pulmonary rehabilitation program. Respiratory failure requiring mechanical ventilation has been considered a contraindication, although successful outcomes of LVRS have been reported in this setting. Although malignancy has also been an exclusion criterion, volume reduction has been carried out at the time of lung cancer resection in patients who otherwise might have been considered inoperable because of poor lung function. Using relatively strict criteria, Cooper and colleagues (9) excluded approximately 80% of patients referred for LVRS, most commonly for homogeneous disease, insufficient lung hyperinflation, or other medical conditions. The NETT identified a subgroup who were at high risk of death from LVRS. Patients who had a FEV_1 that was no more than 20% of their predicted value and either a homogeneous distribution of emphysema on CT or a carbon monoxide diffusing capacity (DLCO) of no more than 20% of predicted, had a 30-day mortality of 16% (16). There were no deaths in patients with these criteria in the nonsurgical treatment arm ($P < 0.001$). Therefore, *LVRS should not be offered to patients meeting these criteria.*

Preoperative evaluation with CT and stress echo appear to be appropriate. A number of studies have assessed the quantification and distribution of emphysema with high resolution CT, spiral CT, CT morphometry, or V/Q scanning. In general, heterogeneous distribution of

emphysema is the best predictor of post-operative increase in static function but not of exercise tolerance or dyspnea. Bossone et al, showed that, despite the difficulty of performing echocardiograms in patients with marked hyperinflation, a negative dobutamine stress echo was a perfect predictor of an absence of major cardiac events following LVRS (17).

Care of the Hospitalized Patient Following Lung Volume Reduction Surgery

The average length of hospital stay following volume reduction surgery has been approximately 10–15 days, including shortening of stay with experience. Overall operative mortality has been approximately 4%–6%, with 1-year mortality in the range of 10%. Common complications are listed in Table 58.5.

Many patients have persistent *air leaks* following surgery. In the series of Cooper et al. (9), 46% of 150 patients had an air leak beyond 7 days. One randomized study showed that buttressing the staple line with bovine pericardium reduced air leaks and drainage time but did not change length of hospital stay compared to patients with nonbuttressed staples (18). Unless a large pneumothorax is present, chest tubes are frequently left attached to a water seal because suction is felt to perpetuate surface leaks. Approximately 5%–10% of patients require postoperative mechanical ventilation beyond 24–48 hours. Respiratory failure may reflect the severity of the underlying emphysema or be related to any of the complications listed above. In addition to air leaks, *postoperative pneumonia* has been a common and serious complication. Fewer than 5% of patients in reported series have required tracheostomy for prolonged ventilator support. Myocardial infarction and cardiac arrest have been observed rarely following LVRS, a finding that reflects the careful selection process and the quality of surgical and anesthetic management in reported series. Gastrointestinal complications, including ileus, bleeding, and bowel perforation, have occurred infrequently.

TABLE 58.5
COMPLICATIONS FOLLOWING LUNG VOLUME REDUCTION SURGERY

Prolonged air leaks, pneumothorax
 Intrathoracic bleeding
 Respiratory insufficiency requiring prolonged mechanical ventilation
 Pneumonia
 Cardiovascular complications (e.g., myocardial infarction, cardiac arrest, atrial arrhythmia)
 Gastrointestinal complications (e.g., ileus, bleeding, bowel perforation)

Lung Volume Reduction Surgery vs. Lung Transplantation

Some patients hospitalized with exacerbations of severe chronic obstructive pulmonary disease may have exhausted medical therapy and ask the hospital physician about surgical options. Consideration of either LVRS or transplant requires that the patient be in generally good health aside from severe lung disease. Most patients with emphysema and severe airway obstruction will not be candidates for transplantation (but may be candidates for LVRS) based on age above 65 years. However, younger patients may require a decision between the two procedures. At this point, the best option for any given 50-year-old patient with severe emphysema is unclear. The 5-year survival rate for lung transplant is approximately 30%–40% and the only 5-year data for LVRS suggest that survival is similar (19). Attractive features of LVRS include the lack of immunosuppression, lesser expense, and the opportunity to fall back on transplant if surgery is not successful in alleviating symptoms or if improvement wanes. Senbaklavaci et al. reported that successful LVRS (resulting in improvement in FEV₁ by $\geq 20\%$ over baseline) delayed the subsequent need for transplantation, improved nutritional state and reduced perioperative mortality following subsequent lung transplant (20). Those patients who had unsuccessful LVRS ($< 20\%$ improvement in FEV₁ over baseline) required transplant 11 months sooner and had a higher perioperative mortality than those with successful LVRS. Further study will need to clarify which procedure is the best option for the young patient with emphysema.

CONCLUSIONS

Lung transplantation and LVRS have emerged as surgical options for the treatment of severe emphysema. Evaluation of potential candidates requires thorough examination, laboratory and pulmonary function testing, and assessment of other medical conditions and risk factors for adverse outcomes. Even with careful patient selection, postoperative complications requiring prolonged hospitalization or readmission are frequent. Because of limited donor availability, lung transplantation remains an option for relatively few patients each year. The National Emphysema Treatment Trial showed improvement in exercise capacity and pulmonary function with LVRS. However, the surgery conferred no survival advantage over medical therapy.

KEY POINTS

- Lung transplantation is an option for a subset of patients with end-stage lung diseases unresponsive to maximal medical therapy and with satisfactory rehabilitation po-

tential. Currently, transplantation is carried out most often for emphysema, cystic fibrosis, pulmonary fibrosis, and pulmonary hypertension.

- The most common complications of lung transplantation are infection, rejection, adverse drug effects, obliterative bronchiolitis, and posttransplant lymphoproliferative disorders.
- Bronchoscopy with bronchoalveolar lavage and transbronchoscopic biopsy is an early and important step in the evaluation of new symptoms or pulmonary infiltrates in the transplant recipient.
- Obliterative bronchiolitis occurs in the majority of lung transplant patients beyond 2–3 years after surgery and is a major cause of late mortality and morbidity.
- The risk for posttransplant lymphoproliferative disorder is greatly increased in patients who are seronegative for Epstein-Barr virus at the time of transplantation. Additional risk factors include cytomegalovirus mismatch and OKT3 immune suppression.
- Lung volume reduction surgery has emerged as a promising therapy for highly selected patients with heterogeneous involvement by severe emphysema.
- Major complications of lung volume reduction surgery include prolonged air leaks, bleeding, pneumonia, respiratory insufficiency requiring mechanical ventilation, and death.
- The National Emphysema Treatment Trial showed no overall difference in mortality at 2-years between medical therapy and LVRS. Patients at high risk and not considered candidates include those with an FEV₁ of $< 20\%$ predicted and either homogeneous distribution of emphysema on CT or a diffusing capacity of $< 20\%$ predicted.
- The NETT study showed the LVRS improved pulmonary function, exercise capacity, dyspnea, and quality of life when compared with medical therapy. A survival advantage was seen with LVRS in those patients with upper-lobe predominant emphysema and low-exercise capacity after rehabilitation.

Pulmonary Hypertension

59

Lewis J. Rubin

INTRODUCTION

The normal pulmonary circulation is a high-flow, low-pressure circuit that is capable of accepting the entire right ventricular (RV) output at a pressure one-fifth of that in the systemic circulation. When pulmonary artery pressure is increased, either as a result of intrinsic diseases affecting the pulmonary vessels, disturbances in ventilation or intrapulmonary gas exchange, or downstream cardiac disease, RV afterload increases. Ultimately, the increased ventricular work imposed by the elevations in pulmonary vascular resistance results in RV dysfunction, right-sided heart failure, and death. Pulmonary hypertension is considered to be present when the mean pulmonary artery pressure exceeds 25 mm Hg at rest or 30 mm Hg during exercise (1). This chapter reviews the causes of pulmonary hypertension, their presenting signs and symptoms, and the initial approach to diagnosis and management.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

The most common presenting symptom of patients with pulmonary vascular disease is dyspnea, which results from the inability of the right side of the heart to increase cardiac output and systemic oxygen delivery to meet the demands of physical activity. Dyspnea typically develops with exertion, but as pulmonary hypertension and RV dysfunction progress, it occurs with lesser degrees of activity. Exertional chest pain, similar to angina pectoris, may occur in severe pulmonary hypertension. It is thought to be a consequence of RV ischemia. Dizziness or syncope, particularly during

or immediately after exertion, is an ominous prognostic sign, indicating an inability to maintain cerebral perfusion because of marked limitations in RV output. Less common presenting symptoms of chronic pulmonary hypertension include a nonproductive cough, hoarseness (resulting from compression of the recurrent laryngeal nerve by enlarged main pulmonary arteries), and hemoptysis. The reader is referred to Chapter 53 regarding the presentation of patients with acute pulmonary hypertension associated with acute pulmonary embolism.

Although the findings of pulmonary hypertension on physical examination are often subtle, particularly in the early stages, important clues to the etiology may be evident. Examination of the jugular venous pulse may disclose a prominent *a* wave indicative of a poorly compliant RV, prominent *c-v* waves indicating the presence of tricuspid insufficiency, or venous distention suggesting an elevated right atrial pressure. Examination of the chest may reveal signs of severe airway obstruction, parenchymal lung disease, or hypoventilation as a consequence of body habitus or thoracic cage deformities. Patients with chronic thromboembolic pulmonary hypertension (CTEPH) may have bruits audible in the chest, which represent flow through partially obstructed vessels (2). An accentuated pulmonic component to the second heart sound (P_2), an S_3 or S_4 gallop, and murmurs of tricuspid or pulmonic insufficiency may be appreciated on cardiac examination. Fixed splitting of S_2 , with or without a soft diastolic murmur audible at the base of the heart, is suggestive of an atrial septal defect with Eisenmenger's syndrome. The presence of ascites or hepatomegaly may be clues to either right-sided heart failure or significant intrinsic liver disease with associated pulmonary hypertension (portal-pulmonary hypertension syndrome). Examination of the extremities may demonstrate clubbing,

which is suggestive of chronic pulmonary disease, congenital heart disease, or chronic liver disease. Central cyanosis suggests severe hypoxemia, caused either by disturbances in ventilatory function or right-to-left shunting with congenital heart disease. Peripheral cyanosis and edema are the result of a severely reduced cardiac output and right-sided heart failure, respectively. Examination of the skin and joints may show signs of a connective tissue disease, such as systemic sclerosis, systemic lupus erythematosus, or rheumatoid arthritis. Patients with portal–pulmonary hypertension caused by cirrhosis may have numerous truncal spider angiomas.

Differential Diagnosis and Initial Evaluation

Once the suspicion of pulmonary vascular disease has been raised by the patient's symptoms or signs, the approach should be directed toward establishing the presence of pulmonary hypertension and clarifying its etiology. A classification of conditions causing pulmonary hypertension is shown in Table 59.1. A meticulous history may provide important clues regarding causes. Prior or recent use of cocaine, anorexigenics (3), or intravenous (IV) drugs, in addition to risk factors for exposure to HIV, should be explored because all have been implicated in the development of pulmonary hypertension. A family history of pulmonary hypertension or death at a relatively young age from "heart disease" may suggest familial primary pulmonary hypertension (PPH), which accounts for approximately 7%–10% of all cases of that disease, or a familial prothrombotic state predisposing to chronic thromboembolic disease. A prior history of deep venous thrombosis or pulmonary embolism should raise the suspicion of CTEPH. A history of Raynaud's phenomenon suggests the presence of a connective tissue disease, although approximately 20% of patients with PPH may also experience this condition. Heavy alcohol use or infection with viral hepatitis raises the possibility of cirrhosis as the underlying etiology. Daytime somnolence, nightmares, and snoring suggest the presence of disordered breathing during sleep, with nocturnal hypoxemia and hypercapnia.

The initial diagnostic approach is outlined in Figure 59.1. Routine tests, including the chest radiograph and electrocardiogram, may disclose evidence of pulmonary hypertension, although the sensitivity of these studies is low for early disease. Echocardiography is often the first study that demonstrates findings of pulmonary hypertension, including right-sided chamber enlargement, flattening or displacement of the interventricular septum (which suggests RV pressure overload), and tricuspid regurgitation. The pulmonary artery systolic pressure can be estimated noninvasively by Doppler techniques based on the magnitude of the tricuspid regurgitant jet. Additionally, valvular disease, congenital heart disease, and conditions affecting left ventricular function can be excluded by transthoracic or transesophageal echocardiography. Contrast echocardiog-

TABLE 59.1

CLASSIFICATION OF PULMONARY HYPERTENSION

Intrinsic pulmonary vascular disease

Primary pulmonary hypertension
Connective tissue diseases (systemic sclerosis, systemic lupus erythematosus)
Pulmonary vasculitis
Eisenmenger's syndrome
Portal–pulmonary hypertension syndrome
HIV-associated pulmonary hypertension
Exogenous substances (anorexigenics, cocaine, L-tryptophan, contaminated rapeseed oil)
Chronic thromboembolic pulmonary hypertension

Pulmonary vascular disease resulting from chronic respiratory disease

Parenchymal lung disease (interstitial lung disease, obstructive airways disease, mixed disorders)
Disorders of ventilation (sleep apnea and obesity hypoventilation syndromes, restrictive chest wall disease)
Chronic hypoxic exposure (altitude)

Pulmonary vascular disease resulting from disorders of left-sided heart filling

Left ventricular systolic or diastolic dysfunction
Mitral valve disease

Pulmonary vascular disease resulting from mechanical obstruction

Mediastinal fibrosis
Foreign bodies (talc, fibers)
Tumor
Parasites
Granulomatous vascular disease

raphy may also disclose the presence of a patent foramen ovale, which occurs frequently in the setting of right atrial pressure overload.

A number of additional studies should be obtained to assist in establishing the etiology of pulmonary hypertension. Serologic studies (e.g., antinuclear antibody, rheumatoid factor, HIV antibody) can exclude connective tissue diseases and HIV infection. Of note, antinuclear antibodies are frequently present in patients with PPH, although usually in a low titer and nonspecific pattern. More detailed serologic testing may be necessary if a specific connective tissue disorder is suspected. Standardized tests of lung function should be performed to exclude significant lung disease. Mild reductions in lung volumes or the diffusing capacity are nonspecific and may be seen in PPH in addition to most other forms of pulmonary vascular disease. Measurement of arterial blood gases while the patient is breathing ambient air and 100% oxygen is important, not

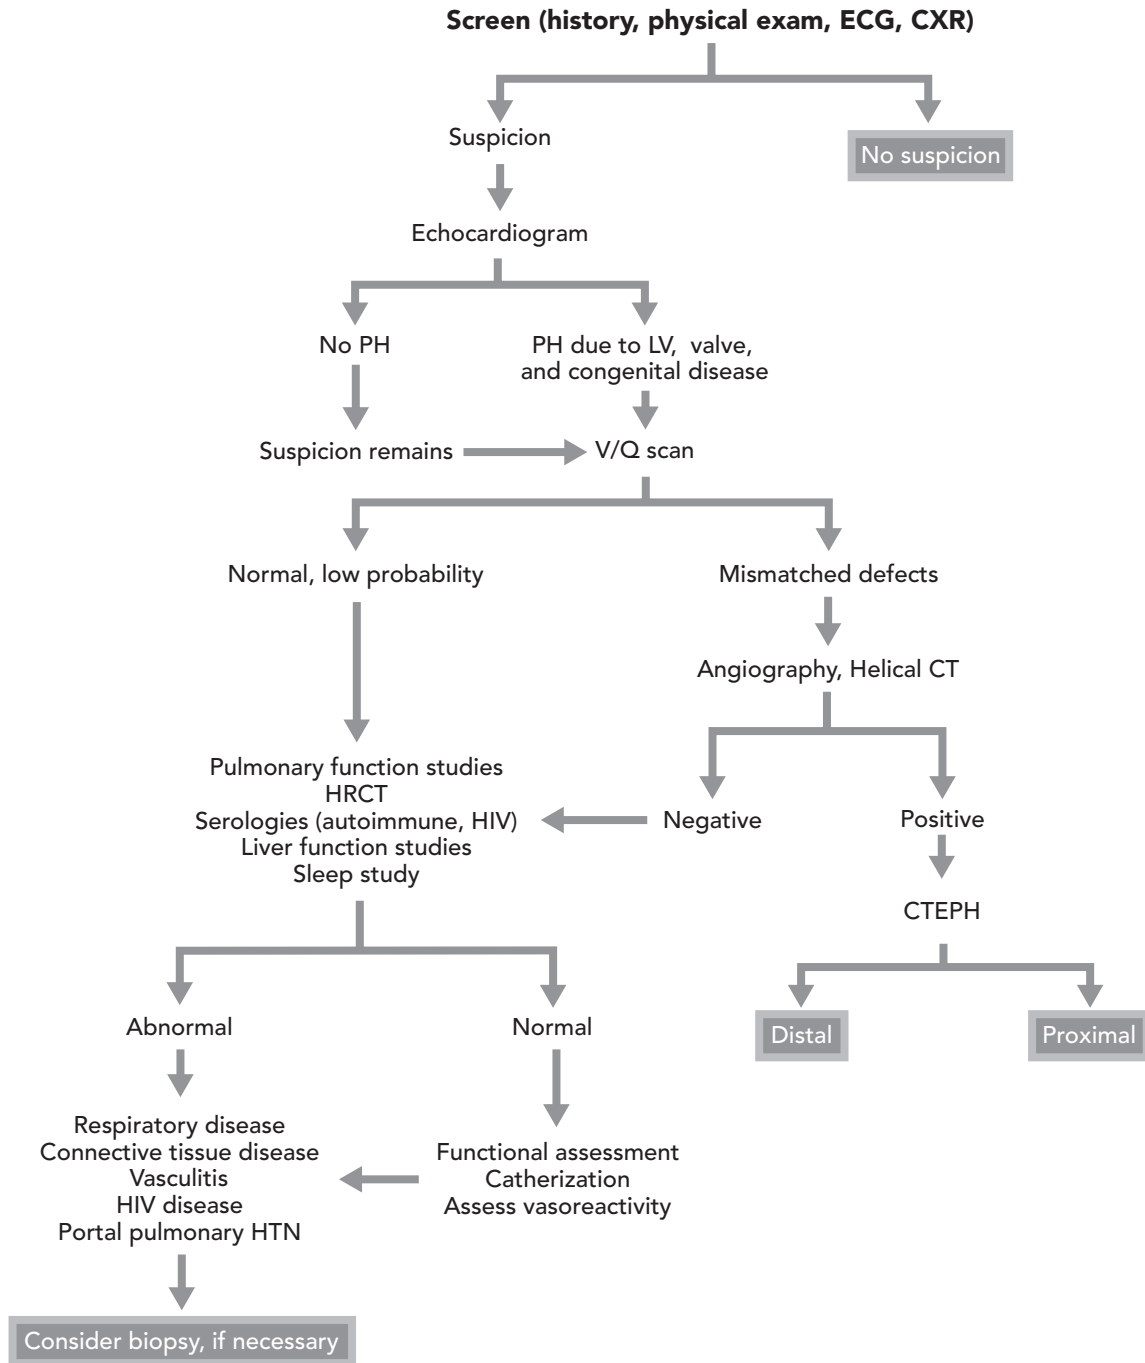

Figure 59.1 Approach to the diagnosis of suspected pulmonary hypertension. CTEPH, chronic thromboembolic pulmonary hypertension; CXR, chest X-ray; ECG, electrocardiogram; HRCT, high-resolution CT scan; HTN, hypertension; LV, left ventricular; PH, pulmonary hypertension.

only to clarify the need for supplemental oxygen therapy but also to determine whether a shunt exists. Similarly, measurement of oxygen saturation during activity, either by direct analysis of an arterial blood sample or by noninvasive measurement (pulse oximetry), may disclose desaturation, which can be effectively avoided through the use of ambulatory supplemental oxygen. Polysomnography is indicated when sleep apnea is suspected.

Imaging studies play a key role in differentiating between causes of pulmonary hypertension. Of these, the ventilation–perfusion lung scan is the most important because it may provide the sentinel clue to the presence of occult chronic thromboembolic disease. Because the ventilation–perfusion scan underestimates the extent of vascular involvement with chronic thrombosis, pulmonary angiography should be performed if the scan shows any

mismatched perfusion defects. Pulmonary angiography not only confirms the presence of thromboembolic disease but also delineates the sites and extent of involvement, information that is necessary to assess candidacy for pulmonary thromboendarterectomy. The lung scan in PPH is typically normal, whereas a patchy, nonsegmental perfusion pattern may be observed in pulmonary veno-occlusive disease. Other studies that can be helpful include spiral and high-resolution computed tomography, which can detect proximal thrombotic disease and occult interstitial lung disease, respectively.

Cardiac catheterization is usually the final diagnostic procedure performed in the evaluation of a patient with suspected pulmonary hypertension. A comprehensive study should include the measurement of right- and left-sided intracardiac and vascular pressures and cardiac output, and a search for the presence of intracardiac shunts or valvular disease. In the appropriate circumstances, testing for the presence of pulmonary vasoreactivity by means of short-acting vasodilators may also be performed during initial hemodynamic study.

Examination of lung tissue is rarely needed to establish an etiology for pulmonary hypertension. Furthermore, lung biopsy is often poorly tolerated by patients with pulmonary vascular disease, owing to their fragile cardiopulmonary status. When a definitive diagnosis cannot be made on clinical grounds, or when the management depends on the histopathologic findings (as in pulmonary vasculitis or other inflammatory conditions), thoracoscopically-guided biopsy is less invasive and carries a lower risk for adverse events than does open lung biopsy. The transbronchial biopsy specimens obtained via fiberoptic bronchoscopy are inadequate for establishing a diagnosis in most cases of pulmonary hypertension. Furthermore, the risk for uncontrollable hemorrhage is significant.

Indications for Hospitalization

The main indications for hospitalization are shown in Table 59.2. In general, much of the initial evaluation can be performed in the outpatient setting in most cases. How-

TABLE 59.2
INDICATIONS FOR HOSPITALIZATION

Initial invasive evaluation (including cardiac catheterization and evaluation of responses to vasodilator testing)
Initiation of oral or intravenous vasodilator therapy
Symptoms consistent with New York Heart Association functional class IV (syncope, bed-bound, anasarca)
Hypoxemia refractory to supplemental oxygen
Worsening renal function
Symptomatic systemic hypotension
Hemorrhagic complications of anticoagulant therapy

ever, patients with a rapid onset of symptoms, those with signs of progressive deterioration of right-sided heart function or severe hypoxemia, and patients who will be undergoing cardiac catheterization with acute vasodilator testing should be admitted.

Indications for Intensive Care Unit Admission

Patients who are hemodynamically unstable, defined as having systemic hypotension or severe hypoxemia requiring high concentrations of supplemental oxygen to maintain an adequate oxygen saturation, or those with evidence of severe right-sided heart failure (ascites, marked pedal edema) should be admitted to the ICU for management. This approach facilitates close monitoring of the patient's status as diagnostic and therapeutic approaches are initiated.

Initial Therapy

The initial therapy of pulmonary hypertension depends on the etiology. Patients with pulmonary vascular disease resulting from severe respiratory disease should be treated with modalities that will improve lung function and gas exchange (4). For example, sleep apnea should be managed with nocturnal use of noninvasive positive pressure ventilation, chronic airflow obstruction should be aggressively treated with bronchodilators and anti-inflammatory agents (Chapter 55), and interstitial lung disease should be treated with corticosteroids or other immunosuppressant or anti-inflammatory agents (Chapter 57), as appropriate. Supplemental oxygen therapy should be used in patients with hypoxemia at rest or during physical activity, both to optimize oxygen delivery to the peripheral tissues and to reduce the contribution of hypoxic pulmonary vasoconstriction to the altered pulmonary hemodynamic state. Patients with CTEPH should undergo placement of an inferior vena cava filter device, initiation of anticoagulation, and evaluation for pulmonary thromboendarterectomy (2) (Chapter 53). Patients with a connective tissue disease should receive the appropriate therapies for their systemic condition (Chapters 111 and 112).

Acute testing of pulmonary vasoreactivity is mandatory before a patient with PPH or connective tissue disease is given a course of vasodilator therapy, because less than 50% of patients respond to vasodilators. Vasodilators can cause significant deterioration in unresponsive patients by producing systemic hypotension, worsening hypoxemia, and diminishing cardiac output (5). Acute testing should be performed during careful hemodynamic study by physicians who have experience with vasodilators and the responses to these drugs in the setting of pulmonary hypertension. Short-acting agents are preferred because they can be discontinued rapidly if adverse effects are noted. The drugs of choice for acute testing are *inhaled nitric oxide*, *IV prostacyclin (epoprostenol)*, and *adenosine*. A

ADMINISTRATION OF COMMONLY USED
VASODILATOR AGENTS

Drug	Route	Dose range
Nitric oxide (NO)	Inhalation	5–40 ppm
Prostacyclin (epoprostenol, PGI ₂)	Intravenous	1–12 ng/kg per minute acutely (Doses vary for long-term use.)
Adenosine	Intravenous	50–300 mcg/kg per minute
Nifedipine ^a	Oral	30–240 mg/d
Diltiazem ^a	Oral	120–900 mg/d
Amlodipine ^a	Oral	5–20 mg/d
Bosentan	Oral	62.5 mg twice daily, increase to 125 mg twice daily after 4 weeks

^a Not recommended for acute testing of vasoreactivity. Doses listed are for long-term therapy only.

positive response is defined as a reduction in mean pulmonary artery pressure and pulmonary vascular resistance to normal or near-normal levels (e.g., <30–35 mm Hg and <5 units, respectively), without significant changes in systemic blood pressure or oxygen saturation or substantial side effects. The response to these agents administered acutely has been shown to predict responsiveness to long-term oral vasodilator therapy. Table 59.3 lists the most useful agents for acute testing and long-term therapy.

Long-term therapy in responders can be initiated with oral calcium channel blockers, which produce sustained hemodynamic and symptomatic improvement and are well tolerated by most patients (5). In general, the doses required to achieve an optimal effect are larger than those used to treat systemic vascular disease, although dose requirements and tolerance are variable. Therapy should be initiated with low doses and increased slowly during several days as vital signs, symptoms, and physical examination findings allow.

Until recently, there were no pharmacologic options for patients who failed to respond to acute testing. However, recent studies have demonstrated that several medications can be useful in the management of pulmonary hypertension that is unresponsive to oral vasodilators. Continuous IV infusion of epoprostenol improves hemodynamics, exercise tolerance, and survival in patients with PPH who fall into New York Heart Association functional classes III and IV (6, 7). Interestingly, continuous epoprostenol infusion produces improvement even in those patients who fail to respond to it acutely, which suggests that the long-term ef-

fects of this drug are a consequence of properties other than vasodilation. Epoprostenol is currently approved by the U.S. Food and Drug Administration for the treatment of PPH and PAH due to connective tissue disease refractory to conventional therapy. Experience with epoprostenol for other forms of severe pulmonary hypertension (connective tissue disease, congenital heart disease) has been limited, but beneficial results have been observed in this population also. Bosentan, a dual endothelin receptor antagonist that is administered orally, has recently been approved for symptomatic PAH (8).

Indications for Early Consultation

The management of patients with pulmonary vascular disease is highly complex and evolving rapidly. Consultation or referral to a center specializing in this area is recommended for those patients with PPH, CTEPH, and pulmonary hypertension associated with connective tissue disease or congenital heart disease because these patients may require complex medical or surgical interventions. Additionally, referral to specialized centers affords these patients access to investigational therapies. Patients with underlying pulmonary disease and persistence of pulmonary hypertension despite maximal medical therapy, and those in whom the etiology remains obscure, may also be candidates for referral or consultation.

ISSUES DURING THE COURSE OF HOSPITALIZATION

General Issues

The physician and patient should discuss the impact of pulmonary hypertension on survival, the avoidance of medications or illicit substances that can aggravate the underlying condition, and the options for management. For women of childbearing age, the issue of pregnancy must be discussed in detail. Pregnancy imposes significant cardiovascular stresses on the patient with pulmonary hypertension, particularly in the later stages, is poorly tolerated, and the mortality is high. Additionally, oral contraceptive agents may aggravate pulmonary hypertension, so alternative methods of contraception are advised. Exposure to high altitude is also not recommended because symptoms may be accentuated by even modest hypoxia.

General Medical Management

As stated previously, *supplemental oxygen therapy* is indicated when arterial oxygen saturation falls below approximately 90%, either at rest or during ambulation. Ambulatory systems allow the patient a greater degree of mobility, and the use of oxygen-conserving devices that deliver gas during

inspiration enables patients to remain out of the home for longer periods of time. Patients with severe hypoxemia requiring high flow rates of oxygen may benefit from the placement of a transtracheal catheter for oxygen delivery, as this approach is more comfortable and may accomplish the goal of achieving a satisfactory oxygen saturation level with lower flow rates. Oxygen should be used for at least 18 hours daily by patients with resting hypoxemia, although continuous use is strongly advised.

Diuretics are useful when there is evidence of right-sided heart failure, including edema or ascites. However, caution should be exercised with their administration because the RV is highly preload-dependent and excessive diuresis can result in clinical deterioration. Loop diuretics such as furosemide are generally effective as first-line therapy. In patients with severe right-sided heart failure, these drugs should initially be given IV, as absorption through the gut may be impaired. Patients with ascites may benefit from the addition of aldosterone antagonists, such as spironolactone. Refractory heart failure may necessitate the administration of more potent diuretics, such as metolazone. Diuresis may also relieve severe hypoxemia resulting from shunting through a patent foramen ovale by reducing the transatrial pressure gradient.

The role of *cardiac glycosides* for isolated right-sided heart dysfunction resulting from pulmonary hypertension is controversial. Some investigators have advocated the use of digoxin when calcium channel blockers are given to counteract the negative inotropic effects of the latter. Digoxin therapy is associated with a decrease in neurohumoral activation, but convincing evidence of improvement in right-sided heart function is lacking. Additionally, the risk for digitalis toxicity may be increased when hypoxemia and diuretic-induced hypokalemia are present.

Anticoagulation

The management of acute pulmonary embolism is discussed in Chapter 53. Patients with CTEPH should be treated with warfarin for life unless absolute contraindications exist. The dose should be adjusted to achieve an international normalized ratio (INR) of approximately 2.5. Persons who are at increased risk for recurrence or who may be resistant to anticoagulation at these levels, such as those with a "lupus anticoagulant" or with the anticardiolipin antibody syndrome, should be treated with doses of warfarin adjusted to achieve an INR of 3–4 (Chapter 98). Anticoagulation has been demonstrated to improve survival in PPH (9), but no data are available for other pulmonary hypertensive conditions. Most experts recommend anticoagulation for patients with severe pulmonary hypertension regardless of the etiology, as these patients are at risk for thromboembolism and have little, if any, pulmonary vascular reserve to draw on if the pulmonary circulation is compromised further.

Vasodilator Therapy

Patients who respond to acute vasodilator testing may be candidates for long-term oral vasodilator therapy. The calcium channel blockers are the drugs of choice, with the most experience to date with nifedipine, diltiazem, and amlodipine (5). Verapamil is not recommended because it is a less potent pulmonary vasodilator and is more likely to produce negative inotropic effects. Although the beneficial effects of angiotensin-converting enzyme inhibitors in systemic hypertension and left-sided heart failure have been well documented, these agents do not appear to be effective in pulmonary hypertension.

Oral vasodilator therapy should be initiated under close monitoring, with gradual adjustment of doses as tolerated. Side effects include headache, dizziness, worsening hypoxemia, and edema. There are no clear advantages of one calcium blocker over another (with the exception of verapamil's lack of efficacy), and intolerance of one drug does not preclude tolerance of another. Edema during calcium channel blocker therapy may be a consequence of the salt and water retention properties of this class of drugs or of worsening cardiac function. If the former is the cause, administration of low doses of diuretics usually results in resolution.

Continuous Intravenous Epoprostenol

Continuous IV epoprostenol is indicated for patients with PPH who fall into New York Heart Association class III or IV. Epoprostenol is administered by continuous IV infusion by means of a portable infusion pump attached to a permanent indwelling central venous catheter. Patients must be trained in the preparation of medication, troubleshooting the delivery system, and sterile technique. Although dosing should generally begin slowly and be increased as tolerated, a more aggressive approach is needed in patients who are severely ill. Side effects of therapy are common but manageable, and include headache, jaw or foot pain, skin rash, and diarrhea. Interruption of the infusion, either through pump malfunction or loss of venous access, is poorly tolerated and can be life-threatening. Dose requirements increase with time, which necessitates close follow-up in the outpatient setting. Continuous IV epoprostenol has been used either as a primary mode of therapy or as a bridge to transplantation, depending on the patient's response to and tolerance of long-term therapy, candidacy for transplantation, and personal preference (6, 7).

Oral Bosentan

Bosentan, a dual endothelin receptor antagonist, may be considered for patients with PAH who fall into New York Heart Association Class III or IV. The target therapeutic dose is 125 mg twice daily (8). Because the main adverse effect of bosentan is altered liver function, monthly liver function testing is required. Mild increases in

aminotransferases (<3 times normal) are common and do not require changes in dosing, while more severe increases (>5 times normal) require discontinuation of the drug.

Pulmonary Thromboendarterectomy

Pulmonary thromboendarterectomy has been demonstrated to produce substantial and sustained hemodynamic improvement in patients with proximal, unresolved pulmonary thromboembolic disease in major vessels. Patients who appear to have this condition should be referred to a center specializing in its diagnosis and treatment to assess their candidacy for thromboendarterectomy.

Transplantation

Single-lung, double-lung, and combined heart–lung transplantation have all been performed for pulmonary hypertension (10). Most centers reserve heart–lung transplantation for patients who have pulmonary vascular disease with irreversible cardiac disease, such as complex congenital heart disease, severe left-sided valvular disease, or left ventricular dysfunction. The median waiting time for single-lung or double-lung transplantation in the United States is currently approaching 2 years, which underscores the importance of early referral for evaluation. The 3-year survival after lung transplantation is approximately 60% (compared with a 20%–30% 3-year survival for untreated patients in New York Heart Association classes III and IV), with most deaths attributable to bronchiolitis obliterans, chronic rejection, or opportunistic infection.

The timing of lung transplantation poses a considerable challenge. Patients must be sufficiently ill to warrant transplantation, yet not so ill that surviving the surgery is unlikely. Close coordination of care between the physician overseeing medical management and the transplant center is crucial. A complete discussion of lung transplantation is presented in Chapter 58.

DISCHARGE ISSUES

Medications should be reviewed at discharge, with special emphasis on the risks associated with warfarin, drug interactions, and the importance of taking vasodilator medications as prescribed without interruptions. Patients discharged on continuous epoprostenol should have a list of emergency phone numbers and a letter to be kept on file in their local emergency department describing the nature of their treatment and emergency procedures to be followed in the event of interruption of the infusion. Dietary instructions, particularly salt and fluid restrictions or supplemental nutrition, should be reviewed. Patients should be encouraged to undertake physical activity to their level of tolerance but to avoid those activities that produce

sustained or serious adverse effects, such as chest pain, extreme dyspnea, dizziness, and syncope. A bracelet or medallion on which the diagnosis, medications, and emergency contact information are inscribed is recommended. A schedule should be developed for routine blood work, as necessary. Follow-up appointments should also be arranged, usually for 2–4 weeks after discharge. Finally, patients should be instructed to call immediately if changes in their condition develop, particularly syncope, hemoptysis, severe dizziness, or worsening edema.

COST CONSIDERATIONS AND RESOURCE USE

Most of the components of medical care for patients with pulmonary hypertension are costly and beyond the means of most people. Accordingly, patients should be encouraged to maintain adequate levels of medical insurance or to apply for government-supported coverage if eligibility can be established. Unfortunately, many patients with severe disease are unable to resume full-time employment after hospital discharge; their applications for disability often require substantial support and documentation by their physician. The unstable nature of this condition (11) necessitates the timely completion of disability applications to ensure that medical coverage does not lapse, even briefly.

Although diuretics and warfarin are relatively inexpensive, drugs such as calcium channel blockers can cost up to \$100 a month. Supplemental oxygen is usually covered by third-party payers as long as hypoxemia is documented. Epoprostenol therapy costs between \$50,000 and \$150,000 a year depending on dose, but it is covered by insurance when prescribed for its approved indication. Bosentan therapy costs approximately \$25,000 per year. The average cost for lung transplantation is \$125,000–\$150,000. Annual costs after transplantation vary, depending on the need for rehospitalization, but are estimated at \$25,000–\$50,000 a year, including the costs of medications. Complex treatments, such as epoprostenol and transplantation, are most efficiently and successfully performed at referral centers that have allocated resources to and gained experience with these approaches. In these centers, training for home epoprostenol therapy can usually be accomplished with short (5–7 days) inpatient stays. Some centers combine even briefer inpatient stays with outpatient training to minimize cost.

KEY POINTS

- Pulmonary hypertension is not a disease *per se*, but rather a hemodynamic abnormality that is common to a large number of divergent conditions. Determining the etiology of pulmonary hypertension is crucial to developing an individualized therapeutic approach.

- The presenting signs and symptoms of pulmonary hypertension are often subtle and nonspecific, particularly early in its course. Dyspnea out of proportion to evidence of heart or lung disease is an important clue.
- Several conditions are associated with pulmonary hypertension and should be explored during the initial assessment, including use of anorexigenics and illicit drugs, HIV infection, portal hypertension, and hereditary conditions.
- A systematic noninvasive approach to diagnosis will usually provide sufficient information to establish an etiology without the need for histologic confirmation.
- Complete cardiac catheterization, which is mandatory in patients with pulmonary hypertension, is used to confirm the severity and source of the hemodynamic abnormalities, help in estimating prognosis, and assess pulmonary vasoreactivity in response to potent, short-acting, titratable vasodilator agents.
- Patients with severe pulmonary hypertension who require complex treatments, such as pulmonary thromboendarterectomy, continuous epoprostenol therapy, or transplantation, should be referred to centers with expertise in these approaches.

Pleural Effusion and Pneumothorax

60

Steven A. Sahn John E. Heffner

INTRODUCTION

The accumulation of fluid or air within the pleural space represents the most common clinical expression of pleural disease. Radiographic evidence of a pleural effusion may develop from a primary disorder of pleural membranes, a complication of intrathoracic pathology, or a manifestation of an underlying systemic disease. A pneumothorax may occur as a consequence of underlying lung disease or traumatic injury to the lung or chest wall. The occurrence of a pleural effusion or pneumothorax commonly represents the initial clinical manifestation of an underlying thoracic or extrathoracic disorder. A well-organized diagnostic approach to patients with pleural abnormalities provides a specific etiologic diagnosis for the majority of patients who present with these conditions.

Pleural effusions occur when (a) an increased inflow of fluid into the pleural space outstrips the resorptive capacity of pleural lymphatics, or (b) the pleural fluid resorptive mechanisms become impaired. *Transudative effusions* have low protein content and occur in patients with normal pleural membranes. They result from increased pulmonary capillary hydrostatic pressure (e.g., congestive heart failure), decreased oncotic pressure (e.g., nephrosis), translocation of infradiaphragmatic fluid into the pleural space (e.g., ascites), decreased intrapleural pressure (e.g., atelectasis), or erosion of central lines through intrathoracic venous structures. Less common causes of transudative effusions include constrictive pericarditis, trapped lung, and superior vena cava syndrome. *Exudative effusions* result from increased permeability of pleural capillaries to protein (e.g., pneumonia), introduction of chyle into the pleural space (chylothorax), impairment of lymphatic drainage (mediastinal lymph node tumors), or obstruction of

lymphatic stomas on the parietal pleura (e.g., pleural malignancy).

Pneumothoraces are categorized as spontaneous, traumatic, or iatrogenic (e.g., after barotrauma or invasive procedures). Spontaneous pneumothoraces are further categorized as primary (occurring in patients without clinically apparent lung disease) or secondary (occurring in patients with underlying lung disease, such as chronic obstructive pulmonary disease).

This chapter outlines a clinical approach to the diagnosis and management of patients who present with a pleural effusion or pneumothorax. Emphasis is placed on discriminating between patients who require extensive diagnostic evaluations and those who can be managed with observation or empiric therapy alone.

PLEURAL EFFUSIONS

Clinical Presentation

The cardinal symptom of pleural effusions is dyspnea, which may first present as exertion-related shortness of breath in patients with slowly developing effusions (malignant effusions) or severe resting dyspnea in patients with sudden-onset, rapidly progressing effusions (traumatic hemothorax). Coexisting lung disease with chronic respiratory impairment allows smaller fluid collections to produce earlier and more severe symptoms. Inflammatory conditions of the pleural space cause pleuritic chest pain, which may remit as enlarging fluid collections separate the visceral and parietal pleural surfaces. Pleural mesotheliomas cause a constant, nonpleuritic pain of the chest wall. Patients are often asymptomatic and present with radiographic

evidence of a small pleural effusion as an incidental finding. Symptoms related to pleural effusions may be obscured by underlying cardiopulmonary conditions, such as congestive heart failure or pneumonia. Additional symptoms include cough, positional dyspnea, and a “feeling of fullness or heaviness” in the chest.

Physical findings include dullness to percussion, egophony, and tubular breath sounds over atelectatic lung regions just above the level of the effusion (Chapter 54). Pleural rubs can occur in patients with pleural inflammation. Rubs are heard best over the posterolateral chest.

Differential Diagnosis and Initial Evaluation

In most patients, radiographic detection of a pleural effusion warrants a diagnostic evaluation that utilizes imaging studies and pleural fluid analysis. A decubitus chest radiograph that detects free-flowing fluid with 1 cm or more of fluid layering indicates that thoracentesis can be performed with minimal risk for complications. Failure of the decubitus radiograph to detect free-flowing fluid does not exclude a pleural effusion and indicates a need for ultrasonographic or computed tomographic (CT) studies to detect loculated fluid. Ultrasonography can confirm the presence of fluid, demonstrate the thickness of pleural membranes, identify the presence of loculations, and localize fluid collections for thoracentesis. A contrast-enhanced chest CT can distinguish pleural fluid from pleural masses and underlying parenchymal consolidation and abscesses. CT imaging may also provide evidence of pleural inflammation, such as pleural enhancement, thickened extrapleural subcostal tissues, and increased attenuation of extrapleural fat. The resolution of CT imaging localizes loculations along the chest wall and in the mediastinum. Conditions associated with pleural effusions, such as mediastinal lymphadenopathy, central line erosions through venous structures with mediastinal hygromas, and pleural calcifications, can be identified by CT.

The finding of a previously undiagnosed pleural effusion mandates thoracentesis for pleural fluid analysis in the majority of patients. Exceptions include patients with typical congestive heart failure and clinically stable patients with asymptomatic pleural effusions in the early postpartum or postoperative period. These patients should be monitored for resolution of pleural fluid.

Pleural fluid obtained by thoracentesis is analyzed for gross appearance, which may be diagnostic or highly suggestive of an underlying diagnosis in some clinical settings (1, 2) (Table 60.1). Chemical analysis determines the exudative or transudative nature of effusions, which narrows the differential diagnosis. Exudates have been traditionally defined by the presence of any one of the following findings (Light’s criteria): (a) pleural fluid-to-serum protein ratio above 0.5; (b) pleural fluid-to-serum lactate dehydrogenase (LDH) ratio above 0.6; or (c) pleural fluid LDH concentration above 67% of the laboratory’s upper limit of

TABLE 60.1
GROSS APPEARANCE AND BIOCHEMICAL ANALYSIS OF PLEURAL FLUID

Gross appearance	
White, opaque	Chylous or pseudo-chylous (cholesterol) effusion
Purulent	Empyema
Malodiferous	Anaerobic empyema
Brown, red-brown, “anchovy”	Empyema caused by <i>Entamoeba histolytica</i>
Yellow-green	Rheumatoid pleurisy
Black	Empyema caused by <i>Aspergillus niger</i>
Ammonia odor	Urinothorax
Biochemical analysis	
Exudative criteria	
	1. PF LDH >67% upper limits of normal serum or PF/S protein >0.5, and
	2. PF LDH >67% upper limits of normal serum LDH, or
	PF protein >2.9 g/dL or PF cholesterol >45 mg/dL.
Glucose <40 mg/dL	Empyema, complicated parapneumonic effusion, rheumatoid pleurisy, malignant pleural effusion, tuberculous pleurisy, lupus pleuritis.
Amylase-rich effusion	Ruptured esophagus with or without empyema (salivary amylase), acute pancreatitis and pancreatic pseudocyst (>100,000 IU/L) (both pancreatic amylase). Malignant pleural effusion (salivary)
PF/S creatinine >1	Urinothorax.
Triglyceride >110 mg/dL	Chylothorax
pH <7.30	Complicated parapneumonic effusion/empyema, rheumatoid pleurisy, lupus pleuritis, tuberculous pleurisy, malignant effusion, esophageal rupture

LDH, lactate dehydrogenase; PF, pleural fluid; S, serum.

normal for serum LDH. Pleural fluid LDH and pleural fluid-to-serum LDH ratio are highly correlated, however, because they both contain test results for the pleural fluid LDH. Some experts, therefore, recommend using an “abbreviated Light’s criteria” that incorporates pleural fluid-to-serum protein ratio and pleural fluid LDH (3).

Other studies have proposed a higher cut off point for the pleural fluid LDH (>80% of the upper limits of the laboratory normal value) to diagnose exudative effusions (4). A meta-analysis determined that pleural fluid cholesterol, pleural fluid-to-serum cholesterol ratio, and pleural fluid-to-serum albumin gradient are about as accurate as each of the three tests within Light’s criteria in identifying exudates (3). Light’s criteria and other dichotomous test strategies with single cut off points frequently misdiagnose exudates in those patients with congestive heart failure who

TABLE 60.2**MULTILEVEL LIKELIHOOD RATIOS FOR LIGHT'S CRITERIA IN DETERMINING THE POSTTEST PROBABILITY OF AN EXUDATIVE EFFUSION**

Protein ratio	MLR	LDH PF	MLR	LDH ratio	MLR
>0.70	168.65	>1.00	44.33	>1.10	38.92
0.66–0.70	53.26	0.91–1.00	10.09	1.01–1.10	16.71
0.61–0.65	6.92	0.81–0.90	2.17	0.91–1.00	5.92
0.56–0.60	3.02	0.71–0.80	3.60	0.81–0.90	1.99
0.51–0.55	1.78	0.61–0.70	2.12	0.71–0.80	1.34
0.46–0.50	0.49	0.51–0.60	0.64	0.61–0.70	0.99
0.41–0.45	0.28	0.41–0.50	0.43	0.51–0.60	0.46
0.36–0.40	0.12	0.31–0.40	0.26	0.41–0.50	0.18
0.31–0.35	0.06	0.21–0.30	0.07	0.31–0.40	0.08
≤0.30	0.04	≤0.20	0.04	≤0.30	0.05

Protein ratio denotes pleural fluid-to-serum protein ratio; LDH denotes lactate dehydrogenase; LDH PF denotes pleural fluid LDH; LDH ratio denotes pleural fluid-to-serum LDH; MLR denotes multilevel likelihood ratio. To use the table in practice, let's work through a hypothetical example:

A patient with congestive heart failure presents with a pleural effusion. After diuresis, the effusion persists and thoracentesis is performed. Results for Light's criteria are shown below:

- Pleural fluid-to-serum protein ratio = 0.45
- Pleural fluid LDH (fraction of upper limit laboratory normal) = 0.65
- Pleural fluid-to-serum LDH ratio = 0.75

By Light's criteria, the pleural fluid is an exudate because the pleural fluid-to-serum LDH ratio is greater than 0.6. The physician, however, has a low suspicion of an exudate and suspects that the patient has a transudate due to heart failure. The physician estimates the pretest probability of an exudate as only 20% and uses serial multilevel likelihood ratios to calculate the posttest probability of an exudate.

The physician first calculates the pretest odds of an exudate using the formula, pretest odds = pretest probability/(1 – pretest probability) = 0.20/(1 – 0.20) = 0.25.

The physician then refers to Table 60.2 to find the multilevel likelihood ratio related to each of the patient's pleural fluid test results:

- Pleural fluid-to-serum protein ratio of 0.45 = multilevel likelihood ratio of 0.28
- Pleural fluid LDH of 0.65 = multilevel likelihood ratio of 2.12
- Pleural fluid-to-serum LDH ratio of 0.75 = multilevel likelihood ratio of 1.34

The physician can now calculate a posttest odds by multiplying the pre-test odds by each of the multilevel likelihood ratios:

$$0.25 \times 0.28 \times 2.12 \times 1.34 = 0.20$$

The physician now calculates the posttest probability of an exudate from the posttest odds with the equation, posttest probability = posttest odds/(1 + posttest odds) = 0.17 or 17%. (See Chapter 6 for more on Bayesian reasoning.)

With the use of serial multilevel likelihood ratios, the patient's pleural fluid test results decreased the physician's pretest estimate of the probability that the patient has an exudate (from 20% to 17%).

have clinical evidence of transudative effusions (5). Multilevel likelihood ratios used in a Bayesian strategy more accurately discriminate between exudative and transudative effusions (6) (Table 60.2). This strategy allows the features of the patient's clinical presentation to be integrated with the pleural fluid test results.

Confirmation of a transudative effusion usually allows the effusion to be attributed to a clinically apparent process, such as congestive heart failure. In most patients, no additional diagnostic evaluation is required. Exudative pleural effusions require exclusion of parapneumonic effusions related to an underlying pneumonia, pleural malignancies, pleural tuberculosis, and pulmonary embolism. Less common causes of pleural effusions, categorized by their transudative or exudative nature, are listed in Table 60.3. Thoracentesis can definitively diagnose the cause of

pleural effusions in 25% of patients and help narrow the differential diagnosis in an additional 50% (1).

Lymphocyte-predominant exudative pleural effusions that remain undiagnosed after thoracentesis may require closed pleural needle biopsy, especially if tuberculosis is considered; closed pleural biopsy is less often positive when the etiology is malignancy. The sensitivity of pleural fluid cytology for the diagnosis of malignancy ranges from 60%–90%. Pleural fluid culture and pleural tissue culture and histology has a sensitivity of up to 85% for tuberculosis. Thoracoscopy can be performed in patients whose condition remains undiagnosed, provided that a specific diagnosis would provide clinically meaningful prognostic or therapeutic information. Thoracoscopy by skilled operators has a sensitivity that approaches 100% for both pleural malignancy and tuberculosis.

TABLE 60.3
CAUSES OF TRANSUDATIVE AND EXUDATIVE PLEURAL EFFUSIONS

Transudative

Congestive heart failure
 Hepatic hydrothorax
 Nephrotic syndrome
 Urinothorax
 Pulmonary embolism (up to 23% of patients with pulmonary emboli)
 Central venous catheter eroded through vascular structures (saline infusion)
 Atelectasis
 Trapped lung
 Constrictive pericarditis
 Duro-pleural fistula (cerebrospinal fluid leak)

Exudative

Parapneumonic effusions and empyemas
 Malignancy
 Tuberculosis
 Chylothorax
 Pulmonary infarction
 Hemothorax
 Collagen vascular disease (rheumatoid arthritis, systemic lupus erythematosus)
 Yellow-nail syndrome
 Drug-induced effusions
 Pancreatitis and pancreatic pseudocyst
 After cardiac injury syndrome
 After coronary artery bypass surgery

Parapneumonic effusions, which are effusions that occur in association with pneumonia, may respond to antibiotics alone (*uncomplicated parapneumonic effusions*) or require drainage (*complicated parapneumonic effusions*) to prevent progression to an *empyema* (frank intrapleural pus). A Bayesian approach (Chapter 6) to determining the need for drainage on the basis of pleural fluid biochemical results and the patient's clinical features is shown in Figure 60.1 (2).

Indications for Hospitalization

Most patients with pleural effusions who require hospitalization are admitted because of the underlying condition that caused the effusion rather than because of the effusion itself. Patients with symptoms caused by a large, slowly progressive effusion who do not otherwise require hospitalization usually can be stabilized with a therapeutic thoracentesis in the emergency department or office. Massive pleural effusions, rapidly progressing effusions, hemothoraces, cardiopulmonary symptoms that do not improve after thoracentesis, a trapped lung associated with moderate-to-severe respiratory symptoms, and parapneumonic effusions or empyemas represent indications for hospitalization.

Indications for Intensive Care Unit Admission

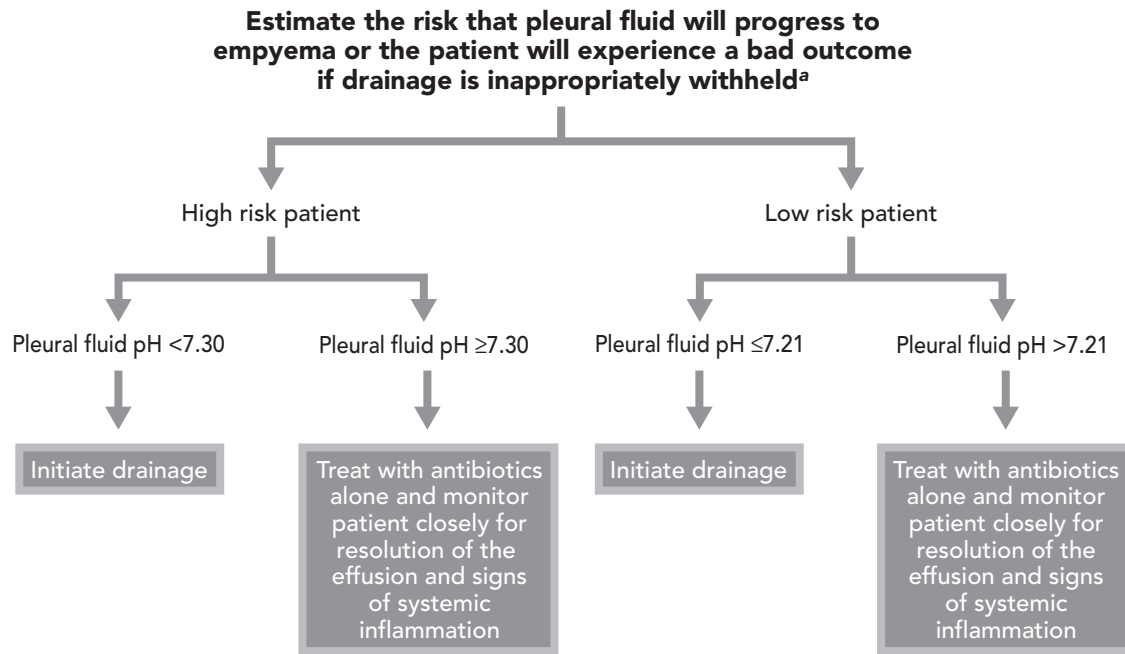

Pleural effusions by themselves rarely merit admission to an ICU. However, large, bilateral effusions can cause respiratory failure, especially in patients with underlying pulmonary dysfunction. Spontaneous hemothoraces complicating anticoagulation therapy or pleural malignancies require close hemodynamic monitoring and observation for the need for emergency thoracotomy. Patients in whom pulmonary edema develops after large-volume thoracentesis ("reexpansion" pulmonary edema) may benefit from short-term observation in a subacute care unit or ICU.

Initial Therapy

The therapy for pleural effusions depends on the underlying etiology of the pleural fluid collection. Patients with transudative pleural effusions require management of the underlying condition. With vasodilator and diuretic therapy for congestive heart failure (Chapter 39), for instance, pulmonary edema will generally resolve in a few days, and any associated pleural effusion will resolve a few days later. Patients with translocation of ascitic fluid into the pleural space may improve after paracentesis. Rare patients with chronic, symptomatic transudative pleural effusions unresponsive to therapy may benefit from either chemical pleurodesis to obliterate the pleural space or the placement of long-term, indwelling pleural drainage catheters.

Parapneumonic and malignant pleural effusions commonly require therapeutic interventions directed at the pleural space. For patients with parapneumonic effusions, urgent drainage must be considered. Delayed drainage in patients with complicated parapneumonic effusions prolongs hospitalization and worsens clinical outcome (7). Free-flowing, complicated parapneumonic effusions of low viscosity respond to *chest tube drainage* in 60%–90% of patients. When the effusion is not free-flowing, percutaneous catheters can be inserted into loculi under ultrasonographic or CT guidance and are highly effective in properly selected patients. Patients with parapneumonic effusions who fail to respond to chest tube drainage because of viscous effusions or intrapleural loculations may improve with the *intrapleural instillation of fibrinolytic agents*, such as streptokinase and urokinase (8). Although the use of these agents is not supported by large prospective, randomized, placebo-controlled trials, uncontrolled case series suggest that loculated, viscous pleural fluid can be drained and surgical interventions avoided in some patients. Measurable systemic fibrinolysis does not occur with the intrapleural instillation of these agents.

Patients with parapneumonic effusions who fail chest tube drainage may be candidates for *video-assisted thoracoscopic surgery* (VATS) if extensive pleural fibrosis and progression to a frank empyema have not occurred. More extensive, "organized" empyema (>6 weeks in duration) requires a standard thoracotomy with decortication. Open drainage

^a Risk Factors for Empyema or Bad Outcome in Parapneumonic Effusion:

- Large effusion (>40% of hemithorax)
- Positive pleural fluid Gram stain or culture
- Multiple pleural loculations
- Toxic/unstable patient with limited cardiopulmonary reserve
- Presence of a virulent pathogen (e.g., *Staphylococcus aureus*, *Klebsiella pneumoniae*, or *Pseudomonas aeruginosa*)

Figure 60.1 Algorithm for selecting patients for drainage of a parapneumonic effusion according to pleural fluid chemical analysis results.

with rib resection is an alternative surgical procedure for extremely ill patients who are not candidates for decortication and have localized collections of pleural pus. The key to successful management is early and effective drainage of the pleural space that results in the complete removal of intrapleural pus and apposition of the lung to the chest wall.

Hospitalized patients with malignant exudative pleural effusions may require therapeutic thoracentesis if symptoms of dyspnea or decreased exercise tolerance are attributable to pleural fluid. Removal of a large volume (>500 cc) of fluid during a single thoracentesis may result in *reexpansion pulmonary edema*, especially in patients with ipsilateral mediastinal shift, which suggests the presence of an obstructing endobronchial lesion or trapped lung. This complication is uncommon if the thoracentesis is interrupted as soon as patients experience chest discomfort, mild dyspnea, or cough. Patients with recurrent malignant pleural effusions may be candidates for *pleurodesis*, a procedure in which the effusion is first drained and then a chemical agent is instilled through the chest tube to cause pleural inflammation and fibrosis. Available compounds include talc slurry, bleomycin, and doxycycline (9). Talc (5 g) has the lowest cost (\$6–\$12 per treatment) and the highest efficacy (90%–95%), as demonstrated in uncontrolled stud-

ies. It is usually well tolerated, although a small number of patients (<1%) experience life-threatening respiratory failure with its use. Doxycycline has a success rate of 75%–90% and is not associated with serious adverse reactions. Bleomycin is the least effective of these three agents and has a drug acquisition cost of \$800–\$1,000 per treatment. Most experts recommend the use of talc slurry or doxycycline for chemical pleurodesis by chest tube. Pleurodesis can also be performed by thoracoscopy with talc poudrage (the insufflation of dry talc). Thoracoscopic pleurodesis has the advantage over chest tube pleurodesis of allowing the lysis of pleural adhesions that interfere with lung reexpansion. A chronic indwelling catheter, which allows the pleural space to drain to relieve dyspnea, results in spontaneous pleurodesis (over a median time period of about 1 month) in 40%–50% of patients (10).

PNEUMOTHORAX

Primary Spontaneous Pneumothorax

Primary spontaneous pneumothorax (PSP) has an estimated incidence of 2.5–18 cases per 100,000 persons. PSP

most commonly occurs in tall, thin men between the ages of 10 and 30 years. Smoking increases the risk for pneumothorax approximately 20-fold in males.

PSP occurs most commonly when an apical pleural bleb ruptures. The blebs are usually acquired as a result of bronchial inflammation but may be congenital. Abrupt changes in barometric pressure have been associated with an increased incidence of spontaneous pneumothorax. About 10% of patients with PSP have an associated small hemorrhagic pleural effusion that may be related to pleural injury from rupture of the bleb or traction on adhesions.

Clinical Presentation

About 90% of cases of PSP occur at rest. The most common symptoms are ipsilateral pleuritic chest pain (96%) and acute dyspnea (80%). The severity of the pain varies from mild to severe and has been described initially as sharp and later as a steady ache. Cough occurs in 10% of patients. Despite the persistence of the pneumothorax, symptoms frequently abate spontaneously by 24 hours. A regular tachycardia is the most common physical finding. There may be reduced chest wall excursion ipsilaterally, a hyperresonant percussion note, absent fremitus, and reduced breath sounds. With a small pneumothorax, chest examination findings may be normal (Chapter 54).

The diagnosis is usually confirmed by visualization of the visceral pleural line removed from the chest wall on an upright posteroanterior chest radiograph; however, an end-expiratory radiograph or a lateral decubitus radiograph with the affected side in the superior position may be necessary to identify the pneumothorax. An arterial blood gas determination typically shows mild-to-moderate hypoxemia and a respiratory alkalosis. In PSP, there is a reduction in forced vital capacity, impaired ventilation-perfusion matching, and some shunting, depending on the size of the pneumothorax.

The risk for recurrence following the initial PSP has been reported to be 32%–52%, and the recurrent PSP is usually ipsilateral. The recurrence rate increases with each subsequent pneumothorax and does not appear to be affected by standard chest tube drainage.

Secondary Spontaneous Pneumothorax

A number of pulmonary disorders are associated with SSP (Table 60.4). Secondary spontaneous pneumothorax is most commonly associated with chronic obstructive pulmonary disease. The incidence of SSP is similar to that of PSP; however, the peak incidence occurs in the seventh decade of life.

Secondary spontaneous pneumothorax can be caused by hyperexpansion of the distal air spaces from obstruction or inflammation in the airways. This leads to alveolar rupture and retrograde movement of air along the bronchovascular sheath to the mediastinum, with eventual rupture through the mediastinal parietal pleura. A second mechanism is rupture of the visceral pleura from an inflammatory parenchymal process.

TABLE 60.4

CAUSES OF SECONDARY SPONTANEOUS PNEUMOTHORAX

Diseases of the airways	Malignancy
Chronic obstructive pulmonary disease	Sarcoma
Cystic fibrosis	Lung cancer
Status asthmaticus	Other
Interstitial lung disease	Catamenial
Langerhans cell granulomatosis	Pulmonary infarction
Sarcoidosis	Wegener's granulomatosis
Lymphangioliomyomatosis	Marfan syndrome
Tuberous sclerosis	Ehlers-Danlos syndrome
Rheumatoid disease	
Idiopathic pulmonary fibrosis	
Radiation fibrosis	
Infectious diseases	
Necrotizing gram-negative pneumonia	
Anaerobic pneumonia	
Staphylococcal pneumonia	
AIDS with pneumocystis pneumonia	
<i>Mycobacterium tuberculosis</i> infection	

Clinical Presentation

Dyspnea is more severe in SSP than in PSP because of the impaired pulmonary reserve. Chest pain appears to be both less common and less severe. Life-threatening hypoxemia or hypotension occurs in about 15% of patients. In contrast to the symptoms of PSP, those of SSP typically do not resolve spontaneously.

The underlying lung disease may result in subtle physical findings. Clinical suspicion of pneumothorax should remain heightened in patients with chronic obstructive pulmonary disease in whom dyspnea and unilateral chest pain develop. However, the presence of underlying lung disease often makes radiographic identification of the visceral pleural line more problematic. Pleural adhesions may result in loculated pneumothoraces, and the edge of a large bulla may simulate the visceral pleural line. In critically ill patients, the supine radiograph will show the pneumothorax gas in a juxtacardiac position or in the costophrenic sulcus, where it may produce a "deep sulcus" sign. CT may be necessary to diagnose pneumothorax in these patients (Chapter 54).

Arterial blood gas measurements in the patient with SSP generally show significant hypoxemia and hypercapnia. The recurrence rate is similar to that for PSP.

Iatrogenic Pneumothorax

Iatrogenic pneumothoraces are complications of diagnostic and therapeutic procedures and are caused by transthoracic

needle biopsies, subclavian venous catheter insertions, thoracentesis, pleural biopsy, transbronchial lung biopsy, and mechanical ventilation (Chapter 23).

Tension Pneumothorax

Tension develops in a pneumothorax when the pleural pressure exceeds atmospheric pressure during the entire respiratory cycle because of an unidirectional flow of air from the lung into the pleural space. Tension pneumothorax can be fatal if not treated promptly. Air continues to accumulate in the pleural space from a “check-valve” mechanism. Experimental studies suggest that the circulatory collapse in tension pneumothorax is related to decreased oxygen delivery to tissues as a result of hypoxemia rather than impaired venous return. Tension pneumothorax occurs in about 1%–2% of cases of spontaneous pneumothorax and more commonly in traumatic pneumothorax and pneumothorax occurring with positive pressure ventilation.

Clinical Presentation

The patient with a pneumothorax under tension presents with severe respiratory distress, cyanosis, marked tachycardia, and hypotension. The ipsilateral hemithorax may be noticeably larger. It can be problematic to differentiate between the involved and uninvolved hemithorax, and the predominant symptoms may be related to hemodynamic instability rather than respiratory distress.

The characteristic triad of tension pneumothorax on chest radiograph includes contralateral mediastinal shift, depression of the ipsilateral diaphragm, and lung collapse.

Management of Tension Pneumothorax

Immediate decompression of the involved hemithorax is mandatory to save the patient's life. With decompression, there is an immediate fall in heart rate and respiratory rate and restoration of the blood pressure. Valuable time should not be wasted awaiting results of radiologic studies, as the clinical presentation is usually highly suggestive of the diagnosis. A large-bore catheter should be inserted into the pleural space of the suspected hemithorax through the second anterior intercostal space. A rush of air seen or heard bubbling through a fluid-filled syringe confirms the diagnosis; symptoms should improve rapidly. A large-bore chest tube should then be inserted without delay.

Management of Spontaneous Pneumothorax

The initial goal in the management of pneumothorax is to remove air from the pleural space and to reexpand the lung, with a secondary goal of preventing recurrence. After the pneumothorax gas equilibrates with tissue gases, a small

nitrogen gradient for absorption exists and the pneumothorax gas is absorbed from the pleural space at a rate of 1.25% of the volume of the hemithorax daily. Figures 60.2 and 60.3 are algorithms for the initial management of patients with PSP and SSP, respectively.

Observation

Patients with a small PSP (<15%) usually do not require pleural space drainage if they are asymptomatic, have normal vital signs, are under age 40, and have no other abnormalities on chest radiograph. In addition, the pneumothorax must have occurred within the previous 24 hours, and there should be no radiographic progression during 6 hours of observation in the emergency department. These patients may be discharged from the emergency department and reevaluated with a chest radiograph in 24–48 hours.

All patients with SSP should be admitted to the hospital, and *virtually all will require chest tube drainage*. Rare patients with small SSPs can be initially observed without tube thoracostomy if they are asymptomatic with normal vital signs, if no progression is shown on a repeat chest radiograph 6 hours later, and if the patient is not a candidate for pleurodesis. However, most patients with SSP have significant symptoms, and therefore observation alone is usually not an option.

Supplemental Oxygen

Administration of supplemental oxygen results in a four-fold increase in pleural gas absorption. Oxygen causes a washout of nitrogen from the blood and reduces total pleural capillary gas pressure, which significantly increases the nitrogen gradient across the pleura.

Simple Manual Aspiration

Simple manual aspiration has a success rate similar to that of intercostal tube drainage for patients with their first PSP (10). Catheter aspiration is simple, causes less morbidity than chest tube insertion, and when successful does not require hospitalization.

A catheter is placed in the pleural space by either a catheter-over-needle device or the modified Seldinger technique (Chapter 27). With a 50-mL syringe attached to a three-way stopcock, air is removed until resistance occurs or 4 L of air has been aspirated, the latter defining a persistent leak necessitating chest tube drainage. An aspiration is successful when the pneumothorax resolves symptomatically and radiographically without evidence of a persistent air leak.

Catheter aspiration is most likely to be successful in PSP when the pneumothorax is several days old, which increases the likelihood that the air leak has stopped. Simple aspiration should not be used for SSP because of the higher

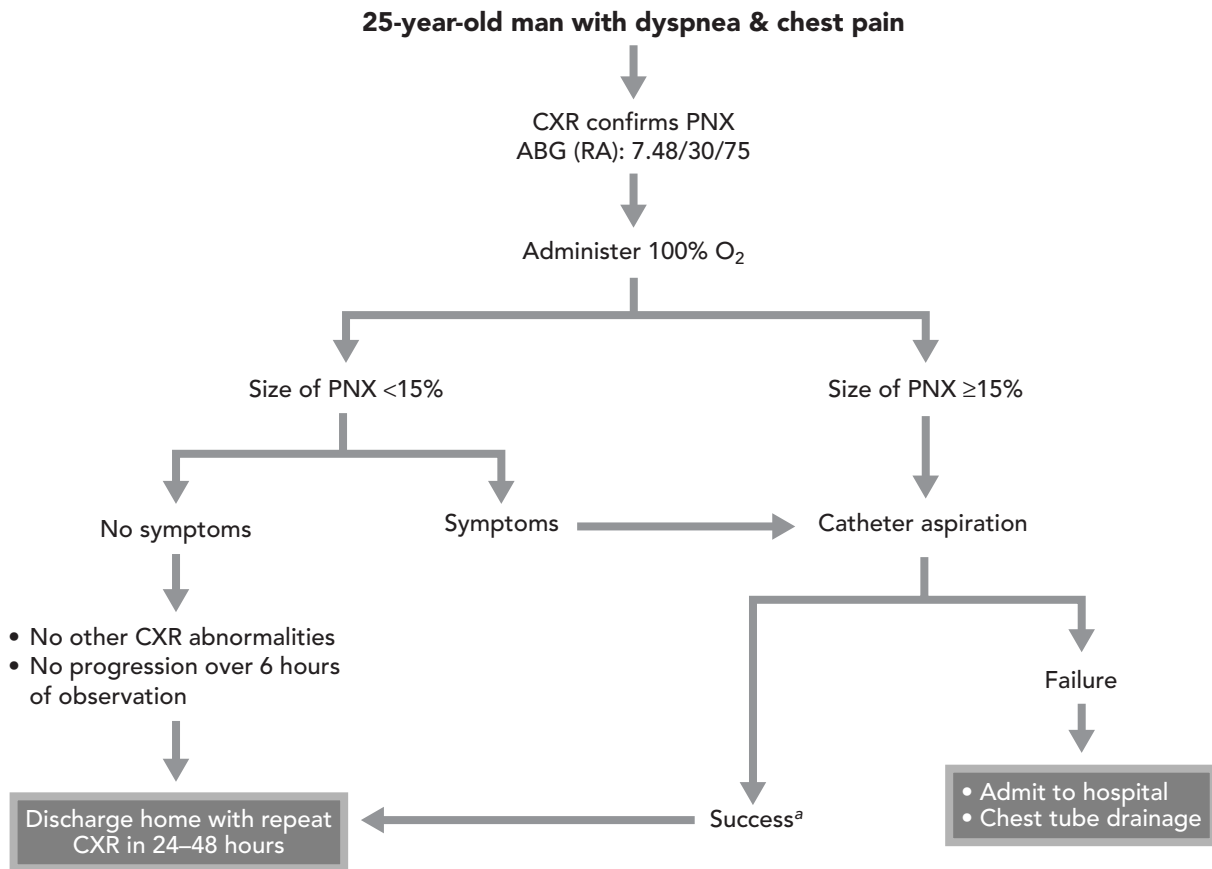

Figure 60.2 Initial management of a hypothetical patient with primary spontaneous pneumothorax.
^aSuccessful catheter aspiration: Air is withdrawn from the pleural space until no more can be aspirated and CXR reveals complete lung expansion.
 ABG, arterial blood gas; CXR, chest X-ray; PNX, pneumothorax; RA, room air.

likelihood of persistent air leak and the more precarious state of the patient.

Chest Tube Drainage

Tube thoracostomy is the treatment of choice for virtually all patients with SSP, with the exception of stable, asymptomatic patients with small (<15%) pneumothoraces who would not be candidates for pleurodesis.

The majority of patients with a spontaneous pneumothorax can be treated with small thoracostomy tubes (8F to 16F). Drainage of the pleural space can be accomplished with either a Heimlich valve or a water seal. Some physicians apply suction to the system immediately, whereas others reserve this option for cases in which complete expansion is not attained by 24 hours. When the lung is completely expanded on chest radiograph, the air leak has ceased, and the drainage system is deemed functional, the tube can be removed within the next 24–48 hours. Some clinicians prefer to clamp the tube for a period of time; others simply observe with continued suction. Randomized trials are not available to help inform this decision.

Chemical Pleurodesis Through a Chest Tube

When standard chest tube or small-bore catheter placement has resulted in complete lung expansion, a chemical agent can be instilled into the pleural space in an attempt to create pleurodesis. Chemical pleurodesis was commonly performed for spontaneous pneumothorax in the past, but it has now been largely supplanted by video-assisted thoracoscopic surgery (VATS) with pleurodesis.

Thoracoscopy

VATS has become the preferred alternative to standard thoracotomy to identify and repair the visceral pleural lesion in patients with SSP and patients with recurrent PSP (11). Wedge resection of the blebs can be accomplished with an endoscopic stapler, or ablation of the blebs with an Nd:YAG (neodymium:yttrium-aluminum garnet) laser. When the bleb is identified and repaired, followed by pleural abrasion or talc poudrage, the recurrence rate approaches zero. VATS also requires only a short hospital stay, is associated with low morbidity, and has a high rate of patient acceptance. Axillary thoracotomy has similar

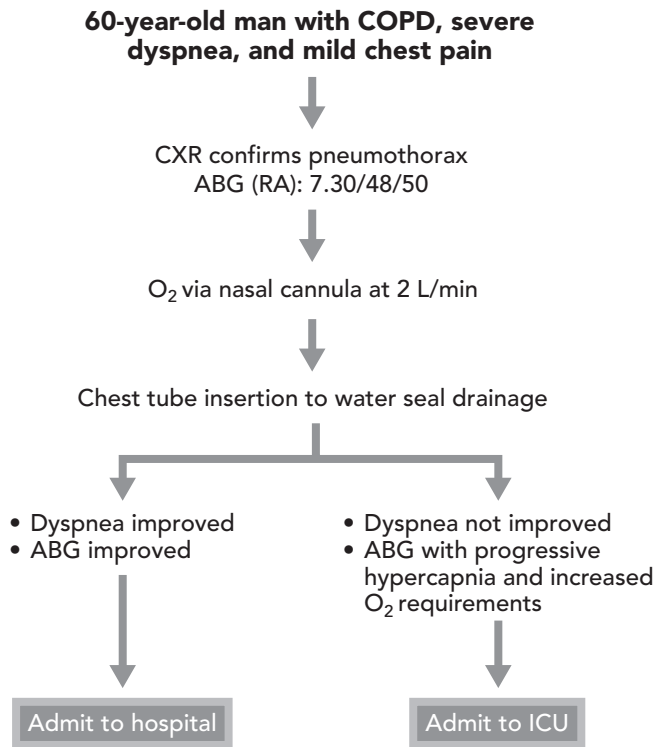

Figure 60.3 Initial management of a hypothetical patient with secondary spontaneous pneumothorax.

efficacy and safety to VATS and is preferred where VATS is not available (12).

For patients with their first PSP treated with chest tubes, spontaneous resolution of air leaks tends to occur by 48 hours. There is little to be gained in PSP, therefore, by conservative treatment of air leaks that persist for longer than 72 hours. In contrast, the relatively high surgical risk for patients with SSP and severe underlying lung dysfunction may prompt a longer trial (7–10 days) of chest tube drainage before proceeding to VATS or limited thoractomy.

Surgical intervention (VATS) is indicated in patients with recurrent pneumothoraces, persistent air leak, bilateral pneumothoraces, and a single episode of pneumothorax when a recurrence is thought to put the patient at great risk. Because spontaneous pneumothorax is usually poorly tolerated in patients with underlying lung disease, most patients with SSP qualify for pleurodesis after their first episode. A recent decision-analysis indicated that VATS could be optimal therapy for the first episode of PSP in men who fail simple manual aspiration (13). Patient preferences should determine whether VATS is performed after the first or second PSP.

COST CONSIDERATIONS AND RESOURCE USE

The treatment of patients with recurrent spontaneous pneumothorax should be individualized and guided by expert

opinion, as few randomized, controlled trials have been performed. Simple aspiration in the Emergency Department allows many patients with PSP to avoid hospitalization.

KEY POINTS

- Discriminating between pleural fluid exudates and transudates is the first step in evaluating pleural effusions.
- The “abbreviated Light’s criteria” using pleural fluid-to-serum protein and pleural fluid LDH has similar diagnostic performance to the traditional 3-component Light’s criteria.
- Confirming a transudate generally narrows the differential diagnosis to a clinically apparent process.
- Factors that indicate a need for drainage of a nonpurulent parapneumonic effusion include a large effusion (>40% of hemithorax), a positive pleural fluid Gram’s stain or culture, multiple loculations, a low pleural fluid pH or glucose level, and a high pleural fluid level of lactate dehydrogenase.
- Therapeutic thoracentesis should be performed cautiously in the patient with a large pleural effusion and ipsilateral mediastinal shift, as there is a high risk of unilateral pulmonary edema.
- Primary spontaneous pneumothoraces occur most commonly in tall, thin male smokers in the second and third decades of life; they recur in 30%–50% of patients.
- Simple aspiration can be successful in primary spontaneous pneumothorax (and hospitalization avoided) if clinical evaluation suggests that the air leak has stopped.
- Tube thoracostomy is the treatment of choice for virtually all patients with secondary spontaneous pneumothorax.
- Video-assisted thoracoscopic surgery (VATS) is the preferred surgical procedure for recurrent spontaneous pneumothorax; the recurrence rate approaches zero if the bleb is identified and treated. Most patients with SSP should undergo pleurodesis after their first pneumothorax.

Pulmonary Nodules and Mass Lesions

61

Michael K. Gould Glen A. Lillington

INTRODUCTION

In this chapter, we discuss three categories of spherical intrapulmonary lesions, with a particular focus on the hospitalized patient: (a) the *solitary pulmonary nodule* (SPN), a spherical and fairly well-circumscribed radiographic opacity with a diameter of 3 cm or less; (b) the *pulmonary mass lesion*, which is roughly spherical and fairly well circumscribed but greater than 3 cm in diameter; and (c) *multiple nodules*, which are spherical and may be of different sizes. As the management of patients in the three categories differs considerably, we discuss each separately.

SOLITARY PULMONARY NODULES

The SPN is a spherical radiographic opacity that measures up to 30 mm in diameter. Use of the term “solitary” indicates that there is only one nodule and that there is no associated atelectasis, post-obstructive pneumonia, mediastinal widening or pleural effusion. We further distinguish nodules that measure less than 8–10 mm in diameter because they are difficult to biopsy or characterize by imaging tests. Most of these “sub-centimeter” nodules are detected incidentally on chest computed tomography (CT) and should be managed by repeating the CT scan every 3–6 months to check for growth, although the optimal interval for follow-up has not been determined.

About 20%–40% of SPNs that measure between 8 and 30 mm in diameter are malignant, mostly bronchogenic carcinomas (Table 61.1). Benign nodules are usually healed granulomas or benign tumors, but a variety of uncommon types include noninfectious granulomas, parasitic lesions, healed infarcts, and pulmonary arteriovenous malformations (1).

The primary management goal is to resect malignant nodules promptly while avoiding thoracotomies for benign nodules. Some nonmalignant SPNs require prompt investigation and treatment, however, particularly when they occur in immunocompromised patients.

Diagnostic Techniques

Most SPNs are incidentally found by *chest radiography*, which can detect most nodules that measure at least 1 cm in diameter. Ideally, nodules located within the chest should be visible in more than one radiographic projection, but nodules are sometimes difficult to visualize in the lateral view. Occasionally, nipple shadows, skin tumors or articular surfaces of ribs can be mistaken for pulmonary nodules. In these circumstances, repeated films in which nipple markers or apical lordotic projections are used will typically help differentiate normal anatomic structures from nodular parenchymal abnormalities.

In general, plain radiography provides few clues regarding etiology. Larger nodules and those with irregular, spiculated margins are more likely to be malignant. Although the sensitivity of chest radiography for detecting intranodular calcification is only 50% (2), certain patterns of calcification (central, laminated, diffuse and “popcorn”) strongly point to a benign diagnosis. These nodule characteristics are often better evaluated by computed tomography (CT). Rarely, a (non-solitary) nodule is associated with an ipsilateral pleural effusion, mediastinal fullness, or atelectasis from bronchial obstruction, in which case bronchogenic carcinoma is likely.

Prior chest radiographs provide crucial information about nodule growth or stability over time. Thus, a critically important first step in SPN diagnosis is to locate any old films for radiographic comparison.

TABLE 61.1
ETIOLOGY OF SOLITARY PULMONARY NODULES

Malignant

Bronchogenic carcinoma 30%
 Carcinoid tumors 5%
 Solitary metastases 5%

Benign

Healed granulomas 35%
 Granulomatous infection or inflammation, active 15%
 Benign tumors (e.g., hamartoma) 5%
 Miscellaneous causes 5%

Computed tomography of the thorax is usually advisable. This provides accurate information about the diameter of a nodule, the pattern of any calcification present, the characteristics of the nodule edge, and the presence or absence of hilar/mediastinal adenopathy. The latter has important implications for staging in patients with malignant nodules, although CT is neither sensitive nor specific for identifying mediastinal metastases (3). Selected high-resolution sections will show attenuation patterns within the nodule, which in some cases (e.g., hamartoma) may be diagnostic. Although the technique is not widely used in current clinical practice, a multicenter study of CT with dynamic contrast enhancement showed that absence of contrast enhancement (<15 Hounsfield units) strongly predicted a benign diagnosis (4).

Positron emission tomography (PET) is a newer and potentially useful functional imaging test for pulmonary nodule diagnosis. The sensitivity and specificity of PET for detecting malignancy are approximately 94% and 83%, respectively (5). The technique is also useful for detecting tumor involvement in the hilar/mediastinal lymph nodes and in distant organs (6).

Non-thoracotomy biopsy of the SPN often differentiates malignancy from benignity. Bronchoscopic biopsy is relatively insensitive unless the nodule is central in location and large. Transthoracic needle aspiration biopsy (TTNAB) under CT guidance is very helpful when it reveals a specific benign or malignant diagnosis, but nondiagnostic results and pneumothorax requiring chest tube placement can be expected in approximately 20% and 5% of cases, respectively (7). With the use of appropriate techniques and needles, it is possible to establish a specific diagnosis by TTNAB in about 50% of patients with benign nodules. The diagnostic yield for malignancy is over 90%, although the yield depends on several factors, including the size and location of the nodule.

Thoracotomy is required in some cases to establish the diagnosis, and it is particularly useful if the probability of

cancer is high. In recent years, video-assisted thoracoscopic surgery (VATS) has become increasingly favored over classic thoracotomy for biopsy and resection of peripheral nodules. Most thoracic surgeons convert the VATS procedure to a classic thoracotomy when malignancy is identified on frozen section (8).

Issues at the Time of Admission

By definition, patients with solitary pulmonary nodules are asymptomatic, and therefore the presence of an SPN is not in itself an indication for admission to the hospital. In most cases, the symptoms and signs that have resulted in a hospital admission are caused by an unrelated disease process that will dominate investigation and management. Investigation of the coexistent ("incidental") SPN, although important, is usually deferred, at least temporarily.

Occasionally, the pulmonary nodule and the clinical syndrome that prompted hospital admission will appear to be related and must be investigated concurrently. Several clinical patterns may be encountered in which such a relationship appears likely.

Remote Metastases Pattern

Metastatic deposits from a malignant nodule may be regional or distant. Regional metastases may result in superior vena cava obstruction or upper airway obstruction due to tracheal compression. The diagnostic clue is the detection on chest CT of extensive mediastinal adenopathy. Distant (remote) tumor deposits may result in a variety of neurologic, hepatic, skeletal, and adrenal syndromes. For patients with non-small cell lung cancer, appropriate imaging studies should be ordered when one of these syndromes is suggested by a thorough history and physical examination. Although biopsy of metastatic lesions usually confirms the diagnosis, TTNAB of the SPN itself may occasionally be necessary.

Paraneoplastic Syndrome Pattern

Paraneoplastic syndromes secondary to bronchogenic carcinoma may be the impetus for hospital admission. These syndromes may include symptomatic hypercalcemia, inappropriate secretion of antidiuretic hormone (SIADH), Cushing's syndrome, cerebrotendinous dysfunction, gynecomastia, and pseudomyasthenia. The clinical characteristics usually suggest the diagnosis, and biopsy evidence of malignancy is confirmatory.

Immunosuppression Pattern

An SPN may be a manifestation of an opportunistic infection, particularly in AIDS patients (9) and organ transplant recipients (10, 11). Other lung lesions are often present. Tests include sputum cultures, blood cultures, bronchoscopy

with collection of bronchoalveolar lavage fluid, transbronchial needle aspiration, and TTNAB. The sensitivities of all these tests are low, and in some instances, a thoracotomy may be needed to determine the etiology. Empiric antibiotic therapy is often advisable if there is evidence of infection.

Incidental Nodule Pattern

In most hospitalized patients with an SPN, the clinical circumstances indicate that the nodule is incidental to the illness that precipitated hospital admission. If it seems likely that the two problems are unrelated, the prudent course is to diagnose and treat the acute illness and defer investigation of the nodule until the acute illness is resolving.

An incidental SPN may be detected in patients admitted to the hospital for acute coronary syndrome. If coronary bypass surgery seems necessary, the usual practice has been to defer consideration of the nodule until the patient has recovered from the cardiac surgery. However, if the probability that the nodule is malignant is high, resection of the nodule at the time of the cardiac procedure may be a reasonable alternative in selected cases (12).

Similarly, patients admitted to the hospital for lung volume reduction surgery (Chapter 58) have a concomitant SPN in up to 10% of cases. The nodule can be resected during the volume reduction procedure in selected instances (13).

Issues During the Course of Hospitalization

Once the illness for which the patient was hospitalized is being resolved, attention may be turned to the SPN. If it is still present and unchanged after therapy for the acute illness, further investigation is warranted. This can be initiated in the hospital and completed on an outpatient basis.

Two features that indicate a very high probability of benignity are (a) radiologic detection of *intranodular calcification in a benign pattern*, and (b) *stability* (no increase in size during a period of at least 2 years, as determined by serial chest roentgenograms). In either of these cases, exploratory thoracotomy can usually be deferred, but obtaining serial chest roentgenograms or CT scans every 6 months for another year or two is usually prudent, especially in patients with small nodules (14).

Management strategies for the *uncalcified nodule of unknown stability* include (a) prompt thoracotomy, (b) non-surgical biopsy of the nodule, and (c) observation ("wait and watch"), a prospective determination of stability through serial chest roentgenograms. If the choice is to pursue nonsurgical biopsy of a solitary nodule, many studies have shown that TTNAB has a much greater sensitivity for malignancy than bronchoscopy since most solitary nodules are located peripherally.

While most clinicians use intuition to estimate the clinical likelihood (or pretest probability) of malignancy in a given patient, more precise estimates can be obtained by

using one of several quantitative models that have been developed (15–17). Although the calculated probabilities of cancer do not permit an exact separation of malignant from benign nodules, they are useful for guiding management. For example, a decision analysis showed that watchful waiting was preferred when pretest probability of cancer was less than 3%; surgery was preferred when pretest probability was greater than 68%; and needle biopsy was preferred at intermediate probabilities, although the choice of strategy was a "close call" (18). A more recent cost-effectiveness analysis (19) concluded that PET imaging is now preferred over needle biopsy when the probability of malignancy falls in the range between 20% and 68% (Figure 61.1).

SPHERICAL MASS LESIONS

For purposes of this presentation, a mass lesion is defined as a roughly spherical and well-circumscribed opacity of the lung that is greater than 3 cm in diameter. Mass lesions have somewhat different etiologies than SPNs (Table 61.2), are more likely to be malignant, and require different management approaches. Although pulmonary masses are usually solitary, we include in this discussion the uncommon instances in which a patient has multiple mass lesions.

Issues at the Time of Admission

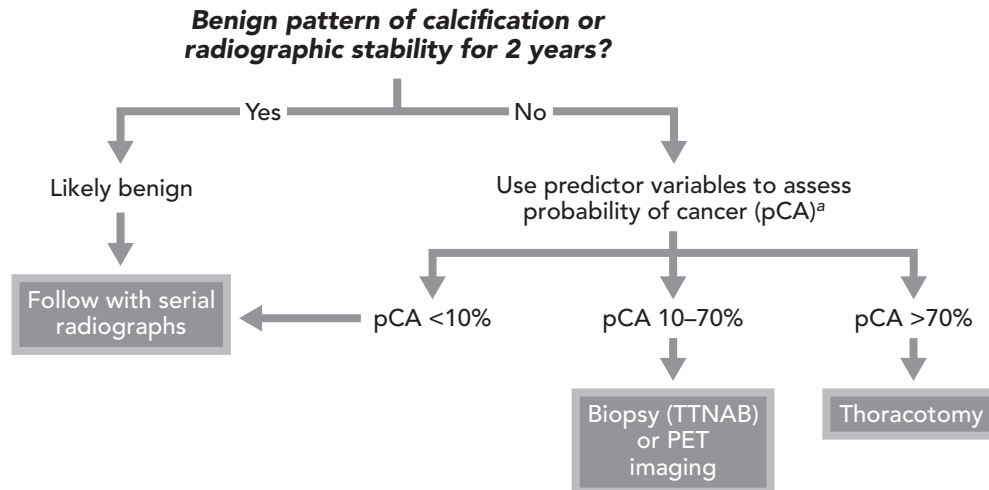

Unlike SPNs, the major types of mass lesions are often accompanied by symptoms and signs that can warrant hospitalization. The clinical picture provides clues to the diagnosis and will guide the choice of management strategies. Several presenting patterns are described.

Pneumonia Pattern

This includes acute onset, fever, cough, purulent sputum, leukocytosis, and dyspnea. The mass lesion is likely to be an example of *spherical pneumonia*, which is more common in children than in adults and is usually bacterial (20). Air bronchograms are often detectable within the mass. A trial of empirical antibiotic therapy is warranted in patients who are mildly symptomatic or asymptomatic. When the presentation is severe and fulminant, prompt attention to ascertaining the specific organisms involved is critical. The diagnostic approach may include blood cultures, sputum cultures, analysis of bronchial secretions collected by bronchoalveolar lavage or a plugged cascading catheter, and cultures of pleural effusions, if present. TTNAB is sometimes advisable. Occasionally, spherical pneumonia is caused by fungal infections.

Immunosuppression Pattern

The clinical picture suggests infection, and the presence and the specific cause (AIDS, organ transplants, drugs) of

^aPredictor variables:

Age (years)
 Smoking status (current or former = 1, never = 0)
 Extrathoracic cancer diagnosed >5 years ago (yes = 1, no = 0)
 Nodule diameter (mm)
 Nodule Spiculation (yes = 1, no = 0)
 Upper lobe location (yes = 1, no = 0)

$pCA = e^x / (1 + e^x)$,
 Where $x = -6.8272 + (0.0391 \times \text{Age}) + (0.7917 \times \text{smoking status}) + (1.3388 \times \text{extrathoracic cancer}) + (0.1274 \times \text{diameter}) + (1.0407 \times \text{spiculation}) + (0.7838 \times \text{upper lobe location})$

Figure 61.1 Proposed algorithm for management of solitary pulmonary nodules. A benign diagnosis is suggested by radiographic stability for at least 2 years, or by a benign pattern of calcification (central, laminated, diffuse, or popcorn pattern). In the absence of these characteristics, the probability of cancer (pCA) may be calculated by using a prediction equation that incorporates age, smoking status, history of previous extrathoracic malignancy, nodule diameter, nodule spiculation, and nodule location. When the pCA is less than 10%, follow-up with serial radiographs is recommended. When the pCA is more than 70%, immediate thoracotomy is usually warranted, unless surgery is contraindicated. For intermediate values of the pCA, initial biopsy is often prudent, although use of PET imaging may be preferable in centers where it is available. In these situations, it is especially important to consider patient preferences because the choice of strategy is a close call. SPN, solitary pulmonary nodule; TTNAB, transthoracic needle aspiration biopsy. (From Swensen SJ, Silverstein MD, Ilstrup DM, et al. *Arch Intern Med* 1997;157:849–855, with permission.)

TABLE 61.2
ETIOLOGY OF PULMONARY MASS LESIONS

Malignant

Bronchogenic carcinoma (including alveolar cell tumors)
 Lymphoma, malignant teratoma
 Plasmacytoma, others

Benign

Benign tumors and pseudotumors
 Granulomas, infectious and noninfectious
 Spherical pneumonia
 Arteriovenous aneurysm, pulmonary infarct
 Cysts (hydatid, bronchogenic, sequestration)
 Conglomerate pneumoconiosis
 Rounded atelectasis
 Mucoid impaction
 Pulmonary hematoma

the immunosuppressed state will usually be apparent. A mass lesion in these circumstances is usually fungal or bacterial. The development of cavitation in the mass is common. Other lung lesions are often visible. Vigorous diagnostic efforts are indicated. TTNAB is often helpful, but an open thoracotomy with biopsy may be required occasionally.

Diffuse Metastases Pattern

Lung masses are often malignant, and extensive regional and distant metastases can produce a clinical pattern with one or more of the following: neurologic deficits, convulsions, superior vena caval obstruction, bone pain or pathologic fractures, hypercalcemia, hepatic abnormalities, and Addison's disease. Mediastinal adenopathy is often prominent. The diagnosis may be established by imaging studies of multiple organs plus biopsy of the lung lesion, the mediastinal nodes, or another accessible lesion. In general, the

clinician should select a biopsy site that establishes the most advanced stage of disease, while minimizing the risk of serious complications.

Endocrine Pattern

Clinical patterns of hypercalcemia, hypercortisolism, gynecomastia, inappropriate secretion of antidiuretic hormone (SIADH), and pseudomyasthenia suggest ectopic hormone secretion by a chest mass associated with bronchogenic carcinoma. Biopsy of the mass or enlarged mediastinal nodes will usually establish the diagnosis.

Systemic Vasculitis Pattern

The patient with Wegener's granulomatosis may present with the clinical picture of persistent fever, malaise, weight loss, rhinitis and sinusitis, uveitis, anemia, hematuria, renal insufficiency, and single or multiple pulmonary nodules or masses. The pulmonary lesions are often basilar in location and may be poorly circumscribed. The diagnosis is supported by the presence of elevated cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA) titers, but open or thoracoscopic lung biopsy is often necessary (Chapter 111).

Pleural Pattern

Mass lesions can appear in conjunction with radiologic evidence of pleural disease in several situations:

1. A juxtaleural mass with an ipsilateral effusion suggests a bronchogenic carcinoma with direct intrapleural extension. TTNAB and/or thoracentesis are usually diagnostic.
2. In a patient with a chronic effusion that waxes and wanes with therapy, intrafissural loculation of the fluid may present as one or more sharply circumscribed large opacities. Comparison of roentgenograms in two projections often reveals loculated fluid, but chest CT is sometimes necessary to establish the diagnosis.
3. A pleural fibroma or a benign mesothelioma may present as an intrathoracic mass that may be quite large. Thoracotomy is often required for diagnosis.
4. In a patient with a history of significant asbestos exposure, a basilar mass can be a manifestation of rounded atelectasis. Several findings must be present to establish the diagnosis by CT criteria, including juxtaleural location, associated pleural thickening, evidence of ipsilateral volume loss and the presence of a "comet tail" that points toward the hilum. This condition is usually asymptomatic.

Issues During the Course of Hospitalization

While the evaluation of a solitary pulmonary nodule in a hospitalized patient can frequently be deferred, it is often prudent to initiate the work-up of a patient with a lung

mass prior to discharge. In most cases, bronchoscopy, TTNAB, or both are indicated, and the mass will often prove to be neoplastic. Benign asymptomatic masses include hamartoma, teratoma, postinflammatory pseudotumor (i.e., plasma cell granuloma), fungal granuloma, intrapulmonary sequestration, hydatid cyst, and posttraumatic pulmonary hematoma. The investigation of such lesions is beyond the scope of this presentation (21).

MULTIPLE PULMONARY NODULES

For the purposes of discussion, this category includes multiple nodules that are 5 mm or more in diameter. It excludes miliary (micronodular, fine nodular) patterns. The number of visible nodules may vary from two to dozens.

Issues at the Time of Admission

Multiple lung nodules may have a number of causes (Table 61.3), but hematogenous metastatic spread from an extrapulmonary primary tumor is the most common. Metastatic deposits in the lung may be asymptomatic or associated with cough and dyspnea. Multiple pulmonary nodules are occasionally found incidentally during hospitalization for another disorder. A wide variety of clinical patterns can be present.

Immunosuppression Pattern

The presence of an immunosuppressed state may be known or suspected from the clinical history. Multiple pulmonary nodules in the AIDS patient can represent Kaposi's sarcoma, lymphoma, or opportunistic infections. Multiple pulmonary nodules in organ transplant recipients can be infectious or neoplastic. The diagnostic approach is similar to that in immunosuppressed patients with a solitary nodule.

TABLE 61.3
ETIOLOGY OF MULTIPLE PULMONARY NODULES

Malignant

Metastatic carcinoma or sarcoma
Kaposi's sarcoma
Lymphoma
Multicentric alveolar cell carcinoma

Benign

Benign tumors
Granulomas, infectious and noninfectious
Septic emboli, hematogenous pneumonias
Opportunistic infections
Miscellaneous

Diffuse Metastatic Pattern

The lung lesions may represent diffuse metastases from an extrapulmonary primary malignancy, and the clinical consequences of the deposits on other organs may have caused the illness requiring hospitalization. Common primary sites include breast, colon, kidney, pancreas, bone, and liver. If the primary tumor has been recognized and diagnosed, the cause of the diffuse pulmonary or multisystem involvement can be inferred, although biopsy confirmation is advisable in most instances.

Systemic Vasculitis Pattern

These patients have evidence of multisystem disease, including fever, arthritis, skin rashes, renal dysfunction, and elevated sedimentation rate. The nodular pulmonary lesions can be rheumatoid nodules, Wegener's granulomatosis, or lymphomatoid granulomatosis. The nodules tend to be large and limited in number. The diagnosis can often be established from the extrapulmonary manifestations (both serologic and histologic), but open or thoracoscopic biopsy of the pulmonary lesions is occasionally required (Chapters 111 and 112).

Asthma Pattern

Multiple nodules in an asthmatic patient can represent areas of mucoid impaction in a patient with allergic bronchopulmonary aspergillosis. The nodules may be single or multiple, large or small, and are primarily perihilar in location. Some of the lesions are elongated, serpentine or branching rather than spherical. Fever, increased dyspnea, marked eosinophilia, and expectoration of semisolid or rubbery "plugs" are common clinical manifestations. Diagnosis is most specifically established with measurement of high serum levels of *Aspergillus*-specific immunoglobulin E (IgE) antibodies. The response to systemic adrenocortical steroid therapy is usually excellent. A 16-week trial of adjunctive therapy with itraconazole demonstrated a clinical response in 46% of participants in the treatment group compared with 19% in the control group (22), so combined therapy with steroids and antifungal therapy should now be considered in all patients. In its early stages, Churg-Strauss syndrome mimics asthma and occasionally presents with multiple lung nodules. Marked eosinophilia, multiorgan involvement, and a positive perinuclear ANCA (p-ANCA) test results provide clues, and biopsy is confirmatory.

Hypoxemic Pattern

Multiple nodules may be a manifestation of pulmonary arteriovenous aneurysms, with right-to-left shunting and hypoxemia. The diagnostic clues are the presence on chest roentgenography or CT of enlarged vessels entering and leaving the nodules, the family history, and the presence

of skin or mucosal lesions of hereditary hemorrhagic telangiectasia.

Acute Sepsis Pattern

Multiple nodules can be a manifestation of hematogenous bacterial pneumonia, most commonly resulting from staphylococcal infection and often associated with right-sided bacterial endocarditis (Chapter 71). Intravenous drug abuse is the usual cause. Some cases are a consequence of pelvic infection, pyelonephritis, or osteomyelitis, and organisms can include anaerobes and gram-negative aerobes. The lung lesions are typically "shaggy" in appearance and cavitation is common when staphylococcus is the causative organism. The diagnosis can be suspected by the identification of a potential source for the infection and confirmed with sputum and blood cultures. Transthoracic or transesophageal echocardiography is helpful in establishing the diagnosis of endocarditis.

Issues During the Course of Hospitalization

If the cause of the illness requiring hospital admission is recognized and treated, it may then become apparent that the multiple lung lesions are *incidental*. The most common cause in such cases is metastatic malignancy. Less common causes include "alveolar" sarcoidosis, benign metastasizing leiomyomas, pulmonary chondromas in Carney's syndrome, healed infectious granulomas, rheumatoid nodules (including Caplan's syndrome), hamartomata, and asbestos-derived pleural plaques. Lung biopsy of one form or another is usually required.

Discharge Issues

In most patients with multiple lung nodules, the diagnosis will be established during the course of hospitalization. Patients with lung nodules undiagnosed at the time of hospital discharge require follow-up to exclude infection, vasculitis, or malignancy. In unusual cases, this will entail clinical observation for recurrent symptoms; more often, it will require outpatient biopsy or follow-up radiographic studies to demonstrate resolution or stability.

Cost Effectiveness and Resource Use

Little is known about cost effectiveness in the management of focal pulmonary lesions. Sputum cytology appears to be cost-effective under some circumstances, especially for centrally located lung masses. Recent studies indicate that selective use of PET imaging is likely to be highly cost-effective, especially when the diagnosis is particularly uncertain (i.e., when the pretest probability of malignancy and the CT results disagree—for example, when the clinical pretest probability is low but CT does not suggest a benign cause) (19, 23, 24).

In many cases, the time, expense, and risk for morbidity associated with aggressive diagnostic workups can be avoided by examining old films and confirming radiographic stability over time. The small investment in time required to locate old films for comparison is well worth the effort.

KEY POINTS

- The prevalence of cancer in non-calcified solitary pulmonary nodules is high. Tissue diagnosis is often necessary.
- Solitary pulmonary nodules are usually benign when intranodular calcification is present in a central, laminated, diffuse or “popcorn” pattern, or when the nodules have been radiographically stable for at least 2 years.
- Solitary lung masses are larger than solitary pulmonary nodules and are even more likely to be malignant.
- Multiple pulmonary nodules can represent hematogenous metastases but also infection or vasculitis.
- For all pulmonary nodules, initial efforts should be directed at obtaining prior films, categorizing the clinical pattern, and treating acute illnesses. Cancer is highly probable in persistent nodules, and tissue diagnosis is generally required.

INTRODUCTION

Many of the signs, symptoms, and laboratory abnormalities associated with infections are nonspecific. They are seen in clinical entities as varied as adverse drug reactions, malignancy, and vasculitis. The challenge in evaluating a patient with potential infection is to determine whether historical information and objective findings detected by physical examination and laboratory evaluation are most compatible with infection or other disease states. If infection is suspected, the organ system involved must be identified. Once there is localization of infection, relatively accurate predictions about bacteriology can be made, and rational choices about appropriate antibiotic therapy can be made. The

microbiology laboratory can be a “friend” or a “foe” in the diagnostic and therapeutic process. It can be invaluable in assisting the clinician in making a specific microbiologic diagnosis and defining appropriate therapy by sensitivity testing. However, the usefulness of information is dependent upon the reliability of the specimen submitted and the ability of the clinician to interpret the results. Submission of inappropriate material and misinterpretation of data can result in misdiagnosis and unneeded or even harmful therapy.

In this chapter, common signs, symptoms, and laboratory abnormalities frequently seen in hospitalized patients with infection are reviewed, with an emphasis on differential diagnosis. In addition, appropriate use of the microbiology laboratory and accurate interpretation of results are discussed.

SIGNS

Fever

Fever at Time of Admission

Hyperpyrexia, occurring in 30% of patients admitted to the medicine service, is a common but nonspecific sign and symptom. Classically, fever has been defined as an oral

temperature higher than 38°C (100.4°F). A more precise definition of fever that accounts for normal circadian rhythms is an oral temperature higher than 37.2°C (99°F) in the morning or 37.8°C (100°F) irrespective of time of day. Rectal temperatures may be extrapolated by adding 0.6°C (1°F) to the oral reading.

Fever at the time of admission is attributable to community-acquired infections in more than 50% of cases. The exact frequencies of various community-acquired infections vary based on factors such as season, geography, and population demographics. In general, the most common community-acquired infections requiring hospitalization are pneumonia, pyelonephritis, cellulitis, and bacteremia (1). Noninfectious causes, accounting for approximately one-quarter of febrile admissions, include a diverse array of diseases involving multiple organ systems (Table 62.1). In the remainder of febrile admissions, no definitive underlying cause is identified.

Although much has been written about the use of fever patterns to aid in diagnosis, the low sensitivity and specificity of a given pattern greatly limits clinical usefulness.

Furthermore, fever may be blunted in the elderly or by the use of systemic corticosteroids. As a general rule, a fever higher than 102°F is unusual in the majority of inflammatory conditions (Table 62.1), and a temperature exceeding this level supports an alternative diagnosis. Extreme pyrexia, defined as a temperature higher than 41°C (106°F), may be seen with a limited number of conditions. Infection, most commonly Gram-negative bacteremia, is the leading cause of extreme hyperpyrexia, followed by a variety of conditions causing impaired thermoregulation (Table 62.2).

The protean causes of fever require a thorough history and physical examination to direct further testing and therapy. History of recent and remote travel, occupation, vaccinations, sexual encounters, and exposure to sick contacts, arthropods, or animals should be elicited, as these may provide important clues to diagnosis. Lymphadenopathy, splenomegaly, the presence of rash, or evidence of embolic phenomena may direct the clinician toward a specific diagnosis.

Appropriate laboratory studies include a complete blood count with differential, electrolytes, tests of renal

TABLE 62.1
NONINFECTIOUS CAUSES OF FEVER AT THE TIME OF ADMISSION

Disorders	T ≤102°F ^a	Characteristics	Disorders	T ≤102°F ^a	Characteristics
Neurologic			Endocrinologic		
Spinal cord injury		Restricted to lesions at T8 or higher	Pheochromocytoma		Associated with large, necrotic tumors
Hypothalamic injury		Trauma, tumor, vasculitis, hemorrhage	Thyrotoxicosis		Associated hypermetabolic state
Intracranial hemorrhage			Adrenal insufficiency		May mimic sepsis with hypotension
Seizures		89% of fevers last <48 h	Miscellaneous

and liver function, and a urinalysis. If the clinical presentation supports a rheumatic or autoimmune process, specific confirmatory blood tests should be obtained. A chest radiograph is generally appropriate if there are signs or symptoms of respiratory involvement or concern for an intrathoracic process. Further radiologic studies should be directed by suggestive findings on the history and physical examination. Admission blood cultures from febrile patients have a yield of only 10%. However, the usefulness of a positive result in establishing a diagnosis, directing therapy, and defining length of treatment mandates that two sets be obtained ideally before antibiotics are administered.

Fever is a physiologic response to an underlying medical condition, and therapy should be directed against the cause rather than overzealous suppression of the sign. If the initial evaluation is suggestive of an infectious cause, antimicrobial therapy should be promptly initiated (Chapter 64). Fever may serve an adaptive function by inhibiting bacterial replication, promoting immune function, and increasing antimicrobial bactericidal activity. Antipyretics should be reserved for situations in which there is extreme patient discomfort, cardiopulmonary disease that may be exacerbated by fever-induced tachycardia, or temperature in excess of 40°C, as prolonged episodes of extreme hyperpyrexia may lead to permanent central nervous system damage or cause cardiac arrhythmias.

Two primary methods exist for ameliorating fever: *antipyretics* and *external cooling*. The latter, reserved for patients with extreme pyrexia, utilizes ice baths, alcohol sponges, cooling blankets, and, in emergency situations, intra-

venous or intraperitoneal administration of cool fluids. Antipyretic options are limited to salicylates, nonsteroidal anti-inflammatory agents, and acetaminophen. Salicylates have been associated with Reye's syndrome in children with varicella or influenza and should not be used in this population. Naproxen (375 mg orally every 12 hours) is the preferred choice for patients with neoplastic fever. Persistent temperature elevation after more than three doses of naproxen essentially excludes the diagnosis of neoplastic fever.

Fever During the Course of Hospitalization

Causes of fever in the second or third hospital day are similar to those at admission, with one-third to one-half of cases attributable to community-acquired infection, and 30% of cases attributable to noninfectious causes (Table 62.1). Fever occurring more than 3 days into the hospital course should prompt investigation for a *nosocomial infection* or *drug fever*. Common hospital-acquired infections include urinary tract infections (particularly in patients with Foley catheters; see Chapter 68), nosocomial pneumonia (Chapter 66), vascular catheter-related infections (either localized or with bacteremia; see Chapter 72), wound infections, and antibiotic-associated colitis (2). Less common infections include infected decubitus ulcers, acalculous cholecystitis, and nosocomial sinusitis.

Not all nosocomial fevers require intervention. Postoperative patients frequently develop fever within the first several days of surgery, but this is rarely infectious, and is generally self-limited. True postoperative infections typically occur 1–2 weeks after surgery (exceptions include wound infections with group A *Streptococcus* or *Clostridium perfringens*, which may occur within several days of surgery) and are associated with local signs of infection. Patients undergoing esophageal (transesophageal echocardiography or upper endoscopy) or bronchial (bronchoscopy) instrumentation may develop transient fevers due to micro-aspiration of acidic gastrointestinal contents causing a chemical pneumonitis (Mendelson's syndrome).

While most causes of nosomial fevers can be identified by careful history and physical exam, occult causes of fever exist. This is particularly true in the ICU, where patients often are sedated or intubated, and abnormal laboratory findings such as leukocytosis and elevated liver-function tests are typically multifactorial. Particular attention should be paid to intravenous catheters and postoperative wounds for tenderness, purulence, or erythema. Decubitus ulcers can be a source of fever and bacteremia and should be diligently sought. Decubiti covered with an eschar should be unroofed, because significant deep-tissue involvement requiring debridement and antibiotics may be underlying the eschar. Acalculous cholecystitis, typically seen in postoperative or posttrauma patients receiving hyperalimentation, classically presents with fever, leukocytosis, right upper quadrant pain, and abnormal liver-function tests.

Nosocomial sinusitis has been reported to cause up to 5% of febrile episodes in the ICU, especially in patients with nasal packing, nasogastric tubes, and nasotracheal intubation. Diagnosis is suggested by the presence of more copious secretions from the oropharynx than from the endotracheal tube.

Febrile drug reactions have been reported to occur in 10% of hospitalized patients. Almost every pharmacologic agent has been anecdotally associated with drug fever. The median delay from the start of a new pharmacologic agent to the onset of fever is 8 days; however, there is substantial variation, with the median delay in fevers attributable to antineoplastic agents being shorter than 1 day. Careful review of pharmacy records may reveal a temporal relationship between starting a new agent and the onset of fever, although idiopathic reactions to medication have been reported to occur months to years after starting therapy. Clues to the diagnosis of drug fever include the presence of relative bradycardia (see subsequent section) and the lack of subjective discomfort during febrile episodes. Although cutaneous eruptions occur in only about 20% of febrile drug reactions, the presence of rash strongly supports an allergic etiology (3). Other noninfectious causes of fever in hospitalized persons include thromboembolic disease, myocardial infarction, Dressler's syndrome, adrenal insufficiency, gout or calcium pyrophosphate disease, and ischemic bowel disease.

Laboratory studies may not be particularly helpful in pinpointing a cause for fever. Total white blood cell count may be normal, high, or low even in the presence of serious infection. Leukocytosis or eosinophilia is present in only 22% of cases of drug fever, and both findings are associated with a number of other conditions included in the differential diagnosis of fever (3). Focality in the history or physical examination should prompt directed cultures. Patients with a new productive cough should have sputum sent for Gram's stain and culture. Those with an indwelling Foley catheter should have urine cultured, but results must be interpreted with caution. Colonization of the urine with Gram-negative organisms is common, but true infection as a cause of fever is unusual unless there is inflammation, as evidenced by the presence of significant pyuria. Similarly, *Candida* species frequently colonize the urine but are not associated with invasive disease unless there are preexisting abnormalities (stones, malignancy, or obstruction). Therapy is not routinely indicated for candiduria in the absence of pyuria.

Patients with new onset of diarrhea should have stool assayed for the presence of *Clostridium difficile* toxin. Testing for the presence of fecal leukocytes is neither a sensitive nor specific surrogate marker for the presence of *C. difficile* toxin and should not be done. Similarly, culturing stools and examining stools for ova and parasites in patients who develop diarrhea in the hospital is not cost-effective and is not recommended. Although meningitis frequently is considered as a cause of fever (usually in the ICU patient who

is sedated and in whom mental status cannot be assessed), meningitis rarely develops in inpatients in the absence of head trauma, manipulation of the spinal cord (i.e., epidural catheterization), or recent neurosurgery. Thus, in the absence of meningeal signs or one of the above predisposing conditions, a lumbar puncture is generally not indicated. The yield of blood cultures in febrile inpatients is only 20%; however, as there are no reliable surrogate markers for bloodstream infection, all febrile patients should have two sets of blood cultures sent.

Chest radiographs may be helpful, as abnormalities suggest infection, aspiration, or pulmonary embolism. The role of sinus computed tomography (CT) scans in diagnosing sinusitis has not been rigorously studied. Most recumbent ICU patients with nasal tubes in place have fluid in their sinuses, and mucosal thickening is a common and nonspecific finding. To make a definitive diagnosis of acute sinusitis, a sinus aspirate with culture is needed. If there are abdominal findings or if there is a suspicion of acalculous cholecystitis or ischemic bowel disease, an abdominal ultrasound or CT scan is indicated.

The management of fever in hospitalized patients is identical to that for fever in a newly admitted patient. Elevated temperature should be viewed as a sign of an underlying disease, and therapy should be directed at the likely source. (Refer to Chapter 64 and chapters discussing specific nosocomial infections for discussion of potential antibiotic regimens). Most drugs causing fevers have short half-lives, and drug fever usually resolves within 48–72 hours of discontinuing the offending drug. Fever resulting from drugs with long half-lives may take substantially longer to resolve. The indications for antipyretic therapy are identical to those discussed in the previous section.

Fever and Rash

Fever and Rash at Time of Admission

The febrile patient with a cutaneous eruption requires urgent evaluation. Although many of the underlying conditions presenting with rash are relatively benign, a few are life threatening, and the rapid institution of appropriate antibiotics may prevent a fatal outcome. Furthermore, a number of these infections are highly contagious, and require prompt isolation of the index patient and identification of potential contacts to avoid secondary cases. Infectious disease emergencies associated with cutaneous manifestations include *meningococemia*, *Rocky Mountain spotted fever*, *toxic shock syndrome*, and *bacterial sepsis*. *Smallpox* and *anthrax* have gained widespread attention as possible markers of a bioterrorist attack. Identification of the specific pathogen causing fever and a rash hinges on the characteristics of the skin eruption (Table 62.3, and see also Chapter 73).

TABLE 62.3**INFECTIONS ENDEMIC TO THE UNITED STATES CAUSING FEVER WITH PROMINENT CUTANEOUS MANIFESTATIONS**

Infection	Petechial, Purpuric	Maculopapular	Vesicular	Other	Comments
Viral infections:					
Acute HIV		X			Adenopathy, pharyngitis, malaise
Enterovirus	X	X	X		Typically summer and early fall
Rubeola (measles)		X			Unvaccinated populations
Adenovirus	X	X			Keratopharyngitis variably seen
Lymphocytic choriomeningitis		X			Rodent exposure, more common in fall
Rubella (German Measles)	X	X			Unvaccinated populations
Varicella (zoster or chickenpox)			X		Acute varicella in unvaccinated. Zoster typically dermatomal
Herpes simplex			X		Predominately genital and perioral
Cytomegalovirus (CMV)		X			Associated with infectious mono syndrome
Epstein-Barr virus (EBV)	X	X			Associated with infectious mono syndrome; often appears after amoxicillin ingestion
Parvovirus B-19		X			Erythema infectiosum
Human herpesvirus 6		X			Roseola infantum
Smallpox			X		First lesions on face, palate, or forearms. Bioterror agent.
Bacterial infections:					
Chlamydia psittaci		X			Associated with bird exposure, pneumonia
Mycoplasma pneumoniae		X	X		Bullous myringitis in ~5%
Rickettsia spp.	X	X	X		Spotted-fever group typically petechial, typhoidal group maculopapular with eschar; rickettsial pox with vesicles
<i>Ehrlichia</i> spp.	X	X			Tick-borne pathogens, associated with leukopenia, thrombocytopenia
<i>Bartonella</i> spp.		X		Vascular cutaneous lesions	Bacillary angiomatosis in HIV infected
<i>Francisella tularensis</i>		X			Ulceroglandular type, typhoidal type
Rat-bite fever agents	X	X			
Secondary syphilis		X	X		Lesions on palms and soles
<i>Neisseria</i> spp.	X	X			Purpura, petechial lesions on palms and soles
<i>Leptospira</i> spp.	X	X	X		Associated with aseptic meningitis, renal failure, hepatitis
<i>Borrelia</i> spp.	X	X			Erythema migrans in Lyme disease
<i>P. aeruginosa</i>		X			Ecthyma gangrenosum
<i>S. aureus</i>	X	X			Impetigo with localized infection, petechia with endocarditis
Group A streptococci		X			Scarlet fever, impetigo
<i>Capnocytophaga canimorsus</i>	X	X			Dog exposure, sepsis in asplenic host
<i>Bacillus anthracis</i> (Anthrax)		X	X	Necrotic eschar late in course	Potential bioterrorism agent
<i>Vibrio vulnificus</i>			X		Exposure to salt water, particularly in patients with liver disease

Adapted from Weber DJ, Cohen MS, Fine JD. The acutely ill patient with fever and rash. In Mandell GL, Bennett JE, Dolin R, eds. *Principles and Practice of Infectious Diseases*, 5th ed. New York: Churchill Livingstone, 2000: 633–650.

The history and physical examination are the mainstays of the initial evaluation. Many of the syndromes in the differential diagnosis can be excluded if there has been no foreign travel (see subsequent section), no outdoor activities suggestive of arthropod exposure, no sexual activity, and no animal exposures. Menstrual history may support a diagnosis of tampon-associated toxic shock syndrome or disseminated gonorrhea. History regarding the initial site, appearance, and rapidity of spread of the rash may aid diagnosis. The physical examination should focus on the distribution of the cutaneous eruption and include a thorough search for associated findings such as pharyngitis, adenopathy, arthritis, nuchal rigidity or altered mental status, genital lesions, or cervical discharge. Gram stain and culture of selected cutaneous lesions may yield a rapid diagnosis. Gram-negative diplococci aspirated from petechiae are consistent with either disseminated meningococemia or gonorrhea; Gram-positive cocci suggest *Staphylococcus aureus* sepsis. Culture of scrapings from the base of ecthyma gangrenosum ulcers may facilitate diagnosis of *Pseudomonas aeruginosa* sepsis. Bullous lesions should be unroofed under sterile conditions and the fluid sent for viral and bacterial diagnostic tests. A skin biopsy is often necessary to diagnose a vasculitic process, infection with *Bartonella* organisms (bacillary angiomatosis), or disseminated fungal infection. Therapy should be directed at the underlying cause of the syndrome and should include aggressive supportive measures as needed (see Chapter 26 for discussion of the sepsis syndrome).

Fever and Rash During Hospitalization

The most common cause of this syndrome is a cutaneous drug reaction, which develops in approximately 3% of hospitalized patients. These reactions are typically maculopapular and are pruritic in only one-half of cases. Infectious causes of rashes in hospitalized patients include bacterial sepsis (with or without disseminated intravascular coagulation), postoperative toxic shock syndrome (particularly among patients with indwelling nasal packings), and disseminated fungal disease (among immunosuppressed patients, those receiving total parenteral nutrition, or those on long term, broad-spectrum antibiotics). Exposure to a sick visitor or health care worker may provide an important clue in the patient with an exanthem and symptoms suggestive of a viral syndrome.

Infectious and noninfectious syndromes causing fever in hospitalized patients are best differentiated by the general appearance of the patient. Drug reactions typically cause minimal prostration, even during periods of extreme hyperpyrexia. Patients with sepsis, toxic shock syndrome, or fungemia often are critically ill or hypotensive and may have alterations in level of consciousness. Cultures of blood, wound discharge, urine, cutaneous lesions, and sputum should be obtained as clinically indicated. Skin biopsy may be necessary if cultures remain negative or if there is

rapid progression of skin lesions. Therapy should be directed at the underlying cause of the syndrome, as elucidated by the initial evaluation.

Fever in the Returning Traveler

At Time of Admission

The differential diagnosis of fever in the returning traveler is broad, ranging from self-limited viral illness to fulminant, life-threatening infection. For the purposes of this chapter, the discussion will be limited to infections that typically require hospitalization for supportive care and treatment. The evaluation of the febrile traveler is best performed by identifying a syndrome (Table 62.4), and refining the differential based on the travel history and specific exposures. The travel history should include directed questions regarding geography (rural versus urban), animal or arthropod contact, unprotected sexual intercourse, ingestion of untreated water or raw foods, and history of pretravel immunizations and adherence to malaria prophylaxis. Routine laboratory studies usually include complete blood count with differential, electrolytes, liver function tests, urine analysis, and blood cultures. Thick and thin smears for malaria should be done if there has been any travel to endemic areas. If the initial smear is negative but the suspicion remains high, thick and thin smears should be repeated in the next 12–24 hours. Other studies are directed by the results of history, physical examination, and initial laboratory tests. They may include stools for ova and parasites, chest x-ray, HIV test, and specific serologies (dengue, leptospirosis, rickettsial illness, schistosomiasis, etc.).

Several general principles are helpful in evaluating the returning traveler with fever:

- Up to 50% of patients have either a self-limited illness that goes undiagnosed or have a “cosmopolitan” fever—one that is neither infectious in etiology nor travel-related. Thus, it is helpful to construct two differentials, one that includes the travel history and one that ignores it.
- People who visit family and friends while abroad or who are adventure travelers (hiking and camping in remote areas with less control of their food and water sources) are more likely to develop travel-related illnesses than are short-term visitors who frequent more standard tourist destinations.
- The goal of the initial evaluation is to identify those patients with acute, potentially life-threatening diseases that are treatable, or those with transmissible diseases that require isolation.
- The incubation period can be helpful in excluding certain diseases. Dengue, leptospirosis, yellow fever, rickettsial diseases, and Q fever usually present clinically within the first 3 weeks after exposure. In contrast, typhoid fever, malaria, tuberculosis, and hepatitis can

TABLE 62.4
INFECTIOUS SYNDROMES IN THE RETURNED TRAVELER

Syndrome	Initial evaluation	Specific pathogens	Syndrome	Initial evaluation	Specific pathogens
Fever & rash	Blood cultures Serologies (guided by history)	Dengue Viral hemorrhagic fever Leptospirosis Meningococemia Yellow fever Typhus <i>Salmonella typhi</i> (Rose spot) HIV (acute)	Diarrhea	Blood cultures Fecal leukocytes Stool bacterial cultures Stool for O & P	Bacterial dysentery <i>E. histolytica</i> Cyclospora Disseminated strongyloidiasis
Pulmonary infiltrate	PPD Sputum for AFB Sputum for O & P	Tuberculosis Ascaris Paragonimus Strongyloides	Jaundice	Liver function tests Evaluation for hemolysis Thick/thin smear Serologies (guided by history)	Hepatitis A Yellow fever Hemorrhagic fever Leptospirosis Malaria
Meningo-encephalitis	Blood cultures Thick/thin smears Lumbar puncture Serologies (guided by history) Nape biopsy (if rabies a concern)	<i>N. meningitidis</i> Leptospirosis Arboviruses Rabies Malaria (cerebral)	Fever without localizing signs or symptoms	Blood cultures Thick/thin smears Serologies (guided by history) Bone marrow (typhoid fever)	Malaria Acute HIV Rickettsial illness <i>Salmonella typhi</i> Visceral leishmania Trypanosomiasis Dengue

present acutely, but may have longer incubation periods of greater than 6 weeks.

The most common infectious etiologies of fever in the returning traveler are malaria, respiratory infections, diarrhea, dengue, leptospirosis, typhoid fever, and rickettsial infections. Numerous other infections have been described and have been reviewed (4).

Malaria

Malaria presents with nonspecific symptoms of fever, chills, drenching sweats and headache. The typical pattern of fever every 48–72 hours occurs uncommonly, but when present strongly suggests infection with *Plasmodium vivax*, *P. ovale* (48 hours) or *P. malariae* (72 hours). Fevers with *P. falciparum* are more hectic and rarely synchronized. Splenomegaly and thrombocytopenia are frequent findings, but rash and lymphadenopathy are unusual. *P. falciparum*, the most severe form of disease, is more likely to be seen in patients traveling to Africa, whereas the other forms of malaria are more likely to occur after travel to Asia and Latin America. *P. falciparum* has a relatively short incubation, with 90% of patients presenting within 1 month of return. In contrast, other forms of malaria are more indolent; only 50% develop symptoms within 1 month of return. Because clinical manifestations are nonspecific, any febrile traveler who has been in an endemic area should have thick and thin smears performed.

Respiratory Infections

Respiratory infections are usually “cosmopolitan” and due to viruses (including influenza), *S. pneumoniae*, my-

coplasma and legionella species. It is important to remember that tuberculosis is common in many less developed areas of the world and can present months after return. Other respiratory pathogens that should be considered depending on area of travel include histoplasmosis and coccidioidomycosis (Mexico). Q fever can also cause respiratory symptoms, and helminths that may migrate through the lung (ascariasis, strongyloidiasis).

Diarrhea

Travel-related diarrhea usually presents within the first month after return. Viruses and bacteria (enteroinvasive and enterohemorrhagic *E. coli*, *Salmonella*, *Shigella*, *Campylobacter*) commonly occur shortly after return and are usually self-limited. In patients with diarrhea that persists for several weeks, *Giardia lamblia*, *Entamoeba histolytica*, cryptosporidia and microsporidia should be considered. In patients with prolonged diarrhea and malabsorption, giardiasis and other small bowel parasites are likely. The diagnosis is usually made by stool culture or examination for ova and parasites. If an etiologic agent is not identified after stool examination and symptoms persist, many would treat empirically with a fluoroquinolone if symptoms suggestive of invasive disease of the large bowel are present (fevers, frequent small volume bloody stools), or metronidazole if bloating and watery diarrhea are present (giardia is the most common cause of these symptoms).

Dengue

Dengue is a mosquito-transmitted disease that has a short incubation period (almost always less than 10 days). It is

common in tropical and subtropical areas (Asia, Central and South America, the Caribbean), but some cases occur in travelers returning from Africa. Dengue presents with nonspecific symptoms of fever, chills, myalgia, arthralgias, and headache. Severe retroorbital pain exacerbated by eye movement is characteristic, and helps distinguish dengue from other travel-related febrile illnesses. Up to 50% of patients will have a maculopapular, diffuse erythematous rash that may be petechial in nature. Leukopenia and thrombocytopenia are common laboratory abnormalities. The diagnosis is usually made clinically and confirmed serologically. Therapy is supportive. Severe complications of dengue (dengue hemorrhagic fever and dengue shock syndrome) are not seen in first-time travelers. These complications are thought to be immunologically mediated and are seen in those sustaining a repeat infection with a different serotype of the virus.

Leptospirosis

Leptospirosis occurs worldwide, whenever humans come into contact with water that has been contaminated by urine from animal reservoirs. Spirochetes enter through abrasions in the skin, mucous membranes or conjunctiva. Following an incubation period of 1–3 weeks, nonspecific symptoms of fever, chills, and headache develop. Severe myalgias (sometimes mimicking an acute abdomen) and conjunctival suffusion may be present and should suggest the diagnosis. Recent outbreaks have been associated with hemorrhagic pneumonitis. The disease is often biphasic. After 3–7 days of illness there is a brief period of well-being followed by onset of fever, meningitis (immune mediated), uveitis and rash. Severe complications include renal failure, hepatitis, and shock. Although organisms can be isolated from blood, CSF, and urine in the first phase of the disease, the diagnosis is usually made clinically and confirmed serologically. Treatment within the first 3 days of illness improves outcome. Penicillin is the treatment of choice in severe disease. Doxycycline is used in mild to moderate disease, or in patients with IgE-mediated reactions to penicillin. Following treatment, the Jarisch-Herxheimer reaction can occur.

Typhoid Fever and Enteric Fever

Typhoid fever (caused by *Salmonella enterica* serotype *typhi*) and enteric fever (caused by other serotypes of salmonella) present with fever, headache, and gastrointestinal symptoms (abdominal pain and constipation are common, whereas diarrhea is rare). An evanescent rash (rose spots) is occasionally present, but the physical examination is usually not helpful in making a diagnosis. Most cases occur in travelers returning from India, Latin America, and the South Pacific. Blood cultures are positive in the majority of cases; salmonella can also be isolated from stool for several weeks after infection. Although multi-drug resistant organisms have been isolated, including a few strains resistant to fluoroquinolones, empirical therapy with either

ciprofloxacin or a third generation cephalosporin is indicated if the diagnosis is suspected.

Rickettsial Infections

Rickettsial infections are transmitted by mites and ticks, have a short incubation period (less than 3 weeks), and present with nonspecific influenza-like symptoms. Helpful clues to the diagnosis include a history of exposure (travel in grassy or wooded areas), a maculopapular rash, and the presence of a painless eschar at the inoculation site. The diagnosis is made clinically and confirmed serologically. Therapy with a tetracycline is indicated if the diagnosis is suspected.

Fever of Unknown Origin

At the Time of Admission

The “classic” 1961 definition of fever of unknown origin (FUO) included patients who had been ill for 3 weeks, had a fever over 38.3°C (101°F) on several occasions, and who remained undiagnosed after 1 week of study in the hospital. The time intervals in this definition are arbitrary and were chosen to exclude individuals with protracted but self-limited viral illnesses and to allow time for standard radiographic, serologic, and cultural data to be collected. With changes in health care delivery, these intervals have been modified to include patients who are undiagnosed after three outpatient visits or 3 days in the hospital. Over the ensuing decades, several new categories of FUO have been included (5):

1. *Nosocomial FUO*: hospitalized patients with fever of 38.3°C or higher on several occasions, caused by a process not present or incubating from admission, in whom the diagnosis remains uncertain after at least 3 days of investigation and in whom microbiologic cultures have been incubating at least 2 days (see pp 609–610)
2. *Neutropenic FUO*: fever of 38.3°C or higher on several occasions in patients with less than 500 neutrophils per cubic millimeter or expected to fall below that level within 2 days, in which the diagnosis remains unknown after at least 3 days of investigation with at least 2 days for cultures to incubate (Chapter 63)
3. *HIV-associated FUO*: a fever of 38.3°C or higher in an HIV-seropositive patient who has been febrile more than 4 weeks as an outpatient or 3 days as an inpatient, in whom the diagnosis remains uncertain after 3 days of investigation with at least 2 days for cultures to incubate (Chapter 74)

Although not formally considered a separate category, FUO in recipients of solid organ transplants is a common scenario with a unique differential diagnosis (Chapter 63).

The differential diagnosis of FUO is extensive (Table 62.5) and includes infection in 25%–40%, neoplasms in 20%–35%, and rheumatologic diseases in 10%–20% of

TABLE 62.5
CAUSES OF FEVER OF UNKNOWN ORIGIN IN THE ADULT

Type	Comment
Infections	
Localized	
Abscesses: liver, subphrenic, abdominal, pelvic	Previous surgery or gastrointestinal procedure are risk factors
Biliary system: cholecystitis, cholangitis	Preexisting cholelithiasis or pancreatitis
Urinary tract: perinephric abscess, intrarenal abscess, prostatic abscess, chronic prostatitis	Negative or intermittently positive urine cultures; obstruction may be present
Infective endocarditis	Culture negative (previous antibiotics for another suspected infection) or fastidious organism (HACEK ^a group)
Osteomyelitis	
Generalized: tuberculosis	Usually extrapulmonary (renal, peritoneal, miliary, meningeal)
Other (less common): Whipple's disease, cat-scratch disease and other <i>Bartonella</i> infections, toxoplasmosis, malaria, disseminated histoplasmosis or coccidioidomycosis, Q fever, brucellosis, leptospirosis, borreliosis, cytomegalovirus, Epstein-Barr virus, splenic, pulmonary and dental abscesses	
Malignancy	Many malignancies cause fever in association with liver metastases or obstruction with associated infection
Hodgkin's disease	
Lymphoma	
Renal cell carcinoma	
Hepatoma	
Other solid tumors	
Rheumatologic diseases	
Still's disease (adult juvenile rheumatoid arthritis)	Usually presents without joint manifestations or classic serologic abnormalities
Systemic lupus erythematosus	
Polyarteritis nodosa	
Rheumatoid arthritis	
Vasculitis	
Polymyalgia rheumatica	
Cryoglobulinemia	
Granulomatous disease	
Granulomatous hepatitis	Need to rule out treatable causes of granulomatous hepatitis
Sarcoidosis	
Inflammatory bowel disease	Without prominent gastrointestinal symptoms
Temporal arteritis	
Other disorders	
Factitious fever	
Familial mediterranean fever	
Wegener's granulomatosis	
Alcoholic hepatitis	
Metabolic disorders: hyperthyroidism, thyroiditis, pheochromocytoma	
Addison's disease	
Recurrent pulmonary emboli	

^a *Haemophilus aphrophilus*, *Actinobacillus actinomycetocomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella kingii*.

cases (5). Several general principles are helpful in approaching patients with classic FUO:

- Most cases of FUO represent unusual manifestations of common diseases, not rare or exotic diseases. About 50% of patients with FUO have one of the following diseases as a cause: tuberculosis, endocarditis, lymphoma, solid tumor, adult Still's disease, vasculitis, or a common rheumatologic disease (systemic lupus erythematosus, Sjögren's syndrome).
- Even after extensive evaluation, the diagnosis remains elusive in 10%–15% of patients. In the majority of these patients (about 75%) fever abates spontaneously, the patient improves, and a diagnosis is never made. In the remainder, classic manifestations of the underlying disease emerge, making the diagnosis obvious.
- Patients with prolonged fever (6 months or longer) have infection, malignancy, or rheumatologic disease as the cause in only 20% of cases. Instead, other diagnoses such as granulomatous diseases, factitious fever,

and exaggeration of the normal circadian rhythm become much more likely.

- Patients with episodic or recurrent fevers (i.e., classic definition of FUO with periods of 2 weeks or longer without fever), like patients with prolonged fever, usually do not have infection, malignancy, or rheumatologic disorder but instead have a number of miscellaneous causes such as Crohn's disease, allergic alveolitis, and Familial Mediterranean fever. Approximately 50% of this group remains undiagnosed, but symptoms resolve.

These points are important in determining how aggressive to be in the evaluation. By the time most patients have been admitted to the hospital, noninvasive tests have been performed, and decisions must be made about more aggressive tests that may be associated with adverse effects. It is important to remember that, with time, the cause is likely to become obvious and, provided the patient is stable (not toxic, with stable weight, and able to carry on daily functions), continued observation or only limited additional evaluation is a reasonable option.

FUO is such a heterogeneous disease state that a routine cost-effective approach to diagnosis has not been established. Potential diagnostic clues should be elicited by careful history taking and physical examination, and further workup should pursue any abnormalities that are revealed. Careful attention to family history, social history (sexual practice, use of intravenous drugs), travel, vocational or recreational exposures, animal exposures, and dietary habits (unpasteurized milk products, raw meats) may provide clues to diagnosis. Careful and repeated physical examinations are important to detect evanescent rashes or subtle physical findings such as conjunctivitis, uveitis, and isolated lymph nodes.

Infection remains a leading cause of FUO, and blood cultures (two or three sets over 24 hours) off antibiotic therapy for at least 48–72 hours are routine in the evaluation. The laboratory should be asked to hold cultures for 2 weeks if bacteremia or endocarditis with fastidious organisms is suspected (e.g., HACEK group, *Brucella* spp.). Cultures on special media should be requested if *Legionella* or *Bartonella* organisms or nutritionally deficient streptococci are considered. If exposure suggests endocarditis caused by *Chlamydia psittaci* or *Coxiella burnetii*, serologic tests are required. "Screening" tests with immunologic or microbiologic serologies have a low yield and should not be done. Specific tests for rheumatologic diseases are indicated if history or physical examination suggest a specific diagnosis. Serologic tests for infections ("febrile agglutinins") are almost never helpful, with the exception of tests for syphilis.

Certain radiographic studies are considered routine. These include chest radiograph, upper gastrointestinal series with small bowel follow-through, and barium enema. The value of gastrointestinal radiography and endoscopy in patients without localizing symptoms is probably low,

but these tests should be considered in patients with prolonged fever in whom gastrointestinal pathology is more common. Radionuclide scanning (i.e., indium-labeled leukocyte scan or gallium 67–citrate) is theoretically attractive for detecting infection and malignancy, but in reality these studies are of little use as screening tests because of the high rates of false positive and negative results. PET scans may be useful in diagnosing infection and malignancy, but large-scale formal studies are lacking. Abdominal and pelvic CT scans are done in most patients with FUO and are powerful tools for detecting intra-abdominal pathology, but an invasive procedure almost always is needed to make a tissue diagnosis. It is also important to remember that a negative CT scan does not obviate the possible need for more aggressive studies. CT scanning is valuable in detecting anatomic abnormalities, but certain diseases such as vasculitis, peritoneal tuberculosis, or peritoneal carcinomatosis may not be detected by CT and may require invasive procedures for diagnosis. Thus, in patients for whom the diagnosis remains elusive despite a negative noninvasive evaluation, laparotomy or laparoscopy should be considered if they have abdominal pain and clinically are incapacitated or deteriorating. Ultrasonography and echocardiography as screening tests are of little value. If a specific diagnosis of endocarditis is suggested, a transesophageal echocardiogram is indicated. Even if this is negative, it does not exclude the diagnosis of endocarditis, and if suspicion is high, a repeat study should be done in 1–2 weeks (especially if a prosthetic valve is present).

Biopsy of potentially pathologic tissue, if suggested by physical examination or abnormal laboratory value, is always indicated, as is aspiration of abnormal fluid collections. Even though the yield of a bone-marrow biopsy is low in FUO (about 5%), the risk is small and this test is usually done. Liver biopsy is more controversial. Abnormal liver function tests are common in FUO, and liver biopsy is associated with potentially serious complications. Nonetheless, a specific diagnosis by liver biopsy is made in about 15% of patients, and if less invasive tests have not yielded the diagnosis and liver function tests are abnormal, a biopsy should be considered. Although not formally studied, a temporal artery biopsy is reasonable in elderly patients with elevated sedimentation rates and no alternative diagnosis.

Whenever an invasive procedure is performed, as much tissue as possible should be obtained so that routine, mycobacterial, and fungal stains and cultures can be done. Newer investigational diagnostic tests such as polymerase chain reaction (PCR) may be helpful if specific diagnoses such as Whipple's disease, herpes simplex infection, or bartonellosis are considered.

If a specific diagnosis accounting for FUO is made, therapy is directed at the underlying cause. Difficulties arise if, despite extensive evaluation, the diagnosis remains elusive. A therapeutic trial is reasonable if a specific diagnosis is strongly suspected (e.g., antituberculous therapy if pulmonary or disseminated tuberculosis is suspected,

intravenous antibiotics if endocarditis is suggested, or tetracycline for brucellosis). In the seriously ill or rapidly deteriorating patient, empiric therapy should be considered. Antituberculous medications (particularly in the elderly or foreign-born patient) and broad-spectrum antibiotics are reasonable in this setting. Two important caveats apply. First, before starting therapy, be sure that all relevant cultures have been obtained. Second, therapeutic end-points must be set. If there is no clinical response after several weeks of therapy, therapy should be discontinued and the situation carefully reevaluated.

There is often a temptation to suppress fever by using corticosteroids. This practice should be discouraged, because infection remains a leading cause of FUO, and many infections can become more invasive and disseminate in the presence of steroid therapy. Suppression of fever by low doses of naproxen (375 mg orally every 12 hours) is said to be relatively specific for fever associated with neoplasm.

FUO During Hospitalization

For information on FUO during hospitalization, see the section on “Fever During the Course of Hospitalization” on page 599.

Hypothermia

Hypothermia at Time of Admission

Hypothermia, defined as a core temperature of 35°C or less, is most often the consequence of accidental exposure to cold and is seen in individuals who are unable to move to a warm environment (e.g., the homeless, alcoholics, the elderly, those who overdose on drugs resulting in unconsciousness, and those who are immobile). Concomitant illnesses frequently are present in those with accidental exposure. These include bacteremia, hypothyroidism, pancreatitis, cirrhosis, diabetes with ketoacidosis, stroke, hypopituitarism, adrenal insufficiency, and hypoglycemia. Drugs such as alcohol, barbiturates and phenothiazines may worsen hypothermia by producing vasodilation, inhibiting shivering, or affecting central thermoregulation. Certain acute illnesses, including bacteremia, uremia, diabetes, congestive heart failure, and hypoglycemia, have been associated with hypothermia in the absence of exposure.

Clinical thermometers often do not read temperatures below 35°C. Therefore, if hypothermia is suspected, an incubator thermometer should be used. In addition to ordering routine laboratory tests, thyroid function studies, amylase, arterial blood gases, chest radiograph, head CT scan (if there is associated mental status change or focal neurologic findings), and blood, urine, and cerebrospinal fluid (if clinically indicated) cultures should be obtained. Thirty to forty percent of patients admitted with hypothermia have a concomitant serious infection (usually bacteremia, pneumonia, cellulitis, peritonitis, or meningitis), and classic

signs and symptoms may be delayed in appearance up to 72 hours (6). Although hemodynamic monitoring may be helpful in distinguishing those with bacteremia, other parameters such as blood pressure, arterial pH, oxygenation, azotemia, and degree of leukocytosis are not reliable predictors (7).

Supportive care including fluids, treatment of acidosis and arrhythmias, and rewarming (either active external or active core rewarming depending on the degree of hypothermia) are indicated. Because of the difficulty in distinguishing the infected from the noninfected patient, and because the mortality rate is higher if infection is present, *all hypothermic patients should be given empiric broad-spectrum antibiotics* to cover both Gram-positive and enteric Gram-negative organisms while awaiting culture results. If there is any suspicion of adrenal insufficiency, stress-dosage glucocorticoids should be administered after a cosyntropin stimulation test is performed (Chapter 109).

Hypothermia During the Course of Hospitalization

Hypothermia developing in the hospital may result from cardiac bypass surgery or continuous arteriovenous hemofiltration. In the absence of these factors, hypothermia is strongly suggestive of sepsis. Hypoglycemia also should be considered, particularly in patients with diabetes or liver disease. Hospitalized patients should be evaluated for potential sites of infection as outlined in the discussion of fever. After cultures are obtained, broad-spectrum antibiotics should be started while awaiting culture results.

Relative Bradycardia

Relative Bradycardia at Time of Admission

Heart rate is directly proportional to temperature, with an expected increase of between 2.4 and 10 beats/min for each 1°F rise in temperature. An inappropriately low heart rate, commonly termed relative bradycardia or Faget’s sign, has been associated with a number of conditions (Table 62.6), particularly infection with an intracellular pathogen. Unfortunately, the lack of a standardized definition for relative bradycardia coupled with the low sensitivity and specificity of this finding limit its clinical utility (8). Furthermore, relative bradycardia is of limited significance in patients who are prescribed negative chronotropic agents (such as β-blockers or verapamil) or who have intrinsic cardiac conduction abnormalities.

With these caveats, if this finding is present, particular emphasis should be placed on obtaining a thorough travel history, because many of the infectious agents in Table 62.4 are found solely in developing countries or are endemic to restricted regions of the United States. *C. burnetii* may be acquired from domesticated animals (particularly parturient cats) and raw milk, and these exposures should be

TABLE 62.6
CONDITIONS THAT MAY BE ASSOCIATED WITH
RELATIVE BRADYCARDIA

Infectious	<i>Rickettsia prowazekii</i> (epidemic typhus)
Flaviviruses	<i>Coxiella burnetii</i> (Q fever)
Dengue fever	<i>Ehrlichia chaffeensis</i>
Yellow fever	<i>Legionella</i> spp.
Bacteria	Parasites: malaria
<i>Salmonella typhi</i>	Noninfectious
<i>Salmonella paratyphi</i>	Drug fever
<i>Leptospira</i> spp.	Lymphoma
<i>Brucella</i> spp.	Central fever
<i>Chlamydia psittaci</i>	
<i>Chlamydia pneumoniae</i>	

sought. An erythematous, blanching, maculopapular skin eruption resembling the rose spots of typhoid fever in a patient without a history of foreign travel suggests Horder's spots, associated with *C. psittaci*, or the rash commonly seen with epidemic typhus.

The low positive predictive value of relative bradycardia does not allow restriction of the laboratory evaluation to the entities listed in Table 62.6. Routine cultures must be performed, in addition to studies directed at diagnosing the organisms classically associated with relative bradycardia. Relative bradycardia in a patient with respiratory complaints suggests an atypical pneumonia, prompting supplementary evaluation for *Legionella* organisms, *C. burnetii*, and *Chlamydia pneumoniae*. Clinical suspicion of infection with *Ehrlichia*, *Chlamydia*, or *Legionella* organisms, *C. burnetii*, leptospirosis, or epidemic typhus may be confirmed by acute and convalescent serum titers. *Legionella* urinary antigen may provide a more rapid diagnosis than serology, but will only detect *L. pneumophila* serogroup 1.

Relative Bradycardia During Hospitalization

A new finding of relative bradycardia in a hospitalized patient suggests either nosocomially acquired *Legionella* pneumonia or a drug fever. Nosocomial legionellosis primarily occurs among patients with a history of heavy alcohol use or smoking, advanced age, or immunosuppression. Although relative bradycardia may be seen with drug fever, it is uncommon, occurring in 10% of cases (3). The evaluation of the patient with nosocomial-onset relative bradycardia is identical to that undertaken in any febrile hospitalized patient.

LABORATORY ABNORMALITIES

Several laboratory abnormalities frequently are associated with infection. Leukocytosis is discussed in Chapter 89 and eosinophilia in Chapter 120.

Atypical Lymphocytosis

Atypical Lymphocytosis at Time of Admission

Atypical lymphocytes, sometimes referred to as Downey cells or reactive lymphocytes, are large cells characterized by morphologic abnormalities such as vacuolated cytoplasm, lobulated nuclei, and prominent nucleoli. A peripheral smear with more than 10% atypical lymphocytes is highly suggestive of the infectious mononucleosis syndrome (9). A number of infectious and noninfectious causes have been associated with atypical lymphocytosis (Table 62.7). However, this may be an incidental finding in otherwise healthy children.

Ascertainment of exposures such as sick contacts, sexual history [cytomegalovirus (CMV), HIV, human T-cell lymphotropic virus (HTLV)], cat exposure (toxoplasmosis), travel (hepatitis A), tick exposures (ehrlichiosis), injection drug use (HIV, hepatitis B and C, HTLV), vaccination history (rubella), and blood transfusion (HIV, HTLV, and CMV) are important in pinpointing an infectious etiology. Common but nonspecific physical abnormalities associated with the infectious mononucleosis syndrome include exudative pharyngitis and cervical lymphadenopathy (9). Rash that develops after the administration of ampicillin is classic for Epstein-Barr virus infection. Jaundice and, rarely, autoimmune hemolytic anemia may be present with the

TABLE 62.7
SYNDROMES ASSOCIATED WITH ATYPICAL
LYMPHOCYTOSIS

Syndrome	Description
Heterophile-positive mononucleosis	
Epstein-Barr virus	Triad of pharyngitis, fever, lymphadenopathy
Heterophile-negative mononucleosis	
Epstein-Barr virus	See text
Cytomegalovirus	Approximately 25% of heterophile-negative cases; minimal pharyngitis and lymphadenopathy
Viral hepatitis	Not associated with pharyngitis
Toxoplasmosis	Choreoretinitis variably present
Rubella	Maculopapular exanthem
Adenovirus	Pharyngoconjunctival fever
Human herpesvirus 6	Acute infection
HIV	Acute infection, often with rash
Human T-cell lymphotropic virus	Primarily in immigrants and their sex partners from endemic areas
Other	
<i>Ehrlichia chaffeensis</i>	Usually with leukopenia
Large granular lymphoma	Clonal lymphocytes

infectious mononucleosis syndrome. A positive heterophile antibody test suggests Epstein-Barr virus but is insensitive; approximately 20% of heterophile-negative cases of mononucleosis are attributable to Epstein-Barr virus and represent false negative test results. Further diagnostic testing for cases of heterophile-negative infectious mononucleosis should be guided by findings on the history and physical examination and limited to diseases such as hepatitis or HIV in which a diagnosis would lead to a therapeutic or public health intervention. Epstein-Barr virus and CMV-related infectious mononucleosis syndromes are generally self-limited and require only supportive care.

Atypical Lymphocytosis During Hospitalization

The development of atypical lymphocytosis after hospital admission is distinctly unusual, with the exception of post-transfusion CMV infections. The risk of primary CMV infection in a previously seronegative patient is approximately 2% per unit of transfused whole blood and is highest in neonates and transplant patients. Nosocomial infections caused by CMV have declined because of the use of concentrated blood products and filters that decrease the number of leukocytes per unit, cold storage of blood products, and screening of donated blood prior to transfusion for high-risk, CMV-negative recipients. Treatment of post-transfusion CMV-related mononucleosis is restricted to supportive therapy.

Interpreting Culture Results and Microbiologic Serologies

The usefulness of the information provided by the microbiology laboratory is directly dependent upon the reliability of the specimen submitted and the ability of the clinician to interpret the results accurately. Specimens submitted for culture should be representative of the suspected infection and should be obtained in such a way as to avoid contamination. For example, cultures from draining sinuses misrepresent the true microbiology of the deeper infection. Sinus tract cultures obtained in association with chronic osteomyelitis are only 50% sensitive and specific for organisms isolated directly from bone at the time of surgery. Similarly, positive cultures from surgical drains that have been in place for days or weeks likely represent colonization of the drainage tube and do not reflect the underlying infection. During the acquisition of cultures, one should try to avoid contamination by indigenous flora and submit an adequate amount. Swabs often are abused. Cultures of swabs of skin or mucous membranes are often uninterpretable or give misleading data because of contamination by normal flora. In addition, swabs contain minimal material and can give false-negative results. Whenever possible, fluid and tissue specimens should be obtained rather than swabs of evacuated abscess or tissue. Specimens should reach the laboratory in a timely manner,

and ideally should be obtained prior to the administration of antibiotics. The clinician should communicate directly with the interventional radiologist or surgeon to emphasize the importance of obtaining adequate specimens. By providing the laboratory with clinical data, specific pathogens can be sought by a variety of culturing techniques.

Upon reaching the laboratory, many specimens undergo direct microscopic examination for bacteria, mycobacteria, and fungi. Because microscopy is much less sensitive than culture, a negative stain does not exclude the presence of infection. The sensitivity of direct stains depends upon microbial load. For example, cerebrospinal fluid is positive in 60%–80% of patients with meningitis; peritoneal fluid is positive in 30%–50% with bacterial peritonitis; sputum for acid-fast bacilli positive in up to 50% of patients with pulmonary tuberculosis, and joint fluid specimens positive in about 50%–70% of cases of septic arthritis. A positive stain indicates the presence of a significant number of organisms and should never be ignored. A negative culture in the presence of a positive Gram's stain suggests prior antibiotic therapy or infection with a fastidious organism.

Most specimens are cultured in a way that allows the amount of growth to be semi-quantitated, and this information can be extremely helpful. Specimens usually are inoculated on growth plates by making three separate streaks on the plates and then are placed in a liquid broth. Growth in liquid medium only is reported by the microbiology laboratory as growth in "broth only" or as "very few" organisms being present. Such results must be interpreted cautiously because they frequently represent contamination, especially when organisms of low virulence (e.g., *Staphylococcus epidermidis* or *Corynebacterium* spp.) are isolated. If the culture report is broth only, submission of another specimen is often helpful in resolving the issue of contamination versus infection. The presence of moderate or numerous organisms is almost always indicative of infection, provided the specimen is appropriate. In some circumstances, the organism isolated and the immune status of the patient are more important than the quantity of organism isolated. For example, isolation of *Nocardia* species, *Cryptococcus neoformans*, or *Coccidioides immitis* from sputum, regardless of quantity, is likely to be indicative of infection. These organisms are not part of the normal flora and when present, they almost always correlate with disease. Similarly, although *Aspergillus* organisms may colonize patients who have received prolonged antibiotic therapy, isolation of even a single colony from an immunosuppressed patient may be significant and requires further evaluation.

A number of nonculture technologies have been applied in the microbiology laboratory to improve diagnostic yield. Common examples include direct fluorescent antibody testing for *Legionella* in sputum, herpesviruses in vesicular fluid, antigen detection for CMV in blood, group A streptococci on throat swabs, *C. neoformans* in blood and CSF, *Legionella* and *Histoplasma capsulatum* in the

urine, and giardia and rotavirus in stool. Polymerase chain reaction (PCR)-based genomic tests are available for parvovirus B19 and herpesviruses in the CSF. In general, these tests are very specific (over 90%), but sensitivity is variable (although better than culture). A negative test does not always exclude the diagnosis. Sensitivity is in excess of 90% for antigen detection of *C. neoformans* in cerebrospinal fluid, PCR for herpes in cerebrospinal fluid, PCR for parvovirus B19 in aplastic anemia and detection of CMV antigenemia in immunocompromised patients with CMV end-organ disease.

Interpretation of culture results ultimately depends upon the clinical response to antimicrobial therapy. Often the clinician can localize the source of the infection, predict bacteriology based upon the organ system involved, and choose empiric therapy based on predicted bacteriology and historic sensitivity patterns. If culture results confirm the initial impression, therapy can be continued with confidence. Laboratory data that contradict initial impressions about bacteriology must be reexamined carefully. If the specimen was obtained from a normally sterile site and organisms are isolated that do not support the original predictions of etiology, a change in therapy may be needed. On the other hand, isolation of an organism from a non-sterile site may represent colonization; if the patient is improving, a change in therapy may not be required. Cultures obtained after starting antimicrobial therapy must be interpreted carefully. Significant infections may take several days to respond even to appropriate therapy, and prolonged fever and leukocytosis may be part of the natural history of the infection. Before changing antibiotics, consultation with an infectious-diseases subspecialist might be helpful to assess whether the clinical course is consistent with an appropriate but delayed response. If a patient is truly not responding to therapy, additional considerations include appropriateness of drug dosage, penetration of the antibiotic into the site of infection, presence of undrained pus, presence of a foreign body, superinfection, emergence of a resistant organism, or the possibility of polymicrobial infection in which not all of the causative organisms are being treated.

Optimally, the diagnosis of an infection is based on isolation of the specific pathogen, but in many circumstances this is not possible. In these situations, confirmation of diagnosis may be sought by using serologic techniques. Making a specific diagnosis by serologic techniques is fraught with difficulty and rarely helps with the acute management of patients. The major pitfalls in serologic interpretation are the assumptions that a negative titer excludes disease and a positive titer indicates that a given organism is causative. Neither of these statements is entirely true.

Many different serologic tests are in existence, and these vary in sensitivity and specificity. Furthermore, the immunologic response to infection is variable. In general, IgM

antibodies appear at 1–2 weeks after infection, peak at 3–4 weeks, and persist for several months before becoming undetectable. IgG antibodies appear later (2–3 weeks), peak later, and can persist for months or years. Thus, depending on which test is performed, when disease samples are tested, and which antibody class is tested, initial results may be negative. Prior antibiotic therapy may delay or abort the development of specific antibodies, and immunosuppressed patients may not develop antibodies even if significant infection is present.

Conversely, a positive titer is not necessarily indicative of active infection. Because IgG antibodies may persist for life, previous exposure to an organism can result in positive serologic tests. To make a definite serologic diagnosis of an infectious disease, one must demonstrate seroconversion or a fourfold rise or fall in antibody titers in paired sera drawn several weeks apart. A single very high titer may be suggestive of disease, but this must be interpreted with caution, because previous infection may result in persistently elevated high titers.

KEY POINTS

- Serious underlying infection may be present in the absence of localizing symptoms or signs.
- Careful attention to historical aspects of illness, as well as meticulous and repeated physical examinations, may reveal subtle clues that allow diagnoses to be made.
- Although often nonspecific, laboratory abnormalities interpreted in a clinical context frequently allow a presumptive diagnosis of infection to be made and empiric antimicrobial therapy to be instituted.
- The microbiology laboratory is invaluable in diagnosis and treatment but requires submission of reliable specimens for culture and accurate interpretation of results.
- Direct communication with the laboratory is critical in examining microbiologic information that can directly impact patient care and outcome.

Infections in Immunocompromised Hosts

Nesli Basgoz

INTRODUCTION

Features of the Compromised Host

A compromised host is an individual who has one or more alterations or defects in the body's defenses, defects that render the individual more susceptible to severe infections. There are several important principles that should guide the approach to these patients:

- The inflammatory response to infection is attenuated, thereby abolishing or diminishing the typical signs and symptoms of inflammation and making early diagnosis difficult. This is particularly dangerous in a patient population in which morbidity and mortality rates from infection are high.
- Therefore, the clinician's approach to even subtle signs and symptoms needs to be rapid and aggressive. Because the range of possible infections is vast, therapy should be tailored to the specific clinical presentation if possible and not be purely "algorithmic."
- However, localizing signs, symptoms, or cultures are not always present. Therefore, empiric broad-spectrum treatment of suspected infection is mandatory in high-risk patients whether or not they have localizing findings of infection.

Host defects can be divided into two major categories, non-specific defects and specific immune defects. *Nonspecific defects* predisposing patients to invasion or infection are pre-

sent in many hospitalized patients. They include alterations in the anatomy and function of major organ systems and alterations of indigenous microbial flora. Chief among anatomic alterations is disruption of skin and mucous membranes. This may occur through chemotherapy-induced mucositis, intravenous catheters, or infections such as herpes simplex and *Clostridium difficile*. Perturbation in organ function also may occur. Treatment of pain syndromes with opiates may result in central nervous system dysfunction and predispose to stasis, obstruction, and infection in the respiratory, gastrointestinal, or genitourinary tracts. Measures to protect mucocutaneous barriers include oral and dental evaluation and treatment before elective procedures such as transplantation, and ongoing hygiene including topical antibacterial and antifungal agents such as Peridex and clotrimazole or nystatin; prevention or treatment of constipation; tailoring of pain regimens to avoid unnecessary sedation; and paying careful attention to vascular access. If signs or symptoms of infection occur in patients who have a disrupted mucocutaneous barrier, empiric therapy targeting flora indigenous to that site should be started.

Microbial flora are altered by many factors. Chronic disease, debilitation, hospitalization, and stasis are associated with a shift in oropharyngeal and respiratory tract flora toward Gram-negative aerobes and with migration of colonic flora into the small bowel. However, antimicrobial therapy has the most dramatic effect on indigenous flora. Broad-spectrum antibiotics with anaerobic activity eliminate

“colonization resistance,” the ability of avirulent anaerobes to prevent colonization by potentially more virulent aerobes or yeast. Results may be particularly disastrous if colonizing nosocomial flora are highly resistant, such as vancomycin-resistant enterococci (Chapter 64). Alteration in microbial flora can be avoided by providing care in an outpatient rather than an inpatient setting; appropriate hand hygiene; preventing stasis or obstruction in the gastrointestinal, genitourinary, and respiratory tracts; and using antimicrobials prudently.

PATTERNS OF IMMUNOCOMPROMISE

Specific defects in immune function are associated with typical infectious disease syndromes; knowledge of these defects and syndromes can direct diagnostic testing and early therapy. The major categories of immune dysfunction are humoral immune dysfunction, granulocytopenia (neutropenia), and cellular immune dysfunction (Table 63.1). Patients develop both granulocytopenia and cellular immune dysfunction after bone marrow transplantation. This chapter describes a general approach to adult patients with the major categories of immune defects, a task made more difficult by the heterogeneous nature of the patient population, and the lack of systematic study of many areas.

SPECIFIC IMMUNOCOMPROMISED STATES

Humoral Immune Dysfunction

Patients with hypogammaglobulinemia lack opsonizing antibodies to encapsulated bacteria, leading to severe infections with *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis* and, less commonly, *Escherichia coli* and other encapsulated pathogens. Patients with multiple myeloma, chronic lymphocytic leukemia, and splenectomy may have hypogammaglobulinemia. Asplenic patients also lack the filtering function of this reticuloendothelial organ. Asplenia may be anatomic or functional (e.g., resulting from sickle-cell disease).

Systematic studies of therapeutic strategies in these patients are lacking. However, because infection may be fulminant, any hypogammaglobulinemic or asplenic patient who develops a fever should attempt to access medical care within 1 hour, at which time blood cultures and other appropriate evaluation should be performed with antibiotic treatment started immediately. In adult patients who appear nontoxic, outpatient therapy with oral ampicillin, 500 mg four times a day, or amoxicillin 500 mg three times per day, is likely sufficient, as this covers most pneumococci, unencapsulated *H. influenzae* (which predominates in adults), and *N. meningitidis*.

TABLE 63.1

SPECIFIC DEFECTS IN IMMUNE FUNCTION AND COMMON ASSOCIATED PATHOGENS

Humoral immune dysfunction: encapsulated bacteria	Cellular immune dysfunction
<i>Streptococcus pneumoniae</i>	Bacteria
<i>Haemophilus influenzae</i>	<i>Salmonella</i> spp.
<i>Neisseria meningitidis</i>	<i>Listeria monocytogenes</i>
<i>Escherichia coli</i>	<i>Legionella pneumophila</i>
Granulocytopenia or neutropenia	<i>Nocardia</i> spp.
Bacteria	<i>Mycobacterium tuberculosis</i> and atypical mycobacteria
Gram-positive	Fungi
Coagulase-negative staphylococci	<i>Cryptococcus neoformans</i>
<i>Staphylococcus aureus</i>	<i>Histoplasma capsulatum</i>
Viridans streptococci, pneumococci, other streptococci	<i>Coccidioides immitis</i>
<i>Corynebacterium</i> spp., especially group JK	<i>Aspergillus</i> spp.
<i>Bacillus</i> spp.	Protozoa
Gram-negative	<i>Pneumocystis jirovecii</i>
<i>Escherichia coli</i>	<i>Toxoplasma gondii</i>
<i>Klebsiella pneumoniae</i>	<i>Cryptosporidium</i> spp.
<i>Pseudomonas aeruginosa</i>	Viruses
Fungi	Herpes simplex
<i>Candida albicans</i> and other <i>Candida</i> spp.	Varicella zoster
<i>Aspergillus</i> spp.	Cytomegalovirus
	Epstein-Barr virus
	Helminth: <i>Strongyloides stercoralis</i>

In adult patients who appear ill, admission and intravenous therapy are required. For pneumococcal coverage, antibiotic selection should depend on the local prevalence of penicillin-resistant *Pneumococcus*, particularly if central nervous system infection is suspected. If the likelihood of penicillin resistance is low, penicillin at a dose of 12–24 million units per day (depending on whether central nervous system infection is suspected) or ampicillin (12 g/d) may be sufficient. If there is a significant risk of penicillin resistance, vancomycin or ceftriaxone should be added until cultures and results of susceptibility testing are available (Chapter 64). In pediatric patients, especially those who did not receive *H. influenzae* vaccination before splenectomy, an agent that treats β -lactamase-producing strains of *H. influenzae* should be used. Possible choices include a second- or third-generation cephalosporin such as cefuroxime or ceftriaxone (in maximal meningeal doses if needed). These agents have the added benefit of treating strains of Gram-negative bacilli that may not be susceptible to ampicillin or amoxicillin.

Hospitalized patients who have a microbiologically documented infection should be treated with the most effective and cost-effective regimen for that organism in that site. In febrile patients who lack a microbiologically documented infection, those with no demonstrable source of bacterial infection, no initial toxicity, and rapid defervescence are at low risk for complications. In such patients, it is reasonable to stop antibiotics after 3 or more days of therapy (particularly if a source of fever other than bacterial infection has become apparent) or to complete a 7- to 14-day course of an antibiotic. Depending on the organism suspected and its local epidemiology, oral agents such as ampicillin, amoxicillin, or second- or third-generation cephalosporins may be used to complete the course.

Finally, all asplenic patients should have available and take an oral antibiotic if they have a fever and cannot access care in 1 hour. Traditionally, this antibiotic has been amoxicillin or ampicillin. However, if encapsulated *H. influenzae* or ampicillin-resistant Gram-negative organisms are of concern, other potential options include ampicillin-clavulanate, oral second-generation cephalosporins, and levofloxacin (1).

Neutropenia

Clinical Features of the Febrile, Neutropenic Host

The differential diagnosis of neutropenia is reviewed in Chapter 89. Patients at high risk of developing infections during granulocytopenia include those with leukemia, those receiving chemotherapy for leukemia or lymphoma, and those receiving chemotherapy for other cancers, including small-cell lung carcinoma, testicular cancer, and sarcomas. Patients with aplastic anemia, cyclic neutropenia, HIV infection, and other chronic conditions in which

neutropenia may be a feature appear to be at lower risk of neutropenic infection.

Many factors influence the risk of infection and the mortality rate in patients with neutropenia. These include the depth of the absolute neutrophil count (ANC) (with the highest risk at <100 cells per mL and a demonstrably increased risk at 500–1,000 cells per mL), a rapid rate of decline of ANC, and longer durations of neutropenia. Modern bone-marrow transplantation usually results in 3–4 weeks of neutropenia; the neutropenia from induction therapy of nonlymphocytic leukemia is shorter. The neutropenia resulting from chemotherapy of solid tumors usually lasts less than 1 week.

Evaluation

Patients who are febrile and neutropenic should have a meticulous history taken, focusing on even minor changes in symptoms and on any recent exposures. There is no strict definition of fever in this population; any temperature above normal may be significant. Many studies consider a single oral temperature $>38.3^{\circ}\text{C}$ or a sustained temperature (over 1 hour) $>38.0^{\circ}\text{C}$ to define the febrile state. Whatever the definition, all fever in the setting of neutropenia should be presumed initially to be infectious. Non-infectious causes of fever, including drug fever, transfusion reactions, thromboembolic disease, or fever caused by persistence or recrudescence of the underlying disease also should be considered. Fever may not always be present even with established infection, so other signs of clinical deterioration (e.g., relative hypothermia or hypotension, tachypnea, altered mental status) also should prompt evaluation and possibly treatment in neutropenic patients, especially in those at high risk (ANC <500 cells per milliliter).

At least two sets of peripheral blood cultures, plus one set from each port of any indwelling catheters, should be obtained prior to antibiotics. A urinalysis and a urine culture also should be done. In the patient who has recently received antibiotics or who has any gastrointestinal symptoms, a stool for *C. difficile* toxin should be obtained. The yield of stool examination for bacteria, ova and parasites, and viruses in patients hospitalized for more than 3 days is low, and it is reasonable to do these tests only if symptoms persist and *C. difficile* toxin is not present. Examination of spinal fluid is not recommended unless signs or symptoms of central nervous system involvement appear. A chest radiograph should be performed; in patients with gastrointestinal symptoms, upright and supine radiographs should also be considered. In patients who have localizing symptoms or signs, and have negative plain x-rays, chest or abdominal CT scan should be obtained. Skin lesions other than simple cellulitis should be aspirated or biopsied for appropriate pathologic examination, stains, and cultures.

The majority of infections in patients with neutropenia occur at a few sites. These include peridontium and oropharynx, lung, gastrointestinal tract (including the

esophagus, small bowel, colon, and rectal and perirectal areas), vascular catheter access sites, other skin sites, and urinary tract, particularly if a catheter is in place. A thorough examination should include evaluation of all of these sites and of the optic fundus.

Decision to Admit

Although admission has been the standard for febrile neutropenic patients because of the high overall risk of medical complications, it is increasingly apparent that low-risk patients can be identified and safely partially or fully treated at home, as discussed in the Infectious Disease Society of America (IDSA) guidelines for the use of antibiotics in febrile, neutropenic patients (2). Low-risk patients lack co-morbid illnesses, systemic toxicity, or uncontrolled cancer; have no evidence of significant localized infection; can be adequately observed at home; and have telephone contact with the providers and rapid access to the hospital. The degree of the neutropenia also has influenced the risk in some studies. Both intravenous antibiotics and oral antibiotics have been studied in the ambulatory setting. Oral therapy improves convenience, avoids catheter use and decreases cost of treatment. Options include newer quinolones such as levofloxacin, oral first-, second- or third-generation cephalosporins, and the combination of ciprofloxacin plus amoxicillin-clavulanate. This latter combination regimen was equivalent to parenteral therapy in a placebo-controlled trial of low risk patients, and is specifically endorsed by the guidelines.

Initial Inpatient Antibiotic Therapy

Initial therapy should take into account the severity of illness, the site suggested by the patient's presentation, allergies, risks for toxicities or drug interactions, and the local and national epidemiology of infection in neutropenic patients. Historically, in patients presenting with presumed infection, a clinical diagnosis of infection is made in 40%–60% of febrile episodes. The infection is confirmed microbiologically in only about one-half of these clinically diagnosed cases. In the past decade, documented infections have shifted from aerobic Gram-negative bacilli (i.e., *E. coli* and *Klebsiella*, *Proteus*, and *Pseudomonas* organisms) toward Gram-positive bacteria (*Staphylococcus epidermidis*, streptococci including vancomycin-resistant enterococci, and corynebacteria). Although cultures of the nares, oropharynx, and stool may aid in infection control and demonstrate the colonizing flora in neutropenic patients, these cultures are not specific for infection, and their routine use is not recommended. Respiratory-tract cultures for *Aspergillus* organisms may be an exception to this rule.

Several different initial empiric antibiotic regimens have been proposed for the febrile neutropenic patient; many are equivalently efficacious. Figure 63.1 summarizes a set of recommendations adapted from the IDSA guidelines.

Subsequent Management of Antibiotics

Guidelines for management of antibiotics after initial therapy are summarized in Figures 63.2 and 63.3.

Early Defervescence on Therapy

The median time to defervescence on antibiotics in neutropenic patients is 5 days. Patients who defervesce within this period can be divided into those in whom a likely site or pathogen is identified and those in whom it is not. If a likely infection is identified, therapy should be altered to provide optimal treatment with minimal toxicity and lowest cost, but broad-spectrum coverage still should be continued. Antibiotic treatment should continue for at least as long as a similar infection in a normal host would be treated. A longer duration should be considered if the initial presentation was particularly severe, if the organism is virulent, if clinical or microbiologic response was slow, or if potential sites of invasion are still present. If patients improve and the ANC is $>1,000$ cells per mL therapy usually can proceed in the outpatient setting with intravenous or oral antibiotics. Ideally, the ANC should be >500 cells per mL before stopping. However, if all clinical signs and symptoms of infection have resolved and a reasonable duration of therapy has been given, discontinuation of antibiotics with careful observation appears safe.

If no cause is identified, patients can be stratified into low- and high-risk groups. Low-risk patients, whose features are summarized in Figure 63.2, are unlikely to require broadening of their initial regimen, are likely to do well on oral antibiotics in the outpatient setting, and are unlikely to develop relapse or other complications after discontinuation of antibiotics. They can be managed with brief courses of mostly oral therapy, completed in the outpatient setting. Approaches to higher-risk patients who respond to empiric antimicrobials are also outlined in the figure.

Persistent Fever During the First Five Days of Therapy

Persistent fever may represent a slower than average response to treatment, an infection with bacteria resistant to the antibiotics used, a loculated infection, a nonbacterial infection, or a noninfectious cause of fever (Figure 63.3). Patients who are well and have ANCs >500 cells per mL may not require alteration or even continuation of therapy in this setting. However, patients who have an ANC <500 cells per mL and who have had no response in fever or clinical status should have therapy altered as follows:

- If an indwelling line is present or there is significant epidemiologic risk for penicillin-resistant pneumococci or viridans streptococci, add vancomycin. If the initial regimen did not include coverage of a resistant Gram-negative pathogen known to be present in the patient or the hospital environment, consider a switch to a β -lactam with better activity or addition of an aminoglycoside. If the ini-

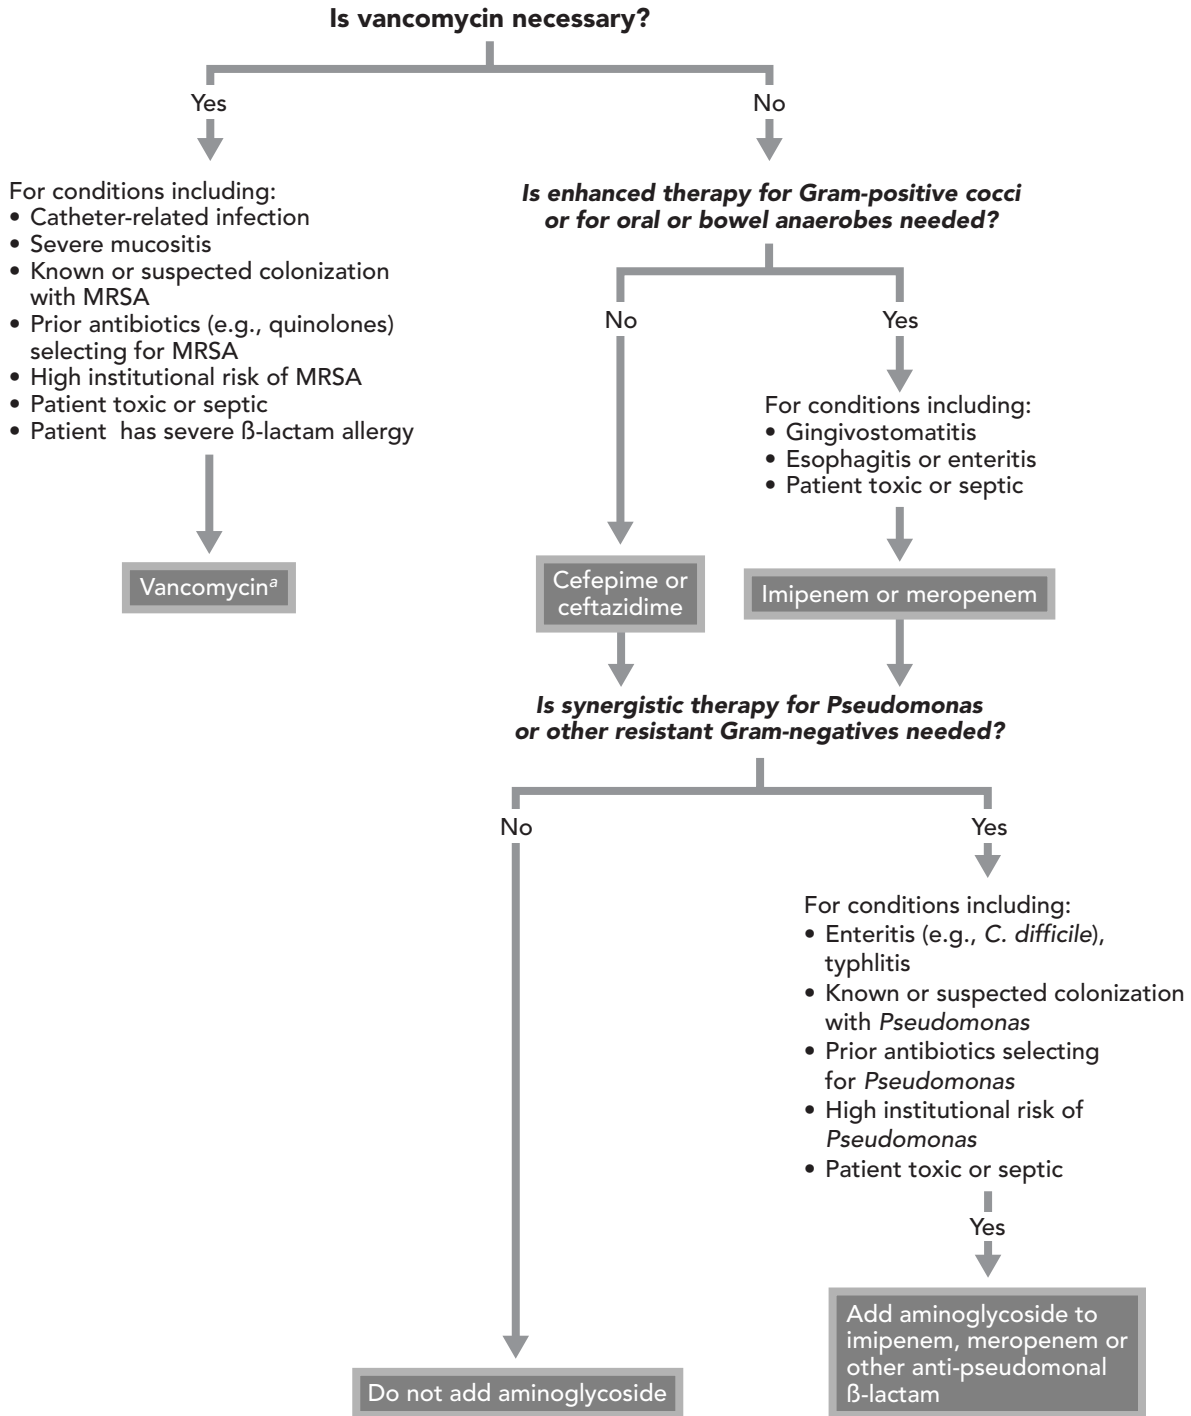

Figure 63.1 Initial inpatient therapy of fever and neutropenia. ^aIf no clinical or microbiologic evidence suggests MRSA, MRSE, or other infection requiring vancomycin by 3–4 days, stop therapy. MRSA, methicillin-resistant *Staphylococcus aureus*; MRSE, methicillin-resistant *Staphylococcus epidermidis*.

tial regimen did not include good anaerobic activity, consider its addition. Also consider unusual infections.

- If loculated infection is suspected, appropriate imaging and local drainage should be performed. Indwelling catheters that have tunnel infections and clinically unre-

sponsive exit-site infections may require line removal for cure. In addition, patients with persistently positive cultures for any organism or infections with *Bacillus* or *Candida* spp. also should have indwelling lines removed.

- Evaluate and exclude noninfectious sources of fever.

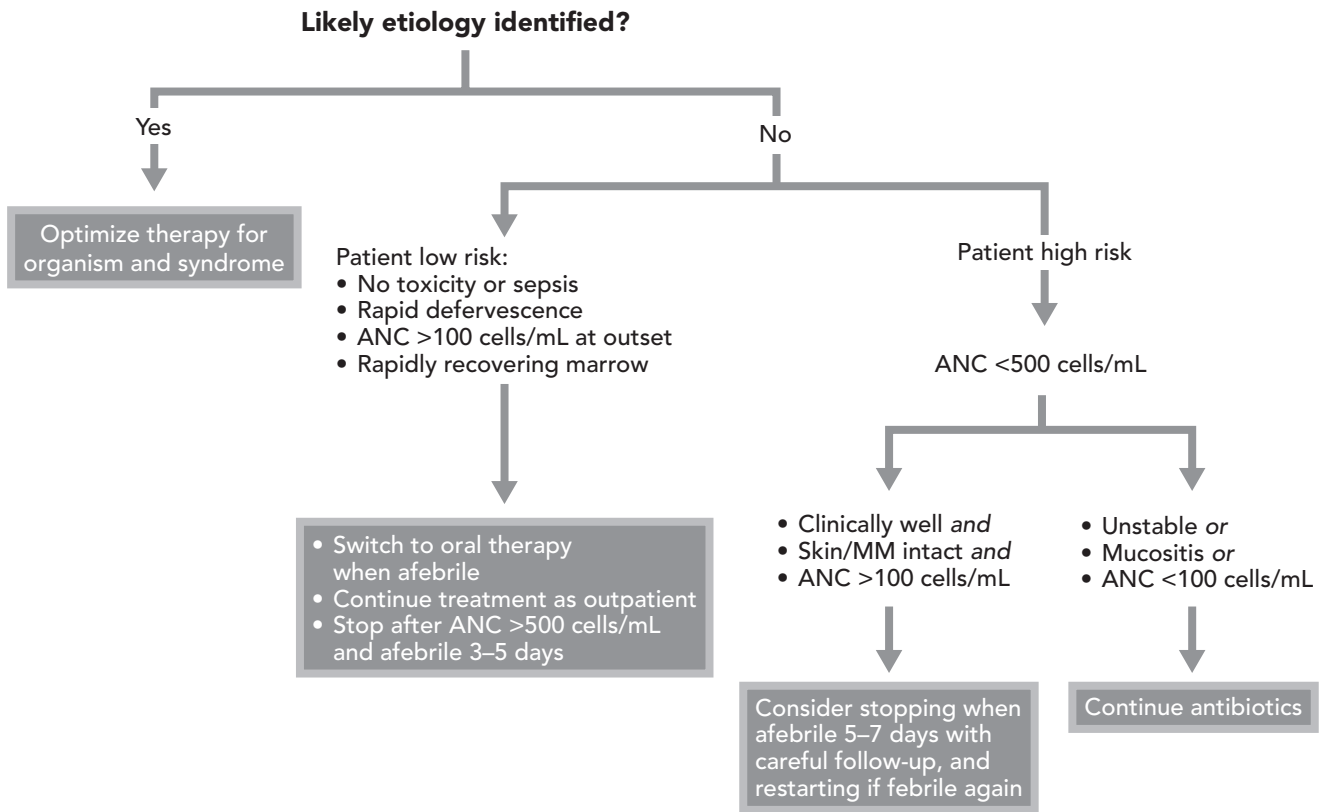

Figure 63.2 Inpatient management of neutropenia with early defervescence on therapy. ANC, absolute neutrophil count; MM, mucous membranes.

Patients who remain neutropenic for extended periods are at risk for invasive mycoses. Antemortem diagnosis is difficult because of the poor sensitivity of diagnostic techniques. Given the morbidity and mortality rates of late or disseminated infection, empiric therapy is required. Presumptive or early treatment of aspergillus has been hampered by the lack of a sensitive diagnostic test. This creates a tension: empiric therapy of aspergillus is expensive and may be toxic, yet by the time clinical and chest CT findings of the disease emerge, mortality is un-

acceptably high. A recently licensed blood test, the *Platelia Aspergillus galactomannan assay*, has been evaluated for early diagnosis in immunocompromised hosts. Depending on patient population, sensitivity is in the 80% range, with even higher specificity. While much needs to be learned about the optimal use of this assay, it already provides a useful adjunct for the early diagnosis of invasive aspergillus (3).

In general, empiric antifungal therapy is indicated for patients who remain neutropenic and febrile (or who

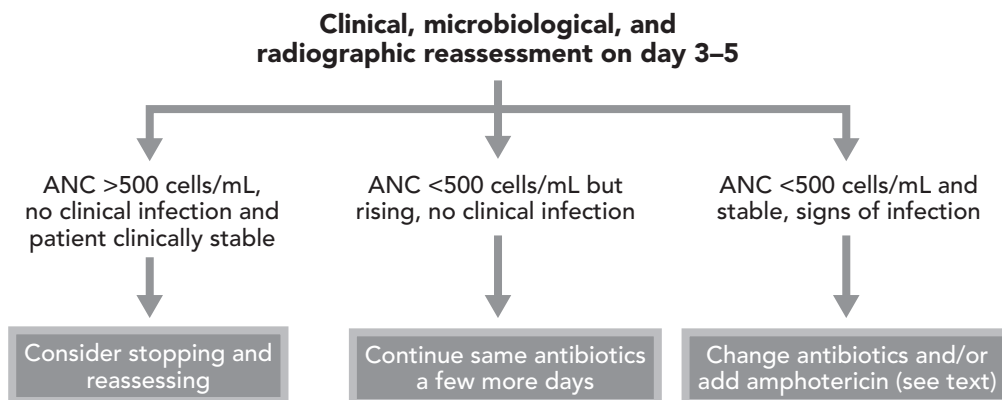

Figure 63.3 Inpatient management of neutropenia with persistent fever on therapy.

redevelop a fever) despite approximately 5–7 days of broad-spectrum antibacterial therapy (4). Amphotericin B is a broad spectrum agent with potent fungicidal activity against most yeasts and molds. There is extensive experience with this drug and most guidelines still favor its use for empiric therapy in febrile neutropenic patients. Voriconazole is an alternative for empiric antifungal therapy. In patients in whom *Candida* organisms appear most likely, doses of 0.5–0.6 mg/kg of amphotericin B per day may be used. This includes patients during the recovery phase of neutropenia, in whom hepatosplenic candidiasis is more common, and patients with any clinical, laboratory, or radiographic signs of this syndrome. Patients with mucous membrane lesions such as mucositis or colitis are also at risk for invasion of colonizing *Candida* organisms. Patients in whom *Aspergillus* organisms are suspected should be started on 1.0–1.5 mg/kg of amphotericin per day. This may include patients who have prolonged neutropenia, respiratory-tract colonization with *Aspergillus* organisms; concurrent defects in cellular immunity; or cutaneous, pulmonary, or central nervous system signs or symptoms suggesting aspergillosis. Liposomal amphotericin preparations are up to 10 or 20 times more expensive, and should be reserved for patients who cannot tolerate the conventional drug or have significant preexisting renal insufficiency. Caspofungin is not recommended for empiric therapy (5).

Patients should be rapidly assessed for deep fungal infection as empiric therapy is being started, with chest radiograph (and computed tomography scan if there are any upper or lower respiratory tract signs or symptoms, or if the respiratory tract is colonized with *Aspergillus* organisms) and abdominal computed tomography or magnetic resonance imaging if hepatosplenic candidiasis is suspected. If a causative agent and clinical syndrome are documented, this should determine the dose and course of antifungal therapy. Treatment of documented candidemia can be completed with fluconazole or amphotericin preparations, depending on speciation and fluconazole susceptibility of the *Candida* species. Intravenous caspofungin is an alternative for patients with species of *Candida* likely to be susceptible, especially those intolerant of the traditional regimens. In *Aspergillus* infection limited to the lung, monotherapy with voriconazole (oral favored over intravenous administration) or amphotericin is reasonable. Though data are limited, in CNS infection or suspected disseminated infection, many experts would favor combination therapy with voriconazole plus caspofungin, with or without high doses of an amphotericin preparation. However, if no fungal infection is found, duration of therapy should be individualized according to the degree of persistent neutropenia and the risk for deep fungal infection.

Prevention of Infection in Neutropenic Patients

Hand cleansing is highly effective. A “neutropenic diet” avoiding fresh fruits and vegetables containing high titers

of bacteria is simple and inexpensive. Although studies show some efficacy for systemic bacterial prophylaxis with oral trimethoprim–sulfamethoxazole (TMP-SMX) or quinolones, their use cannot be recommended routinely. This is because they have no demonstrable effect on mortality rate (since most infection can be successfully addressed by early empiric therapy) and because of the enormous concern over emergence of resistant organisms (Chapter 64). However, they may be appropriate for short periods in patients who have periods of particularly high risk for bacterial infection, such as those undergoing instrumentation. Systemic antifungal prophylaxis is associated with emergence of resistant fungi and is also not routinely recommended. There is no role for active or passive immunization in febrile neutropenic patients. Hematopoietic growth factors should not be employed routinely. Their use is discussed further in Chapter 90.

CELLULAR IMMUNE DYSFUNCTION

Clinical Features of the Host with Cellular Immune Dysfunction

Cell-mediated immunity refers to those aspects of the immune response that are mediated by T lymphocytes, natural killer cells, and mononuclear phagocytes. Although cell-mediated immunity is critical in the control of infection caused by intracellular pathogens such as viruses, fungi, and mycobacteria, it is also important in the control of many extracellular pathogens such as *Pneumocystis jirovecii* and in regulation of the global immune response. Table 63.2 lists some of the conditions causing defective cell-mediated immunity (see Table 63.1 for commonly associated infections). The most commonly encountered condition in adult medicine is iatrogenic immunosuppression. The drugs referred to in Table 63.2 and reviewed in Table 102.4 are used in the treatment of many conditions, including lymphoreticular and other malignancies, connective tissue diseases and other autoimmune diseases. However, solid-organ transplant recipients are the prototypical patients with prolonged and profound depression in cell-mediated immunity. This section focuses on principles of infection in this patient population, though these principles are applicable to other patients listed in Table 63.2. Because infection results in excessive deaths and injuries as well as hospitalization and cost, the most important principle is effective prevention of infection.

Principles of Antimicrobial Prophylaxis in Solid-Organ Transplant Recipients

Prevention must be stressed for two reasons: first, the previously mentioned attenuation in typical inflammatory responses; and second, the interactions and additive toxicities

TABLE 63.2
CONDITIONS ASSOCIATED WITH IMPAIRED
CELL-MEDIATED IMMUNITY

Primary immunodeficiencies
Physiologically decreased CMI in the fetus, the neonate, and the aged
Immunodeficiency secondary to malignancies
Hodgkin's disease and other lymphoid malignancies
Hairy cell leukemia
Thymoma
Immunodeficiency resulting from metabolic factors
Malnutrition
Uremia
Immunodeficiency resulting from coexisting infections
HIV infection
Other viral infections, e.g., CMV, EBV, VZV, hepatitis B and C
Disseminated mycobacterial, fungal, parasitic infections
Iatrogenic immunodeficiency
Total lymphoid irradiation
Immunosuppressive drugs

CMI, cellular mediated immunity; CMV, cytomegalovirus; EBV, Epstein-Barr virus; VZV, varicella zoster virus

of antimicrobial agents with immunosuppressive agents (Table 102.4) (6). Three types of interactions may be seen between cyclosporine, tacrolimus and antimicrobial agents. Several drugs, most notably rifampin, upregulate the metabolism of cyclosporine and tacrolimus by the hepatic cytochrome P450 system, thus decreasing levels of immunosuppression and potentially leading to allograft rejection. Other drugs, such as macrolides and imidazoles, downregulate the metabolism of cyclosporine and tacrolimus, leading to higher levels, potentially with increased toxicity and overimmunosuppression. Finally, additive toxicities include renal toxicity of agents such as amphotericin, aminoglycosides, and high-dosage TMP-SMX with cyclosporine and tacrolimus, and bone marrow toxicity of agents such as high-dosage TMP-SMX with azathioprine or mycophenolate. Careful monitoring for antimicrobial toxicity and for changes in cyclosporine and tacrolimus levels is required in this setting.

The risk of infection is determined by epidemiologic exposures along with the patient's state of immunosuppression. Potential epidemiologic exposures in the hospital include recognized nosocomial pathogens such as *Aspergillus* and *Legionella* organisms, *C. difficile*, and resistant Gram-negative rods. Epidemiologic surveillance and measures to prevent transmission are critical. The net state of immunosuppression is primarily determined by the dose, duration, and temporal sequence of immunosuppressive drugs. Kidney transplants generally require the least immunosuppression, with increasing doses required for hepatic, cardiac, and pulmonary allografts. Prophylactic regimens are continued longer in transplant patients requiring more prolonged immunosuppression. In addition

to both nonspecific and specific immune defects that contribute to immunosuppression, many transplant patients have other factors listed in Table 63.2, most notably infection with the chronic, immunomodulating viruses.

Prevention can be accomplished by using antimicrobial drugs in two different modes. The first is the *prophylactic mode*, in which the antimicrobial is given to every patient. This requires an infection that is common enough and antimicrobials that are safe enough to make prophylaxis worthwhile. The second is the *preemptive mode*, in which antimicrobials are given to a subgroup of patients before they develop symptomatic disease. The preemptive mode requires the use of a clinical or laboratory characteristic to identify a subgroup of patients at high risk, who would be expected to derive maximal benefit from the treatment. Given the current, standard immunosuppressive regimens, there is an expected temporal sequence in which infections occur posttransplant, although patients sometimes deviate from it. A discussion of the evaluation and management of the great variety of syndromes and infections that occur despite prophylaxis is beyond the scope of this chapter. Expert consultation should be sought early to facilitate rapid diagnostic and therapeutic decisions.

First Month Posttransplant

Rare causes of infection in this time period include untreated infection in the recipient and infection conveyed by the allograft. Before the transplant, meticulous evaluation of the donor as well as control of any infection present in the recipient should occur. However, most infections occurring in this time period are the same bacterial or candidal infections of the wound, lungs, urinary tract, or vascular access catheters that occur in nonimmunosuppressed surgical patients. The most important factor in prevention is technically faultless surgery to prevent bleeding and other fluid collections, devitalized tissues, anastomotic leaks, and so forth. Decreasing duration of intubation, of indwelling devices, and of immobilization are also critical. Well-established indications for prophylaxis during this time period include perioperative prophylaxis, prophylaxis of urinary tract infection, and prevention of intraabdominal infection in liver transplantation.

Perioperative antibiotics targeted to the skin and urinary tract, such as cefazolin begun intraoperatively and continued for less than 24 hours postoperatively, are effective in preventing infection in renal transplant patients and have been applied to liver and heart transplantation. In the case of lung transplantation, studies are lacking, but practice has been to use antibiotics targeted to the respiratory flora of the donor and recipient.

Without prophylaxis, the incidence of urinary tract infection in renal transplant recipients is 30%–60%. Urinary tract infection in this setting frequently is associated with signs of upper tract infection, bacteremia, and a high rate of relapse with standard short-course therapy. Prophylaxis

with TMP-SMX, one single-strength tablet daily, or (if sulfa allergic) ciprofloxacin 250 mg at bedtime, decreases the incidence to 5%, is highly cost-effective, and typically is continued for 6–12 months. TMP-SMX has the added advantage of providing prophylaxis against *Pneumocystis jirovecii*, *Nocardia asteroides*, *Listeria monocytogenes*, and *Salmonella* spp. For patients in whom urinary-tract infections recur after this period, long-term UTI prophylaxis may be appropriate after anatomic factors have been evaluated and corrected.

Factors that increase the risk of infection after liver transplantation include intraperitoneal hemorrhage, need for reexploration, and the use of a choledochojejunostomy (rather than a choledochocholedochostomy) as an anastomosis. A decrease in postoperative infection has been reported with prophylactic regimens including quinolones alone, oral gentamicin, polymyxin and nystatin or amphotericin B, and ceftazidime followed by TMP/SMX plus clotrimazole or nystatin. It is common for the biliary tree to be colonized postoperatively. If biliary drainage tubes are used, cultures may reveal enterobacteriaceae, enterococci, and coagulase-negative staphylococci, or more resistant flora if there has been prior hospitalization and antibiotics. In one center, a dose of preemptive therapy with antibiotics targeted to known or suspected biliary flora, given before biliary tract manipulation or liver biopsy, has decreased the rate of cholangitis or intrahepatic abscess.

Although additional prophylaxis may delay the onset of these infections and may be appropriate for short periods while technical or anatomic problems are being addressed, its routine use selects for resistance and should be avoided. Occurrence of typical opportunistic pathogens during this time suggests either excessive nosocomial exposure or significant immunosuppression preceding the transplant.

One to Six Months Posttransplant

Bacterial or candidal infections established in the immediate postoperative period may persist. However, this is the time period during which the typical opportunistic pathogens listed in Table 63.1 appear. Several infections are common enough to warrant routine prophylaxis. Incidence of *P. jirovecii* pneumonia (PCP) in solid-organ transplantation ranges from 10%–15%. This is effectively eliminated by one TMP-SMX single-strength tablet daily given for the first 6–12 months of transplantation or, in the case of lung transplantation, for the patient's lifetime. Alternatives in allergic patients include atovaquone, dapsone, or aerosolized pentamidine. The incidence of deep fungal infection is not high enough to warrant routine prophylaxis. However, mucocutaneous fungal infections are common, and the incidence is decreased by clotrimazole 10 mg twice per day or nystatin swish and swallow 3 mL twice per day. Cytomegalovirus (CMV) causes very significant direct and indirect morbidity and mortality in this population (as summarized in Table 63.3) (7). In seronegative recipients,

TABLE 63.3
EFFECTS OF CYTOMEGALOVIRUS IN TRANSPLANT RECIPIENTS

Direct effects
Acute viral syndrome, may include:
Fever, myalgias, arthralgias, headache
Leukopenia, thrombocytopenia, hepatitis
End organ disease
Allograft
Other tissues
Gastrointestinal tract including bowel, liver, pancreas
Pneumonitis
Encephalitis or retinitis
Myocarditis
Indirect effects
Allograft rejection and injury
Superinfection
Increased risk of post-transplant lymphoproliferative disease associated with Epstein-Barr virus
Possible associations
Bronchiolitis obliterans in lung transplants
Accelerated coronary artery disease in heart transplants
Vanishing bile duct syndrome in liver transplants
Glomerulopathy in kidney transplants

prevention of primary infection using CMV-negative blood products is critical. With the availability of an orally bioavailable formulation of ganciclovir (valganciclovir), some higher risk patients now warrant routine CMV prophylaxis (8). These include patients who are donor seropositive and recipient seronegative for CMV, patients receiving antilymphocyte globulins or other significantly augmented immunosuppression for rejection, and patients early after lung transplantation. Preemptive therapy of viral replication (without symptomatic disease) may be appropriate in many other transplant patients. Treatment of documented viral replication or clinical disease should be done in conjunction with an infectious disease specialist. These same patients at high risk for disease are also at risk for drug resistance, particularly if they receive inadequate doses or durations of antiviral treatment.

More than Six-Months Posttransplant

Patients with a functioning allograft fall into two groups. The first includes those with good allograft function, on decreasing doses of immunosuppression, and free of chronic viral infection. These patients increasingly develop infections observed in the community (e.g., influenza, bacterial pneumonia, urinary tract infection), although opportunistic infections still are seen. The second group is characterized by poor allograft function, one or more episodes of acute or chronic rejection requiring increased immunosuppression, and infection with the chronic viruses. These patients remain at high risk for opportunistic infections, and

it may be appropriate to employ prophylaxis for mucocutaneous fungal and viral infections and for PCP for much longer.

BONE-MARROW TRANSPLANTATION

General principles of bone-marrow transplantation and unique infectious disease considerations are discussed in Chapter 96. Principles of therapy of febrile neutropenia in these patients are similar to those already described.

KEY POINTS

- Compromised hosts may have specific or nonspecific defects in immune function, and these defects are associated with typical infectious disease syndromes. Because the inflammatory response to infection in these patients is attenuated and the morbidity from infection is high, early diagnosis and empiric therapy are critical.
- In patients with impaired humoral immunity, early treatment directed at encapsulated pathogens is essential.
- In the case of febrile neutropenic patients, in whom both bacterial pathogens and fungi are important, guidelines exist for rational empiric antibacterial and antifungal therapy. Although this therapy previously was provided entirely in the inpatient setting, it is increasingly possible to identify patients who can be either managed in the outpatient setting or discharged home early.
- In patients with solid-organ or bone marrow transplants and long-term immunosuppression, knowledge of the

likely pathogens and the usual timing of their occurrence is increasingly allowing design of effective and cost-effective strategies to prevent infection.

Parenteral Antibiotics and Antibiotic Resistance

64

Lisa G. Winston Henry F. Chambers III

INTRODUCTION

Antimicrobial Resistance

Bacterial resistance to antimicrobial therapy has emerged as a significant problem over the past 20 years, with concerns escalating in the 1990s. Local patterns of resistance vary widely, but the percentage of bacterial pathogens with resistance to a single or multiple antibiotics increases yearly. Risk factors for infection with resistant organisms include direct exposure to people carrying them (e.g., the spread of penicillin-resistant *Streptococcus pneumoniae* in day-care centers) or environmental contamination (e.g., colonization with vancomycin-resistant enterococci in hospital wards and intensive care units). However, the true driving force behind the emergence of antibiotic resistance is the use of antibiotics themselves. Indiscriminate prescription of antibiotics, for example for symptoms that are almost always caused by viral infections (1), is part of the problem. In addition, the availability of antimicrobial agents without a prescription in many parts of the world adds to the overuse. In recent years, patterns of prescribing physicians have begun to change in response to growing concerns about bacterial antimicrobial resistance. For example, some practitioners no longer prescribe antibiotics for routine acute otitis media in children because research has shown that most cases resolve without specific treatment.

This paradox of increasing antimicrobial resistance fueling increased use of broad-spectrum antibiotics often

leaves the clinician with the dilemma of how best to care for individual patients. Familiarity with local bacterial resistance patterns, the usual pathogens in common infections, and specific therapy for a few resistant organisms helps clinicians make rational decisions regarding empiric and pathogen-specific selection of antibiotics.

Mechanisms of Resistance

A basic knowledge of the mechanisms that underlie bacterial resistance is important in understanding the potential for clinical failures and for the selection of appropriate antibiotics if resistant pathogens have been isolated or are suspected (Figure 64.1). There are three general mechanisms of bacterial resistance: inability of the antibiotic to reach its target; inactivation of the antibiotic before it reaches its target; or alteration of the antibiotic target itself. These mechanisms may operate independently but often work in concert.

Impaired penetration may result from either the failure of the drug to cross a membrane barrier (e.g., the outer membrane of Gram-negative bacteria) or the presence of a trans-membrane efflux pump that transports drug out of the cell. Antibiotics penetrate the outer membrane of Gram-negative organisms via outer-membrane protein channels. Absence of the proper channel, or down-regulation of its production, can prevent or greatly reduce drug entry into the cell.

Antibiotic inactivation is the principle mechanism of resistance to β -lactam antibiotics and aminoglycosides.

Figure 64.1 Schematic of the envelope of a Gram-negative bacterium illustrating mechanisms of antibiotic resistance. 1. The antibiotic may fail to reach its target secondary to absence or down-regulation of the outer membrane protein channel. 2. The antibiotic may be transported out of the cell by a transmembrane efflux pump. 3. The antibiotic may be inactivated before it reaches its target (e.g., by a β -lactamase in the periplasmic space). 4. A membrane-associated target (e.g., a penicillin-binding protein) may be altered. 5. An intracellular target (e.g., DNA gyrase or topoisomerase) may be altered.

β -lactamases are enzymes that hydrolyze the β -lactam ring. β -lactamases produced by commonly encountered organisms such as *Staphylococcus aureus*, *Haemophilus species*, *Bacteroides fragilis*, and *Escherichia coli* are predominantly penicillinases with relatively weak activity against cephalosporins. β -lactamases produced by more resistant species (e.g., *Pseudomonas*, *Enterobacter*, and *Serratia* spp.) are primarily cephalosporinases, although these enzymes also have penicillinase activity. β -lactamases of gram-negative species are located in the periplasmic space between the cytoplasmic and outer membranes, which effectively produces an enzymatic barrier to antibiotic penetration.

Target alteration is the basis of penicillin resistance in pneumococci, methicillin resistance in staphylococci, vancomycin resistance in enterococci, and fluoroquinolone resistance in both Gram-negative and Gram-positive organisms. In the cases of penicillin and methicillin resistance, the penicillin binding protein targets have been modified in such a way that they bind β -lactams poorly, so usual drug concentrations are ineffective. Vancomycin resistance in enterococci is caused by alteration of the drug's target in the nascent cell wall. Resistance to fluoroquinolones is caused by one or more point mutations in the primary target of the drug (DNA gyrase in *E. coli* and topoisomerase IV in staphylococci).

Resistance may be acquired vertically by selecting subpopulations with advantageous mutations or horizontally by transfer of genetic material encoding resistance determinants. Horizontal transmission has several potential advantages from the standpoint of bacterial survival. The trait can be widely and rapidly disseminated to other

strains with high-level resistance achieved in a single step, and the problem of lethal mutation is avoided. Horizontally acquired resistance genes often are plasmid-encoded, and plasmids can harbor many resistance factors simultaneously.

Goals of Antibiotic Therapy

The general goals of antibiotic therapy are to eradicate infection as quickly as possible and to minimize toxicity. Choosing safe antibiotics with rapidly bactericidal activity is always desirable. Using an antibiotic with the narrowest possible spectrum of action likely helps prevent the emergence and spread of resistant organisms. In addition, broad-spectrum antibiotics dramatically alter normal host flora, which leaves patients vulnerable to organisms of intrinsically low virulence, such as enterococci and yeast. Finally, traditional antibiotics with more focused bacterial coverage frequently are less costly. Thus, in hospitalized patients for whom broad-spectrum or long-term antibiotic therapy is being considered, it is essential that appropriate cultures be taken before antibiotics are started so that therapy can be narrowed once specific pathogens are isolated. It is also important to recognize that many signs, symptoms, and laboratory abnormalities in the hospitalized patient that appear to be infectious in nature (such as fever or opacities on a chest radiograph) in fact may not be (Chapter 62). Therefore, their presence should not automatically lead the clinician to broaden antimicrobial coverage.

Combination Therapy

The use of antibiotic combinations to treat serious bacterial infections is common in hospitalized patients. There are four circumstances in which a clinician should select combination therapy: (1) if synergy between two agents has been shown to result in faster killing of organisms and potentially better outcomes for patients; (2) if combination therapy has been demonstrated to prevent the emergence of resistance; (3) if the agents chosen have distinct anatomic sites of action; or (4) if the infection is polymicrobial, mixed aerobic-anaerobic, or caused potentially by one of several organisms so that no single drug is likely to cover all pathogens. Enterococcal endocarditis is one example of an infection that requires the use of a synergistic combination (e.g., ampicillin plus gentamicin) to produce the bactericidal activity that is required to cure this infection (Chapter 71). Tuberculosis is, perhaps, the best example of a disease in which combination therapy is known to prevent the emergence of resistance (Chapter 67). Although synergism and prevention of resistance have been invoked as reasons for combination therapy for invasive infections caused by certain Gram-negative bacilli, this practice is quite controversial. *Pseudomonas aeruginosa* has been most extensively studied, and evidence supporting the use of combination therapy for *P. aeruginosa* infection is most compelling (see

pages 627–628). Use of rifampin-containing regimens for the treatment of staphylococcal prosthetic valve endocarditis is an example of combination therapy to target different bacterial populations. Rifampin penetrates into and sterilizes valve ring and suture-associated abscesses, whereas vancomycin, β -lactams, and aminoglycosides—the other antibiotics used to treat this infection—do not. Rifampin cannot be used alone in such cases because resistance emerges rapidly. Finally, combination therapy often is used in the treatment of intra-abdominal infections, which frequently are polymicrobial (Chapter 87).

CARE OF THE HOSPITALIZED PATIENT

This section describes the features of the most commonly used antibiotics and the treatment of particularly challenging pathogens. It does not discuss the initial, empiric selection of antibiotics for common infections in hospitalized patients; this is specifically addressed in other chapters. However, it should be emphasized that *an attempt to cover all possible organisms is almost never indicated*. Instead, one should focus on the most common organisms that cause particular clinical syndromes and select an antibiotic regimen that covers these pathogens well, taking local resistance patterns into account. In general, patients who are more severely ill merit broader initial coverage, because one cannot afford to leave an unusual pathogen uncovered.

Overview of the Major Classes of Antibiotics

Aminoglycosides include streptomycin, neomycin, kanamycin, amikacin, gentamicin, tobramycin, sisomicin, and netilmicin. Aminoglycosides inhibit bacterial protein synthesis and are most active against Gram-negative enteric bacteria. They have no activity against anaerobes. Aminoglycosides often are used in combination with another antibiotic, usually a β -lactam. Resistance may be caused by production of an inactivating enzyme, impaired entry into the cell, or target alteration. Aminoglycosides are absorbed very poorly if administered orally, and systemic levels can be achieved only by intramuscular or intravenous administration. Aminoglycosides are highly polar compounds that do not enter cells or penetrate infected tissue and abscesses readily. Clearance is directly proportional to creatinine clearance. They are ototoxic and nephrotoxic. Toxicity is more likely to occur if aminoglycosides are administered for more than 5 days at high dosages in the elderly in the setting of renal insufficiency, or with diuretics or other potentially nephrotoxic agents (e.g., vancomycin or amphotericin-B). In most cases, once-daily dosing of aminoglycosides is the preferred mode of administration. Daily dosing appears to have less toxicity and is as efficacious as more frequent administration. However, daily dosing should not be used in cases of endocarditis and still requires dose adjustment in patients with renal failure.

β -lactam antibiotics include penicillins, cephalosporins, carbapenems, and monobactams. They all are similar chemically, mechanistically, pharmacologically, immunologically, and clinically. β -lactams are the most widely prescribed antibiotics, and their extensive use has exerted enormous selective pressure favoring resistant organisms. Broad-spectrum β -lactams eradicate normal flora, predisposing patients to colonization and superinfection with opportunistic, drug-resistant species. β -lactam antibiotics inhibit bacterial growth by inhibiting bacterial cell-wall synthesis. These compounds are structural analogues of the natural cell-wall substrate D-alanyl-D-alanine, and they covalently bind to penicillin-binding proteins at the active site of cell-wall synthesis. β -lactams are bactericidal only if cells are actively dividing. Resistance to β -lactams results from β -lactamase inactivation of the drug, alteration in target penicillin-binding proteins, or impaired antibiotic entry into Gram-negative bacteria. β -lactams are remarkably nontoxic; most of the serious adverse effects are caused by hypersensitivity. Allergic reactions include anaphylactic shock (0.05% of recipients), serum sickness, and skin rashes.

Penicillins can be divided into three groups: *Penicillins* (e.g., penicillin G) are most active against Gram-positive organisms, Gram-negative cocci, and anaerobes. They are poorly active against Gram-negative rods and are susceptible to hydrolysis by β -lactamases. *Antistaphylococcal penicillins* (e.g., nafcillin) are resistant to staphylococcal β -lactamases and are active against staphylococci and streptococci. They have no useful activity against enterococci, most anaerobic species, and Gram-negative organisms. *Extended-spectrum penicillins* (e.g., ampicillin, ticarcillin, and piperacillin) have improved activity against Gram-negative organisms, but they are destroyed by β -lactamases. Many extended-spectrum penicillins have enhanced activity against *P. aeruginosa*.

Cephalosporins are classified into four major groups or “generations,” depending mainly on the spectrum of antimicrobial activity. As a general rule, first-generation compounds (e.g., cefazolin) have better activity against Gram-positive organisms, and the later generation compounds exhibit improved activity against Gram-negative aerobic organisms. Anaerobic cocci (e.g., *Peptostreptococcus*) are sensitive to most cephalosporins. Cephalosporins are more β -lactamase stable than penicillins and, therefore, usually have a broader spectrum of activity. The cephamycin group of second-generation compounds (cefoxitin, cefotetan, and cefmetazole) are active against anaerobes (including many *B. fragilis*). Third-generation cephalosporins have improved Gram-negative coverage and most (an exception being ceftizoxime) achieve high levels in the cerebrospinal fluid. Cephalosporins are not active against enterococci, *Listeria monocytogenes*, or methicillin-resistant staphylococci. Cephalosporins are rarely the drugs of choice for a specific organism but, because of their broad spectra, they are used widely for empirical therapy. Third-generation

cephalosporins, in particular, exert a strong selective pressure favoring colonization by multidrug-resistant organisms and fungi.

Imipenem and meropenem, are *carbapenems* that have very broad spectra of activity, including Gram-negative rods, Gram-positive organisms, and anaerobes. These compounds are resistant to most β -lactamases. However, *Enterococcus faecium*, methicillin-resistant strains of staphylococci, *Clostridium difficile*, *Burkholderia cepacia*, and *Stenotrophomonas maltophilia* are resistant to carbapenems. Carbapenems are indicated for infections caused by multidrug-resistant organisms. They are effective as single agents for treatment of febrile, neutropenic patients, and they are an antibiotic of choice for treatment of *Enterobacter* infections. Seizures may occur with high doses of imipenem in patients with renal failure.

Monobactams (aztreonam is the only one available in the United States) are active only against Gram-negative organisms. The antimicrobial spectrum resembles that of aminoglycosides. Patients with serious allergic reactions to penicillins or other β -lactams can be safely treated with monobactams, which do not cross-react with other β -lactams.

β -lactamase inhibitors are β -lactam molecules with weak antibacterial activity that inhibit many bacterial β -lactamases. Plasmid-encoded β -lactamases, such as those produced by staphylococci, *Haemophilus influenzae*, *Neisseria gonorrhoea*, *Salmonella* organisms, *Shigella* organisms, *E. coli*, and *Klebsiella pneumoniae*, are most susceptible to inhibition, as are the chromosomal β -lactamases of *Bacteroides* and *Moraxella* spp. The three inhibitors on the market, clavulanate, sulbactam, and tazobactam, are therapeutically similar. Inhibitors are available only in fixed combinations with specific penicillins: ampicillin/sulbactam, piperacillin/tazobactam, and ticarcillin/clavulanate. The spectrum of the combination is determined by the companion penicillin. The activity of the companion penicillin is improved with the addition of an inhibitor only if resistance is caused by β -lactamase production and the inhibitor is active against the β -lactamase produced.

Vancomycin is a glycopeptide antibiotic that inhibits cell-wall synthesis by binding to the terminal D-alanyl-D-alanine of peptidoglycan precursor. Resistance to vancomycin in enterococci results from modification of the precursor by replacement of D-alanine with D-lactate, which eliminates a hydrogen bond critical for binding vancomycin. Vancomycin is bactericidal for Gram-positive bacteria, both aerobic and anaerobic. Vancomycin is administered orally only for the treatment of antibiotic-associated enterocolitis caused by *C. difficile*. However, because of the potential for selection of vancomycin-resistant enterococci, this use of oral vancomycin has fallen into disfavor. Parenteral doses must be administered intravenously. Vancomycin is eliminated by glomerular filtration. In functionally anephric patients, the half-life of vancomycin is

6–10 days. The drug is not removed by conventional hemodialysis but is partly removed by high-flux dialysis. The main indication for parenteral vancomycin is bacteremia caused by methicillin-resistant staphylococci. However, vancomycin is *less effective* than an antistaphylococcal penicillin for treatment of serious infections, such as endocarditis, caused by methicillin-susceptible strains (Chapter 71). Other indications are empiric or definitive therapy for infections (e.g., meningitis) caused by highly penicillin-resistant strains of pneumococcus or Gram-positive infections in patients with serious allergy to β -lactams.

Metronidazole is a nitroimidazole with potent antibacterial activity against most anaerobes, including *Bacteroides* and *Clostridia* spp. Resistance is uncommon among strict anaerobes. The drug has excellent oral bioavailability, achieving serum concentrations equivalent to those following intravenous administration. Metronidazole is indicated for treatment of anaerobic or mixed intra-abdominal infections. It is not active against streptococci and is less active than clindamycin against Gram-positive anaerobes.

Macrolides are bacteriostatic inhibitors of protein synthesis. They are a group of closely related compounds characterized by a 14- to 16-member cyclic lactone ring. Clarithromycin and azithromycin are semisynthetic derivatives of erythromycin. Clarithromycin is virtually identical to erythromycin with respect to antibacterial activity, except that clarithromycin is more active against atypical mycobacteria and *Haemophilus* spp. Compared with erythromycin and clarithromycin, azithromycin is slightly less active *in vitro* against staphylococci and streptococci and slightly more active against *H. influenzae*. Besides azithromycin's enhanced activity against *Chlamydia* spp., the clinical significance of these differences is unclear. These agents are very active for infections caused by *Legionella* organisms. Because of frequent resistance in pneumococci (15%–20%), group A streptococci (20%–40%), and staphylococci (46%–60%), macrolides should not be used as initial, single therapy in severely ill patients if these organisms are suspected. However, macrolides are effective for the outpatient treatment of community-acquired pneumonia (Chapter 65).

Clindamycin is a chlorine-substituted derivative of lincomycin, an antibiotic that resembles erythromycin in activity. Streptococci, staphylococci, and pneumococci are inhibited by clindamycin. Enterococci and Gram-negative aerobes are resistant. *Bacteroides* species and other anaerobes are usually susceptible. Clindamycin penetrates well into abscesses. The most important indication for clindamycin is in the treatment of serious mixed or anaerobic infections caused by *Bacteroides* organisms and other anaerobes. It is probably the antibiotic of choice for lung abscesses. *C. difficile* is resistant, and antibiotic-associated colitis caused by this organism is an important complication of clindamycin therapy.

Tetracyclines are broad-spectrum bacteriostatic inhibitors of protein synthesis. Their spectrum includes Gram-positive and Gram-negative bacteria, anaerobes, and *Rickettsia*, *Chlamydia*, and *Mycoplasma* organisms. Resistance results primarily from an efflux pump. Widespread and indiscriminate use of tetracyclines (including use in animal feed) has promoted resistance. Thus, tetracyclines have fallen into disuse for treatment of many serious bacterial infections. Tetracyclines are still among the drugs of choice for brucellosis, plague, tularemia, and infections with chlamydiae and rickettsiae. Doxycycline can be used alone for outpatient therapy of community-acquired pneumonia or for inpatient therapy in conjunction with other antibiotics (Chapter 65). Tetracyclines deposit in growing bones and teeth and should be avoided in pregnant women and children under age 8.

Trimethoprim-sulfamethoxazole blocks sequential steps in the bacterial folate synthetic pathway, inhibiting growth because bacteria are unable to take up exogenous folate. This combination is active against both Gram-positive organisms (although activity against β -hemolytic streptococci is weak) and Gram-negative aerobes including enteric organisms (such as *E. coli* and *Klebsiella*, *Salmonella*, *Shigella*, and *Enterobacter* organisms), *Nocardia* spp., and *Chlamydia trachomatis*. It is active against many respiratory tract pathogens, including the pneumococci, *Haemophilus* spp., *Moraxella catarrhalis*, and *Klebsiella pneumoniae* (but not *Chlamydia pneumoniae*, *Chlamydia psittaci*, or *Mycoplasma* spp.), making it an alternative to β -lactams for treatment of less serious respiratory infections. However, the high prevalence of strains of penicillin-nonsusceptible pneumococci (PNSP) and *E. coli* (up to 30% or more) that are resistant to trimethoprim-sulfamethoxazole no longer permits this combination to be used for empirical therapy of pneumonia or upper urinary tract infection. Trimethoprim-sulfamethoxazole has no activity against anaerobes.

Fluoroquinolones are synthetic, fluorinated analogues of nalidixic acid. They are active against numerous Gram-positive and Gram-negative bacteria. Newer compounds (e.g., gatifloxacin and moxifloxacin) have similar or slightly less activity than ciprofloxacin against Gram-negative organisms but enhanced activity against Gram-positive organisms and anaerobes. Because of reports of hepatic toxicity, trovafloxacin use is now restricted to inpatients for whom no safe and effective alternative exists. Intracellular pathogens, including *Legionella* and *Chlamydia* organisms and mycobacteria, are inhibited. Resistance results from selection of mutants producing altered drug target. Fluoroquinolones are effective for serious infections caused by multidrug-resistant bacteria, such as *Pseudomonas* and *Enterobacter* organisms. However, increasing use of fluoroquinolones for nosocomial infections has resulted in steadily increasing resistance in formerly susceptible organisms. In addition, the extensive use of fluoroquinolones in the outpatient setting has led to an increase in fluoro-

quinolone-resistant pneumococci. While this resistance is still uncommon, treatment failures have been reported, particularly in patients who previously received fluoroquinolones (2). The safety of fluoroquinolones is unknown during pregnancy, and these drugs may damage growing cartilage. Thus, they are relatively contraindicated in patients under age 18, during pregnancy, and for nursing mothers.

Quinupristin/dalfopristin is a streptogramin antibiotic which combines two semisynthetic derivatives of pristinamycin. The two components act synergistically at the site of the bacterial ribosome to inhibit protein synthesis. Although quinupristin/dalfopristin is effective against a number of Gram-positive organisms, including *S. aureus* and *Streptococcus pyogenes*, it is used mainly for infections with vancomycin-resistant *Enterococcus faecium*, against which it is one of the few active drugs. Note that it is not active against vancomycin-resistant *Enterococcus faecalis*. Use of this drug is limited by side effects, including phlebitis, myalgia, and arthralgia.

Linezolid is the first approved antibiotic of the oxazolidinone class. It is a protein synthesis inhibitor that has activity against staphylococci, streptococci, and enterococci. This drug is useful for infection with resistant Gram-positive organisms, especially vancomycin-resistant enterococci and, in some cases, methicillin-resistant *S. aureus*. Concerns about rapid development of resistance warrant prudent prescribing of linezolid (3). Linezolid is highly bioavailable and can be given orally or intravenously at the same dosage. Thrombocytopenia has been reported, and platelet counts should be monitored, especially with extended use.

Problem Organisms

Multidrug-Resistant Gram-Negative Rods

Pseudomonas aeruginosa frequently causes infections in patients who have been treated previously with antibiotics, patients with loss of skin integrity (e.g., burn victims), neutropenic patients, and patients with cystic fibrosis. It is often isolated from the skin and respiratory tract of hospitalized patients, and respiratory colonization is especially common in intubated patients. Therefore, a positive culture (unless from a sterile site) does not necessarily imply that an infection is present. However, invasive *Pseudomonas* infections are associated with a high mortality rate. Accordingly, patients with suspected serious infection should be treated with antipseudomonal therapy if *Pseudomonas* organisms are isolated from a corresponding site, such as sputum or tracheal aspirate samples, and are predominant in the sample. In addition to pneumonia in the hospitalized patient, *P. aeruginosa* may cause urinary tract infection, skin and soft-tissue infection, osteomyelitis, endocarditis, and bacteremia.

P. aeruginosa is intrinsically resistant to a variety of antibiotics because of its outer-membrane barrier and efflux-pump mechanisms. During therapy with a number of penicillins and cephalosporins, chromosomal β -lactamases, which are not inactivated by currently available β -lactamase inhibitors, may be induced and degrade these drugs. *P. aeruginosa* also has acquired plasmid-encoded resistance to many drugs. Because the development of resistance during therapy has been well documented, the use of combination chemotherapy in severe *P. aeruginosa* infections has been advocated. This recommendation is based on studies suggesting that patients receiving combination therapy, usually an antipseudomonal penicillin and an aminoglycoside, have better outcomes than patients receiving single-drug therapy (4, 5). Because synergism between these two classes often can be demonstrated *in vitro*, it has been postulated that synergism is at least partially responsible for improved outcomes. However, clinical studies have yielded conflicting results, with single agents often equivalent to combination therapy, except perhaps in neutropenic patients (6). Recent studies have demonstrated acceptable outcomes with use of a single, potent agent such as a quinolone (7). Optimal treatment of invasive infection remains controversial (Table 64.1).

In selecting agents to cover invasive infections of *P. aeruginosa*, several factors should be taken into account. If combination chemotherapy is selected, an anti-pseudomonal β -lactam antibiotic and an aminoglycoside are most likely to be synergistic *in vitro*. Synergy sometimes occurs between β -lactam and fluoroquinolone antibiotics, but it does not occur with fluoroquinolone-aminoglycoside combinations. Combinations of two antipseudomonal β -lactam antibiotics should be avoided; these combinations are not synergistic and may even be antagonistic. For example, one β -lactam antibiotic may induce a β -lactamase that degrades the other. As with all infections with a known organism, the antibiotic susceptibilities of the pathogen should be taken into account as soon as they are available.

Enterobacter spp., and the related organisms *Klebsiella*, *Citrobacter*, and *Serratia* spp., also frequently cause infections in the hospital setting. These organisms often are resistant to multiple drugs. They may cause bacteremia, pneumonia, intraabdominal infections, wound infections, and urinary-tract infections. *Enterobacter* spp. produce an inducible β -lactamase that slowly degrades second- and third-generation cephalosporins. With *in vitro* testing of cephalosporins, strains may appear susceptible. However, if there is a high inoculum infection, mutants producing large amounts of β -lactamase proliferate because of their selective advantage. The emergence of resistance during therapy appears to be associated with an increased mortality rate (8). Cefepime, which is referred to as a fourth-generation cephalosporin, is less susceptible to degradation by the *Enterobacter* β -lactamase than are second- and third-generation cephalosporins; therefore,

resistance may be less likely to emerge during treatment with this agent. The addition of a second antibiotic (aminoglycosides have been studied most extensively) does not seem to prevent the emergence of resistance or improve clinical outcomes. Therefore, second- and third-generation cephalosporins are not recommended for treatment of *Enterobacter* infections. Second- and third-generation cephalosporins have been used successfully for infections with *Citrobacter* and *Serratia* spp., but some caution is warranted. The drugs of choice for such infections are trimethoprim-sulfamethoxazole, a fluoroquinolone, or a carbapenem. *Klebsiella* spp. are reliably susceptible to fluoroquinolones, aminoglycosides, and carbapenems and are usually susceptible to third-generation cephalosporins. Extended spectrum β -lactamases (ESBLs) are increasingly common in *Klebsiella* and other aerobic Gram-negative rods. If the presence of this enzyme is known or suspected, cephalosporins should be avoided.

E. coli is the most frequently isolated enteric pathogen. Antibiotic resistance in *E. coli* has surfaced over the past several years. Ampicillin can no longer be used as initial therapy, because more than 50% of community strains are resistant to this drug. Similarly, trimethoprim-sulfamethoxazole is no longer recommended as initial therapy for upper urinary tract infections because of the recent emergence of resistance (Chapter 68).

Penicillin-Nonsusceptible Pneumococci

S. pneumoniae has been recognized for many years as the most common bacterial pathogen in community-acquired pneumonia, meningitis, otitis media, and sinusitis. PNSP are becoming increasingly prevalent worldwide. Resistance is mediated by mutations in penicillin-binding proteins, with which all β -lactam antibiotics must interact; therefore, PNSP are cross-resistant to many other penicillins and cephalosporins. PNSP also frequently are resistant to multiple unrelated antibiotics, including erythromycin, tetracycline, and trimethoprim-sulfamethoxazole. Strains in which the minimum inhibitory concentration (MIC) of penicillin is 0.1 to 1.0 mg/mL have "intermediate resistance," and strains with MICs of 2 mg/mL or greater are designated "highly resistant." This distinction is important because strains with intermediate resistance can, in most instances, be treated like susceptible pneumococci. Special considerations exist in the treatment of pneumococcal meningitis, which is covered in Chapter 70.

If given intravenously for invasive pneumococcal infections other than meningitis, β -lactam antibiotics produce serum levels that are much greater than the MIC for intermediately resistant PNSP and usually exceed the MIC of highly resistant PNSP. Therefore, penicillin and other β -lactam antibiotics remain the mainstay of initial therapy for pneumococcal pneumonia and bacteremia. However, concerns about potential treatment failures have led to the recommendation that a third-generation cephalosporin,

TABLE 64.1**SUGGESTED INITIAL THERAPY FOR COMMON HOSPITAL PATHOGENS IN WHICH DRUG RESISTANCE IS A PROBLEM**

Organism	Initial therapy	Resistance common	Resistance emerging
<i>Escherichia coli</i>	Cephalosporin β-lactam/β-lactamase inhibitor combination Fluoroquinolone Aminoglycoside	Ampicillin Extended-spectrum penicillins Trimethoprim- sulfamethoxazole	Fluoroquinolones Cephalosporins
<i>Klebsiella</i> spp.	Fluoroquinolone Aminoglycoside Cephalosporin	Extended-spectrum penicillins	β-lactam/β-lactamase inhibitor combinations Cephalosporins
<i>Pseudomonas aeruginosa</i>	Antipseudomonal penicillin or Ceftazidime or Imipenem or meropenem or Cefepime	Antipseudomonal penicillins β-lactam/β-lactamase inhibitor combinations Ceftazidime Fluoroquinolones	Imipenem or meropenem
<i>Enterobacter spp.</i>	Plus amikacin or tobramycin ^a Trimethoprim- sulfamethoxazole Fluoroquinolone Imipenem or meropenem Cefepime	2nd- and 3rd-generation cephalosporins	Fluoroquinolones
<i>Streptococcus pneumoniae</i> ^b	2nd- or 3rd-generation cephalosporin Ampicillin or penicillin G (high doses)	Intermediate resistance to penicillin G and ampicillin Erythromycin Trimethoprim- sulfamethoxazole	High-level resistance to penicillin G and ampicillin 2nd- and 3rd- generation cephalosporins
Enterococci	Ampicillin or penicillin G +/- gentamicin ^c	Amikacin Streptomycin Tobramycin Tetracyclines Macrolides	Vancomycin Penicillin G Ampicillin Gentamicin Fluoroquinolones
<i>Staphylococcus aureus</i> ^d	Antistaphylococcal penicillin Vancomycin	Antistaphylococcal penicillins 1st-generation cephalosporins Fluoroquinolones	Vancomycin

Note: In some cases, there is significant resistance to the recommended initial regimen. Therefore, antibiotic therapy should be modified based on the results of *in vitro* susceptibility testing as soon as the results become available. Narrow-spectrum antibiotics should be substituted for broad-spectrum antibiotics whenever the resistance profile permits.

^a Most authorities recommend β-lactam-aminoglycoside combinations for serious infections, except those of the urinary tract.

^b For invasive infections other than meningitis, β-lactam antibiotics remain the initial treatment of choice. If high level resistance is identified, vancomycin, a 3rd-generation cephalosporin, or imipenem are commonly recommended, although high doses of ampicillin or penicillin G still may be effective.

^c Gentamicin should be added in cases of endocarditis and meningitis.

^d Vancomycin is recommended for initial treatment if the local prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) is >5%. Methicillin-susceptible strains usually are susceptible to 1st-generation cephalosporins and fluoroquinolones. However, MRSA strains usually are *not susceptible* to 1st-generation cephalosporins. More than half of MRSA strains are resistant to ciprofloxacin. Although the newer fluoroquinolones are more potent antistaphylococcal agents, resistance develops easily and may emerge during therapy.

imipenem, or vancomycin be used for invasive infections caused by known highly resistant PNSP. Studies to date have not demonstrated poorer outcomes associated with invasive PNSP versus sensitive strains (9).

Methicillin and Vancomycin-Resistant Staphylococci

S. aureus causes serious community-acquired and nosocomial infections. It is an important cause of skin and soft-tissue infections, bacteremia, endocarditis, osteomyelitis, and septic arthritis. *S. aureus* bacteremia is a particular problem because the organism has a tendency to seed deep tissue sites, which may lead to relapse. *S. aureus* produces several toxins that may lead to staphylococcal toxic shock syndrome (Chapter 25) or staphylococcal scalded-skin syndrome. Most hospital strains and the majority of community strains are resistant to penicillin because of the production of β -lactamases.

Methicillin-resistant *S. aureus* (MRSA) is a significant pathogen in hospitalized patients and residents of long-term care facilities, and is increasingly common in the community. Approximately 35% of *S. aureus* isolates in the United States are methicillin-resistant, but local rates vary considerably. MRSA are resistant to all β -lactam antibiotics, as well as multiple other antibiotics. Vancomycin has emerged as the most reliable agent for treating invasive MRSA infections. Unfortunately, vancomycin has relatively poor tissue penetration and slow bactericidal activity, which may lead to treatment failures. A number of agents have been tried in conjunction with vancomycin, but in most cases the combination has not proved superior to vancomycin alone. Many MRSA strains are resistant to fluoroquinolones, so these agents should not be used unless *in vitro* susceptibility is confirmed. Thus, with the increasing prevalence of MRSA, vancomycin use has dramatically increased, contributing to the development of vancomycin-resistant enterococci and the newly described strains of *Staphylococcus aureus* with reduced susceptibility or frank resistance to vancomycin. Although vancomycin is the drug of choice for established infections caused by MRSA, *its use should be severely restricted in other situations*. If one suspects an infection caused by *S. aureus* based on clinical criteria, or *S. aureus* has been isolated but antimicrobial susceptibilities are not yet known, vancomycin often is used empirically. However, *it should be stopped within 48–72 hours if MRSA is not detected*. (See Chapter 72 for a discussion of catheter infections caused by coagulase-negative staphylococci.)

S. aureus with intermediate susceptibility to vancomycin (MIC = 8–16 mcg/mL) were first identified in 1996 and have now been reported from the United States, Asia, and Europe (10). In 2002, *S. aureus* isolates with high level resistance to vancomycin were identified in the United States (11). Unlike the organisms with intermediate susceptibility, those with high level resistance appear to have acquired

one of the resistance mechanisms found in vancomycin-resistant enterococci. Intermediately resistant and resistant isolates appear to evolve from methicillin-resistant strains but remain susceptible to certain other antimicrobials, including trimethoprim-sulfamethoxazole, tetracyclines, quinupristin-dalfopristin, linezolid, and rifampin. In the cases described thus far, patients generally received vancomycin prior to isolation of resistant organisms. Although these organisms remain uncommon, their emergence has generated great concern. The Centers for Disease Control and Prevention have recommended close monitoring for these strains and strict isolation precautions for patients who are colonized or infected.

Vancomycin-Resistant Enterococci

Enterococci, even those considered to be “sensitive,” are intrinsically resistant to a number of antibiotics. For example, although penicillin (or ampicillin) has long been the preferred treatment, enterococci usually have only moderate susceptibility because of penicillin-binding proteins with low affinity. A cell-wall inhibitor (penicillin, ampicillin, or vancomycin) and an aminoglycoside (streptomycin or gentamicin) are required to kill the enterococcus; such killing is usually necessary to cure endocarditis and meningitis. Enterococci are part of the normal gut flora. Because of their intrinsic drug resistance, these organisms proliferate when patients are treated with antimicrobial therapy. Enterococci are among the most common nosocomial pathogens, and debilitated patients with serious underlying diseases are at greatest risk. Use of urinary or vascular catheters and ICU admission also increase a patient’s risk of enterococcal infection. Enterococci cause a number of infections, including urinary tract infection, bacteremia, endocarditis, and intraabdominal infection.

Vancomycin-resistant enterococci (VRE) emerged in the 1990s as difficult-to-treat pathogens that do not possess the same virulence as organisms such as *S. aureus*. Although outcomes appear to be worse in vancomycin-resistant enterococcal bacteremia compared with bacteremia because of sensitive enterococci, the difference is modest and has not been demonstrated in all studies (12). For those rare organisms that do not have high-level ampicillin or aminoglycoside resistance, these agents remain the drugs of choice. Quinupristin-dalfopristin is one option for treating infections caused by vancomycin-resistant *E. faecium*, which accounts for about 80% of VRE infections. Linezolid, given orally or intravenously, appears to be active against vancomycin-resistant *E. faecium* and *E. faecalis*, although experience with species other than *E. faecium* is limited. Efforts have focused on preventing the development and spread of VRE. Treatment with vancomycin, third-generation cephalosporins, and other antibiotics, especially those with anaerobic activity, is a strong risk factor for colonization or infection with VRE. Avoiding overuse of antibiotics is a critical part of combatting the increasing

prevalence of VRE. Current Centers for Disease Control guidelines recommend contact isolation and use of gloves and gowns for examining patients with VRE, although this approach is not efficacious in all settings.

Prevention of Resistance

As previously discussed, antibiotic selection pressure is the primary mechanism by which resistance develops. Using antibiotics in appropriately high doses if indicated also helps prevent the emergence of resistance. The goal of antibiotic dosing is to achieve a sustained antibiotic level that is greater than the organism's MIC. In addition, therapy should be given for the shortest period known to be effective, and empirical antibiotics should be discontinued promptly if an infection is not identified.

Patient-to-patient transmission is also an important consideration. Health care workers frequently are colonized with resistant organisms and may facilitate spread of resistant bacteria. *Strict adherence to hand cleansing after touching patients or the contents of the hospital room is essential.* Recent data support the superiority of using alcohol-based hand rubs over traditional handwashing for this purpose (13). Contaminated objects, such as thermometers, also can transmit bacteria from one patient to another. Therefore, rigorous attention must be paid to appropriate disposal of such items, or to adequate sterilization if they are to be reused. This approach must be adopted in all patients, not just those known to be colonized or infected (analogous to "universal precautions" for handling bodily fluids). If this infection-control practice is applied only to patients at known risk, transmission will probably occur prior to the detection of resistant organisms, even in hospitals with vigilant surveillance in place.

In outbreak situations, the use of barrier devices (e.g., gowns) and isolating infected or colonized patients may be effective. Treating carriers of some organisms, such as MRSA, has been investigated as a means of reducing infection and preventing the spread of resistant organisms. Mupirocin and other agents have been shown to be effective at reducing MRSA colonization in the oropharynx and nares and may reduce the incidence of MRSA pneumonia in patients in the ICU. However, recolonization is common, as is the development of resistance. Another strategy, which may be more helpful in the future, is vaccination against organisms with a propensity for antimicrobial resistance. Administration of pneumococcal vaccine has efficacy in preventing invasive pneumococcal disease.

CONCLUSIONS

The threat of multidrug-resistant bacteria is one of the world's greatest medical challenges. At this point, it seems unlikely that the development of effective new agents will keep pace with the ability of bacteria to evade them. The

potential future consequences are enormous, with some experts predicting a return to the conditions last seen in the preantibiotic era. Controlled use of antibiotics is the key to stemming this accelerating phenomenon. A reasonable compromise must be struck by taking resistance into account in prescribing antibiotics, yet not compounding the problem through the overzealous use of broad-spectrum antibiotics. Knowing the common pathogens in clinical syndromes, along with local resistance patterns, allows one to take a rational approach.

KEY POINTS

- Resistance is a consequence of antimicrobial exposure.
- Always choose drugs with a narrow spectrum of action, if possible; if initial coverage is broad, switch to a narrower-spectrum antibiotic once a pathogen is isolated.
- Always attempt to make a microbiologic diagnosis.
- Therapy should be continued for the shortest duration known to be effective.
- Except in a few instances, there is little evidence supporting the "double coverage" of organisms.

Community-Acquired Pneumonia

65

Ethan A. Halm Michael J. Fine

INTRODUCTION

There are approximately 4 million cases of community-acquired pneumonia (CAP) per year in the United States, resulting in more than 1 million hospitalizations. Thus, CAP is one of the most common inpatient medical conditions in both university and community hospitals, accounting for 2% of all hospital discharges. It is the most common infectious cause of death and is the sixth leading cause of death overall in the United States. The aggregate cost of hospitalization for the disease approaches \$9 billion per year. Wide variations in rates of hospitalization, intensive care, length of hospital stay, choice and duration of antibiotic therapy, and performance of key processes of care for pneumonia have been well documented within different geographic regions, different hospitals in the same area, and even within the same hospital. Substantial differences in hospitalization rates and length of stay for pneumonia persist even after adjusting for disease severity, comorbid conditions, and hospital characteristics.

The traditional approach to managing CAP has been oriented primarily toward inpatient care, with considerable effort expended to determine the specific microbiologic etiology. This often involves repeated diagnostic studies of sputum and blood. The heterogeneity of bacterial and viral causes of CAP has long been recognized. Traditionally, pathogens are classified as “typical,” referring to *Streptococcus pneumoniae* (the most common organism), *Haemophilus influenzae*, *Moraxella catarrhalis*, *Klebsiella pneumoniae*, other Gram-negative bacteria, and *Staphylococcus aureus*, among others. Atypical pathogens include *Mycoplasma pneumoniae*, *Legionella* spp., *Chlamydia pneumoniae* (TWAR), *Chlamydia psittaci*, and respiratory viruses.

There are several limitations to an etiology-oriented approach. First, microbiologic studies emphasize the difficulty of establishing a definitive, etiologic diagnosis in most cases of CAP, even when comprehensive microbiologic and serologic testing is performed. Second, contemporary series have highlighted broad geographic and seasonal differences in the relative incidence of various pneumonia pathogens. Finally, it is not possible to distinguish “typical” from “atypical” pathogens on the basis of the initial history, physical exam, and laboratory studies chapter (1–4).

This chapter describes a cost-effective, outcomes-oriented approach that de-emphasizes reliance on sputum studies in antibiotic selection and advocates the performance of key processes of care, such as the early institution of empiric, broad-spectrum antibiotics active against the most common pathogens. It also presents validated algorithms for risk-stratifying patients on presentation and outlines objective criteria for determining clinical stability so that patients can be safely converted to oral antibiotics and discharged in a timely fashion.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

The overall prevalence of CAP among unselected patients presenting with respiratory complaints ranges from about 3%–10%, depending on the setting. Unfortunately, there are no individual (or combination of) findings on the history, physical examination, or laboratory examination that can rule in or exclude the diagnosis of pneumonia with

adequate accuracy (4). Therefore, the diagnosis of CAP requires both the presence of *symptoms and signs of acute pulmonary infection and evidence of a new radiographic infiltrate*. Patients with pneumonia classically present with several days of fever, chills, sweats, shortness of breath, productive cough with purulent sputum, and pleuritic chest pain. Physical examination also reveals findings of lung consolidation, such as crackles, egophony, and increased fremitus. Unfortunately, the frequency and severity of these various signs and symptoms are highly variable. Nearly all patients (>90%) complain of cough and fatigue, two-thirds have dyspnea and sputum production, and about half have pleuritic chest pain. Nonrespiratory symptoms are present in 10%–30% of patients, including: headache, nausea and vomiting, abdominal pain, diarrhea, myalgias, arthralgias, and mental confusion. Older patients with pneumonia have significantly fewer symptoms than the non-elderly. Because of this phenomenon, the chest radiograph is an integral part of any workup of an elderly patient presenting with fever, constitutional symptoms, or mental status changes, even in the absence of respiratory complaints.

Fever is present in more than 80% of patients presenting with pneumonia, whereas hypothermia is present in 1%. Hypothermia is more frequent in elderly patients and those in nursing homes. Many patients also present with tachypnea, tachycardia, and diminished oxygen saturation. Approximately 80% of patients have crackles on auscultation, although classic physical findings of pulmonary consolidation are present in only 30% or fewer cases.

Differential Diagnosis and Initial Evaluation

The initial evaluation of patients presenting with suspected CAP should be aimed at confirming the diagnosis. Information from the history and physical examination is crucial in distinguishing patients with uncomplicated CAP from those with other pneumonia syndromes. A history of aspiration pneumonia or cerebrovascular disease, an impaired gag reflex, altered mental status, poor dentition, or foul-smelling sputum increases the likelihood of aspiration pneumonia. Post-obstructive pneumonia may present as recurrent episodes of pneumonia, particularly in those with a longstanding history of smoking. Patients who are immunosuppressed because of medications or HIV infection are at risk for opportunistic pathogens in addition to the organisms described previously.

Other noninfectious processes that should be part of the differential diagnosis include congestive heart failure, noncardiogenic pulmonary edema, pulmonary embolism, pulmonary hemorrhage, malignancy, collagen vascular disease or vasculitis, pulmonary-renal syndromes, and hypersensitivity pneumonitis. A careful clinical history and physical examination can usually define the likelihood of most of these nonpneumonia processes. Because of the high prevalence of congestive heart failure, a thorough cardiac history

and examination should be part of the initial evaluation of all patients suspected of having pneumonia.

Given the limited sensitivity and specificity of the history and physical examination, a chest radiograph is essential to confirm the diagnosis of pneumonia. Although the presence of a new pulmonary infiltrate is the gold standard for the diagnosis of pneumonia, it is important to recognize the limitations of chest radiography. There is some evidence that chest radiography might miss more subtle evidence of pulmonary consolidation compared to high-resolution computed tomography. False negative findings have also been reported in patients with dehydration on admission. Contrary to traditional teaching, radiographic appearance cannot accurately predict the etiology of pneumonia, nor does it differentiate bacterial from nonbacterial causes. Furthermore, agreement between radiologists interpreting the same chest radiographs is modest.

The chest radiograph can provide useful information about effusions, air-fluid levels (consistent with lung abscess), masses, and pulmonary vascular congestion. Pleural effusions are present in approximately 10% of patients with CAP. Bilateral effusions indicate more serious pneumonia with a higher risk of death during the short-term. Unusual findings of cavitation or miliary opacities can be helpful in suggesting other diseases. Characteristics of the radiographic infiltrate can be affected by a variety of features including underlying lung architecture, concomitant diseases (e.g., congestive heart failure or neutropenia), radiographic technique, and dehydration. In addition, both alveolar and interstitial opacities on chest radiograph may result from a variety of causes.

Although not necessary in the majority of patients with pneumonia, computed tomography of the chest may be useful in evaluating unusual cases or further characterizing pleural disease, cavitation, lymphadenopathy, or interstitial abnormalities. The absence of a pulmonary infiltrate in a patient suspected of having pneumonia should prompt strong consideration of alternative diagnoses.

There are no features of the history, physical examination, laboratory exam, or chest radiograph that are consistently predictive of a microbiological cause. Furthermore, there are no clinical or radiographic findings that allow one to accurately differentiate typical from atypical bacterial pathogens or bacterial from viral causes. Thus, the terms *typical* and *atypical* are misleading.

The usefulness of routine *sputum Gram stain and culture* is controversial. High-quality, uncontaminated sputum studies can help identify the causative organism and facilitate pathogen-tailored antibiotic therapy. However, sputum Gram's stain and culture tend to have low sensitivity, specificity, and predictive values. For example, the positive predictive value of finding *S. pneumoniae* on Gram's stain is about 30%–50%. The utility of sputum studies is further limited by the fact that about 30% of patients cannot produce an adequate sputum specimen, and 30% have received antibiotics prior to microbiologic testing. Even

when studies are positive, it is often hard to know whether the organism originated in the lung or oropharynx. The diagnostic yield of sputum studies is further limited by the fact that many common pathogens, including *Mycoplasma pneumoniae* and *Chlamydia pneumoniae*, are not seen on Gram stain and are difficult to culture from sputum. Thus, sputum studies generally add little clinically useful information in the initial selection of antibiotics for an individual patient. The antibiotic-susceptibility information generated by sputum cultures is probably their most valuable feature both in terms of assuring appropriate antibiotic sensitivity for an individual patient and for monitoring resistance patterns in a given hospital or community.

Blood cultures are positive in only 5%–10% of patients hospitalized with CAP. About one-half of positive cultures are thought to be contaminants. *Streptococcus pneumoniae* is the most common cause of true positive blood cultures (accounting for about 50% of confirmed bacteremias) followed by *Haemophilus influenzae*, Gram-negative rods, and *Staphylococcus* spp. Patients who are ill enough to be hospitalized should have two sets of blood cultures drawn prior to the initiation of parenteral antibiotics. In one large study, the standard use of blood cultures within 24 hours of presentation was associated with decreased case fatality rates (5). Thus, blood cultures are increasingly viewed as a key process of care in the treatment of this disease. Monitoring antibiotic susceptibility from blood isolates is also a key factor in tracking the progression of drug resistant organisms. However, the clinical utility of subsequent sputum or blood cultures, especially once antibiotics have begun, is extremely limited. Other normally sterile sites such as pleural fluid and cerebrospinal fluid may yield definitive microbiologic data, but these fluids are not routinely obtained unless there are specific clinical indications.

For patients in whom infection by *Legionella* organisms is a concern, radioimmunoassay tests for urinary *Legionella* antigen have demonstrated sensitivity of 75%–99% and specificity of 99%. These tests only detect *Legionella pneumophila* serotype 1, which accounts for about 70%–90% of all pneumonia resulting from *Legionella* organisms. *Legionella* infection can also be diagnosed rapidly by examination of pulmonary secretions with direct fluorescent antibody assays or specialized culture medium, though sensitivity of these tests tends to be lower (25%–80% and 50%–70%, respectively). Unfortunately, there are currently no rapid, commercially available tests for detecting *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Chlamydia psittaci*, or most respiratory viruses.

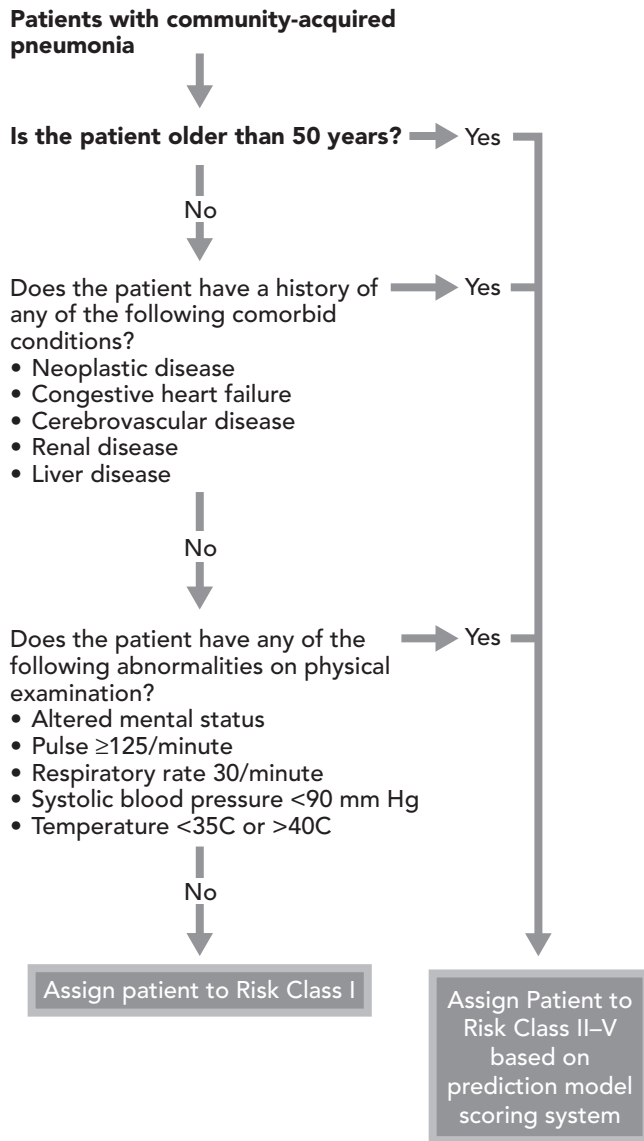

Although an early attempt at identifying a pathogen should be made in all patients, it is important to recognize that definitive microbial etiology is never found in 50%–70% of patients in usual practice, or in 30%–50% of patients in research studies. When an organism is recovered, it is increasingly common to find evidence of mixed infection. Fewer than 8% of patients have antibiotics changed because of the results of microbiological testing.

Because a definitive microbial diagnosis is not available in the vast majority of patients, antibiotic selection is usually empiric. Because of this, one should strongly consider covering potentially life-threatening pathogens such as *Legionella* spp., which are not covered by β -lactam antibiotics, especially in moderate- and high-risk cases. Though traditional teaching has emphasized *Legionella* spp. as the cause of severe pneumonia among the elderly and immunosuppressed, more recent data found that nearly half of patients with confirmed *Legionella* pneumonia had mild or moderate pneumonia and many patients had no major comorbidities or history of immunosuppression. Mixed infection with *Legionella* and other bacterial pathogens was also seen.

Indications for Hospitalization

The hospitalization decision should focus on three main factors: (1) the risk of short-term mortality and complications, (2) the patient's clinical stability, and (3) mitigating medical or psychosocial problems. The overall 30-day mortality rate from systematic reviews of CAP patients was 13.7%, ranging from 5.1% for cohorts that included ambulatory and hospitalized patients to 36.5% for a series of intensive care unit patients (4, 5). A validated prediction rule for quantitation of risk for persons with CAP is presented in Figure 65.1. This Pneumonia Severity Index (PSI) prediction rule relies on information readily available at the time of initial presentation and can be used to stratify patients into five risk classes with mortality rates ranging from 0.1%–27% (6). Use of this prediction rule to aid the admission decision has been endorsed by recent U.S. and Canadian national subspecialty practice guidelines for CAP (1–3, 7). Figure 65.2 outlines an algorithm for using the PSI risk-stratification information in combination with other key clinical data to determine whether a patient should be admitted or treated as an outpatient (8). Patients with contraindications to outpatient treatment caused by hypoxemia (room-air oxygen saturation less than 90% or PaO₂ less than 60 mm Hg), hemodynamic instability (shock or hypotension not responsive to initial fluid resuscitation), or active coexisting conditions requiring hospitalization should be admitted independent of their PSI Risk Class. Absent these acute features, patients should be risk-stratified using the PSI prediction rule depicted in Figure 65.1. Patients in Risk Classes I through III can be considered low risk, with a cumulative 30-day mortality rate of less than 1%, and can be managed as outpatients. Some patients in Risk Classes I through III may have other mitigating factors such as frail physical condition, poor response to oral therapy, substance abuse, or other psychosocial issues that may be relative contraindications to initial outpatient management. For these patients, alternatives to standard inpatient admission include brief inpatient admission, 23 hours of observation, admission to a sub-acute or intermediate care facility, "enhanced" home care (initial home parenteral antibiotic therapy with visiting nurse monitoring), and close outpatient follow-up.

Algorithm

Scoring System

Patient Characteristics	Points Assigned ^a
Demographic Factors	
Age: Males	age (y)
Females	age (y) – 10
Nursing home resident	+10
Comorbid Illnesses	
Neoplastic disease	+10
Liver disease	+20
Congestive heart failure	+10
Cerebrovascular disease	+10
Renal disease	+10
Physical Examination Findings	
Altered mental status	+20
Respiratory rate ≥30/minute	+20
Systolic blood pressure <90 mm Hg	+20
Temperature <35 or ≥40C	+15
Pulse ≥125/minute	+10
Laboratory Findings	
pH <7.35	+30
BUN >30 mg/dL	+20
Sodium <130 mEq/L	+20
Glucose >250 mg/dL	+10
Hematocrit <30%	+10
pO ₂ <60 mm Hg ^b	+10
Pleural effusion	+10

^aA risk score (total point score) for a given patient is obtained by summing the patient age in years (age – 10 for females) and the points for each applicable patient characteristic.

^bOxygen saturation <90% also was considered abnormal.

Stratification of Risk Score

Risk	Risk Class	Based on	Mortality
Low	I	Algorithm	0.1%
Low	II	≥70 total points	0.6%
Low	III	71-90 total points	0.9%
Moderate	IV	91-130 total points	9.3%
High	V	>130 total points	27.0%

Figure 65.1 Prediction model for identification of patient risk for persons with community-acquired pneumonia. (Adapted from Fine MJ, Auble TE, Yealy DM, et al. Improving the appropriateness of hospital care in community-acquired pneumonia: a prediction rule to identify patients at low risk for mortality and other adverse medical outcomes. *N Engl J Med*, 1997;336:243–250, with permission.)

This choice depends on the needed level of clinical monitoring, patient frailty, requirements for functional assistance, and patient and family preferences, as well as the local availability of these options. One implication of the algorithm is that age greater than 65 alone is not sufficient reason for hospitalization.

All patients in Risk Classes IV and V should be admitted to the hospital, given their significantly higher mortality and complication rates unless there are extenuating circumstances (e.g., terminal care). Other indications for admission

include suspected or confirmed suppurative or metastatic complication (empyema, lung abscess, endocarditis, meningitis, or osteomyelitis) or the presence of high risk pathogens (e.g., *S. aureus*, anaerobes, and Gram-negative rods). For patients in Risk Classes I through III who are admitted because of nonmedical factors, consideration should be given to lower cost alternatives of care if such options are available.

A large multicenter, randomized controlled trial of a critical pathway for the treatment of pneumonia provides strong evidence that a PSI-based admission decision algo-

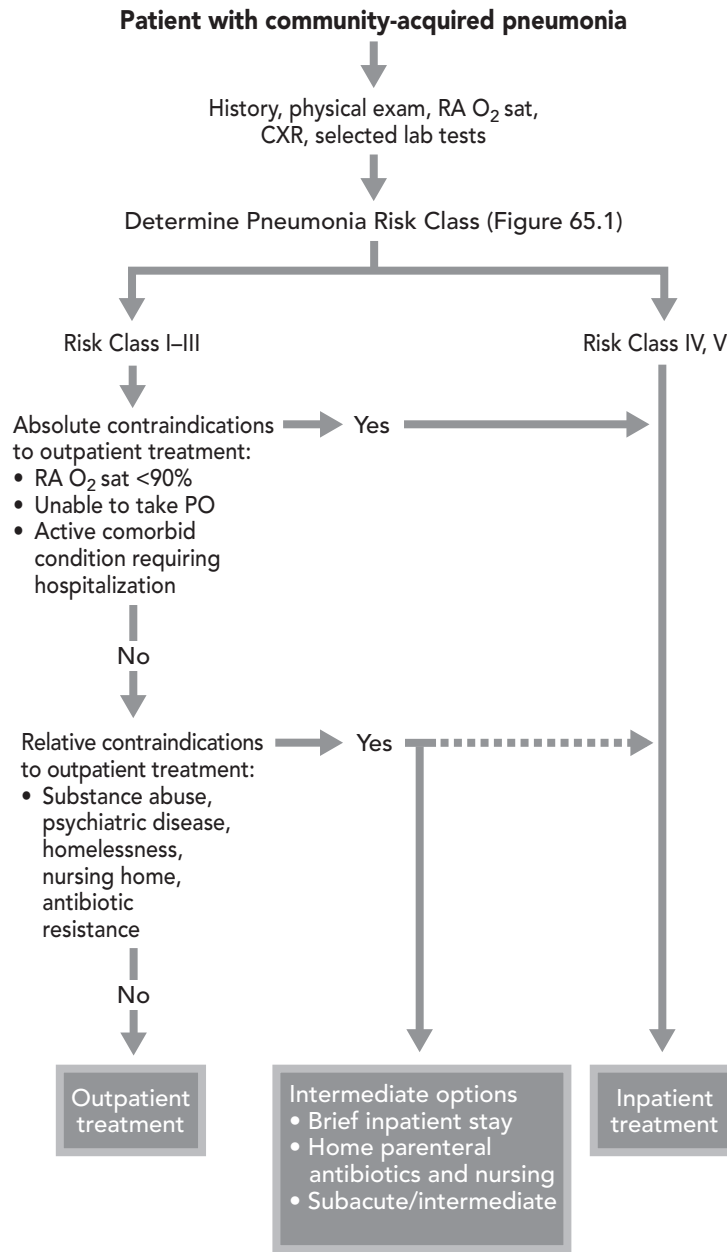

Figure 65.2 Hospitalization decision tree. CXR, chest radiograph; RA, room air.

rhythm is safe and effective (9). Compared to control sites, hospitals randomized to implement the pneumonia pathway admitted significantly fewer low risk patients (defined as PSI Risk Class I through III, 31% vs. 49%). There were no changes in admission rates among moderate- or high-risk cases (Risk Classes IV through V) for whom the protocol recommended hospitalization. Although use of the hospital decreased, there were no differences between the two groups in ICU use, mortality, readmissions, complications or health-related quality of life at 2 and 6 weeks. This study confirms the results of an earlier single institution intervention trial that found that a PSI-based emergency department guideline reduced admissions among low-risk patients from 58%–43% without adverse effects on

mortality, symptom resolution, functional recovery or patient satisfaction (10). It is worth noting that in both studies approximately 30%–40% of low risk patients still required hospitalization because of clinical severity, other active clinical problems, psychosocial circumstances, or patient preferences.

Indications for Initial Intensive Care Unit Admission

In a large, multicenter CAP study, 9.2% of inpatients were admitted to an ICU, including 11.4% of class IV patients and 17.3% of class V patients (6). Clear indications for ICU admission include hemodynamic instability resulting from

sepsis syndrome or hypovolemia, respiratory failure requiring mechanical ventilation, and severe hypoxemia or respiratory distress meriting close observation and frequent monitoring of clinical status or arterial blood gases. Given the high anticipated mortality rate, ICU care is appropriate for many patients in Risk Class V. Patients with coexisting exacerbations of comorbid conditions or with severe metabolic derangements may also benefit from a higher level of monitoring and treatment.

Initial Therapy

Because the responsible pneumonia pathogen is not known in the majority of cases in usual practice, the early initiation of empiric, broad-spectrum antibiotic therapy is strongly recommended. Our recommendations for first-line parenteral therapy in patients hospitalized with CAP are: (1) a second-generation or third-generation cephalosporin (e.g., cefuroxime, ceftriaxone, ceftizoxime, or cefotaxime) plus a macrolide or doxycycline, or (2) an anti-pneumococcal fluoroquinolone (e.g., gatifloxacin, levofloxacin, or moxifloxacin) (1–3, 8). These antimicrobial regimens were associated with 30% lower risk-adjusted odds of death within 30 days compared with therapy with a third-generation cephalosporin alone (11). Combination β -lactam and β -lactamase inhibitors with a macrolide (or doxycycline) is another alternative, although these regimens have not appeared to be as clinically effective in recent outcome studies. Antibiotic regimens that cover both typical and atypical pathogens have also been associated with shorter lengths of stay. Older fluoroquinolones (ciprofloxacin and ofloxacin) have been associated with treatment failure in some patients with pneumococcal disease. The newer fluoroquinolones (levofloxacin, gatifloxacin, moxifloxacin, sparfloxacin, and gemifloxacin) have greater activity against *S. pneumoniae* and *S. aureus*, and provide excellent coverage against atypical bacterial pathogens, including *Legionella* spp. As of January 2005, gatifloxacin, levofloxacin, and moxifloxacin were the primary anti-pneumococcal fluoroquinolones available as intravenous and oral preparations. Because of reports of severe hepatotoxicity, the use of alatrofloxacin/trovafloxacin is restricted to use on inpatients with no other safe and effective alternatives.

As suggested by the most recent American Thoracic Society guidelines, parenteral azithromycin alone may also be appropriate for empiric treatment of selected, low-risk patients (non-ICU patients without underlying cardiopulmonary disease who do not have risk factors for Gram-negative rods or drug-resistant *S. pneumoniae* [2]). However, the Infectious Disease Society of America guidelines do not recommend macrolide monotherapy as first-line therapy (1). Uncertainty about growing resistance to macrolides among drug-resistant pneumococcal isolates may explain some of the discrepancy among the different subspecialty recommendations. For individuals with

β -lactam allergy, an anti-pneumococcal fluoroquinolone (or azithromycin for a low-risk patient) would be a safe, broad-spectrum alternative.

Antibiotic recommendations for the treatment of confirmed cases of *Legionella* pneumonia have changed over the last few years. A fluoroquinolone or azithromycin are now considered to be first line choices, replacing the traditional regimen of high dose erythromycin (1 gram every 6 hours) because of their greater penetration into lung tissue, in vitro activity, and lower toxicity profile. Other acceptable alternatives include tetracycline, doxycycline, or clarithromycin. For severe cases of *Legionella*, many experts recommend adding rifampin to a fluoroquinolone or azithromycin.

Empiric treatment of patients requiring ICU admission should include two drugs to cover the increased risk of *S. aureus*, *Legionella*, drug-resistant pneumococci, *Pseudomonas aeruginosa*, and other Gram-negative bacteria. Patients with no increased risk for *Pseudomonas aeruginosa* or other resistant Gram-negative rod infection should receive one of the following combination regimens: (1) a third-generation cephalosporin plus an anti-pneumococcal fluoroquinolone or macrolide or (2) β -lactam/ β -lactamase inhibitor plus an anti-pneumococcal fluoroquinolone or macrolide (1–3). Observational data suggest that dual therapy is associated with lower mortality rates for patients with bacteremic pneumococcal pneumonia. Those at increased risk for *Pseudomonas aeruginosa* or other resistant Gram-negative rod infection should be treated with an anti-pseudomonal β -lactam plus an aminoglycoside plus an anti-pneumococcal fluoroquinolone or macrolide. Administration of two anti-pseudomonal agents is recommended for synergy until culture and sensitivities can rule out the possibility of resistance. If a definitive diagnosis becomes available, antimicrobial coverage should be narrowed according to the specific drug sensitivities.

There are some situations in which these antibiotic recommendations may not be optimal. Residents of institutional settings such as nursing homes have higher rates of methicillin-resistant staphylococcal pneumonia and may require coverage with vancomycin until culture results and sensitivities are known. Patients with aspiration pneumonia should be treated with an antimicrobial agent with activity against oropharyngeal anaerobes (e.g., clindamycin or β -lactam/ β -lactamase inhibitor). Cases with a more protracted clinical presentation, hemoptysis, significant weight loss, or anemia should raise suspicion of more indolent pulmonary infections such as tuberculosis or fungal disease. In these instances, respiratory isolation should be immediately instituted until tuberculosis can be ruled out.

Increasing rates of drug-resistant *S. pneumoniae* (DRSP) and reduced susceptibility to a growing number of agents make generic antibiotic selection recommendations challenging. While penicillin resistance among DRSP isolates is often of greatest concern, high levels of

cross-resistance to macrolides, tetracyclines, and amoxicillin/clavulanic acid have also been documented (12). Therefore, clinicians need to be cognizant of local antibiotic resistance patterns. Reduced susceptibility of DRSP to the antipneumococcal fluoroquinolones (gatifloxacin, levofloxacin, and moxifloxacin) is uncommon, but is likely to grow given their widespread use.

The laboratory and clinical definitions of drug resistance are also in flux and not always the same. The historical MIC cutpoints for DRSP were based on data regarding the treatment of meningitis, not pneumonia, sinusitis, or otitis media. The Drug-Resistant *Streptococcus pneumoniae* Therapeutic Working Group recommends that the break points for interpreting penicillin susceptibility of *S. pneumoniae* isolates in patients with pneumonia be revised upward (12) to define susceptibility of pulmonary isolates as an MIC ≤ 1 mcg/mL, intermediate ≤ 2 mcg/mL, and resistant ≥ 4 mcg/mL. The clinical significance of intermediate-level resistance in terms of altering antimicrobial therapy for pneumococcal pneumonia is unknown and is an area of active investigation. However, for confirmed, high-level penicillin-resistant *Pneumococcus* spp. (MIC ≥ 4.0 mcg/mL), a highly active anti-pneumococcal fluoroquinolone, vancomycin, or possibly clindamycin are the drugs of choice. Because of concerns about the overuse of vancomycin increasing resistance, empiric use of vancomycin for patients with CAP is not recommended unless there is suspicion or documentation of accompanying penicillin-resistant pneumococcal meningitis (Chapter 70) (2–4).

Indications for Early Consultation

Between 80%–90% of cases of pneumonia are cared for by generalist physicians. There are no data to support the routine use of pulmonary or infectious disease consultation for most uncomplicated cases of CAP. However, early infectious disease consultation should be considered if unusual or highly resistant pathogens are identified. Early pulmonary consultation is indicated when diagnostic bronchoscopy is needed. If pneumonia is complicated by empyema, a surgeon or interventional radiologist should be consulted for placement of a chest tube for pleural drainage. Consultation with a pulmonary specialist also may be helpful for patients with respiratory failure requiring mechanical ventilation or when noninfectious pulmonary processes are suspected. Specialty consultation is also recommended for patients with CAP who fail to improve according to the timeline described below or who are getting worse.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Figure 65.3 shows a sample critical pathway for CAP that delineates the multidisciplinary processes of care during

the hospital stay. The initiation of parenteral antibiotics as early as possible should be a high priority. Patients who receive intravenous antibiotics within the first 8 hours of presentation have higher rates of survival compared with those in whom antimicrobial therapy was delayed (5). Recent data suggest that the receipt of antibiotics within 4 hours of arrival confers an additional survival benefit (13). Practically, this means that a patient needs to receive his or her first dose of antibiotics in the emergency department. All patients should have room-air oxygen saturation assessed, and supplemental oxygen should be administered to those individuals with oxygen saturation less than 90%–92%. The correlation between oxygen saturation measurements by pulse oximetry and the actual PaO₂ may differ at altitude and vary according to the degree of skin pigmentation. Patients with chronic hypoxemia should have oxygen therapy titrated to achieve their normal baseline PaO₂ or oxygen saturation. Intravenous fluids should be administered for volume depletion or inability to take fluids by mouth. Bronchospasm should be treated with bronchodilators delivered by metered-dose inhalers or by nebulizer. If the patient is not ambulatory and is likely to be bedridden for several days, prophylactic administration of subcutaneous heparin should be considered to prevent the development of deep vein thrombosis. Fever and pleuritic chest pain can be treated with acetaminophen or nonsteroidal anti-inflammatory drugs if there are no contraindications.

The risk of clinical deterioration is greatest during the first 2 days of hospitalization (14). Nearly two-thirds of ICU, CCU, or telemetry unit admissions in patients with pneumonia occur on the day of admission. Another 15% occur on the day after admission. Therefore, close monitoring of vital signs, oxygen saturation, need for supplemental oxygen, mental status, and clinical stability is imperative and ought to be performed a minimum of three to four times a day in the first two days. In addition, a nursing assessment of the patient's home situation, activities of daily living, and cognitive abilities should be done in the first 24 hours of hospitalization to help anticipate major problems that may delay hospital discharge significantly once a patient is medically stable. Because the average patient will become clinically stable on days 3 or 4, laying the groundwork to facilitate timely discharge must begin shortly after admission (14).

On day 2, microbiology results should be checked and the antibiotic regimen adjusted as appropriate if a definitive pathogen is identified. The official interpretation of the initial chest radiograph should also be verified, because preliminary readings may be revised or alternative causes for pulmonary opacities suggested. By day 2, most patients should be euvolemic. If the patient is able to take fluids by mouth, supplemental intravenous fluids can be discontinued. Vital signs should continue to be monitored regularly and supplemental oxygen titrated to the oxygen saturation.

Patients who are clinically stable should be encouraged to increase their activity level as tolerated to avoid the deconditioning that can occur with bedrest. Physical therapy should be consulted as appropriate. Discharge planning and patient education about pneumonia should continue.

The time to clinical stability in patients hospitalized with CAP is much more rapid than previously appreciated. Among patients with vital sign abnormalities on presentation, the median time to stabilization of the heart rate (≤ 100 beats/min) and systolic blood pressure (≥ 90 mm Hg) is 2 days. Hospital day 3 is the median day that respiratory rate (≤ 24 breaths/min), oxygen saturation ($\geq 92\%$), and temperature ($\leq 99^\circ$ F [37.2° C]) abnormalities stabilize. By hospital day four, over 75% of all heart rate, blood pressure, respiratory, and temperature abnormalities resolve, as do 65% of all oxygenation deficits. The time to overall clinical stability, defined as stable vital signs, baseline mental status, and ability to eat, varies depending on the pneumonia severity on presentation. The median time to clinical stability is three days for low-risk patients (Risk Class I through III), four days for moderate-risk patients (Risk Class IV), and six days for high-risk patients (Risk Class V) (14).

For patients without metabolic or hematologic derangements or other active comorbid conditions on presentation, the utility of daily laboratory testing is low. Repetition of sputum studies or blood cultures is rarely indicated in uncomplicated cases because the diagnostic yield of such studies is very low once parenteral antibiotic therapy has been initiated. Similarly, repeat chest radiographs are rarely needed and should be reserved for patients who are not improving as expected or who are getting worse.

Administration of a 7- to 10-day course of intravenous antibiotics was once a central tenet of managing patients hospitalized with CAP. Many studies now indicate that early conversion from parenteral to oral antibiotic therapy is safe, clinically effective, and less expensive. Other potential advantages of streamlined antibiotic therapy include decreased incidence of phlebitis and line sepsis, and earlier return to usual activities. Table 65.1 describes criteria for deciding when patients are stable and can be converted from parenteral to oral antibiotics (14, 15). Randomized trial data support the safety of converting patients from intravenous to oral antibiotics shortly after they become stable, often after just a few days of parenteral therapy (15). In addition, newer agents (e.g., fluoroquinolones) can achieve high serum drug levels with oral administration, suggesting the possibility of initial oral therapy in certain uncomplicated patients with a functioning gastrointestinal system.

A variety of clinical characteristics, including initial disease severity, comorbidities, and response to treatment influence when an individual patient reaches clinical stability. However, once a patient reaches stability according to the criteria listed in Table 65.1, the risk of clinical deterioration serious enough to require admission to an ICU, CCU, or telemetry unit is 1% or less, even among the sickest subset of patients (14). Therefore, the use of explicit,

TABLE 65.1

CRITERIA FOR IDENTIFYING IF PATIENTS ARE CLINICALLY STABLE AND READY TO BE CONVERTED FROM PARENTERAL TO ORAL ANTIBIOTIC THERAPY

Patient with stable vital signs for ≥ 24 hours, defined as:

Temperature $\leq 37.8^\circ$ C (100° F)
Heart rate ≤ 100 beats/min
Spontaneous respiratory rate ≤ 24 breaths/minute
Systolic blood pressure ≥ 90 mm hg (without vasopressor support)
Normal oxygenation on room air (O_2 saturation $\geq 90\%$)
Patient able to ingest and digest tablets, capsules, or liquids
No evidence of a metastatic infection site

physiologic criteria for defining appropriateness for conversion to oral antibiotics is more clinically sensible than practice guidelines, critical pathways, or utilization rules that rigidly prespecify days on which certain actions should occur. From an epidemiological standpoint, hospital days three and four appear to be a critical point of inflection in recovery from pneumonia for most uncomplicated cases. Patients who have not met vital sign stability criteria, have suppurative complications, or have *S. aureus* or Gram-negative bacteremia should receive longer courses of intravenous antibiotics.

There are no data to support the traditional practice of observing patients on oral therapy for 24 hours or requiring all temperature measurements to be absolutely normal prior to discharge. Patients can be discharged within 24 hours of stability and antibiotic conversion without any adverse effects on patient outcomes and recovery. Chest physical therapy should not be part of routine care, because randomized controlled trials in patients with pneumonia have found no clinical benefits.

It is important to recognize when a patient is failing to improve as anticipated (as described previously) or is getting worse. Warning signs include persistent heart rate, blood pressure, and respiratory rate abnormalities beyond day four and continued fever spikes or abnormal oxygen saturation beyond day six. Symptoms of worsening dyspnea, wheezing, chest pain, or mental status are also of grave concern. There are several diagnostic and therapeutic issues to consider if patients appear to be off the usual trajectory for recovery (Table 65.2). First, a repeat chest radiograph should be obtained to assess the possibility of a new or increasing pleural effusion. If a new pleural effusion is present, thoracentesis should be performed to determine the presence of empyema or to provide symptomatic relief. Second, culture and sensitivity data should be reviewed, and resistant or unusual infectious pathogens considered. Third, the possibility of a metastatic source of infection should be readdressed. Fourth, the possibility of a noninfectious pulmonary process should be entertained. Finally, an infectious disease or pulmonary

TABLE 65.2**CONSIDERATIONS FOR PATIENTS FAILING TO IMPROVE OR GETTING WORSE AFTER EMPIRIC THERAPY FOR PRESUMED COMMUNITY-ACQUIRED PNEUMONIA**

Reasons for failure to improve or worsening	Recommended approach
Uncovered bacterial pathogen (e.g., <i>Legionella</i>)	Additional microbiologic testing Broaden antibiotic regimen to cover atypical bacterial organisms Consider infectious disease consultation
Uncovered nonbacterial pathogen (e.g., virus, tuberculosis, fungus)	Additional microbiologic testing Broaden antibiotic regimen Consider infectious disease consultation
Resistant bacterial pathogen (e.g., highly resistant <i>Streptococcus pneumoniae</i>)	Check drug sensitivities Switch to/add vancomycin or highly active anti-pneumococcal fluoroquinolone Obtain infectious disease consultation
Nosocomial or opportunistic infection	Notify hospital infection control Reconsider possibility of hospital-acquired or opportunistic infection (e.g., HIV disease) Targeted laboratory testing for immunosuppression
Airway obstruction by mass	Especially if history of recurrent pneumonia, smoking, cancer, or chest radiograph indicates volume loss or adenopathy Consider chest computed tomography, pulmonary consultation, or bronchoscopy
Development of empyema	Repeat chest radiograph, with lateral decubitus films if effusion is present Diagnostic thoracentesis Chest tube drainage if empyema present
Metastatic source of infection (abscess, endocarditis, osteomyelitis, septic arthritis)	Thorough examination and workup looking for evidence of seeding of other organs Repeat chest radiograph, urinalysis, blood cultures, etc. Obtain appropriate fluid samples from normally sterile sites that may be infected
Noninfectious pulmonary process	Consider possibility of pulmonary edema, embolism, hemorrhage, vasculitis, pulmonary-renal syndromes, hypersensitivity pneumonitis, neoplasm, etc. Targeted imaging and laboratory studies

medicine consultation should be considered to assist in subsequent diagnosis and treatment.

DISCHARGE ISSUES

Criteria for identifying when patients are clinically stable and ready to be discharged from the hospital are listed in Table 65.3. The risk of adverse outcomes once clinical stability has been attained is quite low. Conversely, patients who are discharged prior to becoming stable have higher risk-adjusted rates of death or readmission and slower return to usual activities (16). Furthermore, the safety of these types of discharge criteria has been confirmed by several randomized controlled trials and observational studies (9,15).

TABLE 65.3**CRITERIA FOR IDENTIFYING WHETHER PATIENTS ARE CLINICALLY STABLE AND READY TO BE DISCHARGED FROM THE HOSPITAL**

Patients should meet all criteria in Table 65.1 for conversion to oral antibiotics and should also:

- Be tolerating oral antibiotics (give first dose in hospital, but no need to observe for 24 hours on oral antibiotics)
- Have returned to normal (or baseline) mental status
- Have no evidence of acute comorbid condition that necessitates continued inpatient management or close observation (such as active cardiovascular, pulmonary, renal, hepatic, or endocrine disease)

Most patients with pneumonia are ready to be converted to oral therapy on the day they reach stability and to be discharged shortly thereafter. At the time of discharge, patients should have stable vital signs, adequate room-air oxygen saturation, baseline mental status, and be able to tolerate oral medicines and fluids. The presence of other active comorbid conditions that themselves require hospitalization may also delay discharge. Although most patients have a fever curve on a downward trend, it is not imperative that patients have completely normal temperatures prior to discharge. The natural history of pneumonia symptoms can be quite prolonged. More than 80% of all ambulatory and hospitalized patients experience persistent fatigue and cough, and more than 50% complain of dyspnea and sputum production at day 7. Remarkably, prolonged fatigue and cough are present in 65% and 53% of patients, respectively, 30 days after presentation. Though these symptoms are not reasons in themselves for continued hospitalization, it is important that patients be told that it may take a few weeks before their symptoms are fully resolved and they will be able to return to their usual activities.

There may be special circumstances in which patients with poor functional status appear stable but still require low-flow supplemental oxygen, parenteral antibiotics, periodic nursing, physical therapy, or other services not related to their pneumonia. Several alternatives to continued acute care hospitalization can be considered. Some patients may be appropriate candidates for transfer to a sub-acute or intermediate care facility for continued treatment (intravenous antibiotics), monitoring, and rehabilitation. Use of once-a-day parenteral antibiotics (e.g., ceftriaxone, levofloxacin, or gatifloxacin) can minimize the frequency and intensity of visiting nurse services. Low-flow oxygen by nasal cannula can be safely administered at home. Patients who require more intensive oxygen therapy should be treated in postacute care facilities.

Although the optimal duration of antibiotic therapy has not been extensively studied, most experts recommend a total course of 10–14 days. Patients with documented *Legionella* pneumonia should receive 14–21 total days of antibiotics, with the longer courses used in immunosuppressed patients or those with severe pneumonia. The selection of oral antibiotics to finish the course of treatment should be guided by the desired microbial coverage, previous intravenous regimen, patient tolerance, and cost. Culture and sensitivity data, if available, should be reviewed to help guide selection of the narrowest spectrum, most cost-effective agent. Because no definitive pathogen will be identified in 50%–70% of cases, the choice of oral agent will most often be empiric. Options for empiric oral monotherapy (in no particular order) include a macrolide (azithromycin, clarithromycin, erythromycin), an anti-pneumococcal fluoroquinolone, or doxycycline. Doxycycline is the least costly regimen. Among macrolides, azithromycin and clarithromycin are preferred if *H. influenzae* is suspected. These two agents may also result in better

patient compliance compared to erythromycin because of less frequent dosing and fewer gastrointestinal side effects. Other appropriate, but slightly more complicated alternatives are a β -lactam plus a macrolide or a β -lactam and doxycycline. Trimethoprim-sulfamethoxazole can no longer be recommended as a first-line oral agent in pneumonia because of the high rates of pneumococcal drug resistance.

Other opportunities to improve the quality of care and patient health at the time of discharge are *pneumococcal vaccination* and *smoking-cessation counseling*. Hospital-based vaccination of patients with CAP is safe and effective, particularly because it targets patients who have proven to be truly at risk. Patients who are smokers should be strongly advised to quit, and smoking cessation strategies and medications should be discussed. Educational, resource, and motivational information to support smoking cessation are readily available from the American Cancer Society and the American Lung Association.

All patients should have arrangements made for outpatient follow-up to assure compliance with oral therapy and complete disease resolution. It generally is recommended that patients who smoke should have a chest radiograph repeated 4–6 weeks after discharge to exclude the possibility of postobstructive pneumonia caused by lung cancer. It is important to recognize, however, that only 50% of pulmonary infiltrates clear radiographically by 6 weeks.

COST CONSIDERATIONS AND RESOURCE USE

The hospitalization decision is the most important issue from the perspective of reducing the costs of treating patients with CAP. Hospital care for pneumonia is 10–20 times more expensive than outpatient management. The risk-stratification prediction rule outlined previously helps rationalize this critical triage decision. Implementation of this admission decision guideline in two studies resulted in a 25% and 37% relative decrease in hospitalization rates among low-risk patients without any adverse effects on patient outcomes or recovery (9, 10).

Among inpatients, the duration of hospital stay is the single best determinant of total resource use. Thus, optimizing the discharge decision so that patients are converted from parenteral to oral antibiotics soon after reaching stability and are discharged shortly thereafter, as appropriate, should have the second greatest impact on resource use. Adopting this streamlined approach to decision making has been estimated to potentially reduce the total number of hospital days for pneumonia by 60% (14). The early transition to oral antibiotics and the use of less expensive agents is another means of reducing medication costs. Avoiding standard ordering of multiple sputum studies, repeat chest radiographs, and daily blood tests, which have low diagnostic yield and rarely change management, also may reduce inpatient costs.

KEY POINTS

- Evidence-based practice guidelines and critical pathways can greatly reduce practice variation and improve the quality and efficiency of treatment for this common condition.
- By utilizing an admission decision algorithm based on readily available clinical data, clinicians can identify a subset of patients who may be safely managed as outpatients, thereby decreasing the admission rates of low-risk patients.
- Low-risk patients with contraindications to outpatient therapy and moderate- or high-risk patients should be admitted.
- A simple attempt at microbiological diagnosis, with blood cultures, should be performed early, prior to the initiation of parenteral antibiotics. Because there are no features of the history, physical exam, laboratory studies, or chest radiograph that are useful for determining microbial etiology, patients should be quickly started on an empirically guided, broad-spectrum antibiotic regimen covering common “typical” and “atypical” bacterial pathogens.
- Patients who are severely ill should be rapidly stabilized in an ICU or other monitored setting.
- Patients can be converted to oral antibiotics and discharged shortly thereafter once clinical stability criteria have been met, most often by days three or four.
- Shorter courses of parenteral antibiotics can lead to significantly shorter, less expensive hospital stays with excellent clinical outcomes.

Hospital-Acquired Pneumonia

66

Donald E. Craven Catherine A. Fleming Kathleen A. Steger Craven

INTRODUCTION

Hospital-acquired pneumonia (HAP) (or nosocomial pneumonia) is defined as an infection of lung parenchyma not present at the time of hospital admission. Although HAP is the second most common nosocomial infection in the United States, it is the most serious in terms of mortality and morbidity rates (1–4). Crude mortality rates range from 10% to 40% and are highest in elderly, mechanically ventilated patients and those with serious underlying disease, bacteremia, or infection with more virulent organisms such as *Pseudomonas aeruginosa*. In case-control studies, the mortality rate directly attributed to pneumonia has been estimated to be 30% (1–4).

Aspiration of bacteria colonizing the oropharynx is the most common route of pulmonary infection. In nonventilated patients, increased sedation, change in mental status, and vomiting are important risk factors for aspiration. In mechanically ventilated patients, aspiration may occur during intubation or from leakage of secretions around the endotracheal tube. HAP may be caused by a variety of bacteria, and most infections are caused by more than one pathogen (1–4) (Table 66.1). Early-onset HAP occurs during the first four to seven days of hospitalization and is usually caused by “community-acquired pathogens” such as *Streptococcus pneumoniae* or *Haemophilus influenzae*. By comparison, late-onset disease is more often caused by more antibiotic-resistant or multidrug-resistant (MDR) nosocomial pathogens, such as *P. aeruginosa*, *Acinetobacter* spp., or methicillin-resistant *Staphylococcus aureus* (MRSA). Patients who have been in health care facilities, received antibiotics during the previous 90 days, have organ failure or structural lung disease, are immunosuppressed, or are receiving immunosuppressive therapy or dialysis are also

at risk for infections because of MDR pathogens (1–4) (Chapter 64).

ISSUES AT THE TIME OF DIAGNOSIS

Clinical Features and Diagnosis

Despite its poor specificity, most clinicians continue to rely on a clinical diagnosis of pneumonia, which is based on presenting symptoms of fever, cough, and shortness of breath, along with a new infiltrate on chest radiograph and the analysis of expectorated sputum or endotracheal aspirates. One can increase the specificity for the diagnosis of ventilator-associated pneumonia (VAP) by using quantitative analysis and Gram stains of endotracheal aspirates or bronchoalveolar lavage fluid, although these methods are not universally available in hospitals (3–6).

The initial evaluation of patients with suspected HAP is shown in Figure 66.1 and involves confirming the presence of an intrapulmonary process, establishing the presence and severity of infection, and ruling out alternative diagnoses such as atelectasis, pulmonary embolus, or congestive heart failure. Symptoms suggesting HAP include fever, cough, purulent sputum production, dyspnea, change in mental status, and pleuritic chest pain. For mechanically ventilated patients, pneumonia is often heralded by a change in secretions, increased oxygen requirements, new or increased infiltrate on chest radiograph, leukocytosis, or fever.

Physical examination may reveal fever, tachycardia, and tachypnea, with cyanosis and respiratory distress in severe cases. Additional signs may include lung consolidation, pleuritis, effusion, and changes in oxygenation requirements. Alternative causes of persistent fever and

their evaluation in hospitalized patients are discussed in Chapter 62.

Chest Radiography

The finding of a new infiltrate on chest radiograph is necessary but not sufficient to make the diagnosis of HAP. Noninfectious causes of a new radiographic infiltrate in hospitalized patients include congestive heart failure, atelectasis, pulmonary embolus with infarction, and chemical pneumonitis caused by aspiration. In some patients, better assessment of the infiltrate can be made by a computerized axial tomographic (CAT) scan. Adult Respiratory Distress Syndrome (ARDS) and pulmonary hemorrhage also should be considered in critically ill patients. A false negative chest radiograph is rare but may occur in patients with neutropenia, early infection, and pneumonia due to *Pneumocystis jirovecii* (formerly *P. carinii*). Patients with symptoms of pneumonia and a negative chest radiograph may have purulent tracheobronchitis. Multilobar changes, rapid progression of pulmonary infiltrates, or the presence of cavitation all suggest a particularly severe case of HAP. In patients with a significant parapneumonic effusion, diagnostic thoracentesis should be performed to rule out empyema.

Laboratory Tests

Laboratory investigations are essential for definitively diagnosing HAP, assessing the severity of illness, and identifying the cause. Recommended routine laboratory tests in patients with HAP include a complete blood count, two sets of blood cultures, and a sputum Gram stain and culture. Blood cultures identify the infecting organism in 10%–20% of cases and a positive blood culture may predict a more complicated course with a higher risk of death. A properly prepared Gram stain of purulent sputum, the endotracheal aspirate, or bronchoalveolar lavage (BAL) fluid may provide initial clues to the infecting bacteria and important data for correlation with the sputum culture result. Sputum smears that have white blood cells but no bacteria raise suspicion for atypical organisms such as *Legionella*, mycobacterial species, or respiratory viruses. Sputum culture is useful for detecting the presence of resistant organisms, but has low specificity. Additional tests for *Legionella* urinary antigen should be obtained, as guided by institutional epidemiology.

Oxygenation should be assessed by pulse oximetry, with subsequent arterial blood gas determination in those with oxygen saturation less than 92%. Testing for HIV as well as appropriate evaluation for other causes of immunosuppression should be considered when risk factors or the clinical presentation dictate.

A clinical diagnosis of HAP in mechanically ventilated patients with a new infiltrate, fever, sputum production, leukocytosis (usually with a shift to greater numbers of polymorphonuclear leukocytes and band forms), and impaired oxygenation is sensitive but not specific (3–6). The

use of the modified Clinical Pulmonary Infection Score (CPIS), which quantifies temperature, level of leukocytosis, oxygenation, changes on chest radiograph, and purulence of respiratory secretions, has been used to classify patients with HAP and predict outcomes from HAP (7–9). In one study, patients with mild HAP who had a low initial Clinical Pulmonary Infection Score (≤ 6) or a low likelihood of HAP were randomized to treatment with a short course (3 days) of ciprofloxacin versus “standard” therapy (multiple antibiotics for a longer periods of time) (8). Although the number of study patients was small, the group randomized to ciprofloxacin monotherapy had significantly shorter stays in the intensive care unit, fewer superinfections and drug resistant pathogens, and a trend toward decreased mortality.

If sputum is available, it should be cultured before starting antibiotics. In all intubated patients with suspected HAP, an endotracheal aspirate should be obtained for Gram stain and culture and, if available, for quantitative culture. The use of quantitative sputum cultures from blind bronchoalveolar lavage (BAL) or quantitative endotracheal aspirates increases the diagnostic specificity of ventilator-associated pneumonia (VAP) and correlates well with specimens obtained from bronchoscopy with bronchoalveolar lavage (BAL), but quantitative techniques for diagnosing VAP are not widely used in the United States (3–6). Data collected from one large randomized trial of patients with suspected VAP found that patients randomized to diagnosis by bronchoscopy with quantitative bronchoalveolar lavage (BAL) or protected specimen brush samples had significantly lower use of antibiotics and decreased mortality than those managed by clinical diagnosis and non-quantitative endotracheal aspirates (4). Bronchoscopy with BAL should be considered for patients who do not respond to initial, empiric antibiotic therapy.

Criteria for ICU Admission

Indications for ICU monitoring in patients with HAP include hemodynamic instability, respiratory failure, or obtundation sufficient to impede airway protection (3, 4). Manifestations of the Systemic Inflammatory Response Syndrome also may indicate the need for intensive care. Possible indications include advanced age, comorbid illnesses, and the need for higher levels of nursing care required for airway management.

Initial Antibiotic Therapy

Because it is difficult to establish a clear diagnosis of HAP and because aspiration predisposes to multiple pathogens, *we strongly recommend early, empiric, intravenous broad-spectrum antimicrobial coverage based on time of onset and risk factors for MDR bacteria* (3). Clearly, the prevalence of MDR pathogens varies by hospital, intensive care units within a

single hospital, and with time (3) (Tables 66.2, 66.3, and 66.4). Intravenous antibiotics, in appropriate doses, must be initiated promptly after appropriate blood and sputum cultures are obtained to limit progression of disease, improve patient outcomes, and decrease hospital costs (3).

Patients with HAP (early onset and without risk factors for MDR pathogens) should be treated with a 2nd- or 3rd-generation cephalosporin (cefuroxime 1.5 gms q8h or ceftriaxone 2 gms/day); a high-dose quinolone (such as levofloxacin 750 mg/day IV or ciprofloxacin 400 mg IV q8h); or a β -lactam, β -lactamase inhibitor (ampicillin/sulbactam 3 gms IV q6h), as shown in Table 66.3 (1, 3). With the emergence of penicillin-resistant and MDR strains of *S. pneumoniae*, the use of ceftriaxone or extended-spectrum quinolones (such as levofloxacin) may be preferable to

earlier generation quinolones, such as ciprofloxacin. In contrast to the β -lactam regimens, quinolones also have activity against atypical pathogens such as *Legionella pneumophila*.

Broader-spectrum antibiotic therapy of HAP and VAP is recommended for patients with risk factors for MDR pathogens, and for those with late onset disease (1, 3) (as shown in Table 66.4). Initial selection of antibiotic coverage may depend on the prevalence and species, and antibiotic sensitivity of the specific MDR pathogens. Doses should be adjusted for impaired renal function. For Gram-negative bacilli, the following doses are recommended: antipseudomonal cephalosporins (ceftazidime 2 gm q8h IV or cefipime 2 gm q12h IV); β -lactam/ β -lactamase inhibitor (piperacillin-tazobactam 4.5 g q6h); carbapenems (imipenem 500 mg q6h or meropenem 1g q8h); fluoroquinolones (ciprofloxacin 400 mg q8h IV or levofloxacin 750 mg/day IV); aminoglycosides (gentamicin 7 mg/kg/d); tobramycin (7 mg/kg/d); or amikacin (20 mg/kg/d) with serum levels checked. For MRSA, the recommended doses are vancomycin 15 mg/kg q12h IV with doses monitored by serum levels, or linezolid 600 mg bid IV (10). If *Klebsiella pneumoniae* with extended spectrum β -lactamase is suspected, carbapenems should be used instead of cephalosporins. If *Legionella pneumophila* is suspected, the regimen should include a quinolone. A discussion of all possible regimens is beyond the scope of this chapter.

ISSUES DURING THE COURSE OF THE HOSPITALIZATION

Monitoring clinical response to initial therapy, adjusting or streamlining antibiotics based on clinical and microbiologic data, and checking for possible complications are of paramount importance. A critical pathway for the management of HAP is shown in Figure 66.3.

Day 1

The highest priority during the first 2–4 hours after suspicion of HAP is the rapid initiation of appropriate intravenous antibiotics following completion of initial assessments and collection of cultures (1, 3). The patient's room-air oxygen saturation should be measured; if it is below 92%, supplemental oxygen should be given. The need for ICU transfer, respiratory therapy, or intubation should be evaluated regularly during the first 12–24 hours, and thereafter as needed.

The patient's requirements for hydration and nutritional support should be assessed. Unless contraindicated, the head of the bed should be maintained at a 30 degree upright position (1, 3, 11). If resistant organisms or tuberculosis are suspected, the patient should be placed

TABLE 66.4**INITIAL EMPIRIC THERAPY FOR PATIENTS WITH HOSPITAL-ACQUIRED PNEUMONIA (HAP), INCLUDING VAP, AND RISK FACTORS FOR MULTIDRUG-RESISTANT (MDR) PATHOGENS OR LATE-ONSET DISEASE**

Potential MDR pathogens ^a	Combination antibiotic therapy ^e
<ul style="list-style-type: none"> • <i>Pseudomonas aeruginosa</i>^a • <i>Acinetobacter</i> species^a • <i>Klebsiella pneumoniae</i>^{a,c} • <i>Escherichia coli</i> • <i>Enterobacter aerogenes</i> • Methicillin-resistant <i>Staphylococcus aureus</i> (MRSA)^{d,g} 	3rd/4th generation antipseudomonal cephalosporin (ceftazidime, cefepime) OR carbapenem (antipseudomonal) (imipenem, meropenem) OR β-lactam, β-lactamase inhibitor (piperacillin-tazobactam) <u>PLUS</u> fluoroquinolone ^b (levofloxacin, ciprofloxacin) ^f OR aminoglycoside ^{b,h} (gentamicin, tobramycin, amikacin) <u>PLUS</u> linezolid or vancomycin (if MRSA is prevalent) ⁱ

^a Sensitivities vary for gram-negative bacilli. Initial antibiotic therapy should be adjusted or streamlined based on subsequent microbiologic data and clinical response to therapy.

^b If *Legionella pneumophila* is suspected, the combination antibiotic regimen should include a fluoroquinolone rather than an aminoglycoside.

^c For ESBL+ isolates, imipenem or meropenem should be used instead of ceftazidime or cefepime.

^d Outcomes for patients with HAP due to MRSA may be better for linezolid than vancomycin (12).

^e Suggested regimens—equivalent substitutions are appropriate.

^f Levofloxacin at higher dose (750 mg IV qd) approved for the treatment of nosocomial pneumonia has excellent activity against MDR *Streptococcus pneumoniae*. Ciprofloxacin at higher dose (400 mg q8h IV) has also been used to treat HAP, but has decreased activity against *Streptococcus pneumoniae* (which may cause early onset HAP).

^g Rates of methicillin-resistant *S. aureus* (MRSA) have increased in health care facilities, in the community and in persons who have received recent antibiotics.

^h Aminoglycosides do not penetrate well into lung tissue and have renal and ototoxicity. Aminoglycosides should be dosed daily. Initial doses of gentamicin and tobramycin (7 mg/kg/day) and amikacin (20 mg/kg/day) are recommended along with monitoring of serum peak and trough levels along with renal function. Their use should generally be limited to 3–5 days.

ⁱ In patients with HAP due to MRSA, linezolid (600 mg bid) may provide better coverage than vancomycin (12). Doses of vancomycin should be 10–15 mg/kg q12 hrs. Trough levels of 15–20 mcg/mL should be maintained for treating HAP due to MRSA.

on respiratory isolation pending microbiological results. If the patient has restricted mobility, subcutaneous heparin or other appropriate prophylaxis should be administered (Chapter 52). Vital signs and oxygen saturation should be followed closely during the first 12–24 hours.

Day 2

On day two, culture results should be checked and antibiotics should be adjusted to cover the infecting pathogens and stopped if there is no evidence of HAP. The duration of therapy for uncomplicated HAP should be targeted for seven days, especially in patients who demonstrate prompt

clinical improvement (1, 3, 12). If the patient appears to be improving, extubation, transfer from the ICU, a switch to oral antibiotics, and advanced diet and activity can be considered. Although the course of HAP may vary, signs of clinical response should be evident within 48 hours after therapy is initiated. Lack of response to treatment may result from either an incorrect initial diagnosis of pneumonia or inadequate evaluation and therapy, as outlined in Table 66.5. To guide further management, a comprehensive evaluation should be performed and infectious disease and pulmonary consultations should be obtained. At this point, invasive microbiologic sampling to look for resistant or unusual pathogens is usually appropriate (1, 3). Negative cultures should raise the possibility of a noninfectious

pulmonary process. In the patient who has not improved, further radiographic evaluation (including lateral decubitus films, ultrasound, or a computerized tomographic scan) is also indicated at this time to rule out empyema, cavitation, or a post-obstructive process. A spiral computerized tomographic scan or ventilation-perfusion scan should be considered in patients in whom an infectious process is not identified.

Remainder of Hospitalization and Discharge Planning

The most common pulmonary complication of HAP is *empyema*. Thoracentesis is indicated in all patients with a sizable pleural effusion (defined as >10mm on lateral decubitus films) in whom pneumonia is suspected. Empyema is suggested by persistent fevers or leukocytosis associated with a parapneumonic effusion or the finding of a locu-

lated effusion, and the diagnosis is confirmed by thoracentesis. Early diagnosis and prompt drainage of the infected pleural space by needle aspiration, chest tube, or thoracotomy are crucial (Chapter 60). Lung abscess is a relatively uncommon complication of HAP and may be diagnosed by chest radiograph or computerized tomographic scan in patients who are not responding to otherwise appropriate therapy. Extrapulmonary complications may result from the appropriate interventions and treatment. These include *Clostridium difficile* colitis, central venous catheter infections, drug reactions or toxicity, venous thromboembolism, and respiratory-tract superinfection, seen most frequently in intubated patients. These complications may present as a failure to respond to antibiotic therapy (Table 66.5).

The duration of therapy for uncomplicated HAP is usually seven days (3, 12). Some patients with more severe underlying disease, impaired immune systems, or infection with antibiotic-resistant organisms who do not respond may need longer courses of antibiotics. Patients with complications such as empyema or lung abscess may require four to eight weeks of antibiotic therapy along with other therapeutic interventions. If the patient has a rapid response to antibiotic therapy for HAP, the duration of therapy may be shortened. Once the patient’s condition has stabilized, the prescribed course may be completed at home or in step-down facilities. Nosocomial pathogens, such as *P. aeruginosa* and *S. aureus*, may persist in sputum after the patient’s clinical parameters have returned to normal. This invariably represents colonization rather than infection and does not require further antibiotic therapy. Nevertheless, patients should be carefully monitored for relapse (3, 12).

Once the patient is responding to therapy, a nursing assessment should be done. This assessment should attempt to identify risk factors for pneumonia and aspiration, and address the condition of the patient’s teeth, as well as the need for smoking cessation and other patient education. Pneumococcal and influenza vaccination status also should be ascertained. All patients with *Aspergillus*, tuberculosis, *Legionella pneumophila*, or MDR nosocomial pathogens should be reported to the infection-control staff (1, 3). In addition, cases of atypical or resistant organisms should be reported back to referring facilities from which the patient was transferred.

^a Common examples of multidrug-resistant Gram-negatives include *Pseudomonas aeruginosa*, *Acinetobacter baumannii*, *Klebsiella pneumoniae* (extended β-lactamase +).

COST CONSIDERATIONS AND RESOURCE USE

Nosocomial pneumonia increases the duration of hospitalization two- to threefold compared with patients without pneumonia. When comparing infection rates across facilities, patients should be stratified by severity of pneumonia, presence of risk factors, and admission to the ICU, and comparisons should be based on incidence density

(rates per 1,000 ICU or hospital days or, in ventilated patients, rates per 1,000 days on mechanical ventilator).

Appropriate prevention strategies can significantly decrease the incidence of HAP (1–3, 11). Such strategies can be divided into host factors, medications, and devices that facilitate patient colonization and environmental factors. Infection-control measures are aimed at preventing cross-infection or colonization with nosocomial pathogens from other patients and staff. Table 66.6 reviews recommendations that either have been proven in clinical trials or epidemiologic studies, or have been recommended by consensus panels convened by the Centers for Disease Control and

more recent reviews by experts (1–3, 11). Clearly, some of the most effective prevention strategies are low technologic approaches, most of which are widely available, inexpensive, and noninvasive. For these reasons, their potential contribution to preventing cases of HAP may be underappreciated.

Further studies are needed to assess streamlined therapeutic approaches, such as the use of oral regimens or short courses of antibiotics. The time from diagnosis to discharge, length of ICU stay, and days of mechanical ventilation should be monitored, along with other outcome variables such as the numbers of patients requiring tracheostomy. Although most clinical outcomes for pneumo-

nia have focused on mortality rate as the primary endpoint, the use of other outcome measures (such as quality-of-life measures, hospital costs, antibiotic days, days of mechanical ventilation, hospital days, and length of convalescence) should be considered. New data are needed regarding the cost effectiveness of specific clinical strategies for diagnosis, treatment, and prevention of HAP.

KEY POINTS

- Despite an increased understanding of the pathogenesis of pneumonia, HAP continues to occur at disturbing rates and is associated with significant morbidity and mortality.
- The use of quantitative sputum cultures increases the specificity of diagnosis for ventilator-associated pneumonia (VAP) and may reduce antibiotic use and improve patient outcomes, but is not widely available.
- Initial effective therapy of HAP should be based on the stratification of patients by severity of disease, time of onset, and the presence of risk factors for MDR pathogens that necessitate broader empiric antibiotic coverage.
- Early institution of broad-spectrum appropriate antibiotic therapy targeted to all suspected pathogens decreases mortality and morbidity.
- Antibiotic therapy should be streamlined or de-escalated based on the identification and antibiotic sensitivity of the pathogens isolated and the clinical response of the patient.
- The duration of antibiotic therapy for patients with uncomplicated HAP who respond to treatment should be seven days.
- Patients who do not respond to initial therapy, or have evidence of progressive disease, should have a prompt infectious disease or pulmonary consultation to reassess the diagnosis and the need for further diagnostic studies or additional therapy.
- Short-term and long-term prevention strategies for HAP and the emergence and spread of MDR pathogens are strongly recommended to reduce patient mortality, morbidity, and health care costs.

INTRODUCTION

Despite the decline in tuberculosis cases in the United States, tuberculosis continues to be a common reason for admission in many hospitals. Hospitalization may be necessary because of the disease's severe effects, for invasive diagnostic tests when tuberculosis is suspected but not proven, or for initiation of potentially toxic treatment regimens in patients with tuberculosis caused by multidrug-resistant organisms. Tuberculosis may also be diagnosed in patients who are hospitalized for other diseases, such as HIV disease, chronic renal failure, or another immunosuppressive condition. In addition to the considerations that apply to individual patients with or suspected of having this disease, tuberculosis in the hospital setting raises important issues of infection control. Consequently, the disease has implications for the hospital environment and health care worker safety, as well as for specific patients. Because of the need for rapid diagnosis of tuberculosis in hospitalized patients, there are also important implications for the microbiology laboratory.

This discussion will focus on management of the hospitalized patient with known or suspected tuberculosis. However, the separation of inpatient from outpatient management is artificial, and the care of patients with tuberculosis must be provided as a coordinated continuum in order to ensure that therapy is completed successfully. Additionally, there must be communication and coordination with local public health tuberculosis control programs. In many areas such programs provide ongoing patient care following hospital discharge. In addition, tuberculosis control personnel conduct epidemiologic investigations centered on each newly reported case. Promptly notifying the tuberculosis control program of a newly identified case will expedite the investigation of contacts and minimize the effects of secondary spread of *Mycobacterium tuberculosis*.

TUBERCULOSIS IN NON-HIV-INFECTED PATIENTS

Issues at the Time of Admission

Clinical and Radiographic Presentation

The clinical presentation of tuberculosis varies greatly depending on a number of factors, including the site of involvement, extent of disease, and immunocompetence of the host. Most people with tuberculosis present with a subacute or chronic illness with symptoms that have been present for several weeks to months. Although it is traditionally taught that patients with pulmonary tuberculosis present with cough, fever, night sweats, weight loss, and, occasionally, hemoptysis, a recent study found that only 52% of patients had a cough at the time of diagnosis (1). Extrapulmonary manifestations of disease depend on the site of involvement. For example, tuberculous meningitis may present with headache and altered mental status, whereas tuberculous lymphadenitis presents with local swelling of lymph nodes, usually in the neck. Fifteen to 20% of patients with pulmonary tuberculosis will be asymptomatic at the time of diagnosis. Thus, a high index of suspicion should be maintained in high-risk populations.

The characteristic radiographic findings of tuberculosis vary depending on the underlying pathogenetic mechanism of disease. Patients who present with post-primary or reactivation disease usually have upper lobe radiographic opacities, often with cavitation. The most commonly involved lung segments include the apical and posterior segments of the right upper lobe and apical-posterior segment of the left upper lobe. Reactivation tuberculosis in immunocompetent adults does not typically cause intrathoracic lymphadenopathy. In primary tuberculosis, the chest radiograph may demonstrate lower lung zone opacities, usually without cavitation, and in some cases with associated intrathoracic lymphadenopathy. Miliary tuberculosis,

characterized radiographically by diffuse small nodules, can occur with either primary or post-primary disease. Similarly, pleural effusions may occur with primary or post-primary disease, and the effusion may occur with or without evidence of pulmonary parenchymal disease.

Differential Diagnosis and Initial Evaluation

People suspected of having tuberculosis, based on clinical signs and symptoms, should have a chest radiograph performed. If the findings on the chest radiograph are consistent with tuberculosis and/or the patient has respiratory symptoms, three consecutive morning sputum specimens should be obtained for microscopic examination for the presence of acid fast bacilli (AFB) and mycobacterial culture. If the patient is unable to produce sputum spontaneously, sputum induction should be performed using ultrasonic nebulization of hypertonic saline. The sensitivity of AFB sputum smears is approximately 50%, although in some studies more than 70% of patients with pulmonary tuberculosis have had positive smears (2). Among patients with pulmonary tuberculosis, the sensitivity of mycobacterial cultures is around 80%–85%. The yields of sputum microscopy and culture increase in patients with cavitary disease.

Mycobacterial cultures may require days-to-weeks to become positive, depending on the method used. With liquid culture systems, growth can be detected within one or two weeks depending on the number of bacilli in the specimen. The combination of liquid culture systems and specific nucleic acid probes can enable species identification within two weeks. Drug susceptibility tests should be performed for the first-line agents on all initial isolates of *M. tuberculosis*. Regardless of the culture method used, decisions regarding treatment and further diagnostic testing must be made early in the course of the evaluation, without the benefit of drug susceptibility results. Antituberculosis therapy should be started when the clinical suspicion of disease is high, even if the sputum specimens are AFB smear-negative.

Two direct nucleic acid amplification tests (Amplicor, Roche and MTD, Genprobe) have been approved by the FDA for use in AFB smear-positive specimens. Additionally, the MTD test is approved for use in smear-negative specimens. Studies have demonstrated positive predictive values for direct amplification tests in AFB smear-positive specimens of approximately 100%, and negative predictive values of 86%–90% (3). However, the predictive values vary depending on the prevalence of disease in the population studied. When using the tests on smear-negative specimens, the results should be interpreted with caution because the positive predictive value will be low when the clinical suspicion for active tuberculosis is low (Chapter 6). On the other hand, when the clinical suspicion is high, the positive predictive value remains high, even when used with smear-negative specimens.

Fiberoptic bronchoscopy with transbronchial biopsy has been reported to yield a rapid diagnosis in 48% of suspected

tuberculosis cases who have negative sputum smears for AFB (4). In this study, transbronchial biopsy provided the only specimens in which AFB were seen on stained specimens in 26% of the cases, although it did not increase the yield of culture. It is important to note that 60%–90% of pre-bronchoscopy sputum specimens eventually yield positive culture results. Therefore, unless a rapid diagnosis is needed, bronchoalveolar lavage with transbronchial biopsy is usually not necessary in the diagnostic evaluation of persons suspected of having pulmonary tuberculosis. If bronchoscopy is undertaken, transbronchial biopsies should be performed and post-bronchoscopy sputum specimens should be obtained because 35%–70% of post-bronchoscopy specimens will yield positive cultures. In the evaluation of miliary disease, if the initial sputum smears are negative, fiberoptic bronchoscopy with transbronchial biopsy should be performed to exclude other diseases such as fungal infections and malignancies, which can produce a miliary pattern on the chest radiograph (Chapter 63). In all instances, both bronchoalveolar lavage fluid and biopsy tissue should be cultured for mycobacteria and fungi.

The benefits of a rapid diagnosis provided by bronchoscopy must be weighed against the risk and costs of the invasive procedure as well as the potential exposure to health care workers. The authors favor empiric therapy over bronchoscopy in HIV-uninfected individuals in whom there is a moderate-to-high prior probability of tuberculosis, unless a malignancy or other disease is suspected. In San Francisco, of patients with suspected tuberculosis who were smear-negative and who were started on empiric therapy, approximately 50% were eventually found to have tuberculosis (5).

People with suspected extrapulmonary tuberculosis should have appropriate tissue and/or fluids obtained for AFB smear and culture. Patients with suspected tuberculous meningitis should have a lumbar puncture performed. Findings in the cerebrospinal fluid (CSF) that are consistent with tuberculosis include high protein concentration, low glucose concentration, and lymphocytic pleocytosis (2). AFB smears are positive in 10%–20% of cases and cultures are positive in 55%–80%, depending on whether or not multiple specimens are obtained.

Pleuritis with effusion is a common extrapulmonary manifestation of tuberculosis (Chapter 60). Findings in the pleural fluid that are consistent with tuberculosis include a lymphocytic exudate, often with a low glucose concentration. AFB smears of the pleural fluid are rarely positive, except in the setting of tuberculous empyema, and *M. tuberculosis* is isolated by culture in only 20%–35% of patients with proved pleural tuberculosis. Sputum cultures may be positive in 5%–40% of cases (6). The yield can be increased by performing a pleural biopsy, usually done under direct visualization. The combination of pleural tissue histopathology and culture is diagnostic of tuberculosis in approximately 90% of cases.

Neither the clinical presentation nor the radiographic manifestations of tuberculosis are specific for the disease. Other infectious diseases, such as bacterial pneumonias, *Pneumocystis carinii* (now renamed as *Pneumocystis jirovecii*), and other fungal pathogens, may be associated with an upper lobe radiographic infiltrates. Noninfectious causes of upper lobe densities include sarcoidosis, hypersensitivity pneumonitis, and ankylosing spondylitis. Ipsilateral hilar enlargement may occur in the setting of primary tuberculosis, but this finding in adults is highly suspicious for a malignancy, as is a mass-like lesion (Chapter 61).

Indications for Hospital Admission

Most people who have or are suspected of having tuberculosis can be treated effectively in the outpatient setting. Some patients, however, will require hospitalization because of the severity of their illness or for social reasons. Medical indications for hospitalization include severe extrapulmonary disease, pulmonary disease with respiratory compromise or hemoptysis, or, occasionally, a need for further diagnostic tests. Social indications usually relate to the potential for transmitting the infection to others with whom the patient may come in contact. Effective therapy, especially given under direct observation, rapidly reduces infectiousness, thereby decreasing or eliminating the need for hospitalization for isolation. Occasionally, patients with tuberculosis caused by multidrug-resistant organisms will require hospitalization for initiation of a treatment regimen that includes toxic or intravenously administered agents.

Infection Control

Patients with suspected pulmonary and/or laryngeal tuberculosis should be placed in respiratory isolation immediately. Once in isolation, it is important for the patient to remain in the room as much as possible. When the patient leaves the room, he/she should wear an unfitted surgical mask in order to minimize potential transmission of *M. tuberculosis* to others in the environment. Health care workers entering the room should wear a N95 respirator. Hospitalized patients with proven tuberculosis should remain in respiratory isolation until three consecutive AFB smears are negative and there has been clinical improvement with antituberculosis therapy (7). Patients who have smear-negative tuberculosis also pose some risk of transmission, although the risk is less than that in smear-positive cases. Smear-negative patients who have a high probability of tuberculosis should also be kept in isolation for several days or until an effective treatment regimen has been established.

Early identification and isolation of patients at high risk for tuberculosis is very important in preventing nosocomial transmission of *M. tuberculosis*. Unfortunately, the ability to quickly identify those patients who have tuberculosis is relatively poor, and thus the use of isolation rooms is generally inefficient. In one study, isolation of all patients with

suspected tuberculosis would have resulted in a 92-fold overuse of isolation rooms (8). In a study examining the prediction of pulmonary tuberculosis, predictor variables were upper zone infiltrates on chest radiograph, a history of fever or weight loss, and low CD4 lymphocyte count (9). Using these predictors, the investigators developed a model that had a sensitivity of 100%, a specificity of 48%, and a negative predictive value of 100%. The investigators estimated that applying their model could have reduced the number of patients requiring isolation by more than 40% without increasing the risk of transmission. This model and others will need to be validated in other areas with different patient populations and prevalences of tuberculosis before they can be utilized routinely.

Because of the importance of rapid and accurate diagnosis of tuberculosis—both for the benefit of the patient and for efficient infection control—it is essential that hospitals have rapid access to high-quality mycobacteriology services, either on-site or through arrangements with off-site facilities. The industry standard for return of AFB smear results is no longer than 24 hours. The time required for definitive identification of *M. tuberculosis* varies depending on the methods used, but most acute care hospitals should at least be using a liquid culture system to increase the speed of identification. Tests for speciation of any mycobacterium that is isolated and other tests for drug susceptibility can be referred to more specialized laboratories.

Initial Therapy

Individuals with suspected tuberculosis should be given a multidrug regimen as soon as possible to prevent the transmission of *M. tuberculosis*. There are four basic treatment regimens for adults (Table 67.1) (10). Each regimen has an initial phase of two months followed by a continuation phase of 4–7 months. The minimally acceptable duration of therapy for patients with culture-positive tuberculosis is 6 months. The initial phase of therapy should consist of a 2-month period of isoniazid, rifampin, pyrazinamide, and ethambutol. Once the patient has been determined to have tuberculosis caused by drug-susceptible organisms, ethambutol can be discontinued. The continuation phase of therapy should consist of isoniazid and rifampin given for 4 months. With appropriate dose adjustments (Table 67.2), the continuation phase can be given daily, or two or three times a week. Patients who are HIV-negative, have no evidence of cavitation on a chest radiograph, and who have negative smears after 2 months of therapy, can be treated with once weekly isoniazid and rifapentine in the continuation phase. However, if the patient has cavitation evident on a chest radiograph and a positive smear after 2 months of therapy, the once-weekly regimen is not recommended.

In patients who are suspected of having multidrug-resistant tuberculosis, six or more antituberculosis drugs may be appropriate for initial therapy. The composition and duration of regimens for patients with drug-resistant organ-

EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.

^a Definitions of ratings: A = preferred, B = acceptable alternative, C = offer when A and B cannot be given, E = should never be given.

^b Definitions of ratings: I = randomized clinical trial, II = data from clinical trials that were not randomized or were conducted in other populations, III = expert opinion.

^c When DOT is used, drugs may be given 5 days/week and doses adjusted accordingly. Five day a week dosing is rated AIII.

^d Patients with cavitation on the initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month continuation phase.

^e Not recommended for HIV-infected patients with CD4 cell counts <100 cells/ μ l.

^f Options 1c and 2b should be used only with HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on initial chest radiograph (see text). For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

Source: Treatment of Tuberculosis. *Morbidity and Mortality Weekly Report* 2003;52:1–77.

isms must be tailored individually, based on known or presumed drug susceptibility and the history of prior therapy.

Nine-month regimens using isoniazid and rifampin are also effective. As with 6-month regimens, ethambutol should be included in the initial phase of therapy. Shorter treatment regimens may be used in patients with sputum AFB smear-negative and culture-negative pulmonary tuberculosis. Four months of isoniazid and rifampin, preferably along with pyrazinamide for the first two months, is as successful as longer treatment regimens.

The most frequent cause of treatment failure or relapse is non-adherence to the treatment regimen. Therefore, all hospitalized patients should be treated with *directly observed therapy* (DOT). Arrangements should be made prior to discharge to continue DOT. Additionally, combination tablets such as Rifamate (isoniazid and rifampin) and Rifater (isoniazid, rifampin, and pyrazinamide) should be used whenever possible.

Treatment in Special Circumstances

Pregnancy

Antituberculosis therapy should not be withheld from pregnant women who are suspected of having tuberculosis because untreated tuberculosis represents a greater risk to the mother and fetus than does treatment itself. Antituberculosis therapy should be initiated in pregnant women who have a moderate to high suspicion of tuberculosis. Many clinicians do not start pyrazinamide in pregnant women because of the lack of teratogenicity data related to the drug. However, the World Health Organization and the International Union Against Tuberculosis and Lung Disease recommend its use, and in most countries, pyrazinamide is used during pregnancy (10). If pyrazinamide is not used in the initial phase of treatment, the duration of therapy must be increased from 6 to 9 months.

Renal Failure. Some antituberculosis medications are cleared by the kidneys, and some are removed via hemodialysis. Of the first-line antituberculosis drugs, only pyrazinamide and ethambutol are cleared significantly by the kidneys, and thus alterations in dosing may be required in patients with renal insufficiency and those with end-stage renal disease who are receiving hemodialysis (10). Ethambutol and pyrazinamide should be given in standard daily doses but given intermittently, generally three times a week after hemodialysis. Only pyrazinamide (and its metabolites) is cleared to any significant degree by hemodialysis, but if the drug is given after hemodialysis, supplemental dosing is not required. Isoniazid and rifampin are metabolized by the liver and are not removed via hemodialysis, so no dosage adjustments are necessary. Although pyrazinamide can be used in patients with renal failure, it increases the hyperuricemia that is common in such patients. It is important to monitor blood levels of ethambutol and the aminoglycoside/polypeptide antituberculosis drugs when they are being given to patients with renal insufficiency and those receiving hemodialysis.

Hepatic Disease. Most patients with underlying chronic liver disease will tolerate the standard antituberculosis treatment regimen, despite the fact that isoniazid, rifampin, and pyrazinamide are hepatotoxic (Table 67.2). If the serum aminotransferase levels are more than five times the upper limit of normal at baseline, a non-hepatotoxic regimen should be initiated. One such regimen consists of ethambutol, streptomycin, cycloserine, and a fluoroquinolone. If and when the liver function tests return to normal, the standard regimen can be attempted as long as there is close monitoring of liver function tests. If the provider would prefer to use only two hepatotoxic medications instead of three, pyrazinamide can be withheld. This change in the initial treatment regimen will result in no loss of efficacy as long as the duration of therapy is increased to 9 months. A rifamycin should be used in all regimens unless there is a strong contraindication.

Drug Interactions. Several of the antituberculosis drugs are known to interact with other medications (10). The interaction of isoniazid and phenytoin increases the serum concentration of both drugs. When given together, the serum level of phenytoin should be monitored carefully and the dosage adjusted as necessary. Rifampin is a potent inducer of the hepatic cytochrome P450 enzyme system and may accelerate the clearance of drugs such as methadone, coumadin, glucocorticoids, estrogen, oral hypoglycemic agents, digitoxin, antiarrhythmic agents, anticonvulsants, ketoconazole, theophylline, and cyclosporine. Rifabutin is a less potent inducer of the hepatic cytochrome enzyme system; thus, it may be used in circumstances where rifampin cannot be used.

Concurrent use of fluoroquinolones with theophylline may prolong the half-life of theophylline. Antacids with

aluminum, magnesium, or calcium and ferrous sulfate may interfere with the absorption of quinolones. Cycloserine interferes with the elimination of phenytoin, particularly when taken with isoniazid. Thus, the dose of phenytoin should generally be reduced.

Extrapulmonary Tuberculosis. In general, the treatment for extrapulmonary tuberculosis is the same as for pulmonary disease. However, when tuberculosis involves the central nervous system or bones and joints, a longer course of therapy may be indicated (10). Additionally, surgery or corticosteroids are more likely to be necessary in extrapulmonary disease.

Because of the potential lethality of central nervous system (CNS) tuberculosis and the severity of neurologic sequelae, antituberculosis therapy should begin immediately whenever CNS tuberculosis is suspected. Isoniazid and pyrazinamide penetrate the blood-brain barrier well, but the aminoglycosides, rifampin, and, to some extent, ethambutol penetrate well only in the setting of inflamed meninges (10). Of the second-line agents, cycloserine and ethionamide penetrate the meninges even in the absence of inflammation. The continuation phase of therapy may be extended from 6 to 12 months, depending on the severity of illness and response to therapy. Adjunctive therapy with corticosteroids is generally indicated in patients with CNS involvement (see below). Monitoring the effectiveness of therapy requires frequent, careful clinical neurologic assessment and repeat examinations of spinal fluid.

Studies have demonstrated that bone and joint tuberculosis can be treated with 6- to 9-month regimens, although in some cases, surgery may be necessary. Surgery should be considered if there is instability of the bones, a large ileopsoas abscess is present, or the patient is not responding to medical therapy. The success of therapy should be judged by clinical and radiographic evaluations.

Other extrapulmonary sites of disease usually respond well to short-course chemotherapy. Of note, with tuberculous lymphadenitis, lymph nodes may enlarge, new nodes may appear, and nodes may spontaneously drain and create fistulas. These changes are seldom a sign of failure, but represent a vigorous immunological reaction. Similarly, pleural effusions may enlarge or even develop during the early stages of therapy.

Management of Tuberculosis Caused by Drug-Resistant Organisms. A detailed discussion of the management of patients with tuberculosis caused by drug-resistant organisms is beyond the scope of this text. However, there are a few critical points regarding the care of these patients. First, all patients who are suspected or known to have drug-resistant tuberculosis should be treated by or in consultation with a specialist with experience in such situations. Second, at least 3 drugs to which the organism is susceptible should be used. Third, the clinical and bacteriologic response to therapy may be delayed in patients with

TABLE 67.2**DOSES AND ADVERSE DRUG REACTIONS FOR FIRST-LINE ANTITUBERCULOSIS DRUGS**

Drugs	Dose, in mg/kg (maximum dose)				Adverse reactions
	Daily	1 time/wk	2 times/wk	3 times/wk

multidrug-resistant tuberculosis. Fourth, second-line agents (Table 67.3) are associated with frequent side effects and, thus, close monitoring is necessary. Fifth, although the optimum duration of treatment is not known, regimens must be prolonged, generally to 18–24 months, depending on the regimen and the severity of the disease. Finally, surgical intervention may be indicated in some cases.

Adjunctive Therapy. Corticosteroids are indicated as adjunctive therapy in certain forms of tuberculosis. The administration of corticosteroids in patients with tuberculous meningitis reduces neurological sequelae and mortality. Adjunctive corticosteroid therapy is also used for documented tuberculous pericarditis, where it has been shown to reduce the size of the effusion, the need for drainage procedures,

TABLE 67.3**DOSES AND ADVERSE DRUG REACTIONS FOR SECOND-LINE ANTITUBERCULOSIS DRUGS**

Drugs	Daily dose (maximum dose)	Adverse reactions	Monitoring	Comments
Streptomycin	15–30 mg/kg (1 g)	Hearing loss Vestibular dysfunction Renal toxicity	Vestibular/hearing function Measure BUN and creatinine	After bacteriologic conversion, may switch to intermittent dosing ^a
Amikacin	15–30 mg/kg (1 g)	Hearing loss Vestibular dysfunction Renal toxicity	Vestibular/hearing function Measure BUN and creatinine	After bacteriologic conversion, may switch to intermittent dosing ^a
Kanamycin	15–30 mg/kg (1 g)	Hearing loss Vestibular dysfunction Renal toxicity	Vestibular/hearing function Measure BUN and creatinine	After bacteriologic conversion, may switch to intermittent dosing ^a
Capreomycin	15–30 mg/kg (1 g)	Hearing loss Vestibular dysfunction Renal toxicity	Vestibular/hearing function Measure BUN and creatinine	After bacteriologic conversion, may switch to intermittent dosing ^a
Ethionamide	15–20 mg/kg (1 g)	Gastrointestinal upset Metallic taste Hepatotoxicity Hypersensitivity	Measure hepatic enzymes	Start with low dose and increase as tolerated May cause hypothyroidism, especially if used with PAS
Para-aminosalicylic acid (PAS)	150 mg/kg (12 gm)	Gastrointestinal upset Hypersensitivity Hepatotoxicity Sodium load	Measure hepatic enzymes Assess volume status	Start with low dose and increase as tolerated Monitor cardiac patients for sodium load
Cycloserine	10–15 mg/kg (1 g)	Psychosis Seizures Depression	Assess mental status Measure serum drug concentrations	Start with low dosage and increase as tolerated Pyridoxine may decrease central nervous system effects
Levofloxacin	500–1000 mg	Gastrointestinal upset Headaches Hypersensitivity Restlessness	Clinical	Avoid antacids, zinc, iron, sucralfate. Do not use in patients taking drugs that prolong the QT interval.
Moxifloxacin	400 mg	Gastrointestinal upset Headaches Hypersensitivity Restlessness	Clinical	Avoid antacids, zinc, iron, sucralfate. Do not use in patients taking drugs that prolong the QT interval.
Gatifloxacin	400 mg	Gastrointestinal upset Headaches Hypersensitivity Restlessness	Clinical	Avoid antacids, zinc, iron, sucralfate. Do not use in patients taking drugs that prolong the QT interval.

^a Twice weekly dosing, 15–30 mg (1.5 g); three times weekly, 15–30 mg (1.5 g)

and mortality. On occasion, corticosteroid treatment may be used in the setting of tuberculous pleuritis to speed the resolution of pain, fever, and the effusion itself. However, corticosteroid treatment does not reduce the likelihood of pleural fibrosis with consequent lung restriction. Patients with pulmonary tuberculosis resulting in respiratory failure may receive some acute benefit from corticosteroid treatment, although no long-term benefits have been demonstrated.

The vast majority of patients with pulmonary tuberculosis caused by drug-susceptible organisms will respond to a 6-month treatment regimen. However, in patients with underlying multidrug-resistant disease, the response rate is much lower and, in some cases, surgery may be necessary. In patients who have localized multidrug-resistant

tuberculosis and adequate pulmonary reserve, where a poor outcome is anticipated on medical therapy alone, surgical resection may offer some benefit. Surgery (or an interventional radiographic procedure) may also be necessary in patients with severe hemoptysis associated with either active tuberculosis or the residual of previous disease (“Rasmussen’s Aneurysm”).

Indications for Early Consultation

Clinicians should seek expert consultation in managing any patient who has severe pulmonary or extrapulmonary tuberculosis. Additionally, all patients with tuberculosis caused by drug-resistant organisms, particularly multidrug-resistance,

should receive expert consultation. Patients who develop drug toxicity or who are not responding to medical therapy may require a change in therapeutic regimen. These decisions are often complicated and may alter the overall duration of therapy and efficacy of the regimen. Consequently, an expert should be consulted before any change in therapy.

Issues During the Course of Hospitalization

Patients who have begun antituberculosis therapy must be monitored closely for evidence of drug toxicity and for response to therapy. The most common toxicities associated with the first- and second-line agents are described in Tables 67.2 and 67.3. Baseline measurements of serum aminotransferases, total bilirubin, alkaline phosphatase, serum creatinine and glucose, complete blood count with differential cell count and platelet count should be obtained for all patients. Patients receiving ethambutol should have baseline measurements of visual acuity and red/green color discrimination, and patients receiving pyrazinamide should have a measurement of serum uric acid. Repeat laboratory measurements should be made if there are abnormal baseline values or indications of possible toxicity.

Patients should also be monitored for clinical and bacteriologic improvement. Most patients will be afebrile within 2 weeks of initiation of therapy. However, patients with extensive tuberculosis may have prolonged fever despite adequate therapy. Repeat sputum specimens should be obtained at weekly intervals in patients whose initial AFB smears are positive in order to judge the response to therapy. Cultures should be obtained at 1-month intervals until specimens for 2 consecutive months have been negative.

Approximately 85%–90% of patients being treated with an isoniazid- and rifampin-containing regimen will be culture-negative by 2–3 months (10). For patients who do not convert the sputum AFB cultures to negative by 2 months of treatment and who have evidence of cavitation on a chest radiograph, the continuation phase of therapy should be extended from 4 to 7 months in order to complete a total of 9 months of therapy. In addition, the patient's adherence to the treatment regimen should be questioned and measurement of serum drug levels considered. Repeat drug susceptibility testing should be performed if the cultures are still positive after 3 months of therapy. If the patient is clinically deteriorating, two new drugs should be added to the treatment regimen, preferably drugs that the patient has never taken. If the patient is clinically stable, the clinician may wait for the results of drug susceptibility testing before changing the treatment regimen.

Discharge Issues

Most patients with tuberculosis may be discharged when their clinical condition allows or when it is determined that they are no longer infectious. The local department of

public health (DPH) should be notified before discharge so that plans can be made for outpatient therapy including DOT. In addition, in some areas the public health department may be able to provide housing and other incentives to encourage adherence with therapy.

Patients who are discharged to their home while still considered infectious should be asked to limit their contact with others. If they must leave their residence, they should be instructed to wear a mask and cover their mouth when coughing.

TUBERCULOSIS IN HIV-INFECTED PATIENTS

Issues at the Time of Admission

Clinical Presentation

The clinical manifestations of tuberculosis in HIV-infected patients will vary depending on the level of immunosuppression. As the CD4 lymphocyte count decreases, extrapulmonary disease and atypical findings on chest radiographs are increasingly likely. Early in the course of HIV disease, the findings on chest radiographs are not different from typical post-primary disease. However, as the CD4 lymphocyte count decreases, the chest radiograph is more likely to be atypical, with lower zone opacities, absence of cavitation, and the presence of intrathoracic lymphadenopathy, often mimicking primary tuberculosis.

Differential Diagnosis and Initial Evaluation

The variation in the clinical and radiographic presentation of tuberculosis in the setting of HIV-infection described above can result in a lowered clinical suspicion of tuberculosis. Therefore, clinicians should maintain a low threshold for including tests designed to diagnose tuberculosis in HIV-infected individuals who have lung disease and/or fever of unknown etiology. The initial diagnostic approach, however, is the same as discussed above. Fiberoptic bronchoscopy should be performed in HIV-infected individuals whose sputum specimens, including induced specimens, are AFB smear-negative and in whom no other diagnosis has been identified. In one study, bronchoscopy with transbronchial biopsy provided an early diagnosis (positive AFB smear or granulomata on biopsy) in 23 (34%) of 67 HIV-infected patients whose AFB smears were negative or not available (7). Pre-bronchoscopy sputum cultures were positive in 89% of the subjects. Transbronchial biopsy provided the exclusive means for an early diagnosis of tuberculosis in 10% of the patients (11). Therefore, when an HIV-infected patient is undergoing bronchoscopy as part of an evaluation for suspected tuberculosis, a transbronchial biopsy should be performed with bronchoalveolar lavage. Additionally,

post-bronchoscopy sputum specimens should be obtained for AFB smear and culture.

Nontuberculous mycobacteria (NTM) also are a common cause of disease in patients with advanced HIV infection; the two most common are *Mycobacterium avium* complex (MAC) and *Mycobacterium kansasii*. *M. kansasii* may present with symptoms and findings exactly like those caused by *M. tuberculosis*. MAC usually presents as a disseminated disease in patients with CD4 lymphocyte counts less than 50 cells/ μ L. However, MAC complex occasionally causes focal pulmonary disease in patients with higher CD4 lymphocyte counts.

The predictive value for *M. tuberculosis* using a positive AFB sputum smear will vary depending on the relative prevalence of the different mycobacterial species in a given population. Individuals who have AFB seen on microscopic examination of a respiratory specimen should be assumed to have tuberculosis and treated accordingly until the cultures are final and/or the species is identified. For patients in whom MAC is highly likely, azithromycin or clarithromycin can be added to the standard antituberculosis treatment regimen.

Indications for Admission and Isolation

In addition to the indications for admission noted earlier for people who are not infected with HIV, all HIV-infected patients with lung disease of unknown etiology should be considered for admission to the hospital (Chapter 75). Because of the difficulty in distinguishing tuberculosis from other opportunistic pathogens, clinicians should have a low threshold for isolating HIV-infected patients with lung disease of unknown etiology. Although this practice is costly, in some centers all HIV-infected patients with pulmonary disease of unknown etiology are isolated until they are demonstrated to have 3 negative AFB sputum smears.

Initial Therapy

Despite being immunocompromised, HIV-infected individuals with tuberculosis respond well to regimens containing isoniazid and rifampin. Thus, the current recommendations are to begin the same antituberculosis regimens as used in HIV-seronegative patients, with two exceptions (10). On the basis of data demonstrating an increased frequency of rifampin resistance among patients having CD4 cell counts $<100/\mu$ L, it is recommended that patients with <100 cells/ μ L be treated with daily or 3-times weekly therapy in the continuation phase. Twice weekly therapy should not be used in patients with CD4 counts <100 cells/ μ L. Once weekly administration of isoniazid-rifampin should not be used in any HIV-infected patient.

Therapy should be initiated as soon as tuberculosis is suspected because delays in treatment have been associated with a high mortality (9). The duration of therapy for most

HIV-infected patients should be 6 months. However, when breaks in therapy are frequent or prolonged, the duration of therapy should be prolonged to nine months, particularly in patients who are slow to respond to therapy. As with HIV-negative patients, the duration of treatment should be prolonged in patients who remain AFB smear-positive after two months of therapy and who have cavitation on a chest radiograph.

The treatment of tuberculosis in HIV-infected individuals is complicated by the frequency of drug interactions and the possibility of paradoxical reactions. Highly effective antiretroviral agents, such as the protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (NNRTIs) have pharmacokinetic interactions with rifampin derivatives, such as rifampin, rifapentine, and rifabutin. The rifampin derivatives (rifampin $>$ rifapentine $>$ rifabutin) are inducers of the cytochrome P450 enzyme pathway. The PIs and NNRTIs are metabolized via this pathway, so when these drugs are given concurrently with a rifampin, the serum concentration is decreased, possibly to subtherapeutic levels. To further complicate the situation, certain NNRTIs and PIs are inhibitors of the cytochrome P450 through which rifabutin is metabolized. Consequently, serum concentrations of rifabutin will be increased, sometimes to toxic levels. Fortunately, dosage adjustments in rifabutin and/or the PIs and NNRTIs can enable safe and effective dosing of each class of drug. The reader is referred to reviews (12) of this subject and a new CDC website (www.cdc.gov/nchstp/tb) and encouraged to obtain expert consultation because of the complexity of some of the dosage adjustments and the rapidly changing recommendations in this area.

In some patients, suspected tuberculosis turns out to be another mycobacterial infection such as *M. kansasii* or MAC. The current recommendation for the treatment of pulmonary disease caused by *M. kansasii* is the regimen of isoniazid, rifampin (rifabutin), and ethambutol given daily for 18 months, with at least 12 months of negative sputum cultures (13). For patients who do not tolerate one of these medications, clarithromycin or azithromycin are reasonable alternatives. Disseminated MAC should be treated with daily clarithromycin (500 mg twice a day) or azithromycin (250–500 mg once a day), plus ethambutol (15 mg/kg/day). A third drug, preferably rifabutin, should be added if possible (13). Therapy should be continued for life unless immune reconstitution occurs as a consequence of antiretroviral therapy. Secondary prophylaxis can be discontinued if the patient has received a completed course of at least 12 months of treatment for MAC, is asymptomatic with respect to MAC infection, and has a sustained increase (e.g., over at least 6 months) in the CD4 lymphocyte count to >100 cells/ μ L after antiretroviral therapy (14).

Clinicians should seek early expert consultation in the evaluation of HIV-infected patients with new lung disease or febrile illness. Invasive diagnostic procedures are much more

likely to be necessary in the workup of HIV-infected patients than in seronegative individuals. In addition, HIV-infected patients, particularly those receiving antiretroviral therapy, may not tolerate standard regimens, as described above.

Issues During the Course of Hospitalization

HIV-infected patients with tuberculosis should be followed closely for signs of drug toxicity and for response to therapy. Whether or not HIV-infected patients have an increased frequency of side effects is not clear. However, because patients with HIV infection are frequently taking many different medications, the possibility of drug interactions is increased.

The HIV-infected patient should also be monitored carefully for signs of clinical and bacteriologic improvement. Repeat sputum specimens should be obtained in persons who have AFB smear-positive tuberculosis. Studies have demonstrated that sputum conversion rates are similar, regardless of HIV serostatus.

In some patients, clinical and/or radiographic findings worsen during the course of therapy. This is referred to as a "paradoxical reaction" and is thought to be the result of reconstitution of immune responsiveness, owing to either antiretroviral treatment or treatment of tuberculosis. Paradoxical reactions have been reported in 6%–36% of HIV-infected patients with tuberculosis, and the reactions appear to be more common in patients receiving antiretroviral drugs. When the reaction is severe and life threatening, corticosteroids are indicated.

Discharge Issues

It is very important to contact the local public health department well in advance of discharge. Generally, HIV-infected patients with tuberculosis should be treated with DOT. Because many HIV-infected patients may be returning to an institutional or congregate living facility, the rules of each facility must be ascertained before discharge. Most facilities require that patients have three consecutive negative AFB smears before returning.

COST CONSIDERATIONS AND RESOURCE USE

Most patients with suspected tuberculosis do not require hospitalization. The cost of treatment increases significantly if the patient is hospitalized. In fact, inpatient treatment of tuberculosis accounts for 60% of the total costs of tuberculosis treatment in the United States (15). If patients do not require hospitalization for clinical reasons, preventing unnecessary hospitalization would significantly reduce the overall costs of treatment. Most patients, even those with conditions likely to interfere with treatment compliance, can be treated as outpatients using DOT. Thus, hospitalization simply to ensure treatment is rarely neces-

sary. In persons who are hospitalized, enhanced ability to predict who does or does not have tuberculosis (such as with more rapid testing) would also save money by preventing the unnecessary isolation of many patients.

KEY POINTS

- The best way to prevent nosocomial transmission of tuberculosis is to not hospitalize patients unnecessarily.
- When hospitalization is necessary, patients should be isolated immediately and treatment begun as soon as possible in cases in which the clinical suspicion is moderate to high, even if the initial AFB smears are negative.
- Patients with suspect pulmonary tuberculosis may be safely removed from isolation after three negative AFB smears have been obtained and the patient is improving on therapy.
- Suspected cases of tuberculosis should be reported promptly to the local department of public health.
- The current 6-month tuberculosis treatment regimen is highly effective in both HIV-seronegative and seropositive cases, particularly when given under direct supervision.
- In HIV-infected individuals who are taking antiretroviral regimens, the tuberculosis treatment and/or antiretroviral regimen may need to be modified. Expert consultation should be obtained.

Urinary Tract Infection

68

Thomas M. Hooton

INTRODUCTION

Most urinary tract infections (UTIs) are diagnosed and treated in the outpatient setting, but many patients with community-acquired UTIs require hospitalization. Moreover, UTIs are the most common type of nosocomial infections in the United States, resulting in more than 1 million nosocomial UTIs annually, with urinary catheter-associated infections accounting for 88% of the infections (1). Catheter-associated bacteriuria is the most common source of Gram-negative bacteremia in hospitalized patients. Asymptomatic bacteriuria occurs in up to 53% of elderly women and 37% of elderly men who are institutionalized.

UTIs in hospitalized patients are either community-acquired or hospital-acquired and may be limited to the lower urinary tract (cystitis, asymptomatic bacteriuria, or prostatitis) or involve the upper urinary tract (including pyelonephritis and renal or perirenal abscess). It is unusual for patients with community-acquired cystitis or prostatitis to require admission to the hospital. UTI in hospitalized patients, therefore, generally consists of community-acquired acute uncomplicated pyelonephritis in young women, community-acquired complicated upper-tract infection in patients with functional or anatomically abnormal urinary tracts, and nosocomial lower or upper UTIs. Nosocomial UTIs are considered (by definition) complicated, and almost all occur in the setting of obstruction of the urinary tract, vesicoureteral reflux, neurogenic bladder, diabetes, or urologic instrumentation, especially urethral catheterization. A complicated UTI is one that is associated with a condition that increases the risk of treatment failure or serious complications (Table 68.1).

The approach to hospitalized patients with UTI is generally to (a) obtain a urine specimen to confirm the presence of pyuria, (b) make a definitive microbiologic diagnosis and determine the antimicrobial susceptibility profile of the causative uropathogen, (c) start empiric antibiotics, (d) determine whether there are complicating factors that

might compromise antimicrobial management, (e) correct such factors if deemed appropriate, and (f) observe the patient carefully on therapy. *Escherichia coli* is the most common causative uropathogen, but the profile of uropathogens causing complicated UTI, especially nosocomial UTI, is broad (Table 68.2), and antimicrobial resistance is common. Resistance to commonly used antimicrobials appears to be increasing in prevalence even in the setting of uncomplicated UTI (2). Therefore, empiric therapy for a patient ill enough to be hospitalized should be broad-spectrum. The usual duration of therapy is approximately 7–14 days, but therapy might be for a longer or shorter period depending on the patient's underlying complicating factors, site of infection, and clinical response.

LOWER URINARY TRACT INFECTIONS (CYSTITIS, PROSTATITIS, ASYMPTOMATIC BACTERIURIA)

Issues at the Time of Diagnosis

Clinical Presentation

The presentation of hospitalized patients with UTI varies according to the clinical setting. Cystitis, prostatitis, and asymptomatic bacteriuria in the hospitalized patient are likely to have been acquired during the patient's hospitalization. Patients with community-acquired lower UTIs, on the other hand, usually do not require hospitalization. Patients with *acute cystitis*, whether community- or hospital-acquired, generally present with acute onset of dysuria, frequency, urgency, or suprapubic pain in the absence of fever or costovertebral angle tenderness. Symptoms and signs of patients with UTI at the extremes of age or with neurologic disease are often subtle and nonspecific and may be limited to symptoms such as fatigue, irritability, malaise, nausea, headache, abdominal or back pain, or

other vague symptoms. Men with *acute bacterial prostatitis* usually present with a UTI syndrome manifested by dysuria, frequency, urgency, obstructive voiding symptoms, fever, chills, and myalgias. The prostate also is tender and swollen. *Asymptomatic bacteriuria*, by definition (see later in this chapter), occurs in the asymptomatic patient and is detected by urine culture. Screening cultures for asymptomatic bacteriuria are recommended only in selected patients, as discussed below.

Differential Diagnosis and Initial Evaluation

The differential diagnosis for cystitis includes urethritis and vaginitis, and for prostatitis includes cystitis and obstructive uropathy. The clinician usually is alerted to the urinary tract as the source of the patient's symptoms because of the constellation of dysuria, frequency, and urgency in the presence of pyuria. Pyuria often is present in a catheterized patient and may lead the clinician to wrongly conclude that UTI is the cause of the patient's symptoms. Patients should undergo a complete history, physical examination, and laboratory evaluation to make sure that UTI is the correct diagnosis and that other intra-abdominal or genitourinary conditions are not present. A prostate examination is recommended in men in whom the diagnosis of acute

prostatitis is being considered, but *massage is contraindicated* because of the risk of precipitating bacteremia.

In patients with a suspected UTI, a urinalysis to look for pyuria and hematuria should be performed. Pyuria is present in almost all patients with acutely symptomatic UTI, and the absence of pyuria suggests a diagnosis other than UTI. Pyuria is not specific for UTI, however, especially in the catheterized patient. Microscopic evaluation of the urine for bacteriuria is an insensitive test, because pathogens in low quantities ($<10^4$ colonies per milliliter) are difficult to find on the wet mount or Gram stain, even on a spun specimen. A urine Gram stain may be particularly useful because distinction between Gram-positive and Gram-negative infections can influence empiric therapy. The presence of hematuria should be assessed in the noncatheterized patient because it is frequently present in persons with UTI but not in persons with urethritis or vaginitis.

Urine cultures and antimicrobial susceptibility testing of uropathogens should be performed routinely in all hospitalized patients with suspected UTI. The definitive diagnosis of UTI is made in the presence of significant bacteriuria, generally defined as more than 10^5 uropathogens per milliliter of voided midstream urine. Several recent studies have shown that this is an insensitive standard if applied to patients with acutely symptomatic UTI. The Infectious Disease Society of America has defined significant colony counts for acute *uncomplicated* cystitis in women as at least 10^3 colonies per milliliter, for *complicated* cystitis as at least 10^3 colonies per milliliter (except if urine cultures are obtained through a catheter, in which case a level of at least 10^2 colonies per milliliter is considered evidence of infection), and for *cystitis* in men as at least 10^4 colonies per milliliter (3). *Asymptomatic bacteriuria* is identified as the presence of two consecutive clean-voided urine specimens with at least 10^5 colonies per milliliter of the same uropathogen in the absence of symptoms.

From Gupta K, Hooton TM, Stamm WE. Increasing antimicrobial resistance and the management of uncomplicated community-acquired urinary tract infections. *Ann Intern Med* 2001;135:41–50, and Nicolle LE. A practical guide to the management of complicated urinary tract infection. *Drugs* 1997;53:583–592.

Indications for Hospitalization and ICU Admission

Patients with community-acquired lower UTI usually do not require hospitalization. Indications for admission of patients with UTI to the hospital include the inability to maintain oral hydration or take medications, the need to relieve obstruction of the urinary tract or manage another complicating factor, uncertain social situation or concern about compliance, the need for parenteral antibiotics that cannot be arranged for on an outpatient basis, uncertainty about the diagnosis, and severe illness with high fevers, severe pain, and marked debility. Patients with lower UTIs rarely require ICU care, although ICU patients are at high risk for developing cystitis or asymptomatic bacteriuria because most of them require indwelling catheterization.

Initial Therapy

Cystitis

By definition, *cystitis requiring hospitalization or occurring in the hospital is complicated*. Unlike the narrow and predictable spectrum of causative agents in uncomplicated infection, a broad range of bacteria can cause complicated infections, and many are resistant to multiple antimicrobial agents. Although *E. coli* is the predominant uropathogen in complicated UTI, uropathogens other than *E. coli* account for a relatively higher proportion of cases compared with uncomplicated UTIs; these uropathogens include *Citrobacter* spp., *Enterobacter* spp., *Pseudomonas aeruginosa*, enterococci, *Staphylococcus aureus*, and fungi (Table 68.2) (4). Patients with chronic conditions, such as spinal cord injury and neurogenic bladder, are relatively more likely to have polymicrobial and multidrug-resistant infections.

Therapy of patients with complicated UTI must be guided by the results of urine cultures, which provide information on the responsible organism and antimicrobial susceptibility patterns. Any known underlying structural or functional urologic abnormalities related to the UTI must be corrected if possible to decrease the risk of severe complications, persistence, or recurrence of UTI. An ultrasound examination or other imaging procedure should be performed and a urinary catheter placed in a patient who has obstructive symptoms or who does not urinate appropriately under observation.

For empiric therapy in patients with mild-to-moderate cystitis who can be treated with oral medication, the fluoroquinolones provide the broadest spectrum of antimicrobial activity, covering most expected pathogens and achieving high levels in the urine and urinary tract tissue. In contrast to other fluoroquinolones, moxifloxacin and trovafloxacin may not achieve high enough concentrations in urine to be effective for complicated UTI and are not recommended for this indication. If the infecting pathogen is

known to be susceptible, other agents listed in Table 68.3 are reasonable therapeutic choices. β -lactam antibiotics and nitrofurantoin are generally considered to be safe in pregnancy, but a broad-spectrum parenteral agent other than a fluoroquinolone, such as ceftriaxone, should be used empirically in pregnant women for all symptomatic infections other than mild cystitis until susceptibility data are available. Nitrofurantoin should otherwise be avoided in the treatment of complicated UTI.

Fungal UTI is most often caused by *Candida* spp. and usually is associated with diabetes, advanced age, renal transplantation, or the use of indwelling catheters or stents, corticosteroids, or broad-spectrum antibiotics (5). The presence of pyuria and fungal quantification in urine culture may not distinguish colonization from invasive infection, and direct visualization or biopsy may be warranted. An ultrasound or other imaging study should be performed to rule out the possibility of predisposing factors or bladder or renal fungus balls, which may require surgical intervention. The urinary catheter, if present, should be changed or removed if possible. Symptomatic candidal cystitis should be treated with oral fluconazole 200 mg on day 1 followed by 100 mg once daily for 4 days, or local instillation of amphotericin-B 50 mg in 1 L of sterile water at 40 mL/h for 2–5 days. The optimal duration of therapy is not known, and shorter or longer courses are advised by some authorities.

Asymptomatic candiduria usually resolves spontaneously after catheter removal, although it may persist for months. Although the risk of symptomatic infection, especially upper

^a Fluoroquinolones are the agents of choice for empiric therapy, but should be avoided in pregnancy if possible.

^b Trimethoprim-sulfamethoxazole should be used only if the causative uropathogen is known to be susceptible.

^c Amoxicillin or amoxicillin-clavulanate should be used only if the causative uropathogen is known to be susceptible or in addition to a broad-spectrum agent if empiric coverage against enterococci is desirable.

^d Nitrofurantoin should be used only for mild cystitis in pregnant women.

tract infection, appears to be low, persistent asymptomatic candiduria probably should be treated in patients with diabetes, neutropenia, or obstruction or those who have received a renal transplant or are about to undergo invasive urologic surgery. Oral fluconazole or amphotericin B irrigation can be used in such situations.

Asymptomatic Bacteriuria

Screening and treatment of the hospitalized patient for asymptomatic bacteriuria generally is not warranted, although recommendations vary according to the clinical setting. Patients with asymptomatic bacteriuria who may be at high risk for serious complications (and thus warrant a more aggressive approach to diagnosis and treatment) include pregnant women, patients undergoing traumatic genitourinary surgery, and renal transplant patients (6). The choice of antimicrobial agent should be based on the susceptibility of the uropathogen and the safety of the patient. Pregnant women with asymptomatic bacteriuria should be treated with agents considered to be safe in pregnancy, such as amoxicillin, cephalosporins, or nitrofurantoin.

There are some situations in which screening for and treatment of asymptomatic bacteriuria is not indicated and may in fact result in adverse effects and increased antimicrobial resistance. These situations include asymptomatic bacteriuria associated with bladder catheterization or neurogenic bladder, and asymptomatic bacteriuria in individuals older than 65 years.

Prostatitis

The most common organisms causing community-acquired acute bacterial prostatitis are Gram-negative bacilli and, less commonly, enterococci and *S. aureus*. Like complicated UTI, nosocomial prostatitis may be caused by a wider spectrum of bacteria, many of which are multidrug-resistant. Oral or parenteral fluoroquinolones are the antibiotics of choice for treatment of prostatitis because of their broad spectra of activity and excellent penetration into the prostate gland (7). Parenteral agents appropriate for the treatment of hospitalized patients with acute bacterial prostatitis are the same as those for complicated pyelonephritis (Table 68.4). If the urine Gram stain suggests the presence of Gram-positive cocci, a regimen with activity against *S. aureus* and enterococci as well as Gram-negative bacilli (e.g., piperacillin-tazobactam) should be considered. Empiric coverage should include vancomycin if methicillin-resistant *Staph aureus* (MRSA) is a concern. Nitrofurantoin should not be used for the treatment of prostatitis, because it does not achieve reliable tissue levels.

Indications for Early Consultation

A urologic evaluation is indicated at the time of admission if the patient presents with strong evidence of a complicating factor. For example, if the patient has renal colic in the setting of a UTI, an ultrasound or computed tomography

^a Recommended for serious complicated pyelonephritis.

^b Avoid fluoroquinolones in pregnancy if possible.

study should be performed to rule out the presence of a stone or obstruction. A urology consultation should be considered if the patient complains of obstructive symptoms, a large postvoid residual urine volume is found by catheterization or ultrasound, or there is radiographic evidence of an abscess or other complicating factor that may require surgical intervention. An infectious disease consultation should be considered if the diagnosis is in question after an initial evaluation of a febrile patient, the patient is very ill, or the antibiotic choice is complicated by multiple drug allergies, multidrug-resistant uropathogens, multiple sites of infection, young age, or pregnancy.

Issues During the Course of Hospitalization

Intravenous fluids are administered for volume depletion or for inability to take fluids orally. Phenazopyridine, 200 mg orally three times daily, is recommended for patients with severe dysuria. Opiates occasionally may be needed for severe pain, but it is important to make sure that the patient does not have a suppurative complication warranting drainage as the source of the discomfort.

Patients with lower UTI who are treated with antibiotics appropriate for the causative uropathogens usually demonstrate marked improvement in 24–48 hours. The antimicrobial regimen should be tailored once the infecting strain has been identified and antimicrobial susceptibilities are known. This information usually is available within 48–72 hours after the culture is taken. Those on parenteral therapy can be switched to oral treatment after clinical

improvement occurs if the patient can tolerate oral hydration and medications.

Discharge Issues

Most individuals with lower UTIs are ready for discharge if they are able to tolerate oral medications. By the time of discharge, urinary signs and symptoms should be improved markedly, although they may not have resolved. The recommended duration of therapy for complicated cystitis ranges from 7–14 days, but longer therapy may be indicated in patients who have a delayed clinical response. Regimens of antibiotics for 3–7 days can be used if treatment of asymptomatic bacteriuria is indicated. The recommended duration of treatment for acute bacterial prostatitis is 10–14 days.

Patients being treated for cystitis or prostatitis should be instructed to contact their primary physicians or return to the emergency department if there is development, worsening, or recurrence of urinary symptoms, fever, or obstructive symptoms. Following treatment of UTI in pregnancy, a culture should be obtained one week after therapy to ensure bacteriologic cure. If the post-treatment culture is positive, a longer course with an antibiotic to which the causative uropathogen is susceptible should be used. A follow-up urine culture also generally is recommended in the non-pregnant patient, although it has not been established that treatment of asymptomatic bacteriuria in such populations is beneficial. Patients do not necessarily need to be seen for an office visit if their symptoms have resolved. If a follow-up urine culture is desired, patients can drop it off at the laboratory or office.

Prophylaxis may be indicated in some patients who have frequent recurrences of cystitis or pregnant women who have recurrences of asymptomatic bacteriuria.

UPPER URINARY TRACT INFECTION (PYELONEPHRITIS, PERIRENAL ABSCESS)

Issues at the Time of Diagnosis

Clinical Presentation

Acute uncomplicated pyelonephritis in young healthy women is suggested by fever, chills, flank pain, nausea or vomiting, and costovertebral-angle tenderness. Cystitis symptoms are variably present. Although acute pyelonephritis may present as a mild illness, it also may present as a catastrophic illness with sepsis syndrome, shock, and multiple organ system dysfunction (Chapters 25 and 26). Patients with *complicated pyelonephritis* present with similar symptoms and signs, but symptoms associated with the underlying complicating factor, such as nephrolithiasis, may obscure

the diagnosis. Patients with *renal or perirenal abscesses* usually present with fever, chills, back or abdominal pain, and costovertebral-angle tenderness. The pain may be referred to the groin or leg if there is extension of a perirenal abscess. Such patients may have no urinary symptoms or findings if the abscess does not communicate with the collecting system (as is often the case with a cortical abscess). Bacteremia is common in patients with upper UTI, especially those with an abscess.

Differential Diagnosis and Initial Evaluation

Even in patients presenting with classic pyelonephritis symptoms and signs, the clinician must consider other abdominal conditions in the differential diagnosis. Many conditions can be confused with UTI. The differential diagnosis includes appendicitis, cholelithiasis, diverticulitis, gastroenteritis, pelvic inflammatory disease, ectopic pregnancy, and other intra-abdominal or retroperitoneal conditions. Patients should undergo a complete history, physical examination, and laboratory evaluation to make sure that UTI is the correct diagnosis and that other serious conditions do not coexist. An evaluation of the patient's hemodynamic status is warranted because urosepsis is a serious complication of UTI.

A pretreatment urinalysis, urine Gram stain, and urine culture as described previously should be performed for all patients hospitalized with presumptive upper UTI. It is reasonable to obtain blood cultures in moderately-to-severely ill hospitalized patients with UTI to help stage the severity of the infection. A urologic evaluation is warranted at the time of diagnosis if the patient has symptoms or signs suggestive of obstructive uropathy, nephrolithiasis, or another potentially serious complicating factor. Computed tomography is recommended if an abscess is suspected to establish the diagnosis and location. It is sometimes necessary to aspirate fluid collections in order to confirm the diagnosis and to obtain cultures to direct therapy.

Indications for Hospitalization and ICU Admission

Outpatient treatment of UTI is considerably less expensive than inpatient treatment. The availability of broad-spectrum oral fluoroquinolones and once-daily dosing of ceftriaxone, ertapenem, and aminoglycosides allows for the effective outpatient treatment of many patients with upper UTIs, including many complicated infections, resulting in great cost savings. Outpatient therapy has been shown to be safe and effective for selected patients who can be stabilized with parenteral fluids and antibiotics in an urgent care facility and sent home on oral antibiotics under close supervision (8). In general, however, outpatient therapy should be reserved for nonpregnant individuals with mild-to-moderate acute cystitis (uncomplicated or complicated)

or acute uncomplicated pyelonephritis, who are compliant and can be reached easily by telephone for early follow-up, and are likely to return to care in a timely fashion if symptoms do not resolve rapidly. Indications for admission of patients with upper tract infection include the factors mentioned previously for cystitis. In addition, patients with pyelonephritis who have underlying conditions such as pregnancy and diabetes that greatly increase the risk of serious complications generally should be admitted for close observation.

Clear indications for ICU admission or transfer include hemodynamic instability caused by the sepsis syndrome or hypovolemia. Rarely, pyelonephritis is complicated by Acute Respiratory Distress Syndrome and warrants ICU management.

Initial Therapy

Acute Uncomplicated Pyelonephritis

The spectrum of agents responsible for acute uncomplicated pyelonephritis is similar to that in uncomplicated cystitis, with *E. coli* the causative pathogen in approximately 70%–95% of cases and *Staphylococcus saprophyticus* in 5% to more than 20%. The antimicrobial susceptibility of causative uropathogens likewise is similar to that of uropathogens causing uncomplicated cystitis.

Women with uncomplicated pyelonephritis who are ill enough to be hospitalized should receive parenteral therapy with one of several broad-spectrum regimens (Table 68.4). For patients in whom the Gram stain is not suggestive of enterococcal infection, it is reasonable to initiate empiric treatment with ceftriaxone, 1 g per 24 hours. Aminoglycosides given once daily, parenteral fluoroquinolones, and penicillin/ β -lactamase inhibitor combinations are also effective for the treatment of uncomplicated pyelonephritis. As noted previously, certain fluoroquinolones (moxifloxacin and trovafloxacin) may attain suboptimal levels in the urine and should not be used for renal infection. If enterococci are suspected based on the Gram stain, ampicillin plus gentamicin, ampicillin-sulbactam, or piperacillin-tazobactam are reasonable broad-spectrum empiric choices. Trimethoprim-sulfamethoxazole should not be used alone for empiric therapy in areas with a high prevalence of resistance to this agent. Nitrofurantoin should not be used for pyelonephritis.

Complicated Pyelonephritis

As noted in the previous section, complicated UTIs are caused by a broad range of bacteria (Table 68.2), many of which are resistant to multiple antimicrobial agents. Empiric therapy of patients with complicated pyelonephritis must be guided by the results of the urine Gram stain and subsequent culture and susceptibility data. Any known underlying structural or functional complications must be corrected, if possible. For initial empiric treatment, a

broad-spectrum parenteral antimicrobial regimen should be used (Table 68.4). Empiric therapy should cover *S. aureus* until the possibility of infection with this organism can be excluded; this coverage should be active against MRSA (e.g., vancomycin) in areas with a high prevalence of MRSA. For patients with limited vascular access, oral ciprofloxacin, gatifloxacin, levofloxacin, or ofloxacin can be considered because of their excellent bioavailability. If the infecting pathogen is known to be susceptible, trimethoprim-sulfamethoxazole or other agents are also reasonable therapeutic choices. Linezolid 600 mg twice daily can be used orally or parenterally for documented infection with enterococci resistant to vancomycin or methicillin-resistant *S. aureus*.

Fungal infection of the upper urinary tract usually is caused by *Candida* spp. and may be caused by ascending infection or, much more commonly, hematogenous spread (5). Fungus balls in the ureter and renal pelvis are a complication of ascending infection; they may cause hematuria or obstruction. Most patients with renal infection from hematogenous spread do not have symptoms referable to the kidney. Systemic amphotericin B for a total dose of 1–2 g over a course of 4–6 weeks is recommended for renal fungal infection and other simultaneously infected sites (5). Fluconazole also may be effective. Surgery may be indicated for the treatment of fungus balls or complicating conditions.

Perirenal Abscess

A *renal cortical abscess* (renal carbuncle) is usually caused by *S. aureus*, which reaches the kidney through the hematogenous route. Treatment with antibiotics that cover *S. aureus* and other uropathogens causing complicated UTI (Table 68.2) is usually effective, and drainage usually is not required unless the patient is slow to respond. In contrast, a *renal corticomedullary (perinephric) abscess* usually results from ascending UTI in association with an underlying urinary tract abnormality such as obstructive uropathy or vesicoureteral reflux. It is usually caused by common uropathogenic species such as *E. coli* and other coliforms. Treatment with broad-spectrum antimicrobial agents without drainage is usually effective if the abscess is not very large and if the underlying urinary tract abnormality can be corrected. Aspiration of the abscess may be necessary in some cases, and nephrectomy may be required occasionally in patients with diffuse renal involvement or severe sepsis. Perinephric abscesses usually occur in the setting of obstruction or other complicating factors (Table 68.1) and result from ruptured intrarenal abscesses, hematogenous spread, or spread from a contiguous infection. Causative uropathogens are those commonly found in complicated UTIs (e.g., Gram-negative bacilli, *S. aureus*, and enterococci) (Table 68.2), and polymicrobial infections are common. In contrast to the other types of renal abscesses, drainage of pus is the cornerstone of therapy, and nephrectomy is sometimes indicated.

Indications for Early Consultation

A urologic evaluation or consultation with a urologist or infectious disease specialist is indicated for the same reasons as outlined for lower UTI. Moreover, any patient with a known anatomic or functional abnormality of the urinary tract who presents with clinical evidence of upper UTI should have an ultrasound or computed tomography performed to determine the need for surgery or other intervention.

Issues During the Course of Hospitalization

Intravenous fluids and analgesia may be warranted as noted in the previous section. The antimicrobial regimen should be tailored as soon as possible once the infecting strain has been identified and antimicrobial susceptibilities are known. The patient who has clinically improved and can tolerate oral hydration and medications may be switched to oral treatment with an agent to which the causative uropathogen is susceptible. Patients with acute uncomplicated pyelonephritis often can be switched to oral therapy within 72 hours (if susceptibility data are available), although longer intervals of parenteral therapy occasionally are indicated depending on the clinical response. Patients with complicated pyelonephritis or with an abscess respond more slowly.

If there has been little or no improvement in fever and symptoms by 72 hours, a repeat urine culture and an imaging study may be indicated to rule out persistent infection, obstruction, abscess, or other unrecognized urologic abnormalities. Patients whose conditions worsen after initiation of therapy may warrant an earlier evaluation. Conversely, many patients who have no detectable urologic abnormality remain febrile longer than 72 hours, and a urologic evaluation may be reasonably postponed if the patient is otherwise improving. Computed tomography is markedly superior to intravenous urography and ultrasound in demonstrating the parenchymal abnormalities caused by renal infection and in delineating the extent of the disease (9).

Discharge Issues

Most individuals with UTI are ready for discharge when they are able to tolerate oral medications. However, in a patient with multiple medical problems and an extended hospitalization, treatment of a nosocomial UTI may have little impact on the timing of discharge. By the time of discharge, urinary signs and symptoms should be markedly improved, although they may not be resolved. The presence of a low-grade temperature or mild abdominal or back tenderness is not a contraindication to discharge. It is important to make sure that the patient can tolerate the switch to an oral regimen for a few hours before discharge, but *it is not necessary to routinely observe the patient overnight* in the

hospital after the switch. When patients are discharged depends on a number of issues including their social situation, support network, medical condition, insurance, and need for parenteral therapy.

Recommended treatment durations vary from one to three weeks or even longer. For acute uncomplicated pyelonephritis, 6-week regimens are no more effective than 14-day regimens and cause more side effects (10). In those mildly to moderately ill patients who have a rapid response with resolution of fever and symptoms soon after initiating treatment, treatment usually can be discontinued at 7–10 days (11). Of note, however, is that β -lactam regimens shorter than 14 days have been associated with unacceptably high failure rates. Patients with complicated pyelonephritis should be treated for 14–21 days or longer if symptoms and fever have not fully resolved.

Patients should be instructed to contact their primary care physicians or return to the emergency department if there is development, worsening, or recurrence of fever or of urinary or obstructive symptoms. A follow-up urine culture 1 or 2 weeks after treatment is recommended although, as noted previously for lower tract infection, it has not been established that treatment of asymptomatic bacteriuria in such populations is beneficial. Pregnant women should have follow-up urine cultures and be managed as described previously. Patients who have undergone urologic procedures may need to be seen by the urologist after discharge.

COST CONSIDERATIONS AND RESOURCE USE

Several developments in the past decade have resulted in cost-saving strategies in the management of UTI. Most importantly, the availability of the new oral fluoroquinolones and extended interval dosing of certain parenteral antibiotics have had tremendous impact on the cost of treatment of UTI. Thus, many patients with mild-to-moderately complicated UTIs caused by multidrug-resistant uropathogens now can be managed in the outpatient setting. Likewise, hospitalized patients can be discharged from the hospital after an early switch to broad-spectrum oral antibiotics or home parenteral antibiotic therapy. Earlier discharge from the hospital also has been facilitated by the wider availability and decreasing cost of sophisticated imaging studies and less invasive interventional techniques, both of which have allowed for more rapid diagnosis and management of disorders previously requiring surgical therapy.

Because the vast majority of nosocomial UTIs is associated with catheter use, prevention of catheter-associated infections should be given high priority in hospital settings. Effective strategies include avoidance of catheter placement if possible and, if catheter use is necessary,

sterile insertion, prompt removal, and strict adherence to a closed collecting system (12). Silver alloy-coated urinary catheters appear to reduce catheter-associated bacteriuria (12). Intermittent catheterization and, in men, condom catheterization appear to result in lower rates of bacteriuria compared with long-term indwelling catheterization. Other approaches that have been effective in some (but not other) studies include the use of preconnected catheter-collecting tube units, the use of disinfectants in collecting bags, and the regular periurethral application of antimicrobial creams. Treatment of asymptomatic bacteriuria in catheterized patients is not recommended (6).

KEY POINTS

- Because the vast majority of nosocomial UTIs are associated with catheter use, prevention of catheter-associated infections should be given high priority in hospital settings.
- Unlike the narrow and predictable spectrum of causative agents in uncomplicated infection, a broad range of bacteria can cause complicated infections, and many are resistant to multiple antimicrobial agents.
- Therapy of patients with complicated UTIs must be guided by the results of urine culture and antimicrobial susceptibility test results.
- Screening and treatment of the hospitalized patient for asymptomatic bacteriuria generally is not warranted but should be performed in selected populations.
- A urologic evaluation should be considered in patients who have not had marked clinical improvement after 72 hours of therapy.
- Several developments in the past decade have resulted in huge cost-saving strategies in the management of UTI, including the availability of new oral fluoroquinolone antibiotics and extended interval dosing of certain parenteral antibiotics. These agents may obviate the need for hospitalization or may facilitate early discharge in those patients requiring an inpatient stay.

Necrotizing Fasciitis

Dennis L. Stevens

INTRODUCTION

While many types of skin and soft tissue infection exist, this review focuses on cellulitis and necrotizing fasciitis (NF). Cellulitis is a common disease that is rarely life threatening and usually can be managed without hospital admission. It is most commonly caused by group A (GAS), B, C, or G streptococci or *Staphylococcus aureus*. Cellulitis may also be secondary to animal or human bites. NF is a rare but often life-threatening, necrotizing infection of subcutaneous tissue and fascia with relative sparing of the underlying muscle. Progression of necrosis can be alarmingly rapid, and shock and multiorgan failure is common. Despite the availability of highly active antibiotics, the morbidity and mortality rates of NF remain high. This is, in part, because of the failure of treatment strategies to alter the physiologic processes responsible for the local tissue destruction and systemic toxicity.

NF encompasses two microbiologic entities. Type I disease is polymicrobial in etiology, typically being caused by mixed anaerobes (e.g., *Clostridium*, *Bacteroides*, *Prevotella*, and *Peptostreptococcus* organisms), streptococci, and enteric Gram-negative bacilli (e.g., *Escherichia coli*, *Klebsiella*, and *Proteus* organisms). Infection often complicates deep wounds (including surgical wounds) when the vascular supply is compromised, as in severe traumatic injury or diabetes. Type II disease is typically a monomicrobial infection, most commonly caused by GAS (hemolytic streptococcal gangrene), *Clostridium perfringens* (traumatic gas gangrene), *Clostridium septicum* (spontaneous gas gangrene), *Aeromonas hydrophilia* (associated with injuries occurring in fresh water), and *Vibrio vulnificus* (associated with injuries exposed to salt water). In the case of GAS NF, infection may occur following bites or

burns, postoperatively (postpartum sepsis), or spontaneously in the absence of a defined portal of entry.

Both cellulitis and NF present important challenges in diagnosis and management. In patients with cellulitis, several clinical conditions and responsible agents can be associated with an adverse outcome if not recognized. The most important challenge for the management of NF is early recognition. In its early stages, NF is difficult to distinguish from cellulitis and may not even be recognized as an infectious process.

CELLULITIS

Issues at the Time of Admission

Clinical Presentation

Prominent features of cellulitis tend to be local, with cutaneous pain, edema, warmth, erythema, and tenderness. The erythematous margins tend to be indistinct because the process is deep, involving the subcutaneous tissues in addition to the dermis. Regional lymphadenopathy and constitutional symptoms of fever, chills, and malaise are uncommon. Cellulitis most frequently involves the extremities, where it is associated with fungal infection of the toes, chronic stasis dermatitis, and chronic lymphedema following radical lymph node dissection. Cellulitis associated with these conditions is most commonly caused by Group A, C, or G streptococci. Recurrent cellulitis is most commonly caused by streptococci in association with chronic lymphedema or prior saphenous vein bypass grafts. Cellulitis associated with *Staphylococcus aureus* usually occurs with a defined focus of infection such as a suture

line infection, carbuncle, sliver, or other foreign body. Cellulitis caused by *S. aureus* may also be associated with infected joints, olecranon bursitis, osteomyelitis, and a variety of prosthetic devices such as intravenous catheters and prosthetic joints. *Erysipelas* is a distinctive type of superficial cellulitis caused by group A streptococci that is associated with early systemic toxicity, prominent lymphatic involvement, and superficial spread with a raised, well-demarcated margin of brilliant red or salmon-colored erythema. Cellulitis can also be associated with animal bites caused by a variety of organisms that colonize the animals' mucous membranes (i.e., *Pasteurella multocida*, *Prevotella*, *Porphyromonas*, *Fusobacterium*, and *Staphylococcus*) and with organisms colonizing the human mouth (i.e., *Eikenella corrodens* and group A streptococcus).

Differential Diagnosis and Initial Evaluation

When an obvious portal of entry is evident or when symptoms appear in a distal extremity with lymphadenitis tracking proximally, the clinical diagnosis of cellulitis usually is obvious. However, irritation or allergic reactions to wound dressings, venous thrombosis, inflammatory skin lesions such as erythema nodosum, eosinophilic cellulitis or fasciitis, or fixed hypersensitivity reactions may cause similar local signs and symptoms. If inflammation is near joints, it may be important to consider gout or other inflammatory arthritides, olecranon bursitis, or a ruptured Baker's cyst.

In patients who have diffuse cellulitis without a defined portal of entry, establishing a specific diagnosis may be difficult. Superficial cultures of skin sites have low sensitivity and specificity for identifying the responsible agent. In contrast, a defined etiology can be established from Gram stain and culture in patients with a defined portal of entry, a localized area of carbuncle or abscess, or obvious draining pus or an animal bite. If the patient is immunocompromised or toxic or if the process is aggressive, establishing an etiologic diagnosis becomes more important and may require blood cultures, aspiration, biopsy, or surgical assistance. Blood cultures are rarely positive in patients with uncomplicated cellulitis but may be useful in the latter clinical situations. Aspiration can be performed by using a 21- or 22-gauge needle and injecting and aspirating 1.0 mL of preservative-free sterile saline (1). Unfortunately, punch biopsies and aspirates have relatively low-to-moderate sensitivity (5%–40%), partly because of sampling error and partly because of the fact that low numbers of bacteria may be present, suggesting that potent toxins or the host response to toxins mediate the signs of acute inflammation. Patients ill enough to require parenteral antibiotics should have a complete blood count. The need for other tests is dictated by the presence of specific underlying illness.

Outlining the margins of inflammation is useful to assess the progression of disease. This assessment is done with a pen at the initial assessment and periodically thereafter. Patients with any type of soft tissue infection who appear toxic should be evaluated carefully for under-

lying deep or metastatic infections and for the possibility of NF. Clues for NF include pain that is out of proportion to the clinical findings, blisters or bullae, and subcutaneous necrosis. Patients with cellulitis over a joint should have a careful physical examination to rule out concomitant infectious bursitis or arthritis. Septic arthritis also may occur in distant joints, and all joints should be evaluated (Chapter 113).

Indications for Hospitalization and Intensive Care Unit Admission

Most patients with uncomplicated cellulitis can be managed in an outpatient setting, even if they require parenteral therapy (2–4). Admission is indicated if patients have clinical signs or laboratory tests suggesting systemic toxicity or if the possibility exists of NF, septic arthritis, or an abscess that may require surgical drainage.

ICU admission generally is necessary in patients who have evidence of septic shock. *Patients with necrotizing fasciitis can deteriorate quickly.* Thus, if the physician has a clinical suspicion of NF, admission to the ICU, aggressive fluid management, and assessment of markers of organ function should be the standard of care (even if the patient is initially stable). One useful marker of a high risk of deterioration is a normal or low white blood cell count. If deep necrotizing infection is suspected, an elevated creatine kinase may also be supportive evidence.

Initial Therapy

In general, cellulitis is caused by staphylococci or streptococci, and a variety of cephalosporins, nafcillin, clindamycin, or newer fluoroquinolones have been useful (Table 69.1). Empiric choices have become more difficult during the past three to four years because of evolving staphylococcal resistance (Chapter 64). For example, 10%–15% of methicillin-sensitive *S. aureus* organisms are now resistant to erythromycin and clindamycin. The prevalence of both hospital-acquired and community-acquired methicillin-resistant *S. aureus* (MRSA) infections is also increasing dramatically in the western world. In addition, aggressive soft tissue infections caused by MRSA have been described in communities across the United States, Australia, and Japan (5). With the prevalence of MRSA approaching 50% in many communities, empiric treatment of *S. aureus* infections must now be based on the clinician's judgment of severity. Specifically, suspected staphylococcal infections in patients who are toxic should be treated with vancomycin, linezolid, or daptomycin. Once susceptibility results are known, antibiotics can step down to more conventional agents. In contrast, in the patient with localized staphylococcal infections who is not toxic, cephalosporins or penicillinase-resistant penicillins can be used, along with careful monitoring for evidence of failure. GAS cellulitis can be treated with penicillin, a cephalosporin, or a penicillinase-resistant penicillin. In penicillin-allergic

TABLE 69.1**PRIMARY AND ALTERNATIVE THERAPEUTIC CHOICES FOR SOFT TISSUE INFECTIONS**

Disease entity	Primary therapeutic agent	Alternative
Erysipelas	Penicillin	Macrolides Clindamycin
Cellulitis		
Localized, mild infection	Cephalosporin Nafcillin Dicloxacillin	Trimethoprim-sulfamethoxazole Fluoroquinolones Clindamycin
Localized, severe infection or MRSA	Vancomycin Linezolid Daptomycin	None
Diffuse, mild, no portal (Groups A, C, or G streptococci)	Penicillin	Clindamycin Cephalosporin
Diffuse, toxic	Clindamycin	
Animal bite	Ampicillin/sulbactam Amoxicillin/clavulanate	Cefoxitin Cefotetan Doxycycline Carbapenem
Human bite	Ampicillin/sulbactam	Cefoxitin Cefotetan Fluoroquinolone + clindamycin
Necrotizing fasciitis		
Mixed aerobic/anaerobic	Ampicillin/sulbactam + ciprofloxacin + clindamycin or metronidazole	Carbapenem Piperacillin/tazobactam
Group A streptococcus	Clindamycin	

patients, clindamycin is a reasonable choice because erythromycin resistance has become more prevalent.

Issues During the Course of Hospitalization

Early administration of antibiotics is the most important immediate management concern. Patients may deteriorate systemically during the first 8–12 hours of antibiotic administration, and potentially septic patients should be monitored closely over this time. NF also may become evident only after hospital admission (see the earlier section on clinical presentation).

Most patients will have less pain and feel better within 24 hours of antibiotic treatment (3). After 3 days, improvement should be evident in virtually all patients, but some degree of fever may persist for several more days. Expansion of the margins of cellulitis almost invariably occurs in the first 24–36 hours after administration of antibiotics. In streptococcal infections in particular, such expansion may be dramatic over the first day. After this, the rate of increase should slow, but margins may continue to expand for 2–3 days. Inflammation in the area may persist for 1–2 weeks, and improvement may be especially slow in diabetic patients or in poorly vascularized limbs.

Elevation of the involved extremity helps reduce the swelling and pain. If it becomes apparent that the degree of pain and swelling requires immobilization of the limb for

more than a few days, prophylaxis for deep venous thrombosis should be considered (Chapter 52).

Initial blood culture results should be reviewed to ensure that therapy is appropriate and to determine whether the spectrum of antibiotics chosen can be narrowed. Chronic wounds may become colonized with a variety of bacteria, including enterococci, enteric Gram-negative bacilli, and *Pseudomonas* organisms. In this setting, results of superficial cultures do not necessarily reflect the pathogens causing the initial infection.

As noted previously, the presence of *S. aureus* in blood cultures means that patients should be monitored carefully for the presence or development of signs of endocarditis. These patients should also have an echocardiogram (Chapter 71). In severely immunocompromised patients, skin flora such as coagulase-negative staphylococci or diphtheroids may cause intravenous site cellulitis. However, in other settings, the isolation of these organisms from blood is almost invariably a result of sample contamination at the time the blood culture was taken, and antibiotic therapy should not be modified in response to such a report.

By the second to fourth day of hospitalization, fever and pain should be improving, the area of cellulitis should be stable or regressing, and the patient should be feeling better. If such improvement is not evident, the initial diagnosis should be reassessed, and possible reasons for failure should be considered (Table 69.2). If a deep abscess

TABLE 69.2**CONSIDERATIONS IF PATIENT IS NOT RESPONDING TO THERAPY BY HOSPITAL DAY 4**

Scenario	Considerations				
Alternate or concomitant diagnosis	Immune-mediated soft tissue inflammation (e.g., vasculitis or erythema nodosum)	Underlying deep infection (e.g., osteomyelitis or pyomyositis)	Deep venous thrombosis	Gout, pseudogout or other monoarthritis (or peri-arthritis)	Ruptured Baker's cyst (for leg cellulitis only)
Correct diagnosis but incorrect antimicrobial agent	See Table 69.1	Consider drug-resistant organism			
Correct diagnosis and antimicrobial agent	Drug not being administered	Oral medication not being absorbed (consider gastric pH)	Ineffective drug dosing (e.g., dosing too low or too infrequent, or drug interactions)		

is suspected, the use of imaging techniques, such as computed tomography (CT) and magnetic resonance imaging (MRI), may guide therapy (6,7).

In patients with uncomplicated cellulitis who are afebrile by the fourth or fifth hospital day, a switch may be made from parenteral to oral antibiotics. Patients with *S. aureus* bacteremia require parenteral therapy for at least 2 weeks if no evidence of an endovascular infection is seen and 4 weeks if it is. Neutropenic patients should be continued on therapy until their neutrophil count recovers or the cellulitis has completely resolved.

Discharge Issues

Patients may be discharged as soon as their infections are stable or improving. In the absence of septic shock, NF, or a requirement for surgery or therapy for serious intercurrent illness, a hospital stay longer than 3–4 days rarely should be required.

Patients should be told at discharge that, depending on the initial severity of the cellulitis, the signs and symptoms may remain for days and even weeks, especially if the cellulitis involves the lower extremities. Slowly improving residual swelling may be present for weeks. Limb elevation and support hose should generally be recommended.

Patients with erysipelas or streptococcal cellulitis who have required hospitalization are at risk of recurrent infection, especially if they have chronic underlying skin lesions (i.e., psoriasis) or impaired lymphatic or venous drainage (i.e., radical mastectomy or saphenous vein stripping). Such patients should be warned of the risk and the need for prompt treatment if cellulitis recurs. They should also be counseled about preventive foot or hand care (e.g., prompt treatment of tinea pedis and prevention of damage around nails).

NECROTIZING FASCIITIS

Issues at the Time of Admission

Clinical Presentation

The early diagnosis of necrotizing fasciitis may be difficult because patients may manifest only severe pain in a limb, along with malaise, chills, and fever (8). Later the area of intense pain may become red, hot, shiny, swollen, and exquisitely tender. Subsequently, there may be blue–black discoloration indicative of superficial necrosis near the center, blistering or bullae formation, and edema that extends beyond the margins of skin erythema. Crepitus may be palpable in patients with NF resulting from gas-forming organisms such as the *Clostridium* spp. (gas gangrene) or mixed aerobic/anaerobic bacteria (necrotizing fasciitis type 1) (7). In contrast, group A streptococcus does not produce gas.

Group A streptococcus causes two types of presentations with necrotizing fasciitis. Approximately 50% of patients with NF caused by group A streptococci may have only fever, chills, and severe pain. In many, hypotension and evidence of renal impairment precede the skin manifestations of NF. In these patients, elevated serum creatinine, hypotension, marked tachycardia, and severe pain should prompt surgical consultation to inspect the deep tissues and to obtain culture material (8,9). While plain radiographs, CT scans, and MRI may demonstrate swelling and edema in NF, they do not provide a definitive diagnosis. An elevation of serum creatinine kinase (CK) may provide additional clues facilitating surgical intervention.

The remaining 50% of patients with necrotizing fasciitis caused by group A streptococcus have an obvious portal of entry, such as a surgical incision, episiotomy, laceration, insect bite, or chicken pox lesion. These patients initially

have cutaneous evidence of local infection and drainage. They then go on to develop toxicity or rapid localized spread and evolution to bullae formation, sloughing of skin, and ecchymosis. All this may occur despite antibiotic treatment, and this progression requires emergent surgical consultation.

Differential Diagnosis and Initial Evaluation

Fever and severe pain should lead to consideration of NF. In 50% of patients, the severe pain is at the exact site of recent, nonpenetrating trauma. *There may not be cutaneous evidence of soft tissue infection.* Depending on the location of the infection, patients who have NF without signs of cellulitis may be incorrectly diagnosed as having muscle strain, gout (or other arthritides), early herpes zoster reactivation, acute myocardial infarction, pulmonary embolus, or deep venous thrombosis.

Laboratory clues to NF include elevated CK, a marked left shift in the differential white blood cell count (8,9), elevated serum creatinine in patients who are not yet hypotensive, low serum albumin, low serum calcium, and markedly elevated C-reactive protein (8,10). Plain radiographs demonstrating tissue gas suggest necrotizing fasciitis type 1 or gas gangrene. CT and MRI scans will demonstrate the level of infection but are not specific for necrotizing fasciitis unless gas is present in the tissue. Because group A streptococcus does not form gas in the tissue, and because necrotizing fasciitis caused by this microbe occurs following nonpenetrating trauma in half the cases of NF, CT and MRI may not distinguish trauma from infection. This dilemma is most evident in women with postpartum group A streptococcal intrauterine infection, in whom the uterus is still swollen and enlarged from the birthing process.

Etiologic diagnosis is important in NF. The presence of soft tissue gas and foul smell suggests anaerobic organisms. Gram stain and cultures from aspiration of bullae or necrotic tissue often yield the responsible pathogens, and blood cultures are positive in approximately 50% of patients (7,8,11,12). Culture of surgical specimens also demonstrates the etiologic pathogen.

Indications for Hospitalization and ICU Admission

All patients in whom the diagnosis of NF has been entertained should be admitted to hospital for *supportive therapy, antimicrobials, and surgical debridement* if appropriate. Patients with NF can deteriorate rapidly, with development of sepsis and progression of the necrosis. Patients with concomitant sepsis syndrome (Chapter 26) require ICU admission. Patients not admitted to the ICU should have vital signs checked and a clinical assessment of the affected area made frequently until the diagnosis of NF is ruled out, surgery is performed, or the margins have stabilized.

Initial Therapy

If it is available immediately, the Gram stain result of an aspirate or biopsy may be used to guide therapy. Mixed Gram-positive and Gram-negative bacteria indicate type I disease, and broad-spectrum coverage for Gram-negative and anaerobic organisms is needed (Tables 69.1 and 69.3). Because of the risk of antimicrobial resistance in Gram-negative organisms, using at least two antibiotics active against enteric Gram-negative bacilli is recommended until culture results are obtained. A carbapenem or a third generation or fourth generation cephalosporin with metronidazole, in combination with ciprofloxacin or an aminoglycoside, is a reasonable option. In the absence of a Gram stain, patients should receive treatment for type II disease until a diagnosis is made. All persons with traumatic wounds or infections associated with the gastrointestinal tract require assessment for tetanus immunization status. Patients with NF caused by group A streptococcus should receive clindamycin. Clindamycin inhibits toxin production by bacteria, and animal studies (6) as well as one retrospective human study (13) support its use.

Surgical debridement is the mainstay of therapy for NF of all types, and the appropriate surgical team should be consulted early when NF is suspected (14,15). Surgical consultation also should be considered for infections of the hand, particularly infected cat, dog, or human bite wounds, and for patients with a history of intravenous drug abuse. The use of *hyperbaric oxygen* for the treatment of NF is controversial. Its use is not indicated in the treatment of GAS (type I) NF. It still is being advocated for the treatment of Fournier's gangrene (a life-threatening necrotizing polymicrobial infection of the genitals and perineum) and is indicated in gas gangrene.

A recommendation to use intravenous immunoglobulin (IVIg) to treat streptococcal toxic shock syndrome cannot be made with certainty. While ample evidence exists for the role of extracellular streptococcal toxins in shock, organ failure, and tissue destruction, IVIg contains variable quantities of neutralizing antibodies to some of these toxins, and definitive clinical efficacy data are lacking (16). One observational study demonstrated better outcomes in patients receiving IVIg, but these patients were more likely to have had surgery and were more likely to have received clindamycin than the historical controls (17). A second study, which was double blinded and placebo controlled, showed no significant difference in mortality and no change in the "time to no further progression of necrotizing fasciitis" (18).

Issues During the Course of Hospitalization

On day 2, definitive culture results should be available, and the antibiotic regimen can be adjusted appropriately (Table 69.3). Most patients require more than one procedure for debridement. Until day 5, clinical assessment of the

TABLE 69.3
MANAGEMENT OF NECROTIZING FASCIITIS

1. Admit to the ICU
2. Emergent consultation to infectious disease and general surgery
3. Establish an etiologic diagnosis
 - a. Gram stain and culture of drainage, bullous fluid
 - b. Gram stain and culture of surgical tissue samples
4. Emergent empiric antibiotics administration based upon Gram stain material
5. Aggressive, goal-directed intravenous fluid resuscitation
 - a. Crystalloid/normal saline (20–30 cc/kg bolus) (19)
 - b. Colloid (albumin/fresh frozen plasma). Note: Patients with necrotizing fasciitis frequently have profound hypoalbuminemia due to capillary leak.
6. Transfusion. Note: Acute anemia evolves rapidly because of absorbed toxins that are also hemolysins.
7. Calcium replacement. Profound hypocalcemia is a common finding in patients with necrotizing fasciitis, particularly those with staphylococcal or streptococcal TSS.
8. Surgical debridement. The extent of surgical debridement of nonviable tissue varies but will be apparent from the surgical consultation obtained under item 2 above.
9. Renal dialysis. Renal failure occurs early in necrotizing fasciitis, particularly in those infected with group A streptococcus and *Clostridium perfringens* or in association with staphylococcal TSS.
10. Ventilator support. ARDS develops in 60% of patients with some types of necrotizing fasciitis, particularly those caused by group A streptococcus.
11. Echocardiogram for persistent hypotension
12. Invasive monitoring for persistent hypotension or low cardiac output
13. Vasopressors for high-output hypotension. Note: Avoid pressors in low cardiac output hypotension because of the risk of symmetrical gangrene
14. Intravenous gamma globulin (IVIg). See the discussion on necrotizing fasciitis (“Initial Therapy”).
15. Consider the use of activated protein C. However, there are no data to support its use in this setting, and it may be contraindicated in patients undergoing surgery.

ARDS, acute respiratory distress syndrome; TSS, toxic shock syndrome.

patient’s pain and well-being and of the involved area should be performed every four to six hours. In patients with extensive disease, general anesthesia may be required daily for dressing changes and examination. Surgical re-exploration is indicated if new areas of necrosis are apparent, if the rate of extension of erythema does not slow or begins to increase, or if patients complain of increasing pain or malaise. Repeated operative debridement should be performed until the infection is controlled.

Between days 5 and 10, continued progression of NF becomes less likely. However, in patients who have required extensive surgery, superinfection is possible. Extension of infection during this time should prompt reculture of tissue. Skin grafting can be performed once the wound base is granulating well, at which time physical therapy should be consulted regarding rehabilitation. A nursing assessment should then be carried out, the home situation should be reviewed, and the anticipated length of stay and rehabilitation should be discussed with the patient and family members.

Issues of systemic management and duration of antibiotic therapy are the same as those for cellulitis. No clear guidelines have been formulated for the duration of antibiotic therapy. Ten days is a reasonable minimum, but a longer duration may be advisable if fever has persisted beyond the fifth day or the wound is still not healthy at day 10.

Because GAS are transmitted in families and secondary cases of streptococcal GAS have occurred, some public health jurisdictions require reporting of streptococcal toxic shock syndrome, and some physicians now recommend treating household contacts of cases with 10 days of cefazolin or a macrolide (7,20,21). Reporting those patients who are readmitted with erysipelas or surgical-site GAS cellulitis to the infection-control service is also important, as surgical-site infections of GAS are extremely rare and often are associated with outbreaks of serious nosocomial infection.

Discharge Issues

Timing of discharge largely depends on surgical issues surrounding skin grafting and the management of dressings. The main disease-related issues are wound care and rehabilitation. Home care for dressing changes and physiotherapy are nearly always required. Patients should be warned that pain may persist for weeks or months but should not worsen, and the risks for and appropriate response to surgical-site infections should be discussed. Recurrent NF is not a risk, but cellulitis in a limb with damaged vascular supply is, so skin care and nail care issues should be discussed as appropriate once the patient has recovered sufficiently.

COST CONSIDERATIONS AND RESOURCE USE

Physicians increasingly recognize that few patients with uncomplicated cellulitis require hospitalization. Guidelines for the management of skin and soft tissue infections are not available but will soon be published by the Infectious Disease Society of America. Currently, no guidelines exist to assist in determining whether hospitalization is indicated.

The prompt recognition of patients at risk for pathogens other than GAS and *S. aureus* (who may require broad-spectrum antimicrobial therapy or an antimicrobial other than those used to treat these pathogens) may hasten recovery. Once the patient with cellulitis has been stabilized and shows no evidence of disease progression, oral antimicrobials can be instituted, and the patient can be discharged.

In patients with NF, early surgical intervention can facilitate a definitive diagnosis and prompt surgical debridement, both of which can hasten recovery and discharge. The use of hyperbaric oxygen therapy is costly and has a questionable role in the management of necrotizing soft tissue infections. The only possible indication is for clostridial myonecrosis.

KEY POINTS

- During the past 20 years, invasive group A streptococcal infections such as necrotizing fasciitis have increased in incidence and severity.
- Diagnosis of severe GAS soft tissue infections may be difficult early in the course. Initially, patients may have only severe pain, flu-like symptoms, and fever.
- Most cases of cellulitis are caused by GAS or *S. aureus*. However, a meticulous history must be performed to specifically ask about exposure to fish and other animals, recent travel, trauma, recent surgery, insect bites, animal bites, human bites, exposure to salt water or fresh water, and presence of underlying immunocompromising conditions.
- Patients with systemic toxicity out of proportion to the physical findings of soft tissue infection require aggressive diagnostic and therapeutic efforts, primarily focused on ruling out necrotizing fasciitis.
- Methicillin-resistant *S. aureus* strains have increased dramatically throughout the world and cause a variety of soft tissue infections, including impetigo, abscesses, necrotizing soft tissue infections, and toxic shock syndrome.

INTRODUCTION

Meningitis is defined as inflammation of the meninges identified by an abnormal number of white blood cells in cerebrospinal fluid (CSF). Meningitis may be caused by a variety of infectious agents (viruses, bacteria, fungi, and protozoa) as well as by a manifestation of various noninfectious disorders (e.g., collagen vascular disorders, malignancies, and medications). In patients who present with the meningitis syndrome, it is incumbent upon the physician to strongly consider the diagnosis of acute bacterial meningitis and to initiate an appropriate diagnostic plan and management for this disorder. This chapter focuses on the approach to the patient with presumed *acute bacterial meningitis* and considers other entities in the differential diagnosis.

The epidemiology of bacterial meningitis has changed in recent years. In the 1980s, *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae* accounted for more than 80% of cases, most caused by *H. influenzae* type b. Recently, however, the incidence of invasive infections caused by *H. influenzae* type b has been dramatically reduced by the widespread use of conjugate vaccines against *H. influenzae* type b in children (1). In contrast, the incidence of *S. pneumoniae* meningitis is unchanged. This, too, may change in the future with the introduction of the heptavalent pneumococcal conjugate vaccine, which is now recommended for all infants and children in the United States (2).

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

More than 80% of patients with acute bacterial meningitis present with fever, headache, meningismus, and signs of cerebral dysfunction (3). The meningismus may be subtle

or marked and may be accompanied by the Kernig or Brudzinski sign. These signs, however, are elicited in only about 5% of adult patients with acute bacterial meningitis. Other findings include cranial nerve palsies and focal cerebral signs (10%–20% of cases) and seizures (30% of cases). Papilledema is seen in fewer than 5% of patients early in infection, and its presence should suggest an alternative diagnosis. Some patients may not manifest many of the classic symptoms or signs of bacterial meningitis. For example, elderly patients may present insidiously with lethargy or obtundation, no fever, and variable signs of meningeal irritation. A high index of suspicion must be maintained for the diagnosis of bacterial meningitis in an elderly or alcoholic patient with altered mental status.

The etiologic diagnosis of bacterial meningitis may be suggested in patients with certain symptoms, signs, or underlying conditions. Patients with meningitis caused by *S. pneumoniae* often have contiguous or distant foci of infection such as pneumonia, otitis media, mastoiditis, sinusitis, or (rarely) endocarditis; serious infection also may be observed in asplenic patients and in those with multiple myeloma, hypogammaglobulinemia, alcoholism, malnutrition, chronic liver or renal disease, malignancy, diabetes mellitus, or basilar skull fracture. Meningitis caused by *N. meningitidis* may occur in epidemics and in patients with deficiencies in the terminal complement components (C5 through C9). About 50% of patients with meningococcemia, with or without meningitis, also present with a prominent rash located principally on the extremities. Early in the course of illness, the rash is typically erythematous and macular, but it quickly evolves into a petechial phase with further coalescence into a purpuric form.

Patients susceptible to *Listeria monocytogenes* meningitis include neonates, the elderly, alcoholics, cancer patients, immunosuppressed adults, and those with diabetes mellitus, liver disease, chronic renal disease, collagen vascular disorders, and conditions associated with iron overload. Outbreaks have been associated with consumption of

contaminated food. Patients with *L. monocytogenes* meningitis may experience seizures and focal neurologic deficits early in the course of infection, and some patients may present with ataxia, cranial nerve palsies, or nystagmus.

Differential Diagnosis and Initial Evaluation

The diagnosis of bacterial meningitis rests on examination of CSF following lumbar puncture. Table 70.1 shows typical CSF findings and a comparison with other microorganisms that can produce the meningitis syndrome. There may be considerable overlap in CSF findings in cases of meningitis caused by various agents, necessitating use of other specialized tests to establish the correct diagnosis (see later in this chapter). Performance of a CSF Gram stain is a rapid, inexpensive, and accurate method to identify the causative microorganism in 60%–90% of patients with bacterial meningitis; the specificity is nearly 100%. The probability of identifying the organism may decrease in patients who have received prior antimicrobial therapy. If the Gram stain is negative, a CSF latex agglutination test to detect antigens of common meningeal pathogens can be considered. Unfortunately, the overall sensitivity of the latex agglutination test ranges from only 50%–100%; the sensitivity is lower for *N. meningitidis*. The routine use of CSF bacterial antigen tests has been questioned. They are currently not being performed in most clinical laboratories because positive results usually have not modified therapy and false-positive and false-negative results may occur.

Many other infectious agents can cause the meningitis syndrome and should be considered in the differential diagnosis (3). Viruses are the major cause of the *acute aseptic meningitis syndrome*, defined as any meningitis for which a cause is not apparent after initial evaluation and routine stains and cultures of CSF. Most of these cases (80%–85%) are caused by enteroviruses. These viruses are worldwide in distribution and are spread by the fecal–oral route, usually

during periods of warm weather. Other viruses causing this syndrome include arboviruses, mumps virus, lymphocytic choriomeningitis virus, several herpesviruses, and HIV. Enteroviral meningitis is usually an acute illness, with fever in over 75% of patients. Headache is nearly always present in adults, photophobia is common, and more than half of patients have nuchal rigidity. The duration of illness is usually less than one week, and many patients report improvement after lumbar puncture, probably as a result of reduction of intracranial pressure. Currently, etiologic diagnosis is problematic, although recent advances in polymerase chain reaction technology should facilitate the diagnosis of enteroviral meningitis.

Meningitis caused by *Mycobacterium tuberculosis* accounts for approximately 0.7% of all cases of clinical tuberculosis in the United States (Chapter 67). The clinical presentation of tuberculous meningitis in adults is usually indolent, but patients also may present acutely, with a rapidly progressive meningitis syndrome indistinguishable from acute bacterial meningitis. On examination, fever is an inconstant finding, and signs of meningeal irritation are absent in 25%–40% of cases. Up to 30% of patients have focal neurologic signs on presentation, most frequently consisting of cranial nerve palsies. Identification of tuberculous organisms in CSF is difficult because of the small population of organisms present. Generally, fewer than 15%–25% of specimens are smear-positive, and up to 20% of patients have persistently negative CSF cultures, even if as many as four CSF specimens are cultured. Use of polymerase chain reaction testing to detect the fragments of mycobacterial DNA in CSF appears to be the most promising technique for the rapid diagnosis of tuberculous meningitis.

Spirochetes also can produce meningitis, with most cases caused by *Treponema pallidum* and *Borrelia burgdorferi*. The incidence of *syphilitic meningitis* is greatest in the first two years following initial infection, occurring in 0.3%–2.4% of untreated patients. Patients with syphilitic

TYPICAL CEREBROSPINAL FLUID FINDINGS IN PATIENTS WITH VARIOUS INFECTIOUS CAUSES OF MENINGITIS

Cause	White blood cells, cells/mm ³	Primary cell type	Glucose, mg/dL	Protein, mg/dL
Bacterial	1,000–5,000 ^a	Neutrophilic ^b	<40 ^c	100–500
Viral	50–1,000	Mononuclear ^d	>45	<200
Tuberculous	50–300	Mononuclear ^e	<45	50–300
Syphilitic	10–500	Mononuclear	35–75	30–300
Cryptococcal	20–500 ^f	Mononuclear	<40	>45

^a Range from <100 to >10,000 cells/mm³.

^b About 10% of patients have a lymphocyte predominance on presentation.

^c Should always be compared with a simultaneous serum glucose; ratio of CSF:serum ≤ 0.4 in most cases.

^d May be neutrophilic early in infection.

^e May see “therapeutic paradox” in which a mononuclear predominance becomes neutrophilic during therapy.

^f More than 75% of AIDS patients have <20 cells/ μ L.

meningitis usually present with headache, nausea, and vomiting; meningismus and fever are seen in approximately one-half of cases. In contrast, meningovascular syphilis is found in 10%–20% of individuals with central nervous system involvement and occurs months-to-years after syphilis acquisition. If untreated, focal deficits may progress and become irreversible. No single routine laboratory test is definitive for the diagnosis of neurosyphilis. Although the specificity of the CSF VDRL test is generally high, blood contamination may lead to a false-positive serologic result. More problematically, the sensitivity is low, with reactive tests in only 50%–85% of patients. Therefore, a reactive CSF VDRL test in the absence of blood contamination is sufficient to diagnose neurosyphilis, but a nonreactive test does not exclude the diagnosis. The CSF fluorescent treponomal antibody (FTA-ABS) also has been examined as a possible diagnostic test for neurosyphilis; a nonreactive test effectively rules out the diagnosis. Polymerase chain reaction testing has been utilized, although further large-scale studies are needed to determine the sensitivity and specificity of this technique.

The nervous system is involved clinically in at least 10%–15% of patients with Lyme disease. Headache is the single most common symptom, followed by photophobia, nausea, and vomiting; neck stiffness is seen in only 10%–20% of cases. About one-half of patients have mild cerebral symptoms such as somnolence, emotional lability, depression, impaired memory and concentration, and behavioral changes. Approximately 50% of patients have cranial neuropathies, most commonly facial nerve palsy. The best currently available test for the diagnosis of Lyme disease is specific serum antibody to *B. burgdorferi*; a positive test in a patient with a compatible neurologic abnormality is strong evidence for the diagnosis. However, currently available serologic tests are not standardized, and there is marked variability between laboratories. Specific *B. burgdorferi* antibody also appears in CSF, and demonstration of intrathecal production of antibody suggests neurologic involvement. The technique of polymerase chain reaction for identifying *B. burgdorferi* DNA in CSF has been used successfully in some preliminary studies.

Many *fungus pathogens* have been reported to invade the central nervous system, although meningitis is seen most frequently with only a few of the species. Meningitis caused by *Cryptococcus neoformans* is usually seen in patients who are immunocompromised (Chapters 63 and 76). The most important diagnostic test is the CSF latex agglutination test for detection of cryptococcal polysaccharide antigen. A presumptive diagnosis is indicated by a CSF titer of at least 1:8. A serum cryptococcal polysaccharide antigen also may be detected in severely immunocompromised patients. *Coccidioides immitis* is endemic in the semiarid regions and desert areas of the southwestern United States, where approximately one-third of the population is infected. Less than 1% of patients develop dis-

seminated disease, usually within the first six months following infection, with one-third to one-half of those having meningeal involvement. Dissemination of infection has been associated with extremes of age, male gender, nonwhite race, pregnancy, and immunosuppression. Meningeal infection usually follows a subacute-to-chronic course, although it may present acutely. Common complaints include headache, low-grade fever, weight loss, and mental status changes. Signs of meningeal irritation are usually absent. CSF examination typically reveals a pleocytosis, often with a prominent eosinophilia. Only 25%–50% of patients have positive CSF cultures. CSF complement-fixing antibodies are present in at least 70% of cases of early meningitis and in virtually all patients as the disease progresses.

Primary *amebic meningoencephalitis* most often is caused by the protozoan *Naegleria fowleri*. Sporadic cases occur if persons swim or play in water containing the amoebae, or if swimming pools or water supplies have become contaminated. Following an incubation period of 3–8 days, there is the sudden onset of high fever, photophobia, headache, and progression to stupor or coma. This presentation is usually indistinguishable from that of acute bacterial meningitis. Early symptoms of abnormal smell or taste may be reported because of involvement of the olfactory area. CSF examination reveals a neutrophilic pleocytosis, low glucose, elevated protein, and red blood cells. The Gram stain is negative, although examination of fresh, warm specimens of CSF can reveal the ameboid movements of the motile trophozoites. Death generally occurs within two or three days of the onset of symptoms in untreated patients.

In addition to the infectious causes described here, numerous noninfectious diseases also may produce the meningitis syndrome (Table 70.2). These entities also must be considered in the differential diagnosis.

Indications for Hospitalization and Initial Intensive Care Unit Admission

All patients with a suspected or confirmed diagnosis of acute bacterial meningitis should be hospitalized. Admission to the ICU is indicated by the presence of sepsis or neurologic compromise (Chapters 26 and 115). Patients should be admitted to the ICU if there is clinical evidence of increased intracranial pressure (obtundation, coma, hypertension, bradycardia, palsy of cranial nerve III; see Chapter 117), other cranial nerve palsies, focal cerebral signs, or seizures.

In patients with the acute meningitis syndrome, it is critical to distinguish between acute bacterial meningitis and the acute aseptic meningitis syndrome, the latter caused primarily by viruses (as described previously). Although the patient's general appearance and laboratory studies may be helpful in making this distinction, examination of the CSF profile is most important (Table 70.1). One study found that

any of the following findings—a CSF glucose concentration less than 34 mg/dL, a CSF: blood glucose ratio less than 0.23, a CSF protein concentration greater than 220 mg/dL, or more than 2,000 leukocytes or 1,180 neutrophils per cubic millimeter in CSF—predicted bacterial rather than viral meningitis with 99% certainty. However, considerable overlap exists in the CSF findings in patients with these disorders. For example, in enteroviral meningitis, a neutrophil predominance may be seen early in up to two-thirds of cases, with a tendency toward a shift to a lymphocyte predominance on follow-up lumbar puncture performed within 6–48 hours. Several authorities have suggested that in patients with a clinical diagnosis of viral meningitis and a neutrophil predominance on initial CSF analysis, a shift to a mononuclear predominance within 6–8 hours (in patients who have not received antimicrobial therapy) suggests a viral cause. Other studies have contradicted these findings. If the decision is made to withhold initial antibiotics in the patient who appears to have viral meningitis, the patient should be observed carefully, and antimicrobial therapy should be administered if there is evidence of clinical deterioration or if a repeat CSF analysis fails to reveal the typical lymphocyte predominance. Measurement of serum C-reactive protein (CRP) or procalcitonin may also be useful in discriminating between bacterial and viral meningitis, as they tend to be elevated in patients

with acute bacterial meningitis (4). In patients with acute meningitis in whom the CSF Gram stain is negative, serum concentrations of CRP or procalcitonin that are normal or below the limit of detection have a high negative predictive value for the diagnosis of bacterial meningitis. These patients can be carefully observed without initiation of antimicrobial therapy. However, the decision regarding hospital admission must be individualized and depend upon the clinical presentation, the level of concern by the clinician for the diag-

nosis of bacterial meningitis, and the ability to carefully observe the patient and ensure close follow-up.

Initial Therapy

Figure 70.1 shows the initial approach to management in the patient with presumed bacterial meningitis. Patients without focal neurologic deficits or papilledema should undergo rapid lumbar puncture to determine whether the CSF formula is consistent with that diagnosis. If purulent meningitis is present, targeted antimicrobial therapy should be initiated based on results of the Gram stain (Table 70.3). However, if these means can identify no causative agent or if performance of the lumbar puncture is delayed, empiric antimicrobial therapy should be initiated based on the patient's age and underlying disease status (Table 70.4). In patients who present with a focal neurologic examination or papilledema and in whom bacterial meningitis is suspected, a computed tomography (CT) scan of the head should be performed prior to lumbar puncture to rule out the presence of an intracranial mass lesion. However, because the time involved in waiting for a CT scan significantly delays performance of lumbar puncture and initiation of appropriate therapy, emergent empiric antimicrobial therapy, after obtaining blood cultures, must be initiated before sending the patient to the CT scanner (Table 70.5). Although empiric antimicrobial therapy prior

to lumbar puncture may decrease the yield of subsequent CSF cultures, the CSF formula, Gram stain, and/or measurement of serum concentrations of CRP or procalcitonin likely will provide evidence for or against the diagnosis of bacterial meningitis. Some clinicians routinely order CT scans of the head before performing a lumbar puncture in adult patients with suspected bacterial meningitis. In a study of 301 patients with bacterial meningitis (5), the baseline clinical features associated with an abnormal finding on CT scan were an age of at least 60 years, immunocompromise, a history of central nervous system disease, a history of seizure in the week before presentation, and the following neurologic abnormalities: an abnormal level of consciousness, an inability to answer two consecutive questions correctly or to follow two consecutive commands, gaze palsy, abnormal visual fields, facial palsy, arm drift, leg drift, and abnormal language. Although the decision to perform a CT scan prior to lumbar puncture must be individualized, these are useful guidelines in determining specific groups that are unlikely to have abnormal findings on neuroimaging studies.

In addition, many patients presenting with suspected or proven bacterial meningitis should receive *adjunctive dexamethasone therapy* (6,7). Several clinical trials in infants and children with predominantly *H. influenzae* type b meningitis demonstrated that adjunctive dexamethasone decreases morbidity, with a lower incidence of neurologic and

Tobramycin ^a	5 mg/kg	8
Trimethoprim–sulfamethoxazole ^d	10–20 mg/kg	6–12
Vancomycin ^{a,e}	30–45 mg/kg	8–12

Unless indicated, therapy is administered intravenously.

^a Need to monitor peak and trough serum concentrations.^b Higher dose recommended for pneumococcal meningitis.^c Oral administration.^d Dosage based on trimethoprim component.^e May need to monitor cerebrospinal fluid concentrations in severely ill patients.

audiologic sequelae. Thus, adjunctive dexamethasone should be used routinely in all infants and children with *H. influenzae* type b meningitis at a dosage of 0.15 mg/kg every 6 hours for 2–4 days. If it can be given with or before antimicrobial therapy, dexamethasone should also be used in children with pneumococcal meningitis. In adult patients with bacterial meningitis, the routine use of adjunctive dexamethasone has been controversial until recently. In a prospective, randomized, double-blind trial in 301 adults with bacterial meningitis, adjunctive dexamethasone was associated with a reduction in the proportion of patients with unfavorable outcomes, including death (8). The benefits were most striking in the subgroup of patients with pneumococcal meningitis and in those with moderate-to-severe disease, as assessed by the score on the Glasgow Coma Scale at the time of admission. On the basis of these data and the apparent absence of serious adverse outcomes in patients who received dexamethasone, *the routine use of adjunctive dexamethasone is warranted in most adults with pneumococcal meningitis*; dexamethasone can be given with or just before the first dose of an antimicrobial agent (9). Adjunctive dexamethasone should not be used in patients who have already received antimicrobial therapy. If the etiology of meningitis is subsequently found not to be *S. pneumoniae*, dexamethasone therapy should be discontinued. The use of adjunctive dexamethasone is of particular concern, however, in patients with pneumococcal meningitis caused by penicillin-resistant or cephalosporin-resistant strains who are treated with vancomycin, as a diminished CSF inflammatory response may significantly reduce CSF vancomycin penetration and potentially delay CSF sterilization. In the

study cited above, only 78 of 108 CSF cultures that were positive for *S. pneumoniae* were submitted for in vitro susceptibility testing, and all were susceptible to penicillin, a finding that is unusual in many areas of the world. In patients with pneumococcal meningitis caused by strains that are highly resistant to penicillin or cephalosporins and who do receive corticosteroids, careful observation and follow-up are critical.

Indications for Early Consultation

All patients with suspected bacterial meningitis should receive infectious diseases consultation to assist with antimicrobial therapy, especially in view of recent trends in the susceptibility of meningeal pathogens to standard antimicrobial therapy (see later in this chapter). The infectious diseases consultant also can assist with ensuring adequate antimicrobial dosages and dosing intervals, which are generally different from those for treating infections outside the central nervous system.

In patients with bacterial meningitis who have evidence of focal neurologic signs, seizures, or signs of increased intracranial pressure, neurology or neurosurgery consultation is recommended. Status epilepticus that is continuous for 90 minutes or longer can cause permanent neurologic sequelae (Chapter 118). Early termination of seizure activity usually can be accomplished using a short-acting anticonvulsant with a rapid onset of action (e.g., lorazepam or diazepam). A long-acting anticonvulsant then should be administered immediately. If this approach fails to control seizure activity, the patient should be intubated, mechanically ventilated, and treated with phenobarbital.

Patients with elevated intracranial pressure may benefit from neurosurgical insertion of an intracranial pressure monitoring device (Chapter 117). Pressures exceeding 20 mm Hg are abnormal and should be treated; there is also rationale for treating smaller pressure elevations (i.e., above 15 mm Hg) to avoid larger elevations, or so-called plateau waves, that can lead to cerebral herniation and irreversible brain-stem injury. Methods available to reduce elevated intracranial pressure include elevation of the head of the bed to 30°, hyperventilation to maintain the partial carbon dioxide pressure (PaCO₂) between 27 and 30 mm Hg, use of hyperosmolar agents, and use of corticosteroids (for details, see Chapter 117). Some experts have questioned the routine use of hyperventilation to reduce intracranial pressure in patients with bacterial meningitis. In infants and children with bacterial meningitis and evidence of cerebral edema on CT scan, hyperventilation may reduce intracranial pressure at the expense of significant reductions in cerebral blood flow. However, a controlled trial exploring this issue has yet to be performed. Patients whose intracranial pressure continues to be elevated despite these measures may be treated with high-dosage pentobarbital therapy, with appropriate intracranial, electroencephalographic, and hemodynamic monitoring. Pentobarbital is

administered until the intracranial pressure is reduced below 20 mm Hg or the electroencephalogram demonstrates a burst-suppression pattern. This mode of treatment for elevated intracranial pressure in bacterial meningitis is of unproven benefit and must be considered experimental.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Following definitive identification and susceptibility testing of the pathogen causing meningitis, antimicrobial therapy should be modified for optimal treatment. Table 70.3 shows the recommendations for therapy of causative microorganisms of bacterial meningitis; recommended dosages in adults with normal renal and hepatic function are in Table 70.5 (3).

One microorganism deserves special comment. The therapy of meningitis caused by *S. pneumoniae* recently has been modified based upon current pneumococcal susceptibility patterns, with emergence of strains that are both relatively and highly resistant to penicillin G (3,10). Based upon these antimicrobial susceptibility trends and because sufficient CSF concentrations of penicillin are difficult to achieve with standard high parenteral dosages, *penicillin can no longer be recommended as empiric antimicrobial therapy if S. pneumoniae is considered a likely pathogen in a patient with purulent meningitis*. Patients with pneumococcal meningitis should be considered to have a highly resistant strain upon organism identification and treated with the combination of vancomycin plus a third-generation cephalosporin (either cefotaxime or ceftriaxone). If the physician determines that the organism is susceptible to penicillin (minimum inhibitory concentration [MIC] <0.1 mcg/mL), penicillin G or ampicillin can be used. If the organism is relatively resistant to penicillin (MIC between 0.1 and 1.0 mcg/mL), a third-generation cephalosporin (cefotaxime or ceftriaxone) is recommended. However, if the organism is highly resistant to penicillin (MIC ≥2.0 mcg/mL), the combination of vancomycin plus the third-generation cephalosporin should be continued for the full treatment course. This is based on anecdotal reports of vancomycin treatment failure in pneumococcal meningitis and from experimental data in which the combination of vancomycin and the third-generation cephalosporin was synergistic in the therapy of meningitis caused by highly penicillin-resistant pneumococci. The addition of rifampin or use of the combination of a third-generation cephalosporin plus rifampin should be considered in patients with documented infection caused by penicillin-resistant or cephalosporin-resistant *S. pneumoniae*, especially if dexamethasone is administered. Meropenem, a carbapenem with less proconvulsive activity than imipenem, yields microbiologic and clinical outcomes similar to either cefotaxime or ceftriaxone. The newer fluoroquinolones (e.g., levofloxacin, moxifloxacin, gatifloxacin) are active *in vitro* against resistant pneumococci;

one study found trovafloxacin to be therapeutically equivalent to ceftriaxone with or without vancomycin for treatment of bacterial meningitis (11). However, more clinical trials are needed before these agents can be recommended for use in patients with pneumococcal meningitis.

Strains of *N. meningitidis* with intermediate resistance to penicillin have been reported, accounting for about 3% of isolates in the United States (12). The clinical significance of these isolates is unclear because most patients with meningitis caused by these organisms have recovered with standard penicillin therapy. However, isolated reports of penicillin treatment failure have been described. Based on these data, some authorities would treat patients who have meningococcal meningitis with a third-generation cephalosporin (either cefotaxime or ceftriaxone) pending results of *in vitro* susceptibility testing.

Following the initiation of appropriate antimicrobial therapy in patients with acute bacterial meningitis, evidence of clinical improvement (represented by increased responsiveness) is usually seen within 2–4 days, with most patients becoming afebrile within 4–5 days (2–3 days for meningococcal meningitis). Table 70.6 shows the approach to patients who fail to improve or who develop complications.

Unfortunately, many patients with bacterial meningitis develop complications. The major central nervous system complications include cerebrovascular involvement, brain

swelling, hydrocephalus, and intracerebral hemorrhage. In addition, systemic complications include septic shock, acute respiratory distress syndrome, and disseminated intravascular coagulation. Patients with bacterial meningitis must be monitored carefully for these complications, and appropriate therapeutic measures must be taken.

DISCHARGE ISSUES AND COST CONSIDERATIONS

Patients with acute bacterial meningitis must be treated with appropriate dosages of intravenous antimicrobial therapy for a full duration of therapy (Table 70.7) (3,10). Oral antimicrobial therapy is not recommended, and the intramuscular mode of administration is also discouraged because CSF penetration of antimicrobial therapy diminishes with reduction of meningeal inflammation. Traditionally, patients with bacterial meningitis have been hospitalized for the duration of parenteral antimicrobial therapy. Several recent studies have suggested that outpatient therapy is appropriate for selected cases of pediatric meningitis, based on data that the complications of meningitis occur most frequently within the first 2–3 days and that serious adverse complications are exceedingly rare after 3–4 days of antimicrobial therapy. The advantages of home therapy include decreased costs of hospitalization and decreased risk of development of nosocomial infections, as well as the psychologic, physical, and nutritional benefits. Basic criteria have been suggested for use of outpatient antimicrobial therapy in pediatric patients with bacterial meningitis (3). These guidelines advocate outpatient therapy for patients who have received inpatient therapy for at least 6 days and have no significant neurologic dysfunction, focal findings, or seizure activity; are clinically stable and taking fluids by mouth; have received at least one dose of the outpatient antimicrobial agent in the hospital; have access to home health nursing for the administration of the antimicrobial; have a daily examination by a physician; and have reliable parents with transportation and a telephone. Although not validated, these guidelines

TABLE 70.6
APPROACH TO COMPLICATIONS DURING HOSPITALIZATION IN PATIENTS WITH BACTERIAL MENINGITIS

Problem/complication	Recommended approach
Seizures	Close observation in ICU; administration of anticonvulsants; neuroimaging (CT or MR)
New focal neurologic deficit	Neuroimaging (CT or MR); neurologic consultation
Increased intracranial pressure (ICP)/ Hydrocephalus	Neurosurgical consultation
Subdural effusion	Observe; aspirate if patient develops focal neurologic findings and/or increased ICP or if clinical suspicion of empyema exists
Inappropriate secretion of antidiuretic hormone	Fluid restriction; nephrology consultation
Fever beyond 5 d	Evaluate for subdural effusion, disease at other foci, and nosocomial infection; repeat CSF analysis if clinically indicated; consider drug fever if patient has clinically improved

TABLE 70.7
DURATION OF THERAPY OF BACTERIAL MENINGITIS

Microorganism	Duration of therapy, d ^a
<i>Streptococcus pneumoniae</i>	10–14
<i>Neisseria meningitidis</i>	7
<i>Haemophilus influenzae</i> type b	7
Enteric Gram-negative bacilli	21
<i>Listeria monocytogenes</i>	≥21
<i>Streptococcus agalactiae</i>	14–21

^a These are general recommendations; individual therapy may be different based upon clinical response.

also may be appropriate for adult patients, provided that compliance can be assured and the patient is in a safe environment, with access to a telephone, utilities, food, and a refrigerator (13). In addition, completion of antimicrobial therapy in a skilled nursing facility may be appropriate for selected patients who need continued care but do not require acute hospitalization.

Despite the availability of effective antimicrobial therapy, the morbidity and mortality rates from bacterial meningitis remain unacceptably high. In a review of almost 500 cases of acute bacterial meningitis in adults, the overall case fatality rate was 25% and did not vary significantly over the 27-year period of the study (14). Among patients with single episodes of bacterial meningitis, the in-hospital mortality rate was 25% in those with community-acquired meningitis and 35% in those with nosocomial meningitis. The three factors associated with a higher overall mortality rate were age older than 60 years, obtunded mental state on presentation, and onset of seizures within 24 hours of admission.

Furthermore, patients must be monitored carefully for long-term complications of bacterial meningitis. Persistent neurologic sequelae in infants and children with bacterial meningitis have included sensorineural hearing loss, seizure disorder, hemiplegia, and mental retardation. In a recent study that assessed neuropsychological outcome in 51 adults with bacterial meningitis and otherwise good recovery, a cognitive disorder was found in 27% of the patients with pneumococcal meningitis (15). Further studies are needed, however, to make decisions about planning neuropsychological follow-up in patients with bacterial meningitis to determine who is at risk for these complications.

KEY POINTS

- The epidemiology of bacterial meningitis has changed significantly in the past several years following introduction of *H. influenzae* type b conjugate vaccines, dramatically reducing the threat of *H. influenzae* type b meningitis in infants and children.
- Targeted or empiric antimicrobial therapy, based on the patient's age and underlying disease status, should be initiated as soon as possible in patients with presumed bacterial meningitis.
- Antimicrobial therapy should never be delayed while awaiting tests such as CT scans.
- Adjunctive dexamethasone therapy has been shown to reduce morbidity in infants and children with acute *H. influenzae* type b and *S. pneumoniae* meningitis. Adjunctive dexamethasone, administered concomitant with or immediately prior to the first dose of antimicrobial therapy, should also be used in adult patients with suspected pneumococcal meningitis.
- Empiric antimicrobial therapy for meningitis caused by *S. pneumoniae* should consist of vancomycin plus a

third-generation cephalosporin (either cefotaxime or ceftriaxone), pending results of susceptibility testing.

- Complications of bacterial meningitis, including seizures and increased intracranial pressure, must be recognized and treated aggressively.
- Selected patients with bacterial meningitis may be considered for outpatient antimicrobial therapy.

Endocarditis

71

Paul M. Sullam

INTRODUCTION

Despite long-standing research interest, improved diagnostic modalities, and the use of antimicrobial agents for prophylaxis, infective endocarditis remains an important medical problem. The overall incidence of this disease has not changed over several decades (1.8–11.6 cases per 100,000 population). Endocarditis is still associated with mortality rates of 16%–30%, even with the prompt initiation of therapy. In addition, the management of patients with endocardial infection has become increasingly complicated because of the emergence of new populations at risk, the application of echocardiography to stage the infection, and the increasing prevalence of drug-resistant microbes.

In view of these issues, the evaluation and treatment of individuals with endocardial infection requires considerable expertise in a variety of disciplines. This chapter provides an overview of the key aspects of managing such patients. Prosthetic valve endocarditis is reviewed in Chapter 41, and antibiotic prophylaxis is discussed in Chapter 30 (Tables 30.6 and 30.7).

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

Endocarditis is a relatively uncommon disease, with an estimated 10,000–15,000 cases per year in the United States. Patients with underlying structural heart abnormalities are at markedly increased risk for infection (Table 71.1), and such defects can often be identified retrospectively in many patients with endocardial infection. Increasingly, however, patients are being diagnosed in whom no predisposing condition can be implicated. In fact, given that in approximately 50% of cases no underlying cardiac abnormality can be detected (1), the absence

of a detectable underlying abnormality does not exclude the possibility of infection.

The clinical manifestations of endocarditis are highly variable. Most patients have generalized *constitutional symptoms*, suggesting infection or chronic illness (Table 71.2). In some patients, the predominant manifestations of endocarditis stem from systemic embolization, presenting as a stroke, splenic pain, or sudden loss of limb perfusion. Intravenous drug users tend to develop tricuspid valve endocarditis, which may produce pulmonary emboli, often multiple. Signs of *cardiac involvement* may predominate, presenting as progressive congestive heart failure or palpitations. Although findings such as Osler nodes or Janeway lesions strongly indicate the presence of endocarditis, these symptoms are distinctly unusual (5%–10% of patients). Murmurs are present in 80% or more of patients, but these are mainly preexisting systolic murmurs. A changing or pathologic murmur was found in only 5% of patients in older series, but some more recent studies report a frequency of 35%–59% (2).

Differential Diagnosis and Initial Evaluation

Because the clinical manifestations of infective endocarditis are protean and usually not pathognomonic, the differential diagnosis of this disease is quite broad. A patient who presents with fever, malaise, and other generalized signs may appear to have rheumatic fever, influenza, tuberculosis, osteomyelitis, occult abscess, underlying malignancy, or collagen vascular disease. Local findings, such as stroke, may lead to an initial diagnosis of atherosclerotic thromboembolic disease. Occasionally, patients are diagnosed after an initial evaluation for anemia or hematuria.

Thus, the diagnosis of endocarditis requires the presence of a constellation of symptoms in conjunction with microbiologic or echocardiographic findings. Infective endocarditis should be considered in any patient with unexplained fever for longer than one week, especially if an

TABLE 71.1
CONDITIONS PREDISPOSING TO
ENDOCARDITIS: INCIDENCE AND RELATIVE
RISK OF INFECTION

Cardiac lesion	Cases/100,000/y	Relative risk

Mitral-valve prolapse, no murmur	4.6	1
Normal valve	4.6	1

underlying cardiac abnormality is present. Endocarditis also should be suspected in persons with unexplained embolic phenomena, splenomegaly, or cardiac valve dysfunction. In addition, the diagnosis should be entertained in patients with idiopathic bacteremia, especially if caused by Gram-positive cocci. In fact, studies suggest that endocarditis should be considered in all patients with bacteremia due to *Staphylococcus aureus*, even if this occurs within a nosocomial setting or if an infected intravascular device is present (3).

Role of the Microbiology Laboratory

Blood cultures have remained an essential aspect of managing patients with infective endocarditis. Because patients

TABLE 71.2
SIGNS AND SYMPTOMS OF ENDOCARDITIS

Janeway lesions	4–10
Roth spots	0–11

Ranges shown compiled from clinical series.

with endocarditis usually have sustained bacteremia, the presence of multiple positive blood cultures is strongly indicative of endocardial infection. Recovery of a specific pathogen also allows testing *in vitro* for antimicrobial sensitivities, which facilitates the selection of effective antimicrobial therapy. In addition, blood cultures are valuable for monitoring the response of the patient to therapy (see later in this chapter). Thus, blood cultures should be obtained in all patients with suspected endocarditis.

The exact number needed depends in part on the underlying pathogen. For viridans-group streptococci, a single 10-mL blood sample is positive in 90% of patients, and, if three specimens are obtained, at least one is positive in 98% of cases. Similar high rates of recovery have been reported for staphylococci. Thus, for endocarditis caused by the most prevalent organisms, three blood cultures obtained one hour or more apart should be adequate. The detection of fastidious organisms, such as *Legionella* or *Bartonella* species, may require a larger number of blood samples or specialized culture techniques. Blood cultures also may be falsely negative in patients already receiving antibiotics. In such cases, specialized blood-collection systems that remove antibiotics can be used to improve recovery. For some pathogens, such as *Coxiella burnetii* (the agent of Q fever), diagnosis typically involves serologic methods.

Role of Echocardiography

In patients with native valve endocarditis, transthoracic echocardiography (TTE) can detect vegetations in about 50% of cases (range: 32%–71%) (3–5). The sensitivity of TTE is much lower for prosthetic valve infections (15%–30%). If a vegetation is detected by TTE, the specificity is 99% for both native valve and prosthetic infections. Compared with TTE, transesophageal echocardiography (TEE) is superior for evaluating patients with endocarditis. In native valve infection, the sensitivity is at least 85%, with more recent series reporting values of 95%–100%. In patients with prosthetic valve infection, the sensitivity is reduced only slightly (85%). The specificity of TEE is also excellent for both native and prosthetic valve infection (99%–100% in most series).

In addition to its ability to diagnosis endocarditis by revealing vegetations, echocardiography can provide valuable structural, hemodynamic, and prognostic information (Chapter 36). TEE is especially good at detecting complications such as myocardial abscesses, ruptured chordae tendinae, perforated leaflets, or prosthetic dysfunction. Echocardiography also can be used to quantify valve regurgitation or degree of cardiac failure. Such complications, even if subclinical, may provide strong evidence in favor of prompt surgical replacement of the infected valve. Vegetations greater than 10 mm in diameter are associated with a significantly higher risk of embolization (6). Moreover, vegetations that fail to regress with antimicrobial therapy are also associated with embolic phenomena.

Guidelines from the American College of Cardiology and the American Heart Association summarize clinical settings in which echocardiography is definitely or possibly warranted (Table 71.3) (7). At a minimum, echocardiography should be considered for patients in whom the diagnosis of infective endocarditis remains uncertain and in patients in whom an intracardiac complication is suspected. Whether TTE or TEE should be the initial mode of evaluation remains controversial. In one cost-benefit analysis, employing TEE as the initial echocardiographic test was more cost effective than using TTE only in selected cases that had been first evaluated by TTE (8). TEE is associated with a complication rate of 0.5%–1.5%; complications can include serious events, such as esophageal rupture. For this reason, the noninvasive TTE remains the preferred initial procedure. In patients for whom this evaluation is nondiagnostic, TEE should be considered.

Duke Criteria

In an attempt to standardize the case definition of endocarditis, a group of investigators at Duke University developed a set of major and minor criteria for diagnosing endovascular infection (9) (Tables 71.4 and 71.5). Using this scoring system, patients can be stratified into categories of *definite*, *possible*, or *rejected* (no endocarditis). Several independent studies have confirmed the validity of the Duke criteria, which have sensitivity rates of 80%–89% and specificity rates of nearly 100%, with higher values reflecting recent refinements in the criteria.

Although the Duke criteria provide a useful diagnostic framework, not all patients with suspected endocarditis need to be formally evaluated by these standards. In many patients, the clinical presentation, in combination with blood culture results, is sufficient to support the diagnosis. Moreover, in over 50% of cases identified by these guidelines, echocardiography provided unequivocal evidence of endocardial infection, obviating the need for further diagnostic assessment. Aside from its value in a research setting, therefore, the Duke criteria are probably best used in selected cases, such as when the echocardiogram is equivocal, technically inadequate, or not feasible.

Indications for Hospitalization

Patients with infective endocarditis generally are hospitalized, for several reasons. First, hospitalization may facilitate the rapid and intensive evaluation of patients required during the first few days of management. Second, antimicrobial therapy is usually given intravenously, which, until recently, could be done only in an inpatient setting. Third, hospitalization permits close monitoring for the embolic and hemodynamic complications that may occur, particularly during the two weeks of treatment. Notwithstanding these advantages, several groups have proved the feasibility of outpatient therapy, either following a few days of hospitalization or from the onset of treatment. In most studies, outpatient therapy was generally reserved for individuals with the best chance of an uncomplicated course; nearly all had streptococcal endocarditis, which has the highest rate of successful medical treatment. Patients with

TABLE 71.3

AMERICAN COLLEGE OF CARDIOLOGY/AMERICAN HEART ASSOCIATION GUIDELINES FOR ECHOCARDIOGRAPHY IN ENDOCARDITIS

Indication	Class ^a (native/prosthetic valve)
1. Detection and characterization of valvular lesions, their hemodynamic severity, or ventricular compensation ^b	I/I
2. Detection of vegetations and characterization of lesions in patients with congenital heart disease	I/I
3. Detection of associated abnormalities (e.g., abscesses, shunts, etc.) ^b	I/I
4. Reevaluation studies in complex endocarditis (e.g., virulent organisms, severe hemodynamic lesion, aortic valve involvement, persistent fever or bacteremia clinical change, or symptomatic deterioration)	I/I
5. Evaluation of patients with high clinical suspicion of culture-negative endocarditis ^b	I/I
6. Evaluation of bacteremia without a known source ^b	IIa/I
7. Risk stratification in established endocarditis ^b	IIa/IIa
8. Routine re-evaluation in uncomplicated endocarditis during antibiotic therapy	IIb/IIb
9. Evaluation of fever and nonpathological murmur without evidence of bacteremia	III/(II–III) ^c

^a Class I: evidence and/or general agreement that an echocardiography is useful; Class IIa: conflicting evidence or divergence of opinion about usefulness, but weight of evidence/opinion favors it; Class IIb: usefulness is less well established; Class III: evidence or general opinion that echocardiography is not useful.

^b Transesophageal echocardiography (TEE) may provide incremental value in addition to information obtained by transthoracic echocardiography (TTE). The role of TEE in first-line examination awaits further study.

^c Prosthetic valves—IIa: for persistent bacteremia; III: for transient bacteremia.

TABLE 71.4
MODIFIED DUKE CRITERIA: DEFINITIONS

Major criteria

1. Positive blood culture for infective endocarditis (IE)
 - A. Typical microorganism for endocarditis from two separate blood cultures: viridans-group streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*; or community-acquired enterococci, in the absence of a primary focus; or
 - B. Microorganisms consistent with IE, from persistently positive blood cultures, defined as follows: At least two positive cultures of blood samples drawn more than 12 h apart, or All of three or a majority of four or more separate blood cultures, with first and last drawn at least one h apart
 - C. Single positive blood culture for *Coxiella burnetii* or antiphase I IgG antibody >1:800
2. Evidence of endocardial involvement
3. Positive echocardiogram for infective endocarditis (TEE recommended in patients with prosthetic valves, rated at least “possible IE” by clinical criteria, or complicated IE [paravalvular abscess]; TTE as first test in other patients), defined as follows:
 - i. Oscillating intracardiac mass on valve or supporting structures, or in the path of regurgitant jets or on implanted material, in the absence of an alternative anatomic explanation, or
 - ii. Abscess, or
 - iii. New partial dehiscence of prosthetic valve
4. New valvular regurgitation (increase or change in preexisting not sufficient)

Minor criteria

1. Predisposing heart condition or intravenous drug use
2. Fever: $\geq 38.0^{\circ}\text{C}$
3. Vascular phenomena: arterial embolisms, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, Janeway lesions
4. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, and rheumatoid factor
5. Microbiologic evidence: positive blood culture but not meeting a major criterion as noted above, or serologic evidence of active infection with organism consistent with endocarditis

HACEK, *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography. See Table 71.5 for application of these findings.

complications of endocarditis at the onset of treatment were excluded, as were patients with underlying renal or eighth nerve impairment who required aminoglycosides. Under these conditions, outpatient treatment can achieve cure rates comparable with those seen in inpatient therapy.

If ambulatory management is chosen, patients must be carefully monitored for complications and drug toxicity. In addition, these patients must be able to aseptically manage long-term indwelling intravenous catheters. Finally, there should be a high level of confidence that antimicrobials will be administered properly, either by the patient or by a skilled infusion service. As for when to initiate outpatient therapy, recent guidelines recommend that most patients receive two weeks of inpatient therapy prior to initiating outpatient treatment (10). This approach permits close monitoring for complications and prompt intervention if needed.

Initiation of Antimicrobial Therapy

The selection of antibiotics for treating infective endocarditis should be based on the identification of a specific

pathogen from blood cultures and *in vitro* assays for sensitivity. Because such information may not be immediately available at the time of diagnosis, combination therapy directly against the most likely organisms should be initiated once blood cultures have been obtained. Empiric therapy should be tailored to the underlying risk factors for infection (Table 71.6). Thus, patients with native valve endocarditis should receive treatment directed against streptococci, enterococci, and *Staphylococcus aureus*; that is, penicillin, nafcillin, and gentamicin. The same regimen should be adequate for endocarditis in intravenous drug users unless methicillin-resistant *Staphylococcus aureus* (MRSA) strains are likely to be present. Infection with MRSA should be considered in intravenous drug users who have been hospitalized recently or in geographic regions with a high prevalence of resistant strains (Chapter 64). If MRSA infection is suspected, vancomycin combined with gentamicin should be used until blood culture results and antimicrobial sensitivities are available. For patients with prosthetic valve infection, vancomycin should be used in combination with an aminoglycoside and rifampin pending microbiologic results.

TABLE 71.5
DUKE CRITERIA**Definite endocarditis**

Pathologic criteria

- (1) Microorganisms: demonstrated by culture or histology in a vegetation, embolus, or intracardiac abscess or
- (2) Pathologic lesions: vegetations or intracardiac abscess present, confirmed by histology showing active endocarditis

Clinical criteria (as defined in Table 71.4)

- (1) Two major criteria, or
- (2) One major + three minor criteria, or
- (3) Five minor criteria

Possible infective endocarditis

- (1) One major criterion and one minor criterion, or
- (2) Three minor criteria

Rejected

- (1) Firm alternative diagnosis explaining evidence of infective endocarditis, or
- (2) Resolution of manifestations with antibiotic therapy for four d or less, or
- (3) No pathologic evidence of infective endocarditis at surgery or autopsy, after antibiotic therapy of four d or less, or
- (4) Does not meet criteria for possible infective endocarditis, as above

Once a pathogen is recovered from blood cultures, antimicrobial therapy should be targeted to that specific organism. The optimal regimen depends on *in vitro* sensitivities, whether a native or prosthetic valve is involved, and the patient's underlying medical condition. A detailed discussion of all possible regimens for every endocardial pathogen is beyond the scope of this chapter. However, recommended regimens for native valve endocarditis caused by the most common organisms are shown in Table 71.7. Because prosthetic valve endocarditis is more difficult to eradicate, this infection requires multidrug therapy for 4–6 weeks.

ISSUES DURING THE COURSE OF HOSPITALIZATION**Role of Consultants**

The management of patients with endocarditis is complex. Selection of the correct antimicrobial regimen is often not straightforward because it must be tailored to each specific pathogen and its *in vitro* susceptibilities. In addition, considerable expertise is needed to manage the numerous complications associated with this disease as well as the adverse effects that can result from treatment. It is not surprising, therefore, that errors in the management of endocarditis are common, ranging from failure to obtain blood cultures to inappropriate delay in surgical treatment (11). Although the impact of an infectious diseases consultant on the outcome of such cases has not been formally addressed, patients with *S. aureus* bacteremia have been shown to benefit significantly by this intervention. In particular, patients who were treated according to the recommendations of an infectious diseases specialist had a higher rate of cure as well as lower rates of complications and relapses (12). Because it is likely that expert guidance has a similar beneficial effect on the management of infective endocarditis, all patients with this disease should be evaluated by an infectious diseases specialist.

Patients with evidence of mechanical complications or congestive heart failure should be evaluated promptly by a cardiologist. Relevant issues include the need for hemodynamic monitoring, temporary pacing, and valve replacement. Patients with prosthetic valve infection are more likely to develop complications requiring valve replacement and thus should be seen by both a cardiologist and a surgeon. These specialists can also help obtain previous data from invasive and noninvasive studies or observations from the time of surgery. Such information can be critical in determining whether there has been a change in valve function over time.

TABLE 71.6
MICROBIOLOGY OF INFECTIVE ENDOCARDITIS IN DIFFERENT RISK GROUPS

Microorganism recovered (% of cases)	Native valve endocarditis	Intravenous drug users	Prosthetic valve endocarditis	
			Early	Late
Viridans-group streptococci	50	20	7	30
<i>Staphylococcus aureus</i>	19	67	17	12
Coagulase-negative staphylococci	4	9	33	26
Enterococci	8	7	2	6
Miscellaneous	19	7	41	26

TABLE 71.7
TREATMENT REGIMENS FOR INFECTIVE ENDOCARDITIS

Organism	Regimens	Comments
Viridans-group streptococci		Prosthetic valves: 6 wks penicillin + 2 wks of gentamicin initially
Penicillin MIC ≤ 0.1 mcg/mL	1) Penicillin ($2-3 \times 10^6$ U IV Q4 h) $\times 4$ wks 2) Ceftriaxone (2 g IV QD) $\times 4$ wks 3) Penicillin + gentamicin (1 mg/kg Q8 h) $\times 2$ weeks	Vancomycin (1 g Q12 h) $\times 4$ wks for patients with hypersensitivity to β -lactam antibiotics
Penicillin MIC ≥ 0.1 to 0.5 mcg/mL	Penicillin $\times 4$ wks + gentamicin (1 mg/kg Q8 h) $\times 2$ weeks	
Penicillin MIC ≥ 0.5 mcg/mL <i>Staphylococcus aureus</i>	Penicillin + gentamicin $\times 4-6$ weeks 1) Nafcillin (1.5-2 gms Q4 h) $\times 4-6$ wks + gentamicin $\times 3-5$ d 2) Nafcillin + gentamicin $\times 2$ wks 3) Vancomycin $\times 4$ wks + gentamicin $\times 3-5$ d	Uncomplicated right-sided disease only Vancomycin should be used only in MRSA infections or if serious penicillin allergy is present. Combination therapy is recommended for prosthetic valves
Enterococci	1) Penicillin + gentamicin $\times 4-6$ wks 2) Vancomycin + gentamicin $\times 4-6$ wks	6 wk therapy if symptoms >3 mo
Coagulase negative staphylococci (<i>S. epidermidis</i> , etc.)	1) Vancomycin + rifampin (300 mg PO Q8 h) $\times 4-6$ wks + gentamicin (1 mg/kg Q8 h) $\times 2$ wks 2) Nafcillin $\times 4-6$ wks	Add rifampin and gentamicin for prosthetic valves; ?native valves
Gram-negative enterics (e.g., <i>Pseudomonas</i>) HACEK group	Gentamicin (5 mg/kg/d) + ureidopenicillin $\times 4-6$ wks + surgical consultation 1) Ceftriaxone $\times 4$ wks 2) Ampicillin (2 g Q4 h) + gentamicin (5 mg/kg/d) $\times 4$ wks	Most strains are resistant to nafcillin: check MICs/MBCs Response to medical treatment alone is variable Check <i>in vitro</i> sensitivities
Fungi Culture negative	Amphotericin B (0.6-1.0 mg/kg/d) + surgery 1) Ampicillin + nafcillin $\times 4$ wks + gentamicin $\times 2$ wks 2) Vancomycin + gentamicin $\times 4-6$ wks	Native valves Prosthetic valves

HACEK, *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, *Kingella*.

Monitoring Response to Therapy

Day 1

On the first day of hospitalization, patients should be carefully evaluated for evidence of *endocarditis-associated complications*. In particular, signs of valve dysfunction, congestive heart failure, conduction abnormalities, and peripheral embolization should be sought. If such signs are present, the patient may be a candidate for surgical valve replacement (see later in this chapter). Intravenous antibiotic therapy should be initiated immediately after collecting three sets of blood cultures. Additional routine tests, such as a complete blood count, electrocardiogram, and chest radiograph, should be obtained.

Days 2 Through 7

During the first week of hospitalization, patients should be evaluated daily for a *response to therapy*. Fever usually resolves after one or two days of treatment in cases of

streptococcal endocarditis and by day 7 in patients with endocarditis caused by *Staphylococcus aureus*. Patients also should be examined daily for signs of embolization and other complications because these occur predominantly during the first week of treatment. Complications occur frequently during this period (9), even if patients are diagnosed and treated promptly (Table 71.8). Serum concen-

TABLE 71.8
COMPLICATIONS OF ENDOCARDITIS

Complication	Incidence, %
Congestive heart failure	17-41

Stroke	17-43
Mycotic aneurysm	1-6
Peripheral embolization	8-10
Renal involvement	7-27

trations of aminoglycosides should be measured if these agents are to be used for more than a week. In selected patients, vancomycin levels help to confirm that therapeutic concentrations have been achieved or to avoid toxicity.

Week 2

The second week of therapy is an important time point for assessing *response to antimicrobials*. Fever lasting longer than 7–9 days suggests myocardial abscess formation, embolization, or metastatic foci of infection. Such patients should undergo echocardiography to look for structural complications. When clinical or laboratory findings indicate a site of embolization (e.g., the brain), computed tomography or magnetic resonance imaging may be warranted. Because blood cultures usually are sterile by the second week of successful therapy, all patients should have repeat blood cultures obtained in week 2. Persistent bacteremia is indicative of complications and requires further evaluation. Additional parameters to be followed during this period are liver and renal function, and antibiotic levels. Moreover, patients should continue to be monitored for evidence of valve dysfunction.

The second week of therapy is also a useful time to *identify potential sources of bacteremia* that led to endocardial infection. The anatomic sites to be evaluated should be directed by the organism recovered from the initial blood cultures. Patients with streptococcal endocarditis should be examined for dental disease. Patients with endocarditis due to *Streptococcus bovis* are at increased risk for occult bowel pathology and therefore should be evaluated for lesions such as colonic carcinoma.

For some patients, therapy is completed at the end of 14 days. At the time of discharge, these patients should be evaluated as described below. Patients receiving 4–6 weeks of total therapy should continue to be evaluated for the onset of complications or drug-related toxicities until the completion of therapy. Issues for these patients at the end of therapy are identical to those receiving short-course treatment.

Indications for Valve Replacement

Despite prompt antimicrobial treatment, 14%–49% of patients with infective endocarditis require cardiac surgery. Indications for surgery include infection with an untreatable organism (e.g., fungi), development of congestive heart failure, mechanical complications (e.g., cusp fenestration or papillary muscle rupture), myocardial abscess formation, repeated large or critical vessel embolization (e.g., cerebral or coronary), and persistent bacteremia (13). *Once these indications have become apparent, surgery should be performed promptly.* This is because delay may increase the risk for further complications (which may be catastrophic), and valve surgery in patients with endocarditis is not intrinsically more risky than the same procedure in uninfected individuals. In fact, stratified by degree of congestive

heart failure, patients undergoing valve replacement for active endocarditis have rates of survival comparable to those undergoing elective valve surgery. Moreover, the incidence of subsequent prosthetic valve infection is not increased in patients having valve replacement for active endocarditis.

ISSUES AT THE TIME OF DISCHARGE OR COMPLETION OF THERAPY

Although patients with endocarditis traditionally received therapy exclusively in the hospital, many inpatients now successfully complete treatment in other settings, such as skilled nursing facilities, infusion centers, or home. To be eligible for discharge before completion of therapy, several criteria should be met. First, the patient should be free of complications that might require prompt surgical intervention, such as significant valve dysfunction. Second, the antimicrobial regimen selected should be unlikely to require intensive monitoring or dosage changes resulting from adverse events or toxicities. Third, the agents chosen should have pharmacokinetic and chemical properties well suited to nonhospital settings. In cases in which nursing resources are limited, for example, drugs that can be administered once daily, such as ceftriaxone, are preferable to those requiring multiple daily doses. For patients receiving home intravenous therapy via an electronic multidose infusion pump, the antibiotics must be stable at room temperature for at least 24 hours. Because of restricted reservoir capacity, other infusion devices require that the drug remain soluble at high concentrations. Thus, the proper matching of antimicrobial regimens with infusion devices and therapeutic setting can be complicated. For this reason, many centers have an infusion team that actively participates in the discharge planning of patients selected for antimicrobial therapy in the nonhospital setting.

By the end of treatment, the patient should be afebrile, hemodynamically stable, and free of new complications. In some patients, an evaluation for underlying sites of bacteremia will have been either initiated or completed by this time. To confirm that endocardial infection has resolved, one or two additional blood cultures should be obtained 7–14 days after completing antimicrobial treatment.

Endocarditis is a destructive process, producing permanent deformities of the cardiac valves that leave patients with a *100-fold increased risk of recurrent disease*. Thus, all patients with a history of infective endocarditis should receive antimicrobial prophylaxis when indicated, such as prior to certain dental procedures (Tables 30.6 and 30.7). Despite long-standing guidelines, such recommendations are often not followed. Common errors include failure to recognize the need for prophylaxis, failure by physicians to inform the patient of the lifetime risk for endocarditis, not warning the patient's dentist about the medical history, and incorrect selection or dosage of antimicrobial agents.

To enhance the likelihood that patients will receive adequate prophylaxis in the future, they should be informed about their risk for reinfection and instructed about their lifetime need for antibiotic prophylaxis. It is important to emphasize the need for patients to alert their dentists or physicians of their high risk for recurrent infection. The American Heart Association produces a wallet card that can be carried by patients to document their medical histories. This card also details the recommended prophylactic regimen for specific procedures, which can be used by physicians or dentists as a reference. Good oral hygiene and regular dental care should also be encouraged because they are associated with a reduced risk of recurrent endocarditis (14).

In addition to problems with recurrent infection, patients with endocarditis are at increased risk for progressive valvular dysfunction, leading to hemodynamic impairment and the need for valve replacement. In a 15-year prospective follow-up of patients with native valve endocarditis, 47% required valve replacement during the period of observation. Patients with aortic valve involvement were at particular risk, with 55% undergoing valve surgery. For approximately two-thirds of patients, hemodynamic deterioration and valve replacement occurred within the first two years after having endocarditis. These results indicate that patients with a history of endocardial infection need to be monitored periodically for signs of valve dysfunction and congestive heart failure. Echocardiography may be indicated in some patients to detail the sites and extent of valvular involvement as well as to examine overall cardiac function.

COST CONSIDERATIONS AND RESOURCE USE

Few studies have attempted to analyze the costs associated with managing endocarditis. A decade ago, medical and surgical management were estimated to cost approximately \$18,000 and \$60,000 per case, respectively (15). Costs for medical management were based on expenses for inpatient therapy, so it is likely that outpatient treatment would be considerably less expensive. However, no systematic analysis of the relative savings associated with this approach has been published.

KEY POINTS

- Infective endocarditis is a relatively uncommon disease associated with a significant mortality rate. Many patients require surgical treatment, either at the time of infection or in the subsequent years.
- The management of patients with this infection requires expertise in areas of microbiology, infectious diseases, and cardiology.

- Patients suspected of having endocarditis need a prompt and definitive diagnostic evaluation followed by the rapid initiation of appropriate therapy.
- Selection of specific antimicrobial agents requires knowledge of the underlying risk factors for infection coupled with results from *in vitro* assays of antimicrobial sensitivity.
- In addition to choosing antibiotics, proper management entails careful monitoring for complications, identifying patients in need of surgery, and posttreatment follow-up for long-term valvular dysfunction.
- The physician managing such patients also should be certain that both the patient and his or her primary care physician are aware of the patient's lifelong need for antimicrobial prophylaxis in conjunction with certain dental or invasive procedures.

INTRODUCTION

Each year, approximately 150 million intravascular catheters are placed in 30 million patients in the United States. These devices allow the provision of medications, transfusion of blood products, parenteral nutrition, and hemodynamic monitoring. Unfortunately, intravascular devices are also the source of many infections. Local infections at the insertion site, bacteremia, septic thrombophlebitis, endocarditis, and metastatic complications of hematogenous spread from the catheter to bone, joints, ocular tissues, or solid organs are the most common infectious complications. Overall, an estimated 850,000 *catheter-associated infections* (CAIs) and 250,000 *catheter-associated bacteremias* (CABs) occur annually in the United States. Of these, approximately 80,000 CABs occur in the intensive care units (ICUs). CABs are associated with significant increases in mortality (12%–25%), morbidity, duration of hospitalization (mean, additional seven days), antibiotic use, and additional costs to the health care system of about \$25,000 per episode (1–3).

Today, many options are available for intravascular access (Table 72.1). The incidence and management of infectious complications vary with the type of device, the quality of infection control practices, and, most importantly, the condition of the patient. This chapter focuses on those CAIs attributable to intravenous access devices that are most often seen among adult patients in acute care settings.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

Catheter-related infection should be suspected whenever evidence of local infection develops at the catheter insertion/exit site or cutaneous tunnel in a patient with a current or recent intravascular catheter or when unexplained fever or other evidence of systemic infection is noted. The type of catheter is a major factor affecting the probability and site of infection and the clinical presentation (4, 5).

Short-Term Catheters

The use of short-term peripheral venous catheters is only rarely complicated by infection. When infection does occur, it is usually confined to the insertion site; bacteremia is present in 0.1%–0.3% of cases. Although these catheters are not used for outpatient treatment or home infusion therapy, they are often used to treat patients in long-term care facilities. These catheters remain in place for an average of 48–72 hours. Such patients may be referred for evaluation of suspected CAI. Infection may be inapparent until after the peripheral catheter has been removed, so a diagnosis of CAI should be considered when unexplained fever or focal signs of infection at a prior catheter site develop after discharge.

Nontunneled short-term central venous catheters (CVCs) are usually made of polyurethane and remain in place for an average of one week. These catheters are often

TABLE 72.1
INTRAVENOUS CATHETERS ASSOCIATED WITH INFECTION

Type of catheter	Site	Expected duration of use
Short peripheral catheter	Forearm or hand	Days
Nontunneled polyurethane CVC	Subclavian, internal jugular, or femoral veins	Days
Nontunneled silicone CVC	Subclavian	Weeks to months
Midline catheters	Proximal basilic or cephalic veins	Days to weeks, sometimes months
Peripherally inserted CVC (PICC)	Basilic, cephalic, or brachial veins	Weeks to months
Tunneled CVC	Subclavian, internal jugular, or femoral veins	Months
Totally implantable port	Subclavian or internal jugular veins	Months

CVC, central venous catheter.

placed in critically ill patients. Local pain, erythema, phlebitis, and purulence are clues to infection at the catheter insertion site. Fever is unusual in uncomplicated infection at the insertion site and suggests a more serious local condition (e.g., abscess, cellulitis, or septic thrombophlebitis), bacteremia, or metastatic suppurative complications. However, the absence of fever does not exclude a diagnosis of complicating bacteremia, especially among elderly patients and in cases of sepsis or immunosuppression. CAB should be suspected when staphylococcal or fungal bloodstream infection is detected in the absence of an obvious source for the bacteremia or fungemia other than the intravenous catheter.

Long-Term Catheters

The most common types of catheters likely to be encountered among outpatients are those intended for long-term use: peripherally inserted central venous catheters (PICC), tunneled central venous catheters, and totally implantable intravascular devices (ports). Midline catheters are also sometimes included in this category, although they were originally intended for short-term use. Overall, totally implantable intravascular devices have the lowest rate of infection among long-term catheters, probably because there is no portal of entry for bacteria. A “pocket” infection should be suspected in the presence of erythema or necrosis of the skin over the reservoir of a totally implantable intravascular device or when a purulent exudate is found in the subcutaneous tissue containing the reservoir. Tunneled catheters also have a low infection risk. Infection should be suspected when pain or local signs of inflammation are evident in the tissues overlying a tunneled catheter or within 2 centimeters of the exit site.

The absence of local signs of infection does not exclude a long-term catheter infection. In fact, it is extremely difficult to make a clinical diagnosis of infection involving the intravascular portion of a long-term catheter because local signs are usually not present. Fever is the most common clue but is not always found or may be intermittent. As with

short-term catheters, CAB should be suspected when unexplained staphylococcal or fungal bloodstream infection, endocarditis, abscesses, or other evidence of hematogenous spread are observed (6).

Differential Diagnosis and Initial Evaluation

Diagnosing CAB is often based on the interplay between clinical and microbiological findings. Local signs at the insertion site are almost always present in patients with short-term peripheral catheter infections, except in neutropenic patients. If a purulent exudate is present, a Gram stain of an aspirated specimen should be obtained to help guide initial treatment. Cultures are also important to determine the causal organism and its microbial susceptibility when systemic antibiotic treatment is planned. For peripheral catheters (short venous or PICC), aseptic phlebitis may produce tenderness, swelling, and erythema and can easily be confused with local infection. A palpable venous cord is not as common as other signs of phlebitis. When a tender, palpable cord is present in a febrile patient, especially with overlying cellulitis or exudate, *septic thrombophlebitis* may be present (Chapter 52). Purulent material found in association with local insertion site or exit site infection, complicating long-term catheter use, should always be cultured for fungi in addition to bacteria.

Fever is the hallmark of CAB, but an outpatient with a vascular catheter is likely to have an underlying illness and to have received therapies that may increase the risk for fever, such as chemotherapeutic agents. A thorough history, examination, and targeted laboratory and radiographic studies are necessary to exclude other potential causes of fever. However, unless another source is apparent, CAB should be suspected. In the absence of local signs, the diagnosis depends on a high index of suspicion and the results of blood cultures (1).

Performance of *two percutaneous blood cultures* is the best method for diagnosing bacteremia. These cultures should be obtained before antibiotic treatment is initiated. However, the skin must be properly cleaned before blood

cultures are obtained (1); failure to do so increases the potential for blood culture contamination. Blood cultures obtained in an emergency department, where other urgent matters often take precedence over appropriate culturing technique, are often contaminated. As a corollary, intravascular catheters placed in an emergency department or during other patient emergencies should be replaced within 24 hours to reduce the risk for infection (1).

Cleaning the skin with soap will remove dirt and surface lipids and improve the efficacy of whatever antiseptic is used. Alcohol preparations, tincture of iodine, povidone-iodine, or chlorhexidine solutions are effective antiseptics, but only when properly applied to clean skin. Alcohols have an immediate onset of action and broad-spectrum activity but are ineffective when the skin is not clean. Tincture of iodine also has a rapid onset of action but has the disadvantage of staining the skin and producing serious allergic reactions in some patients. Povidone-iodine has a slower onset of action and must be in contact with the skin for three to five minutes to achieve antiseptics, a time requirement that is not often met. A 2% tincture of chlorhexidine preparation is now recommended by the Centers for Disease Control (CDC) guidelines for the prevention of catheter-related infections (1). Proper hand cleansing, gloving of the health care personnel who obtain the blood cultures, and good practices in the clinical laboratory are also important to prevent contamination.

Blood culture contamination should be suspected if only one blood specimen demonstrates microbial growth, especially when skin commensals, such as coagulase-negative staphylococci, are found. When two blood samples obtained from different sites grow the same organism, true bacteremia is more likely. However, when coagulase-negative staphylococci are found in both specimens, the isolates should be identified at the species level and their antibiograms compared to ensure that they are, in fact, identical. Blood samples drawn through catheters should also be obtained aseptically after cleansing the hub with alcohol. When local infection is present, bacteremia without another source is sufficient to establish the diagnosis of CAB, especially if the same organism is isolated from the two sites. When evidence of insertion or exit site infection is not present, implicating the intravascular catheter as the source of infection is more difficult. The two main methods used are culturing the catheter and culturing the blood, but neither is ideal, and no “gold standard” is universally accepted (1).

Culturing the Catheter

The *roll-plate semiquantitative catheter culture technique* is the most commonly used method to culture a suspected catheter. With this method, the catheter is removed and its distal 2-centimeter segment is rolled on an agar plate, which is then incubated. The presence of 15 or more colonies of bacteria is taken as presumptive evidence of

catheter colonization sufficient to cause bacteremia or fungemia. The roll-plate method cultures only the external surface of the catheter. Therefore, it is less sensitive when the infection arises from intraluminal colonization that is introduced through the catheter hub, which is particularly common with long-term catheters. The sensitivity may also be reduced when antibiotic-impregnated catheters are used. Hence, the utility of the roll-plate technique for diagnosing or excluding CAB is controversial.

Quantitative catheter culture by sonication technique improves the detection of intraluminal colonization. By sonication, a catheter is considered colonized if at least 1,000 colonies of bacteria are isolated from the catheter segment. Other alternative methods for culturing the catheter include flush techniques, vortex, and centrifugation methods. Like the roll-plate technique, all these methods have one major disadvantage—a requirement for catheter removal.

Culturing the Blood

Blood culture techniques to diagnose CAB rest on the assumption that the quantity of bacteria in blood drawn from an infected catheter will exceed the quantity obtained from a peripheral blood sample. A ratio of 5:1 (catheter blood colony count per milliliter to peripheral blood colony count per milliliter) is used as the cutoff for implicating the catheter as the source. Differential time to positivity (DTP) is defined as the time necessary for simultaneous blood cultures, taken through the catheter and via a peripheral puncture, to become positive. When DTP was 120 minutes or more, it was found to be highly sensitive and specific in diagnosing CAB (7). Two disadvantages of these methods are the laboratory time and expense needed to perform the quantitative cultures as well as the lack of routine reporting of DTP by most laboratories.

The single most important diagnostic step in diagnosing CAB is the demonstration of microbial growth in two or more percutaneous blood cultures of a catheterized patient with no other obvious source of infection. *Catheter tip cultures and quantitative blood cultures should not be performed unless their results would change the treatment plan.* Whether or not the catheter is removed, all CRI should be treated with appropriate antibiotics, administered parenterally (8).

Indications for Hospitalization and Initial Management

The management of CAI depends on at least four factors: (a) the severity of the infection (local or systemic), (b) the condition of the patient, (c) the known or suspected organism, and (d) the type of catheter (6) (Table 72.2). *Uncomplicated local infections of short-term peripheral venous catheters* usually can be treated by removing the catheter and administering a short course (3–5 days) of an oral

TABLE 72.2**MANAGEMENT OF CATHETERS WHEN CATHETER-ASSOCIATED INFECTION IS SUSPECTED OR DIAGNOSED**

	Short-term peripheral intravenous catheter	Short-term central venous catheter	Long-term catheter
Routine replacement	Every 48–72 h	No recommendation	Not indicated
Local insertion or exit site tunnel infection	Remove catheter	Remove catheter, replace at new site (if needed)	Removal not usually required unless infection is present
Catheter-associated bacteremia known or suspected; uncomplicated	Remove catheter	<ul style="list-style-type: none"> • If patient is septic, remove catheter; replace at new site (if needed) • If patient is not septic, change catheter over guidewire; replace if catheter culture is positive 	<ul style="list-style-type: none"> • Immediate removal not usually required unless patient is septic • If bacteremia persists >48 h on antibiotics or patient fails to respond, always remove catheter • If coagulase-negative staphylococcal bacteremia, treat with antibiotics 5–7 d; if early relapse occurs, remove catheter • If catheter need is long-term, consider elective replacement • If <i>Staphylococcus aureus</i>, Enterobacteriaceae, or <i>Candida</i> species bacteremia, catheter removal is indicated as soon as feasible
Catheter-associated bacteremia with complications ^a	Remove catheter	Remove catheter	Remove catheter

^a Complications include septic thrombophlebitis and endocarditis or evidence of hematogenous spread.

antibiotic with antistaphylococcal activity. Such patients do not require hospitalization. Blood cultures should be obtained if the patient is febrile or has other evidence of systemic infection. If the index of suspicion for bacteremia is high or if evidence of septic thrombophlebitis is present, the patient should be admitted and treated with parenteral antibiotics.

Uncomplicated insertion or exit site infections of long-term catheters can usually be treated without removing the catheter (Table 72.2) unless caused by *Staphylococcus aureus*, Gram-negative bacilli, or *Candida* species (9). Obvious soft-tissue abscesses should be drained. Parenteral antibiotics can be administered through the catheter, so hospitalization is not mandatory if the patient is stable. Percutaneous blood cultures should be obtained before treatment is started. Tunnel infections are more serious; they require catheter removal and are best treated, at least initially, in the hospital.

All patients with known or suspected *complicated bacteremia* should be admitted to the hospital. Such complications include septic thrombophlebitis, endocarditis, and evidence of hematogenous spread of infection, and catheter removal is always required, in addition to appropriate antibiotic therapy (Table 72.2). Complicated bacteremia also should be suspected when bacteremia persists for more than 48 hours after catheter removal and initia-

tion of appropriate antibiotic treatment (Table 72.3). In these situations, additional investigations should be done, such as venogram to rule out septic thrombosis and transesophageal echocardiography to detect valvular vegetations in cases of endocarditis (Chapter 71) (9).

Patients with *uncomplicated bacteremia* always require parenteral antibiotic treatment, but catheter removal may not be necessary, depending on the causal organism (Table 72.2). Because the organism is usually not known at the time of initial evaluation, patients should generally be admitted to begin empiric antibiotic treatment. If the decision is made to retain the catheter in a clinically stable patient who is not neutropenic and who has access to supervised outpatient treatment, hospitalization can sometimes be brief or even avoided entirely. Persistent bacteremia (or fungemia) for more than 48 hours on appropriate parenteral therapy is an indication for catheter removal and a search for infectious complications, regardless of the etiologic agent (10).

When coagulase-negative staphylococci are the cause of long-term catheter infection, removal of the catheter has little impact on the acute outcome of the bacteremia. However, the risk of recurrent bacteremia is decreased if the catheter is removed, so elective replacement is usually indicated if the catheter is needed for long-term management. When *Staphylococcus aureus* is involved, immediate

catheter removal is necessary because the acute mortality rate, complication rate, and relapse rate are higher when the catheter is retained (9). All patients with catheter-related candidemia should be treated, either with amphotericin B, an azole (e.g., voriconazole), or an echinocandin (e.g., caspafungin) based on the susceptibility of the organisms. Antifungal therapy should be given for 14 days after the last positive blood culture (9). Catheters should be removed in cases of catheter-related candidemia because salvage rates with systemic antifungal therapy are only in the 30% range (9). Gram-negative bacillary infections, especially those caused by *Pseudomonas* species, are difficult to cure without catheter removal.

Initial Antimicrobial Treatment

As with all infections, the goal of empiric antibiotic treatment of CAB is to provide a drug regimen with bactericidal activity against the most likely pathogens until culture data are available to guide definitive treatment decisions. Factors affecting the decision include the severity of illness, the extent of infection, the prevalence of organisms associated with CAB in the institution or among comparable patients (e.g., bone marrow transplant recipients), the prevalence of antimicrobial resistance among these organisms, and the recent history of infections and antibiotic treatment in the individual patient (9). Treatment must be individualized, and no single empiric regimen is appropriate for all patients. Most importantly, the treatment regimen should promptly be narrowed once the causative organism is identified.

Coagulase-negative staphylococci, most of which are resistant to nafcillin and other β -lactam antibiotics, are the most common pathogens associated with CAB. However,

empiric vancomycin treatment is not essential unless the patient is neutropenic or profoundly immunosuppressed, because these infections are usually indolent and the treatment outcome is not better when vancomycin is included in the initial treatment regimen (10).

S. aureus is the most common pathogen associated with morbidity and mortality from CAB. Knowledge of the local prevalence of methicillin resistance among nosocomial staphylococcal bloodstream infections is helpful in determining the need for empiric use of vancomycin when CAB is suspected. Even where the prevalence is low, vancomycin should be included in the empiric treatment regimen if the patient is septic or has a prior history of infection or colonization with methicillin-resistant *S. aureus*. For vancomycin-resistant *S. aureus* or in patients colonized with vancomycin-resistant enterococci or allergy to vancomycin, linezolid or quinupristin/dalfopristin should be used (9). Otherwise, treatment with nafcillin plus an aminoglycoside is usually adequate. However, in the absence of methicillin-resistant organisms, penicillinase-resistant penicillins, such as nafcillin or oxacillin, should be used to avoid the unnecessary use of vancomycin (9).

Additional empirical coverage for Gram-negative bacilli and *Pseudomonas aeruginosa* with ceftazidime or cefepime should be considered for severely ill or immunocompromised patients when CAB is suspected, as well as in institutions where pseudomonas infections are not uncommon (Chapter 64).

Indications for Early Consultation

Surgical consultation should be obtained when septic thrombophlebitis is suspected, deep tissue metastatic

TABLE 72.3

DIAGNOSTIC CONSIDERATIONS IN PATIENTS WHO CONTINUE TO HAVE PERSISTENT BACTEREMIA OR FEVER AFTER EMPIRIC TREATMENT FOR CATHETER-ASSOCIATED BACTEREMIA

Reason for failure to improve	Recommended approach
Infected catheter remains	Remove catheter
Resistant bacterial organism (e.g., methicillin-resistant <i>Staphylococcus aureus</i> , <i>Enterococcus faecium</i>)	Evaluate susceptibility; broaden coverage; obtain infectious diseases consultation
Nonbacterial pathogen (e.g., <i>Candida</i> species, atypical pathogens)	Perform additional microbiological cultures to exclude these agents and mycobacteria
Inadequate treatment regimen	Check drug dosage, route, interval; consider measuring serum concentrations if vancomycin or aminoglycosides are being used
Complicated bacteremia (e.g., endocarditis, septic thrombophlebitis, septic pulmonary emboli, mycotic aneurysm)	Repeat physical examination and selected laboratory and imaging studies to diagnose these entities; obtain echocardiogram; obtain infectious diseases consultation; consider surgical consultation
Seeding of organs, abscess formation	Repeat physical examination and selected laboratory and imaging studies to diagnose these entities; obtain ophthalmology consultation; obtain infectious diseases consultation; consider surgical consultation
Other processes	Repeat physical examination and targeted laboratory and imaging studies to identify other causes of fever; consider drug fever, venous thrombosis, pulmonary embolism

abscesses are detected, endocarditis is diagnosed, or surgically implanted catheters require removal. Consultation with an orthopedic surgeon should be sought when complicating bone or joint infection is present. Early and serial retinal examinations are important for all patients with CAB, and consultation with an ophthalmologist can be helpful in detecting early retinal changes, especially when *S. aureus* or *Candida* species are the cause of blood-stream infection. Most cases of uncomplicated CAB do not require consultation with infectious disease specialists, but consultation is warranted when prolonged antibiotic treatment is being considered and when complicated infection is present.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Catheter Infections Developing After Admission

Most infections attributable to intravascular catheters develop in the acute care setting. When short-term peripheral catheters and long-term catheters become infected during hospitalization, the presentation and evaluation are the same as at the time of admission, described in the preceding section. The most important CAIs that develop during hospitalization are related to short-term central venous catheters. These catheters are associated with an increased risk for local infection at the insertion site.

Short-term central venous catheters are frequently used in ICU patients, most of whom are seriously ill and at high risk for fever and infection from a variety of sources. Hence, diagnosing CAB is extremely difficult. When bacteremia is suspected, two simultaneous blood cultures should be obtained from the CVC and percutaneous sites. The quantitative blood culture method may be employed to help establish the diagnosis of CAB; otherwise, differential time to positivity could be useful. The diagnosis of CAB would be established when the blood culture drawn through the CVC becomes positive at least two hours before a simultaneously drawn peripheral blood culture (7).

Suspected short-term central venous CAB is initially managed according to the same principles that apply to long-term CAB, with one additional consideration: the possible role of *guidewire exchange* (Table 72.2). Replacing central catheters over a guidewire reduces the potentially serious risks associated with new insertion at an alternate site and is the preferred method of catheter replacement when infection is not suspected and catheter tip culture is required to rule out CAB. The procedure is contraindicated if evidence of infection at the insertion site is present (pain, purulence, erythema) and if the patient is septic. In a febrile patient without these contraindications in whom CAB is suspected, replacement over a guidewire is

reasonable, and culturing the tip of the removed catheter aids in the diagnosis of the suspected CAB. Guidelines from the Centers for Disease Control and Prevention (CDC)/Hospital Infection Control Practices Advisory Committee (HICPAC) recommend that a quantitative or semiquantitative culture of the catheter be obtained at the time of removal. If the culture is positive, then subsequent replacement of the catheter at a new site is also recommended (1).

Expected Response to Therapy

Uncomplicated infections at the insertion site should resolve quickly. If the patient's condition does not improve after 48 hours or if a fever develops or worsens, the site should be carefully examined to identify cellulitis, an undrained abscess, septic thrombophlebitis, or other local complications (Table 72.3). In addition, blood cultures should be obtained to exclude the possibility of a secondary bacteremia.

Likewise, among patients with CAB, blood cultures should be negative after 48 hours of initiating appropriate antibiotic treatment. If bacteremia persists beyond 48 hours, a comprehensive evaluation and consultation with an infectious diseases clinician are indicated to determine whether the patient has developed a deep-seated infection (10) (Table 72.3). If the implicated catheter was not removed when the problem first appeared, immediate removal is now necessary. The treatment regimen should be evaluated to determine whether the proper antibiotics were administered at the appropriate time and whether the dosage was adequate to achieve bactericidal activity against the pathogen. Additional studies to identify endovascular complications of CAB should also be initiated, especially if the original infection was caused by *S. aureus*. Septic thrombosis, endocarditis, and septic pulmonary emboli are relatively rare but life-threatening complications in this setting. Transesophageal echocardiogram, chest radiographs, venous Doppler studies, and, rarely, a peripheral or central venogram should be considered.

If the patient remains febrile more than five days, other complications of CAB should be considered, even in the face of sterile blood cultures. When *S. aureus* or *Candida* species cause CAB, hematogenous spread can produce metastatic abscesses and other infections in the retina, solid organs, soft tissues, bones, and joints. Detecting these complications is difficult, especially in severely ill patients who cannot provide information about localizing symptoms. The retina should always be examined, and ophthalmologic consultation is warranted. Abdominal ultrasonography will aid in the detection of occult splenic, hepatic, and renal abscesses. Additional studies that are sometimes needed include bone scans, computed tomography or magnetic resonance imaging, and white blood cell scans. Of course,

patients with CAB are usually at risk for many other causes of fever, and these should not be overlooked when a diagnosis is being pursued.

DISCHARGE ISSUES

The duration of parenteral treatment required to cure CAB is variable, and clinical data have not completely elucidated the optimal duration (9). Uncomplicated infections caused by coagulase-negative staphylococci usually do not require treatment for more than five to seven days, even when the catheter is not removed. Uncomplicated Gram-negative bacillary CAIs should be treated for 10–14 days with appropriate antimicrobial therapy, and the catheter should be removed (9).

Antifungal therapy for 14 days after the last positive blood culture is recommended for uncomplicated CAI caused by *Candida* species (9). Most experts also recommend a 10-day to 14-day course of treatment for uncomplicated *S. aureus* CAB (10,11). However, the risk for hematogenous seeding, which potentially leads to serious endovascular infections, is high with both of these organisms. Failure to diagnose these complications and extend the duration of treatment accordingly accounts for a large proportion of the relatively high rates of delayed morbidity and mortality associated with CAB. The required duration of antifungal therapy for complicated CAB depends on the specific problem (e.g., endocarditis) and the need for surgical intervention. Treatment of CAB caused by *S. aureus* should be extended to 4–6 weeks when complications are diagnosed. If the blood cultures are not sterile after 48 hours or the patient's condition does not improve, treatment should also be continued for at least four weeks unless an alternate diagnosis is found (10,11).

No data are available to define the optimum duration of hospitalization for CAB. However, experience with outpatient and home infusion programs suggests that completion of therapy outside the hospital is a good option for many patients (12). Criteria for discharge include (a) clinical improvement and resolution of fever, (b) sterilization of blood cultures, (c) establishment of reliable venous access for parenteral treatment, and (d) access to supervised outpatient or home infusion therapy. Patients who meet the first three criteria but cannot be managed as outpatients might be transferred to step-down units or skilled nursing facilities until treatment is completed.

Patients who are able to participate in their own catheter care should be trained to do so before discharge. Essential information should cover dressing care, how to avoid contamination of the insertion site or hub, and which symptoms and signs should prompt medical evaluation. In addition, gloves and instructions for safe needle handling and an impervious needle disposal container should be provided if the patient or caregivers will be at risk for needle injury or blood exposure.

COST CONSIDERATIONS AND RESOURCE USE

The most important strategy for improving resource utilization relevant to CAB is to *reduce the nonessential use of intravascular catheters*. Decreasing the number of catheters used, the number of catheter lumens, and the total days of catheterization decreases infection rates. This can be accomplished through judicious use of parenteral treatments and changing to oral regimens when the patient's condition warrants the switch. It is important to choose the type of catheter with the lowest incidence of infection that is appropriate for the expected duration of catheterization. The use of *antimicrobial or antiseptic impregnated catheters* in adults whose catheter is expected to remain in place longer than five days is recommended if, after implementing a comprehensive strategy to reduce rates of CAB, the CAB rate remains above the goal set by the individual institution, based on benchmark rates (10). Catheters impregnated with minocycline and rifampin were shown to be highly effective in preventing CAB, even more so than antiseptic catheters coated with chlorhexidine gluconate and silver sulfadiazine. This was particularly true for catheters with an expected dwell time of longer than seven days (13). In addition, CAI can be prevented by adherence to CDC guidelines for catheter placement, care and replacement, and removal (1). The use of maximum sterile barriers during CVC insertion is particularly cost-effective (14).

For patients who do acquire CAI, significant resources can be saved by early discharge to a lower level of care for parenteral treatment, provided that adequate support services to ensure uninterrupted therapy and observation for new complications are available.

KEY POINTS

- Many cases of catheter-associated infection can be avoided by judicious use of intravascular catheters, proper placement and care of catheters, and removal as soon as intravenous access is no longer indicated. Antimicrobial or antiseptic-impregnated catheters can also lower infection rates in patients expected to have prolonged catheterization.
- Attention to antisepsis and infection control practices can reduce the number of false-positive blood cultures when catheter-associated bacteremia is suspected and decrease unnecessary use of vancomycin and other antimicrobial agents.
- Immediate long-term catheter removal is not always required, depending on the etiologic agent. However, to avoid relapse, elective replacement is advised if ongoing venous access is needed.
- Patients with catheter-associated bacteremia usually do not require hospitalization once they are clinically stable, have negative blood cultures, and have been

evaluated to exclude complications that increase morbidity and mortality and mandate a longer course of treatment.

INTRODUCTION

The concept of using naturally occurring organisms as weapons is not new. History has documented numerous attempts at biological warfare (Table 73.1). Only in the past several years, however, has the health care community become aware of the growing threat of a biological weapons attack. For many, the first notice came with the October 2001 bioterrorism attack, in which anthrax was spread through the U.S. postal system, resulting in 18 cases of anthrax with five fatalities. This attack, along with the 2003 outbreak of severe acute respiratory syndrome (SARS), further demonstrated the underpreparedness of the United States health care system to respond not only to bioterror attacks, but also to other highly transmissible emerging infections.

THE CURRENT STATE OF HOSPITAL PREPAREDNESS

Limited data indicate that most hospitals are inadequately prepared to deal with attacks by weapons of mass destruction, including bioterrorism. A large-scale bioterrorism drill performed in Denver, Colorado, simulating aerosolized plague attacks resulted in over 3,000 simulated casualties within 4 days (1). One of the most valuable insights from this drill was that the systems and resources currently in place are inadequate to manage the stress of a large-scale bioweapons attack.

Fortunately, much of what should be done in anticipation of a biological attack is also applicable to any public health disaster or infectious disease outbreak, making these expensive but necessary preparations “dual-use” in nature. In contrast to preparation for chemical spills or terrorism (where preparation relies largely on prehospital hazardous material teams and equipment, immediate treatment in the streets, and cordoned-off crime scenes), preparation for biological terrorism relies much more on

education, a robust public health system, and broad interagency collaboration.

Not only must hospitals prepare to deal with the consequences of bioterrorism, they must also take measures to reduce their vulnerability as terrorist targets. As the epicenter of community emergency response, hospitals are valuable and often extremely vulnerable assets. While many public buildings have secure perimeters and require visitor searches, most hospitals have no such security measures. Hospital security is challenged by the appropriate desire to maintain ready access for patients, family members, and staff. To would-be perpetrators, these entryways may represent a tempting access point.

Today, rapid progress in the development and enrichment of our public health infrastructure is ongoing, but the system is not yet where it needs to be. Currently, no unified surveillance system is in place. The complexities of disease reporting and the lack of consistent feedback lead to physician frustration and poor compliance with current public health reporting mechanisms. Because our surveillance systems and response networks are underprepared, an even greater burden is placed upon the individual clinician to be alert to the possibility of biological warfare. Clinicians must be able to make an accurate diagnosis, to begin treatment of affected patients, and to notify and coordinate care with responsible public health authorities.

Simulation exercises and experience with disasters have taught us that communication during a crisis is often limited. Planning activities—such as mini-simulations (tabletop exercises) and disseminating contact information of key authorities—appear to significantly enhance local abilities to respond to true crises.

GENERAL CONSIDERATIONS FOR DIAGNOSIS AND TREATMENT

Because biological agents introduced by humans may cause disease syndromes nearly indistinguishable from

TABLE 73.1
HISTORICAL TIMELINE OF BIOTERRORISM

Year	Incident
190 BCE	Hannibal hurls venomous snakes onto enemy ships
400 BCE	Scythian archers use arrows dipped in blood and manure or decomposing bodies
1346	Mongols hurl plague-infected corpses over enemy walls
1405	Spanish contaminate wine drunk by French soldiers with blood of leprosy patients
1650	Polish soldiers place saliva from rabid dogs into hollow shell casings
1710	Russians invading Estonia hurl plague-infected corpses over enemy walls
1763	British officers give blankets used by smallpox victims to American Indians in Pennsylvania, resulting in a devastating smallpox outbreak
1860s	Confederate sympathizers during the American Civil War attempt to ship garments and bedding used by yellow fever victims to New York
1863	Confederate soldiers during the American Civil War leave dead animals in wells and ponds to contaminate Union soldiers' water supply
1972	Ratification of Biological and Toxin Weapons Convention outlawing offensive bioweapons
1992	Dr. Ken Alibek flees former USSR; debriefing indicates substantial bioweapons program
1984	Salad bars in 10 Oregon restaurants contaminated with <i>Salmonella</i> , sickening 750 people
2001	<i>Bacillus anthracis</i> attacks via the U.S. Postal System

naturally occurring illnesses, and because patients may not fall ill until days after exposure, bioterrorism may be difficult to distinguish from naturally occurring disease. Therefore, distinguishing the results of intentional release of a disease agent from a naturally occurring illness often

requires the clinician to think "epidemiologically." Disease patterns with unusual organisms, large numbers of victims at the same stage of illness, unusual antibiotic resistances, or unusual seasonal presentations should all raise the question of bioterrorism (Table 73.2). For example, one case of rapidly progressive influenza-like illness may not herald a bioterrorist attack, but a pattern of several patients with the same syndrome should certainly raise the specter of bioterrorism. High risk biological agents have been identified and hospital-based physicians should be familiar enough with them to rapidly assess patients and begin treatment.

Biological attacks may either be overtly announced, or covert, with the first signs of attack being mildly symptomatic, minimally ill patients or hundreds of critically ill ones. In either case, early recognition of the disease outbreak and identification of the disease agent are critical to minimizing the number of casualties. Epidemiologic models have demonstrated that *rapid implementation of a post-attack prophylaxis program is the single most important means of reducing losses following a bioterrorist attack*. However, before prophylaxis can be initiated, the disease agent must be identified.

SPECIFIC BIOLOGICAL AGENTS

The Centers for Disease Control and Prevention (CDC) have issued a list of high-likelihood, potential bioterrorist agents. These have been prioritized according to ease of dissemination, transmissibility, mortality, potential for major public health impact, potential to cause public fear and social disruption, and requirement of special action for public health preparedness (Table 73.3) (2). Category A agents

TABLE 73.2
CHARACTERISTICS DISTINGUISHING A NATURAL DISEASE OUTBREAK FROM A BIOTERRORIST ATTACK

Natural outbreak	Bioterrorist attack
Gradual presentation of victims with no readily identifiable common exposure	Sudden presentation of large numbers of victims with a similar disease or syndrome (e.g., many cases of rapidly progressive pneumonia) who may have a readily identifiable common exposure
Cases present at varying stages of disease progression	Many cases present at similar stage in disease progression because of common source of exposure
Expected disease course for that specific pathogen with appropriate response to standard therapy	More severe disease than is usually expected for that specific pathogen or failure to respond to standard therapy
Slowly progressive disease with prodromal symptoms (e.g., natural progression of bubonic plague to pneumonic plague)	Rapidly progressive disease suggesting an unusual form of disease transmission (e.g., primary pneumonic plague with rapidly progressive fulminant pneumonia and no prodromal bubonic form of the disease)
Normal antibiotic sensitivities	Highly virulent strains possibly with antibiotic resistance
No announcement of attack	Possible announcement of bioterrorist attack
Presentation of common illnesses (such as influenza)	Presentation of a single case of any disease caused by CDC Category A, B, or C agent (Table 73.3)
Presentation of disease in the usual geographic area during the usual transmission season	Presentation of disease in an unusual geographic area or transmission season

TABLE 73.3
CRITICAL BIOLOGICAL AGENTS

Category A. High-priority agents include organisms that pose a risk to national security because they can be easily disseminated or transmitted person to person; cause high mortality with potential for major public health impact; might cause public panic and social disruption; and require special action for public health preparedness.

- Variola major (smallpox)
- Bacillus anthracis* (anthrax)
- Yersinia pestis* (plague)
- Clostridium botulinum* toxin (botulism)
- Francisella tularensis* (tularemia)
- Filoviruses
 - Ebola virus (Ebola hemorrhagic fever)
 - Marburg virus (Marburg hemorrhagic fever)
- Arenaviruses
 - Lassa fever virus (Lassa fever)
 - Junin virus (Argentine hemorrhagic fever) and related viruses

Category B. Second-highest priority agents include those that are moderately easy to disseminate; cause moderate morbidity and low mortality; and require specific enhancements of CDC’s diagnostic capacity and enhanced disease surveillance.

- Coxiella burnetii* (Q fever)
 - Brucella* species (brucellosis)
 - Burkholderia mallei* (glanders)
 - Alphaviruses
 - VEE virus (Venezuelan encephalomyelitis)
 - EEE and WEE viruses (eastern and western equine encephalomyelitis)
 - Ricin toxin from *Ricinus communis* (castor beans)
 - Epsilon toxin of *Clostridium perfringens*
 - Staphylococcus enterotoxin B
- A subset of List B agents includes pathogens that are foodborne or waterborne. These pathogens include but are not limited to:
- Salmonella* species
 - Shigella dysenteriae*
 - Escherichia coli* O157:H7
 - Vibrio cholerae*
 - Cryptosporidium parvum*

Category C. Third-highest priority agents include emerging pathogens that could be engineered for mass dissemination in the future because of availability; ease of production and dissemination; and potential for high morbidity and mortality and major health impact.

- Nipah virus
- Hantaviruses
- Tick-borne hemorrhagic fever viruses
- Tick-borne encephalitis viruses
- Yellow fever
- Multidrug-resistant tuberculosis

are most likely to cause mass casualties if deliberately disseminated as small-particle aerosols and require broad-based public health preparedness. These agents, therefore, are a priority for preparation and training and will be discussed further here.

Because many of these diseases have been functionally eradicated and are very rare in the developed world, the medical literature often provides few data upon which to base clinical decisions. Consequently, public health experts have formed consensus-based guidelines to aid clinicians in making such decisions. Bioterrorism web sites at the CDC (www.bt.cdc.gov), the Agency for Healthcare Research and Quality (AHRQ) (www.bioterrorism-uab.ahrq.gov), and at various other institutions (for example, www.bioterrorism.uab.edu) are extremely useful as frequently updated sources of such information.

Anthrax

Clinical Presentation and Course

Classically, inhalational anthrax is a biphasic illness. After 0–6 days of incubation, the first phase appears as a nonspecific influenza-like illness characterized by mild fever, malaise, myalgias, nonproductive cough, and occasional chest or abdominal pain. Rhinorrhea and nasal congestion are uncommon with inhalational anthrax; the presence of these symptoms may indicate an etiology other than anthrax in patients presenting with influenza-like symptoms. The second phase of the illness appears 2–3 days later and is characterized by the abrupt onset of high fever, dyspnea, chest or abdominal pain, diaphoresis, cyanosis, and shock. Recent inhalational cases in the United States have manifested with sweats and gastrointestinal symptoms. Hemorrhagic meningitis and altered mental status are seen in up to 50% of cases as the disease spreads to the central nervous system. Death occurs within 24–36 hours (Table 73.4) (3).

TABLE 73.4
DISTINGUISHING INHALATIONAL ANTHRAX FROM INFLUENZA

Sign or symptom	Anthrax	Influenza or other influenza-like illness
Fever or chills	+++++	+++
Fatigue or malaise	+++++	+++++
Cough	++++	++++
Shortness of breath	++++	0
Chest discomfort or pleuritic chest pain	+++	+
Headache	++	++++
Myalgias	++	++++
Sore throat	0	++++
Rhinorrhea	0	++++
Nausea or vomiting	++++	+
Abdominal pain	+	+

Adapted from Centers for Disease Control and Prevention. Considerations for distinguishing influenza-like illness from inhalational anthrax. *Morb Mortal Wkly Rep* 2001;50:984–986.

Diagnostic Evaluation

Basic laboratory evaluation may show hemoconcentration or leukocytosis but is generally not helpful in making the diagnosis of anthrax. Gram stain and culture of fluid from cutaneous vesicles, blood, or cerebrospinal fluid will often show Gram-positive bacilli.

Rapid influenza tests may be useful in differentiating influenza from other influenza-like illnesses, including anthrax. However, the sensitivity of rapid influenza tests is relatively low (45%–90%). When the rapid influenza test is not positive, viral culture may be helpful in identifying true cases of influenza.

In asymptomatic patients with suspected exposure to inhalational anthrax, public health authorities have used nasal swab culture as an epidemiologic screening tool to confirm exposure to *B. anthracis*. The predictive value of this tool is not known, and, at present, the CDC does not recommend routine use of swab culture to rule out infection with *B. anthracis*.

Chest radiography in patients with inhalational anthrax often exhibits mediastinal widening and occasionally infiltrates or pleural effusion. In contrast, most cases of influenza are not associated with chest radiographic abnormalities. Computed tomography of the chest should be strongly considered in any patient with an influenza-like illness who presents with chest radiographic abnormalities. Computed tomography of the chest in cases of inhalational anthrax was first reported during the outbreak in October 2001. Findings included prominent mediastinal lymphadenopathy, pleural effusion, mediastinal edema, and basilar air space disease (4).

Prophylaxis and Treatment

In any suspected case of inhalational anthrax or in cases of cutaneous anthrax with signs of systemic involvement, extensive edema, or head and neck lesions, intravenous multidrug antimicrobial therapy should be started immediately. Based on animal and *in vitro* studies, the recommended agents include ciprofloxacin 400 mg every 12 hours or doxycycline 100 mg every 12 hours *plus* one of the following drugs: rifampin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, or clarithromycin. For uncomplicated cases of cutaneous anthrax that do not involve the head or neck, oral ciprofloxacin 500 mg every 12 hours or doxycycline 100 mg every 12 hours alone are sufficient therapy. Because the major complications of systemic anthrax are caused by toxins released from the bacteria, it has been suggested that corticosteroid therapy could be of some benefit in treating cases of inhalational anthrax, but there are no controlled trials to inform this decision (5).

Prophylactic therapy for patients with confirmed exposure to *B. anthracis* must be promptly initiated. Again, oral ciprofloxacin (500 mg every 12 hours) or doxycycline (100 mg every 12 hours) is sufficient prophylactic therapy. Chil-

dren or breastfeeding mothers may take amoxicillin at the appropriate dosage for prophylaxis only, but confirmed cases should be treated with ciprofloxacin or doxycycline, despite their known adverse effects in children (6). In any suspected or confirmed exposure to anthrax, public health authorities should be notified and involved in case management in order to assist with epidemiologic investigation. Currently, there is no vaccine for *B. anthracis* available to the public.

Infection Control

Anthrax is not transmissible through person-to-person contact. Universal precautions are generally sufficient to protect contacts from exposure to the disease. Decontamination with a soap and water bath is sufficient for gross exposures.

Smallpox

Clinical Presentation and Course

Infection occurs through direct contact with mucous membranes or through aerosol exposure. After an incubation period of 12–14 days, variola viremia causes a prodromal illness characterized by high fever, malaise, vomiting, headache, and myalgias, followed 2–3 days later by a characteristic macular rash of the face, hands, and forearms. As the rash spreads, the macules change to papules and eventually to pustular vesicles. Lesions are most prominent about the extremities and face and tend to develop synchronously, a characteristic that helps discriminate variola from varicella infection. Within 7–10 days, the rash begins to form scabs, leaving depressed pigmented scars when they heal. Scabs contain readily recoverable virus throughout the entire healing period; therefore, all patients should be considered infectious until all scabs are shed.

Diagnostic Evaluation

There is no widely available laboratory test to confirm smallpox infection. Thus, clinical presentation is the key to early diagnosis. The presence of a centrifugal, synchronous rash in the appropriate clinical setting must lead to consideration of the diagnosis of smallpox. If a case of smallpox is suspected, the patient must be placed in isolation until appropriate assessment is completed by public health authorities. Pustular fluid should be sampled only by persons recently vaccinated against smallpox. Samples should be handled by a Biosafety Level 4 (BSL-4) laboratory.

Prophylaxis and Treatment

Although animal trials with cidofovir are promising, there is currently no antiviral treatment for smallpox. In the United States, routine smallpox vaccination ceased in 1972.

Those vaccinated prior to 1972 retain partial immunity to the virus. Currently, vaccination of military personnel and civilian volunteers is ongoing. An emergency supply of smallpox vaccine and a limited supply of vaccinia immune globulin (VIG) are under the control of the CDC and state health departments (7). Efforts are underway to increase the national stockpile of smallpox vaccine as well as to develop safer and more effective cell culture–derived vaccines.

Infection Control

Smallpox victims must be immediately isolated. All household and face-to-face contacts should be vaccinated and placed under surveillance. Because smallpox is rapidly spread via aerosol transmission, it poses a particular threat in hospitals, which have a limited number of negative pressure isolation facilities. Given the serious nature of this disease, home care and quarantine is a likely and reasonable alternative to inpatient hospital treatment.

Plague

Clinical Presentation and Course

Yersinia pestis, a Gram-negative coccobacillus, is the causative agent of plague. Microscopically, the bacteria have a characteristic bipolar appearance that is commonly referred to as “safety pin” pattern. When a human is infected by the bite of an infected flea, symptoms of bubonic plague develop 2–8 days later. These include sudden onset of influenza-like symptoms and the development of acutely swollen, painful lymphadenopathy, typically in the groin, axilla, or cervical regions. Septicemic plague is characterized by disseminated intravascular coagulation, necrosis of small blood vessels, purpuric skin lesions, and gangrene of acral regions such as the digits and nose.

Pneumonic plague can develop secondarily from bubonic or septicemic plague or can develop primarily when aerosolized bacilli are inhaled. After a 2–4 day incubation period, the first symptoms are fever, hemoptysis, and dyspnea. Other symptoms include nausea, vomiting, abdominal pain, and diarrhea. As the disease progresses, a fulminant pneumonia develops, with lobar consolidation, respiratory failure, sepsis, and death. Primary pneumonic plague, which results from aerosolized release of *Y. pestis*, typically does not cause the cutaneous lesions that are seen with the naturally occurring form of the disease.

Diagnostic Evaluation

Gram stain and culture of blood, cerebrospinal fluid, sputum, or lymph node aspirate may reveal the organism. Giemsa staining reveals bipolar “safety pin”-appearing bacilli. Cultures demonstrate growth within 24–48 hours.

Definitive laboratory diagnosis of *Y. pestis* can be made via antigen detection, immunoassay, immunostaining, or polymerase chain reaction performed at the CDC and other government-operated laboratories.

Prophylaxis and Treatment

Currently, no vaccine is available for plague. In the past, antibiotic therapy with streptomycin 15 mg/kg intramuscularly twice a day for 10 days was considered first-line therapy for pneumonic plague. Small numbers of human cases and animal data suggest that intravenous gentamicin or doxycycline are also effective treatments. Quinolones may also be efficacious, but no human data exist for this class of drugs. Laboratory and animal studies indicate that doxycycline or fluoroquinolone antibiotics given orally for seven days are adequate prophylaxis for those potentially exposed to plague (8).

Infection Control

Because plague is readily transmissible via aerosolized particles, strict isolation for the first 48 hours of treatment is required to prevent secondary spread of the disease. Patients with the pneumonic form of the disease must remain in isolation for four days after initiation of antibiotic therapy.

Botulism

Clinical Presentation and Course

Botulinum toxin blocks acetylcholine release, and ultimately neurotransmission, by binding to the presynaptic nerve terminal at the neuromuscular junction and at cholinergic autonomic sites. Within 24 hours and up to several days after inhalational exposure, symptoms develop, beginning with bulbar palsies characterized by dysarthria, dysphagia, blurred vision, and ptosis. With progression of disease, skeletal muscle is affected, manifested by descending, symmetrical, flaccid paralysis that may culminate in respiratory failure.

Diagnostic Evaluation

Physical examination reveals an afebrile, alert, and oriented patient. Bulbar palsies and flaccid paralysis are present while sensation remains intact. Laboratory tests are not generally useful in the early diagnosis of botulism intoxication. Definitive toxin testing is available through the Centers for Disease Control.

Prophylaxis and Treatment

Respiratory failure is the most common cause of death due to botulinum toxin (9). Therefore, supportive care with mechanical ventilation is the most important treatment for

botulism intoxication. Because recovery may take weeks or months, this may require intensive nursing care for a prolonged period of time. A limited supply of antitoxin is available through government agencies. Recombinant vaccines are currently being developed.

Infection Control

Botulism is not transmissible from person to person; therefore, no special isolation procedures are required for affected patients.

Viral Hemorrhagic Fevers (VHFs)

Clinical Presentation and Course

Infection with VHF is characterized by high fever, headache, fatigue, myalgias, abdominal pain, and malaise following a 2–21 day incubation period. The VHFs are a group of disorders caused by filoviruses (Marburg, Ebola), arenaviruses (Lassa fever), and other related viruses. As the diseases progress, increased vascular permeability underlies many of the clinical findings. These findings include gastrointestinal bleeding, generalized mucous membrane hemorrhage, petechial or ecchymotic rash, conjunctival injection, nondependent edema, and hypotension. These diseases may progress rapidly to shock and death (10).

Diagnostic Evaluation

Routine laboratory testing may indicate leukopenia, thrombocytopenia, elevated hepatic aminotransferases, and prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT). No widely available rapid testing is available for the viruses responsible for VHFs. Definitive serologic diagnostic testing is available through government laboratories. Because of the highly contagious nature of these diseases, great care should be taken in handling all body fluid specimens.

Prophylaxis and Treatment

There is no widely available vaccine for VHFs. In limited studies, ribavirin administered intravenously has been effective in treating some cases of Lassa fever and Argentine hemorrhagic fever. Postexposure prophylaxis with orally administered ribavirin also seems to be effective. Otherwise, treatment is supportive and includes administration of crystalloids, blood products, and pressors as indicated.

Infection Control

Contact and droplet precautions, including the use of HEPA filter masks, should be employed when caring for

patients with VHFs, particularly in cases with respiratory involvement. In patients with prominent cough, vomiting, diarrhea, or hemorrhage, a negative pressure room is recommended to prevent aerosol transmission of the disease. Decontamination of infected materials with household bleach is adequate (10).

ISSUES AT THE TIME OF ADMISSION OR PRESENTATION

Perhaps the most difficult problem at the time of initial hospitalization is how to best utilize limited resources. The use of an emergency management organizational plan, such as the Hospital Emergency Incident Command System (HEICS), is critical in a mass casualty situation. HEICS utilizes a standardized organizational chart with predefined job roles and task checklists, which are widely adopted by other responding agencies. Job titles with specific roles and color-coded vests or armbands help delineate individual functionality to other staff members. Systems such as this can be tailored to the specific organization or situation and are critical in management of limited resources during crises.

Another critical issue at the time of initial contact is determining whether patients need to be hospitalized. Patients mildly affected by a highly contagious disease agent for which only supportive care is available may be better served with home isolation and quarantine rather than hospitalization. Patients who are hemodynamically unstable or require aggressive supportive care should be admitted to intensive care units, preferably with contained air-handling or negative pressure capabilities when an aerosolizable pathogen may be involved. Patients who are concerned that they may have been exposed and have no findings of disease should receive appropriate prophylaxis and be followed on an outpatient basis.

During a bioterrorism incident, people seeking medical evaluation can be expected to overwhelm hospitals. Significant numbers may be suffering from anxiety and stress-induced physical symptoms that may mimic the effects of exposure. Thus, hospital staff dealing with a bioterrorism incident will be challenged by the need to triage patients who show signs of having been infected by an agent and others whose symptoms are psychogenic in origin. Coupling appropriate triage protocols with the availability of psychological support staff is vital. When dealing with patients who have mild symptoms, an observation area may help facilitate recovery of the “worried well” and identification of those who are truly ill. Hospital organizations should have an alternative site identified and equipped (e.g., ambulatory clinics, physical therapy area), with personnel trained in assisting the ED, for when large numbers of casualties arrive or are expected.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Dealing with a bioterrorism or large-scale infectious disease outbreak can also be expected to subject hospital personnel to high levels of sustained physical and psychological stress. Staff members will be working long hours under additional stressors and will be exposed to infectious agents. Under these circumstances, health care workers can be expected to fall ill, as occurred in the SARS outbreak of 2003 (11). In addition to fatigue, health care workers will have to cope with additional personal protective equipment, prophylactic medications, and concerns for their own health and that of their family members. With this in mind, some health care workers may choose not to come to work, further diminishing the capacity of the health care system. Appropriate education and planning efforts may increase the confidence of staff and physicians in maintaining personal safety while carrying out their professional roles.

In addition to potential staffing issues, hospitals must address equipment and supply issues. For most hospitals, even small numbers of additional patients requiring isolation or mechanical ventilation could prove to be overwhelming. Personal protective gear, medications, disinfectant supplies, and other disposable equipment may be consumed rapidly. While bioterrorism “push packs” of medications and other supplies are readily available from the Strategic National Stockpile managed by the CDC, it is important that hospitals make efforts to assess their needs for additional supplies and equipment from other resources in order to maintain the appropriate readiness for mass casualties. For urban hospitals, interactions with the Metropolitan Medical Response System and their local or state Emergency Management Association provide a source of community-based supplies for disasters.

Early communication with government and public health authorities at the local, regional, state, and national level is vital. Because of the importance of establishing causality and isolating perpetrators, hospital personnel must work with public health and public safety to preserve and maintain a chain of evidence. A hospital-based command center will help coordinate the appropriate dissemination of public information with local authorities, medical staff, hospital administration, and the public information officer. This coordination enables public health authorities to assist with triage, supplies, and diagnosis, while enabling law enforcement to assist with crowd control and quarantine or isolation.

ISSUES AT THE TIME OF HOSPITAL DISCHARGE

As with any patient who recovers from a grave illness, follow-up is vitally important, not only to ensure the

patient’s well-being, but also for public health surveillance. Any patient who survives a bioterrorist attack should be closely monitored after discharge for signs of disease recurrence or long-term sequelae from the disease or its treatment. In addition, patients may suffer psychological consequences, including anxiety, paranoia, and posttraumatic stress disorder. Appropriate counseling should be provided.

KEY POINTS

- Recent concerns over bioterrorism have exposed our underpreparedness for both bioterror attacks and large-scale casualties from naturally occurring emerging infections.
- A clear communication plan must be coupled with vigorous planning and simulations to adequately prepare hospitals for bioterrorism attacks.
- The rapid implementation of a post-attack prophylaxis program is the most important strategy to limit losses following a bioterrorism attack.
- Evidence-based guidelines for managing emerging infections (including those potentially spread by bioterror) are maintained by federal agencies such as the Centers for Disease Control and the Agency for Healthcare Research and Quality.
- At the time of a large bioterror attack, hospitals must be prepared to triage, communicate (within their walls and with appropriate authorities), and deal with the psychological issues of patients, the “worried well,” and providers.

- Anemia 726

INTRODUCTION

The global pandemic of HIV infection continues 25 years after the recognition of the first cases of AIDS in North America. In the United States, an increasing number of cases are attributed to sexual transmission between heterosexuals or injection drug use. In urban settings, minority populations are disproportionately affected. The incidence of HIV infection has increased in rural regions and parts of the country, such as the southeastern states, that had formerly been spared, and women now account for more than 25% of Americans living with HIV infection.

Before the era of prophylaxis and treatment of opportunistic infections, the course of HIV disease was often biphasic. Years of indolent immunologic decline and rela-

tive paucity of symptoms were followed by rapidly progressive immunodeficiency, complicated by malignancies and multiple bouts of infection, which often proved fatal. The risk for certain infections rises markedly as the number of CD4 lymphocytes (normal $>500/\mu\text{L}$) declines below key levels (Table 74.1).

The use of prophylactic antibiotic therapy appropriate for the stage of disease led to significant declines in the incidence of *Pneumocystis jirovecii* pneumonia (formerly *P. carinii*, though still abbreviated "PCP") and *Mycobacterium avium* complex (MAC) infection, but patients continued to be hospitalized and die of other complications of advanced immunodeficiency, such as dementia, wasting, and high-grade non-Hodgkin's lymphoma.

The development of zidovudine (AZT) and other nucleoside reverse transcriptase inhibitors marked the beginning of the era of *antiretroviral therapy*. Administration of this first generation of drugs, alone or in combination with other drugs, resulted in modest prolongation of life but did not prevent progression of the underlying immunodeficiency. The face of antiretroviral therapy changed markedly in the mid-1990s. A better understanding of the pathogenesis of HIV disease and the introduction of two more classes of agents (*non-nucleoside reverse transcriptase inhibitors* and *HIV protease inhibitors*) allowed the design of combination

TABLE 74.1
RISK FOR OPPORTUNISTIC INFECTIONS
BY CD4 STRATUM

CD4 cell count (per cubic millimeter)	Infections
200–500	Bacterial pneumonia, herpesvirus infection, mucosal candidiasis, oral hairy leukoplakia, tuberculosis
50–200	<i>Pneumocystis jirovecii</i> pneumonia (PCP), cryptococcal meningitis, toxoplasmosis
<50	Cytomegalovirus (CMV), <i>Mycobacterium avium</i> complex (MAC), progressive multifocal leukoencephalopathy

regimens that resulted in more potent suppression of viral replication. The paradigm shift was catalyzed by the recognition that active viral replication in blood, lymphoid tissue, and other compartments is continuous from the time of initial HIV infection and accounts for the progressive loss of immune function during the presymptomatic phase of illness. Furthermore, sensitive tests were developed that measured serum HIV RNA levels, and these measurements were found to be the *single best predictors of disease progression and death* in patients who had not received antiretroviral therapy (1). For example, persons with a baseline value of 5,000 copies per milliliter have a cumulative risk for disease progression of 30% if followed off therapy for nine years; this risk is 75% if the count is 50,000 copies per milliliter. When antiretroviral therapy is used, it is always given as a combination of at least three drugs at full dosage, with the goal of reducing viral load to below detectable limits and thereby minimizing the chance of development of drug-resistant mutations. When patients on antiretroviral combinations are hospitalized, every effort should be made to continue the drugs. Should dose interruption become necessary, the entire regimen should be stopped rather than risking the development of drug resistance by administering a partial, suboptimally effective combination. Because several of these agents induce or inhibit one of the cytochrome P-450 enzymes, drug interactions may occur with many classes of agents used in the hospital, including antiarrhythmics, sedative/hypnotics, anticonvulsants, and calcium channel blockers. Some of the most important interactions are shown in Table 74.2 (2).

Many patients who have tolerated and adhered to regimens of *highly active antiretroviral therapy* (HAART) have had extraordinarily gratifying responses, achieving clinical stability and partial immunologic reconstitution reflected by increases in the CD4 lymphocyte count. This has accounted for a marked decrease in hospitalization and mortality rates for HIV-related complications among patients receiving this therapy (3). However, the enthusiasm for HAART has been somewhat tempered by the recognition of long-term toxic-

ity of these regimens, including mitochondrial toxicity leading to lactic acidosis, and metabolic perturbations including glucose intolerance and hyperlipidemia. The latter two problems have raised concerns that patients receiving this therapy might be at increased risk for premature atherosclerosis. Finally, physicians must recognize that successful antiretroviral therapy may alter the natural history of opportunistic complications of HIV infection. *The immune reconstitution syndrome* may be observed within several months of initiation of HAART and is manifested as paradoxical worsening of undiagnosed or partially treated infections such as CMV or tuberculosis (4).

TABLE 74.2
DRUG INTERACTIONS WITH HIV
PROTEASE INHIBITORS

Drug levels raised to toxic range by indinavir, nelfinavir, and ritonavir: do not coadminister

Amiodarone	Midazolam
Astemizole	Quinidine
Ergot alkaloids	Triazolam

Drug levels raised to toxic range by ritonavir: do not coadminister

Alprazolam	Flecainide
Bupropion	Flurazepam
Clonazepam	Meperidine
Clorazepate	Piroxicam
Diazepam	Propafenone
Encainide	Zolpidine

Drug levels raised 1.5-fold to 3-fold by ritonavir: coadminister with caution and close monitoring

Amlodipine	Nifedipine
Carbamazepine	Nimodipine
Dexamethasone	Ondansetron
Diltiazem	Pravastatin
Dronabinol	Prednisone
Erythromycin	Quinine
Fentanyl	Sertraline
Felodipine	Tamoxifen
Lidocaine	Trazodone
Lovastatin	Verapamil
Nicardipine	Warfarin

Drugs that affect concentration of HIV protease inhibitors

Carbamazepine	Decreases nelfinavir levels; avoid coadministration.
Ketoconazole	Increases indinavir, nelfinavir levels; reduce dose of protease inhibitor.
Phenobarbital	Decreases nelfinavir levels; avoid coadministration.
Phenytoin	Decreases nelfinavir levels; avoid coadministration.
Rifampin	Decreases indinavir levels; avoid coadministration.

Patients admitted to the hospital with complications of HIV infection discussed below and in the chapters that follow may have previously been unaware of their HIV infection, had little or no access to ongoing medical care, or been unable to cope with the significant toxicity and adherence demands of combination antiretroviral therapy. In contrast, patients who have benefited from aggressive therapy and monitoring are living longer and becoming increasingly likely to be hospitalized for unrelated medical problems (3).

SYMPTOMS, SIGNS, AND LABORATORY ABNORMALITIES

Fever

When Presenting at the Time of Admission

Fever, either alone or in combination with other findings, is a common symptom and sign in HIV-infected adults. Because fever is ubiquitous during the course of HIV infection and the differential diagnosis is broad, the evaluation should take into consideration acuity versus chronicity, risk for opportunistic infection given disease status (see above and Table 74.1), and the presence or absence of other localizing findings or laboratory abnormalities.

The initial consideration in a patient who presents with acute or subacute onset of fever is *bacterial infection*, which occurs at increased frequency during all stages of HIV disease. Common sources include the lower respiratory tract and sinuses. Endocarditis should be considered in persons actively injecting drugs (Chapter 71), and catheter-associated infections should be suspected in patients with indwelling catheters (Chapter 72). The presence of diarrhea raises the question of enteric pathogens, and headache and altered mental status make it imperative to exclude bacterial meningitis. The history and examination should focus on attempting to define possible sources of bacterial infection. Laboratory evaluation follows the prototypical approach to fever (Chapter 62), with acquisition of blood and other cultures as clinically indicated. Note that the sensitivity of cultures in patients on antimicrobial agents for opportunistic infection prophylaxis may be decreased. Because pneumonia secondary to unusual pathogens such as *Nocardia* and *Pseudomonas aeruginosa* can develop in HIV-infected adults, sputum culture may be more useful in these patients than in immunocompetent patients with community-acquired pneumonia (Chapter 65).

Once the evaluation is complete, patients with known sources are treated accordingly with antimicrobials. Although there are no data about immediate treatment versus observation for those without a clear source, the treatment threshold for hospitalized patients in general should be low, particularly because the incidence of bacteremia with invasive infection caused by certain organisms

(e.g., pneumococci) is high. HIV-infected patients with fever and neutropenia secondary to cytotoxic chemotherapy should always receive empiric antibiotics, and those with neutropenia secondary to other medications, such as AZT or ganciclovir, may also be at increased risk for bacterial infection.

When fever at the time of presentation is more chronic in nature, the prior probability of bacterial infection (with the notable exception of sinusitis) decreases, and opportunistic infections and other complications become more likely. Importantly, clinical series studying unexplained fevers in HIV-positive patients suggest that an etiology can be found approximately 90% of the time (5); the corollary to this is that a "diagnosis" of "fever due to HIV" should be regarded with suspicion. The most common diagnoses in HIV-infected patients presenting with chronic fever are occult PCP and *disseminated MAC*. Various clinical and laboratory findings may suggest other diagnoses (Table 74.3).

A cost-effective diagnostic evaluation will consider epidemiologic information in addition to the clinical data already discussed. For example, the probability of *Bartonella* infection rises in the patient who owns kittens, as does the probability of histoplasmosis in the patient from the midwestern United States. Judicious use of the microbiology laboratory in advanced disease, especially to detect serum cryptococcal antigen and MAC in blood cultures, is appropriate, but extensive and repeated culturing adds little to the diagnostic yield in most cases. Similarly, no data support the routine use of imaging studies such as computed tomography of the central nervous system or abdomen if localizing signs or symptoms are absent. More invasive testing is guided by initial diagnostic results.

Specific therapy is initiated if a treatable diagnosis is established. If no explanation for fever is obtained during the hospitalization, observation (with or without the administration of antipyretics) is reasonable for stable patients. Empiric antimicrobial trials may be considered when suspicion for a given underlying opportunistic infection is

TABLE 74.3
CHRONIC FEVER IN HIV-INFECTED PERSONS

Symptom/finding	Associated diagnoses
Skin lesions	Herpes virus, <i>Bartonella</i> , <i>Mycobacterium haemophilum</i> , drug fever
Lymphadenopathy	Mycobacteria, lymphoma
Hepatosplenomegaly	Mycobacteria, <i>Bartonella</i> , histoplasmosis, lymphoma
Abdominal pain	<i>Mycobacterium avium</i> complex, cytomegalovirus, lymphoma
Visual complaints	Cytomegalovirus
Headache/neurologic findings	Cryptococcal meningitis, toxoplasmosis
New hematologic abnormalities	Mycobacteria, histoplasmosis, lymphoma

reasonably high. For example, a trial of agents effective against MAC may be justified in a patient with chronic fever, anemia, and a CD4 cell count below 50/ μ L whose evaluation is otherwise unrevealing and whose MAC blood culture results are pending (Chapter 67).

When Presenting During the Hospitalization

When fever supervenes during the course of hospitalization, nosocomial bacterial infections are the greatest concern, and the evaluation and therapeutic approach should proceed as in other patient populations (Chapter 62). Because HIV-infected persons are also predisposed to allergy to multiple classes of drugs (especially antibiotics), this is the other important consideration in the differential diagnosis. As is the case with other forms of drug fever, patients may have isolated fever or fever with additional findings, such as rash, hematologic cytopenias, and liver enzyme abnormalities. A typical time course is the development of fever 7–10 days after initiation of therapy (e.g., trimethoprim-sulfamethoxazole for PCP). Given this differential diagnosis, costly evaluation for new opportunistic processes is not initially indicated when fever occurs as a new issue during hospitalization.

Lymphadenopathy

The significance of and approach to lymphadenopathy in an HIV-positive person are guided by the pattern of nodal enlargement and stage of HIV disease. Persistent isolated or asymmetric lymphadenopathy should always be assumed to represent a secondary infectious or neoplastic process. The most frequent pathogens are *Mycobacterium tuberculosis* and MAC, although fungal infections and bartonellosis may also present with localized lymphadenopathy. Necrotizing adenitis caused by MAC is a common manifestation of immune reconstitution in individuals started on HAART when CD4 cell counts are below 50/ μ L. Kaposi's sarcoma (KS), lymphoma, and other lymphoproliferative lesions, such as Castleman's disease, are the most likely neoplasms. The diagnostic utility of noninvasive tests is limited; lymph node sampling must be performed for diagnosis. Cytologic examination and microbiologic staining and culture of a fine-needle aspirate may be sufficient to establish the diagnosis, but this procedure should be followed by excisional lymph node biopsy if it is nondiagnostic.

Generalized lymphadenopathy presents a different set of considerations. Syphilis can manifest this way and is always important to exclude, as many HIV-infected adults are at risk for exposure to other sexually transmitted diseases. Some patients with early HIV disease and preserved immune function have persistent generalized adenopathy, which reflects active HIV replication in lymphoid tissue. Lymph node sampling will reveal only reactive lymphoid hyperplasia in these cases; thus, generalized adenopathy

does not require further evaluation in an asymptomatic person with a preserved CD4 cell count and a normal complete blood cell count. Interestingly, adenopathy usually wanes as immunodeficiency progresses. Therefore, the presence of new or progressive generalized adenopathy in a patient with advanced immunodeficiency should prompt lymph node sampling to investigate the diagnoses mentioned above.

Rash

A wide array of inflammatory, allergic, infectious, and neoplastic skin lesions can develop in HIV-infected persons, and a full discussion of these is beyond the scope of this chapter. The constellation of fever and rash in general is discussed in Chapter 62. This section reviews several cutaneous eruptions that may be particularly important in the hospitalized HIV-infected patient.

Raised red or purple lesions may represent KS or bacillary angiomatosis caused by *Bartonella* species. Although some morphologic features may be more suggestive of one lesion than another, punch biopsy with silver staining for organisms is often necessary for definitive diagnosis. Recognition of cutaneous KS may provide important clues in patients with unexplained pulmonary or gastrointestinal complaints or lymphadenopathy. Similarly, cutaneous bacillary angiomatosis, which must be treated in its own right, may also be an important indicator of systemic disease with bacteremia, in addition to skeletal, hepatic, and lymphatic involvement.

A diffuse maculopapular exanthem most often represents a drug reaction to antimicrobial agents, antiretroviral drugs, anticonvulsants, or other classes of drugs. Patients with this finding should be carefully examined for desquamation and involvement of conjunctiva and oral mucosa that indicate Stevens-Johnson syndrome. A small number of HIV-infected patients with recurrent staphylococcal toxic shock syndrome have also been described, so it is important to search for other clinical and laboratory criteria (Chapter 25) for this diagnosis in patients who present with a generalized exanthem.

Vesicles are most commonly indicative of *herpes simplex* or *herpes zoster*, but they may also be seen with other opportunistic infections. If lesions do not clearly follow a dermatomal pattern, establishment of the specific viral agent may affect dose and duration of antiviral therapy (*herpes zoster* requires higher dosing than does *herpes simplex*). Currently, this is most rapidly accomplished by scraping the base of a fresh vesicle and swabbing a slide, which is then air-dried and stained for viral antigen.

Finally, a petechial or purpuric rash in an afebrile patient may imply significant thrombocytopenia that is a consequence of either HIV-related immune-mediated platelet destruction, drug toxicity, or thrombotic microangiopathy. This finding warrants checking platelet count, performing coagulation studies, and examining the peripheral blood smear for findings of microangiopathy.

Hepatosplenomegaly

Enlargement of the liver, spleen, or both may be caused by HIV-related processes or by unrelated comorbidities. Patients who have acquired HIV through sexual exposure are clearly at higher risk for hepatitis B and probably also have a slightly elevated risk for hepatitis C infection. Needle-sharing injection drug users are at risk for both hepatitis B and hepatitis C. Alcoholic liver disease is common in HIV-infected adults, as alcohol abuse is a frequent comorbidity. In general, these hepatic diseases are more likely than HIV-specific processes to lead to complications of portal hypertension and liver failure. In immunodeficient persons with HIV infection, hepatitis C can have a more aggressive course because viral replication and hepatic injury occur more rapidly.

The infections and malignancies that secondarily involve the liver and spleen generally do so during the course of widespread systemic involvement. Thus, symptoms such as weight loss and fever are common. Common infiltrative infections include mycobacterial disease, fungal disease (particularly histoplasmosis and cryptococcosis), and bartonellosis, which leads to a distinctive picture of *hepatosplenic peliosis*. In Africa and the Mediterranean region, visceral leishmaniasis is an important diagnostic consideration. Lymphoma and metastatic malignancy account for the majority of neoplastic hepatic lesions, whereas KS may involve the spleen and extrahepatic bile ducts but rarely involves the liver. Nonspecific laboratory findings (e.g., anemia, elevated alkaline phosphatase) are commonly seen with all these diagnoses, but their predictive value is poor. Marked pancytopenia may be more suggestive of histoplasmosis or leishmaniasis, whereas marked elevation of lactate dehydrogenase is characteristic (but not diagnostic) of high-grade lymphoma. Microbiologic studies of blood in the evaluation of hepatosplenomegaly often obviate the need for liver biopsy. Appropriate studies include fungal and mycobacterial blood cultures and determination of the serum cryptococcal antigen titer. If the patient has resided in an area endemic for histoplasmosis, a urine antigen test should also be ordered.

Liver biopsy should be performed only if these less invasive studies are unrevealing.

Abnormal Liver Enzymes

Elevated hepatic aminotransferases should first and foremost prompt the usual considerations of underlying viral hepatitis or alcoholic liver disease in an HIV-infected patient (Chapter 82). Of the opportunistic infections, only cytomegalovirus (CMV) infection causes prominent hepatocellular injury, and mild aminotransferases rises are commonly noted during active CMV infection of other organs. When newly elevated aminotransferases are observed in HIV-infected persons, drug-related hepatotoxicity should also be considered. Common offenders include ritonavir,

nevirapine, antituberculous agents (isoniazid, rifampin, pyrazinamide), trimethoprim-sulfamethoxazole, fluconazole, and didanosine (DDI). Flares of underlying hepatitis B or C may occur with immune reconstitution. When possible, potentially hepatotoxic drugs should be discontinued and other agents substituted to assess the potential contribution to abnormal enzymes. The HIV protease inhibitor indinavir commonly causes isolated hyperbilirubinemia without aminotransferase elevation; this finding should not provoke dose interruption.

Rises in hepatobiliary alkaline phosphatase are common in patients with advanced HIV disease. Abdominal imaging should be performed to differentiate between obstructive and nonobstructive etiologies (Chapter 84). Because gallstone disease is less likely in this setting than in the general population, computed tomography is preferred over ultrasonography as the initial imaging study because of the anatomic detail of the liver and surrounding structures it provides. When variable intrahepatic and extrahepatic biliary obstruction is demonstrated and no mass lesion is seen, the most likely diagnosis is *AIDS cholangiopathy*, a fibrosing process sometimes seen in association with CMV, *Cryptosporidium*, or microsporidial infection of the biliary tree. Diffuse abdominal or right upper quadrant pain is common with this syndrome, and rarely bacterial cholangitis may supervene. Endoscopic retrograde cholangiopancreatography may be considered because sphincterotomy provides symptomatic benefit to about half those patients with pain. However, the symptoms commonly recur. Antimicrobial therapy of associated opportunistic infections has not resulted in any improvement in the progressive course of AIDS cholangiopathy.

If biliary obstruction is excluded by right upper quadrant imaging, the differential diagnosis in the presence of elevated alkaline phosphatase shifts to cholestatic and infiltrative disorders. Medications especially likely to cause cholestasis are trimethoprim-sulfamethoxazole, antituberculous drugs, and phenothiazines. Occasionally, hepatic involvement with CMV disease manifests with a cholestatic pattern. All the infiltrative opportunistic infections and neoplasms listed above in the differential diagnosis of hepatomegaly may be accompanied by a rise in alkaline phosphatase. Computed tomography may show homogeneous enlargement of the liver, multiple inflammatory lesions, or a smaller number of space-occupying lesions; the presence of large mass lesions points toward lymphoma, but the ability of imaging studies to distinguish between this neoplasm and infections is limited. As was previously discussed for the evaluation of hepatomegaly, the yield of liver aspiration and biopsy is low for treatable diagnoses, and so these procedures are reserved for situations in which less invasive tests and biopsy of tissue from other sites fail to establish a diagnosis. In patients with advanced disease, MAC infection is statistically the most likely explanation for multiple liver lesions and alkaline phosphatase elevation.

Elevated Creatinine

The approach to azotemia in a person with underlying HIV infection must be broadly based because *a significant proportion of cases of renal failure are a consequence not of HIV-specific renal pathology but rather of a variety of problems common to all hospitalized patients* (Chapter 100). Thus, hypovolemia, hypotension, sepsis, and the nephrotoxicity of drugs such as aminoglycosides and nonsteroidal anti-inflammatory agents all may play important roles.

With this caveat, several HIV-related renal problems do deserve consideration in the setting of increasing creatinine levels (6). Several of the antimicrobial agents used to treat opportunistic infections may cause renal failure. Trimethoprim-sulfamethoxazole can lead to an acute interstitial nephritis; the urine sediment often shows leukocytes with or without cellular casts. This drug may also cause isolated hyperkalemia via inhibition of potassium tubular secretion, but it is unusual for this to be a dose-limiting toxicity. Another sulfa drug, sulfadiazine, may cause obstructive renal failure through deposition in the distal tubules because of its poor solubility. Thus, if patients are being treated with high doses of sulfadiazine for toxoplasmosis, vigorous hydration is necessary to prevent this complication. Pentamidine, which is used for the treatment of PCP, may also cause tubular injury that leads to hyperkalemia or acute renal failure. Tenofovir, a nucleotide antiviral drug, may rarely cause proximal tubular dysfunction and hypokalemia. The HIV protease inhibitor indinavir may crystallize in urine and cause clinically apparent nephrolithiasis in 15% of patients taking this drug; cases of acute and chronic renal failure from interstitial nephritis are also reported.

The incidence of thrombotic thrombocytopenic purpura is also increased in HIV-seropositive patients; it can be triggered by intercurrent infection. In this case, other clinical findings, such as fever and altered mental status, accompany the renal failure. Laboratory abnormalities include thrombocytopenia and marked elevation of lactate dehydrogenase in addition to azotemia and microscopic hematuria. Obstructive uropathy should always be considered in patients with known lymphoma because of the possibility of retroperitoneal involvement. Finally, *HIV nephropathy* refers to several different histologic abnormalities that may lead to acute renal failure or, more commonly, progressive renal dysfunction and end-stage renal disease. Focal sclerosing glomerulonephritis is the most common pathologic pattern and tends to present with nephrotic-range proteinuria before the onset of renal failure. Patients who present with the nephrotic syndrome may be candidates for renal biopsy to exclude other potentially treatable glomerular lesions. Aggressive antiretroviral therapy may prevent or attenuate the course of HIV nephropathy.

Anemia

Mild anemia with hematocrits in the range of 30%–35% is common as a result of both HIV disease and

its treatment, and in general it does not warrant extensive evaluation. Patients with advanced HIV infection often have a component of anemia of chronic disease with inappropriately low reticulocyte counts. Another common contributor to chronic anemia is AZT therapy, which leads to macrocytosis and anemia. Mean corpuscular volume may reach 130 fL as a result of AZT administration alone, without signifying one of the common causes of megaloblastic anemia. However, the presence of megaloblastic changes in polymorphonuclear leukocytes does warrant the exclusion of vitamin B₁₂ or folate deficiency. More than 50% of patients with the nonspecific anemia of HIV infection or AZT-associated anemia have low circulating levels of endogenous erythropoietin; if so, they will usually respond to recombinant erythropoietin therapy. The mean dose required for response in these patients is 25,000 units per week, administered subcutaneously in three divided doses. In general, this therapy is reserved for patients who have symptoms related to moderate or severe anemia. Responders show a trend toward normalization of the hematocrit within two to four weeks of the start of therapy.

Patients who may require more detailed evaluation of anemia include those with more severe anemia (hematocrit less than 25%–27%), rapid onset of anemia (which is atypical of the etiologies mentioned above), or coexistent abnormalities of other blood cell lines. The diagnosis of hemolysis or blood loss may be obscured by the inability of chronically ill patients to mount an appropriate reticulocytosis. Acute blood loss should always be considered in the hospitalized patient with a hematocrit drop. *Gastrointestinal bleeding is more likely to result from one of its usual etiologies than from HIV-related complications of the gastrointestinal tract* (Chapter 78). HIV-specific lesions that may rarely present with frank gastrointestinal bleeding include lymphoma, KS, and CMV colitis.

Although many patients have a positive microscopic direct antiglobulin (Coombs') test result as a consequence of the hyperglobulinemia caused by HIV, clinically important autoimmune hemolytic anemia is very uncommon. Hemolytic processes that deserve consideration include thrombotic thrombocytopenic purpura (see "Elevated Creatinine") and unrecognized glucose 6-phosphate dehydrogenase deficiency in African-American or Mediterranean patients receiving drugs such as dapsone or trimethoprim-sulfamethoxazole.

Severe anemia resulting from bone marrow failure can be an isolated hematologic abnormality or can be accompanied by other depressed cell lines. Although any of the infiltrative disorders that involve marrow can cause anemia alone, the development of a hypoproliferative normochromic, normocytic anemia makes several diagnoses more likely. An uncommon pattern of antiretroviral hematologic toxicity is AZT-induced pure red cell aplasia. Patients who experience this toxicity typically have profound suppression of hematopoiesis and a dramatic

fall of the hematocrit within weeks of beginning AZT therapy. The time course and absence of macrocytosis differentiate this response from the more common hematologic effects of this drug mentioned above. Hematopoiesis generally recovers when AZT is discontinued. Red cell aplasia can also occur as a result of parvovirus B19 infection. In contrast to immunocompetent children, in whom fever, rash, or arthritis often develop during this infection, HIV-infected adults most frequently have bone marrow suppression as the predominant or sole clinical manifestation of parvovirus infection. Rapid diagnosis can be established by examining the serum for viral genome with a polymerase chain reaction assay, a highly sensitive test in this setting because of the intensity and duration of viremia in these immunocompromised hosts. If parvovirus B19 is diagnosed, the therapy of choice is infusion of pooled immunoglobulin, which contains adequate neutralizing antibody to clear the infection and thereby resolve the red cell aplasia. In patients with advanced disease and CD4 cell counts of less than 50/ μL , the most common etiology of isolated severe hypoproliferative anemia is disseminated MAC infection. As is the case when MAC infection presents in the liver, other symptoms and signs of widespread infection are often present. The diagnosis is usually established by blood cultures with use of appropriate media.

When multiple cell line abnormalities are present, other marrow infiltrative processes deserve consideration. Because splenic infiltration also occurs with these diseases, the etiology of cytopenias may be multifactorial, with hypersplenism playing a role. Non-Hodgkin's lymphoma, tuberculosis, and cryptococcosis can all present with prominent hematologic abnormalities, and other signs and laboratory findings that accompany these diseases should be elicited. An important diagnostic point is that *only one-third of HIV-related lymphomas present with lymphadenopathy*; thus, the absence of this finding does not exclude the diagnosis. Pancytopenia is particularly common in HIV-infected patients with disseminated histoplasmosis. This endemic opportunistic infection may have protean manifestations, including acute or chronic fever, systemic inflammatory response syndrome, interstitial pulmonary infiltrates, acute renal failure, and disseminated intravascular coagulation. A urine polysaccharide antigen assay has a sensitivity of 97% in cases of extrapulmonary histoplasmosis in HIV-positive patients; false-positive results have been reported only with other invasive fungal infections, such as coccidioidomycosis and blastomycosis (7).

Nonspecific bone marrow abnormalities are common in HIV-infected patients, but the likelihood of finding previously undiagnosed treatable lesions via bone marrow sampling is very low. All the etiologies of anemia discussed above can be diagnosed by alternative means. Before the availability of urine antigen testing, bone marrow aspiration and biopsy were useful for the diagno-

sis of histoplasmosis, but the antigen test has obviated the need for marrow sampling to establish this diagnosis. Studies reviewing the evaluation of HIV-infected patients for fever of unknown etiology generally confirm the poor diagnostic utility of this test (8). Thus, bone marrow sampling should rarely be used in this population, except as a staging procedure for systemic lymphoma.

KEY POINTS

- The prognosis of HIV infection has improved with effective antiretroviral therapy.
- Disease stage is an important determinant of whether acute medical problems are HIV-related or incidental (i.e., the more advanced the disease, the more likely a complication is to be HIV-related).
- In the hospital, antiretroviral drugs should be continued when possible, but beware of drug interactions.
- Fever should be evaluated based on the company that it keeps (disease stage, signs, symptoms, and laboratory abnormalities).
- In the hospitalized patient, new fever more likely represents nosocomial infection or drug reaction than a new opportunistic infection.
- Several rash morphologies provide important diagnostic clues for systemic disease.
- Hepatosplenomegaly and hematologic abnormalities often signify disseminated infection or neoplasm, but biopsy of liver or marrow is rarely helpful diagnostically.
- Acute renal failure is more likely to be secondary to factors that are not HIV-specific than to be attributable to HIV nephropathy.

INTRODUCTION

Pulmonary disease is a common reason for hospital admission among persons with HIV infection. The spectrum of pulmonary disease is broad and includes HIV-associated as well as non-HIV-associated disorders. As a result, the diagnostic approach to respiratory symptoms in an HIV-infected person can be challenging. However, knowledge of the spectrum of pulmonary disease and of the characteristic presentations of the most common diseases often enables the differential diagnosis to be narrowed. This chapter offers an overview of the spectrum of pulmonary disease in HIV-infected persons and describes a diagnostic approach to the patient with respiratory symptoms. A detailed discussion of *Pneumocystis jirovecii* pneumonia (formerly known as *P. carinii*, though still abbreviated "PCP") and community-acquired bacterial pneumonia, the two most common pneumonias seen in this population, is presented. Pulmonary tuberculosis in HIV-infected patients is discussed in Chapter 67.

SPECTRUM OF PULMONARY DISEASE

The spectrum of pulmonary disease in persons with HIV infection is broad, and illness can range in severity from self-limited (e.g., upper respiratory tract infection) to life threatening (e.g., PCP). The relative frequencies of the diseases depend on a number of factors. Overall, the most

common cause of respiratory complaints among HIV-infected patients presenting to an outpatient facility is upper respiratory tract infections or acute bronchitis. However, PCP or bacterial pneumonia are more likely causes of severe illness that requires hospital admission. Table 75.1 summarizes common infectious and noninfectious causes of pulmonary complications in hospitalized patients.

DIAGNOSTIC APPROACH

The clinical presentations of HIV-associated pulmonary diseases vary and overlap. Thus, no symptom, sign, or combination of findings is diagnostic of a particular disease. The goals of the history and physical examination are to establish a basic differential diagnosis and to assess the need for and the approach to further evaluation. The history should also provide a subjective assessment of the severity of the disorder.

The cardinal respiratory symptoms in persons with HIV infection are the same as in those without HIV infection (1). The occurrence of specific respiratory symptoms, especially cough, should be taken seriously and evaluated appropriately. On the other hand, it is extremely unusual for patients with HIV infection to have asymptomatic respiratory disease; thus, screening for the presence of a respiratory process in a patient without symptoms is rarely indicated (2).

The approach to the medical history should be the same as in a person without HIV infection, but there should be an

emphasis on identification of possible exposures to infectious diseases. The history should seek to identify any possible exposure to persons with or suspected of having tuberculosis, or to environmental fungi, such as *Coccidioides immitis* or *Histoplasma capsulatum*. Any history of prior respiratory diseases, such as asthma, should be sought. A focused review of the past medical history can provide important clues to the etiology of the current respiratory symptoms. For example, bacterial pneumonia and tuberculosis are more common among HIV-infected patients who are injection drug users. Bronchitis and bacterial pneumonia are more common in HIV-infected cigarette smokers than in nonsmokers or former smokers. Moreover, patients with a long history of cigarette use may have chronic obstructive lung disease as the etiology of their respiratory symptoms, rather than an HIV-associated opportunistic infection or neoplasm (3). Traveling to or living in a region where the endemic fungi are found are strong determinants of the risk for infection and subsequent disease caused by these organisms. In addition, tuberculosis is more common in certain geographic areas and populations (4).

A number of the HIV-related opportunistic infections frequently recur. PCP is an example. PCP prophylaxis decreases the recurrence rate of PCP, but breakthroughs can occur, especially at low CD4 cell counts. Similarly, patients who have had cryptococcosis, coccidioidomycosis, or histoplasmosis are at high risk for relapse. Fluconazole (cryptococcosis, coccidioidomycosis) and itraconazole (histoplasmosis) decrease the relapse rate, but prophylaxis does not preclude their occurrence. In many institutions, the two major diagnostic considerations for respiratory complaints in hospitalized HIV-infected patients are PCP and bacterial pneumonia. Thus, distinguishing between the two pneumonias is often the focus of the diagnostic approach (Table 75.2). PCP characteristically presents with a dry, nonproductive cough accompanied by fever and dyspnea. Symptoms are usually subacute. In contrast, pneumonia caused by *Streptococcus pneumoniae* or *Haemophilus influenzae* characteristically presents with acute symptoms of fever, shaking chills, dyspnea, pleuritic chest pain, and a cough productive of purulent sputum. The presence of purulent sputum is a strong negative predictor for PCP; its presence in a patient who has documented PCP nearly always indicates a concurrent bacterial infection.

The physical examination should emphasize the lungs and potential extrapulmonary sites of involvement. At least 50% of patients with PCP will have an unremarkable lung examination, and many patients with bacterial pneumonia will have focal lung findings (Table 75.2). Extrapulmonary findings may provide important clues to the risk for and nature of the pulmonary disorder. For example, the finding of oral candidiasis is indicative of severe immunocompromise and, therefore, of the risk of opportunistic disorders. An altered mental status in a patient whose CD4 cell count is 200/ μ L or less may suggest *Cryptococcus neoformans* as the cause of both the neurologic and pulmonary problems. Cutaneous lesions may suggest disseminated fungal disease, whereas lymphadenopathy or organomegaly may suggest either disseminated mycobacterial or fungal disease, or non-Hodgkin's lymphoma (5). Pulmonary involvement can develop in patients with mucocutaneous Kaposi's sarcoma (KS); however, the absence of mucocutaneous involvement does not preclude the possibility of significant pulmonary KS.

Although no laboratory abnormality is specific for a particular pulmonary disease, tests that can be useful include the complete blood cell count and measurement of the serum lactate dehydrogenase (LDH) and arterial blood gases. HIV-infected patients with neutropenia are at higher risk for bacterial and *Aspergillus* species infections. The white blood cell count is frequently elevated relative to the baseline value in persons with bacterial pneumonia. In contrast, the white blood cell count varies in persons with PCP (Table 75.2). The serum LDH is frequently elevated in persons with PCP; the sensitivity of an elevated serum LDH for PCP is in the range of 83%–100%. However, the serum LDH is relatively non-specific and it may be elevated in

ABG, arterial blood gas; LDH, lactate dehydrogenase; WBC, white blood cell.

many pulmonary and nonpulmonary conditions. The arterial blood gas values are also nonspecific. However, in persons with PCP, an arterial blood gas determination is essential in determining the severity of disease and the need for adjunctive corticosteroid therapy.

The CD4 cell count is an essential piece of laboratory data and many patients who have a previous diagnosis of HIV infection will know their CD4 count. It is an excellent indicator of the risk for development of specific conditions (Chapter 74) (6). Some pulmonary complications, such as bacterial pneumonia, tuberculosis, and non-Hodgkin's lymphoma, may occur at any CD4 cell count. However, the incidence of these diseases increases as the CD4 cell count declines. When it is 200/ μ L or less, bacterial pneumonia is often recurrent and *Mycobacterium tuberculosis* infection is often disseminated. In addition, PCP and pneumonia caused by fungal pathogens (*C. neoformans*) become signif-

icant considerations. When the CD4 cell count is 100/ μ L or less, *Pseudomonas aeruginosa* infection and pulmonary involvement with KS are increasingly common. Finally, diseases caused by endemic fungi (*H. capsulatum*, *C. immitis*), cytomegalovirus, nontuberculous mycobacteria, and *Aspergillus* species almost always occur at the lowest CD4 cell count ranges (below 50/ μ L).

The radiographic manifestations of HIV-associated pulmonary diseases also vary and overlap. To complicate matters, multiple diseases can present concurrently. Nevertheless, each disease has a characteristic radiographic presentation that, combined with clinical data, can suggest a diagnosis. Classically, PCP presents with diffuse bilateral reticular or granular opacities (Figure 75.1). Thin-walled cysts or pneumatoceles are seen in approximately 15%–20% of patients with PCP. Pneumatoceles may predispose patients to the development of pneumothorax,

Figure 75.1 Pneumocystis pneumonia. Chest radiograph of an HIV-infected patient demonstrating diffuse bilateral granular opacities.

another radiographic finding suggestive of PCP. Less typical patterns include focal opacities, miliary infiltrates, nodules, and cavities. Intrathoracic adenopathy and pleural effusions are very rarely associated with PCP. In a patient with confirmed PCP, these radiographic findings usually represent a concurrent process. In mild cases of PCP, the chest radiograph may be normal. Patients with suspected PCP and a normal radiograph require additional evaluation (Figure 75.2).

Bacterial pneumonia caused by *S. pneumoniae* characteristically presents with patchy or focal consolidation in a segmental or lobar distribution, similar to what is seen in an immunocompetent person. An associated pleural effusion is seen in approximately 25%–30% of patients with bacterial pneumonia. In severe cases of pneumonia, the abnormalities may be diffuse. Bacterial pneumonia caused by *H. influenzae* may present with diffuse opacities similar to those of PCP, although it may also present with patchy or focal consolidation. The presentation of tuberculosis depends on the relative degree of immunosuppression (Chapter 67).

ISSUES AT THE TIME OF ADMISSION

Pneumocystis pneumonia and community-acquired bacterial pneumonia are the two most common pulmonary diseases leading to hospital admission of HIV-infected patients. Many of the issues arising at the time of admission, during the course of hospitalization, and after discharge are also relevant to other HIV-related pulmonary processes. This section addresses some of these issues in addition to specific concerns related to PCP and community-acquired pneumonia.

Clinical Presentation and Initial Evaluation

The characteristic clinical presentations of PCP and bacterial pneumonia have been described (Table 75.2). In a patient with respiratory symptoms and known or suspected HIV infection, an algorithm that utilizes the chest radiograph and the presence or absence of purulent sputum can often lead to an efficient diagnostic and treatment plan (Figure 75.2).

Indications for Hospitalization and Intensive Care

There are no specific admission criteria developed and validated for HIV-infected patients with pulmonary disease. The admission decision should therefore rely on an assessment of the severity of pulmonary disease, the patient's general health, and patient and clinician resources (Table 75.3). Outpatient management requires that patients have access to medical follow-up should their condition deteriorate or should side effects of the treatment develop. In settings where this is limited, it may be more prudent to hospitalize a patient than to attempt outpatient therapy.

Clear indications for ICU admission or transfer include respiratory failure requiring mechanical ventilation, hemodynamic instability or compromise requiring intravenous fluids and vasopressors, and altered mentation compromising the ability to protect adequately against aspiration. In settings without the resources to monitor patients closely outside the ICU (e.g., a "close observation" unit), patients who do not have these indications but who have severe respiratory impairment, rapidly progressive pulmonary disease, hypotension, or multiple organ system failure should also be considered candidates for ICU admission. In the setting of advanced HIV disease, patients may choose not to be intubated or receive certain other types of medical care. In these instances, intensive care may not be desired or warranted (Chapters 17 and 19).

Indications for Respiratory Isolation

Hospitalized HIV-infected patients with a clinical or radiographic presentation that is suggestive of tuberculosis or with known tuberculosis should be placed in respiratory isolation (7). If hospitalization continues to be necessary, isolation should be continued until tuberculosis is excluded or the patient has been on effective therapy for at least 2 weeks.

Numerous reports of clusters of PCP cases among different immunocompromised populations support the theories that PCP can result from person-to-person transmission and that *de novo* infection can occur in the setting of immunosuppression (8). However, the USPHS/IDSA guidelines for preventing opportunistic infections state that

TABLE 75.3
INDICATIONS FOR HOSPITAL ADMISSION OF HIV-INFECTED PATIENTS WITH PULMONARY DISEASE

Pulmonary

- Respiratory rate
 - Elevated respiratory rate ≥ 30 breaths per minute
- Arterial oxygenation
 - Decreased PaO₂, elevated alveolar–arterial O₂ gradient requiring oxygen
- Exercise tolerance and cardiopulmonary reserve
 - Decreased exercise tolerance limiting ability to carry out daily activities
 - Decreased cardiopulmonary reserve from underlying condition (e.g., COPD, CHF)
- Chest radiograph
 - Suspected tuberculosis and concern for transmission to other immunocompromised persons at place of residence
 - Diffuse parenchymal disease and concern for progression
 - Pneumothorax and concern for progression, need for observation/chest tube

General health

- General appearance and vital signs
 - Altered mental status
 - Ill-appearing
 - Temperature $\leq 35^{\circ}\text{C}$ or $\geq 40^{\circ}\text{C}$
 - Heart rate ≥ 125 beats/min
 - Systolic blood pressure ≤ 90 mm Hg
- Coexisting disease(s)^a
 - Neurologic
 - Psychiatric
 - Gastrointestinal
 - Liver
 - Renal
 - Hematologic
- Coexisting condition(s)^a
 - Illicit drug use
 - Alcohol use

Patient resources

- Homeless or unstable housing
- No family or friends to assist patient with daily activities

Clinician resources

- Inability to provide appropriate follow-up

^a If compromises outpatient therapy and medication adherence. CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease.

“although certain authorities might recommend that HIV-infected persons who are at risk for PCP avoid sharing a hospital room with a patient who has PCP, data are insufficient to support this recommendation as standard practice” (6).

Empiric Therapy Versus Definitive Diagnosis

The diagnostic evaluation of an HIV-infected patient with suspected bacterial pneumonia may include sputum Gram stain and culture and should include two blood cultures.

However, in the majority of patients with bacterial pneumonia, no etiological diagnosis will be made and empiric therapy will be necessary. Because *Pneumocystis* cannot be cultured, the diagnostic evaluation of a patient with suspected PCP involves microscopic examination of stained respiratory specimens obtained by sputum induction or bronchoscopy. These tests are sensitive (reported range of sensitivities for sputum induction, 55%–95%; for bronchoscopy, 89%–98%) and specific for the diagnosis. However, they may not always be available and, in the case of bronchoscopy, are invasive and require the presence of a bronchoscopist. For patients who present with “classic” PCP, an argument can be made for initiating empiric PCP therapy and reserving diagnostic procedures for the subset of patients who fail to respond to 5–7 days of therapy. An equally compelling argument can be made for establishing a diagnosis in all HIV-infected patients with pulmonary disease severe enough to require hospitalization so as to optimize therapy and follow-up. Should the promising results reporting the use of non-invasive specimens (e.g., oropharyngeal washing) combined with sensitive polymerase chain reaction (PCR)-based assays for the diagnosis of PCP be confirmed, then the diagnosis will be made non-invasively (without sputum induction or bronchoscopy) much more often (9).

Treatment Regimens

The considerations in choosing a specific treatment for community-acquired bacterial pneumonia in an HIV-infected patient should be similar to those in an immunocompetent host (Chapter 65) (10). In addition, coverage for *P. aeruginosa* and *Staphylococcus aureus* should be considered when the CD4 cell count is below 50/ μL , there has been recent injection drug or antibiotic use, or there is cavitation seen on the chest radiograph.

The choices of specific treatment for PCP depend on the severity of disease, as determined by arterial blood gas measurement (Table 75.4). The regimens for mild disease are of comparable efficacy, and the decision about which regimen to use depends on the clinician’s preference, in addition to consideration of potential adverse effects. Patients with moderate-to-severe PCP should be treated with trimethoprim-sulfamethoxazole (unless there is a history of a severe reaction) and adjunctive corticosteroids. *Corticosteroids* should be initiated at the time that PCP therapy is begun. In a patient with suspected PCP, the decision of whether or not to use corticosteroids must be based on the severity of disease (PaO₂ ≤ 70 mm Hg or alveolar–arterial O₂ gradient > 35 mm Hg), not on the management approach chosen (e.g., definitive diagnosis versus empiric therapy). Empiric PCP therapy (including corticosteroids) may be initiated while the diagnostic evaluation is in progress. If the diagnosis of PCP is excluded, corticosteroids should be discontinued promptly. Patients with moderate-to-severe pulmonary disease who are

TABLE 75.4**PNEUMOCYSTIS PNEUMONIA TREATMENT REGIMENS FOR MILD AND MODERATE–SEVERE DISEASE^a**

PCP treatment regimen	Dose(s), route, frequency	Major side effects
Mild disease (PaO ₂ >70 mm Hg AND alveolar–arterial O ₂ gradient <35 mm Hg)		
TMP/SMX	15 mg/kg (TMP) PO daily (q6–8h)	Fever, dermatologic, gastrointestinal, hematologic
TMP + dapsone	15 mg/kg PO daily (q6–8h) + 100 mg PO once daily	Dermatologic, gastrointestinal, hematologic
Clindamycin + primaquine	1,800 mg PO daily (q6–8h) + 30 mg (base) PO once daily	Dermatologic, gastrointestinal, hematologic
Atovaquone	750 mg PO twice–thrice daily	Dermatologic, gastrointestinal
Moderate–severe disease^b (PaO ₂ ≤70 mm Hg OR alveolar–arterial O ₂ gradient ≥35 mm Hg)		
TMP/SMX	15 mg/kg (TMP) IV daily (q6–8h)	See above
Pentamidine	3–4 mg/kg IV once daily	Renal, pancreatic
Clindamycin + primaquine	1,800 mg IV daily (q6–8h) + 30 mg (base) PO once daily	See above
Trimetrexate + leucovorin ± dapsone	45 mg/m ² IV once daily + 20 mg/m ² PO q6h ± 100 mg PO once daily	Hematologic, dermatologic, fever

^a Recommended duration of therapy is 21 days.

^b Adjunctive corticosteroids (prednisone 40 mg PO twice daily for 5 days, then 40 mg PO once daily for 5 days, then 20 mg PO once daily for 11 days; or IV equivalent of methylprednisolone) should also be administered. TMP/SMX, trimethoprim-sulfamethoxazole.

treated with empiric PCP therapy and corticosteroids must be closely followed; in these patients, there should be a low threshold for pursuing a definitive diagnosis. Patients intolerant to trimethoprim-sulfamethoxazole may be started on one of the other regimens listed. No direct comparison of these regimens has been conducted. Whichever therapy is chosen, the recommended duration of therapy is 21 days.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Time Course for Resolution

The time course for resolution of clinical symptoms and signs depends on the specific cause of pneumonia, severity of the pulmonary disease, and overall health of the patient. The typical time course for resolution of community-acquired bacterial pneumonia in an HIV-infected patient is similar to that in an immunocompetent person (Chapter 65). Usually, clear signs of clinical improvement should be evident within 2–5 days. The time course for resolution of PCP is generally longer. With successful therapy, fever, tachypnea, and oxygen requirements may persist or worsen for several days before improving. Thus, patients whose condition is neither improving nor significantly worsening may be treated for 7–10 days before a change in therapy is considered. However, if the patient's condition significantly

worsens, a number of considerations must be addressed promptly (Table 75.5). If the diagnosis is in doubt or if there is concern regarding a subsequent pulmonary disease, additional diagnostic evaluation is warranted. In these difficult cases, expert consultation is often helpful.

Initiation of Antiretroviral Therapy

Retrospective studies suggest that critically ill HIV-infected patients who receive antiretroviral therapy during their hospitalization have an improved survival compared to patients who do not receive this therapy (11). However, prospective studies are needed before firm recommendations can be made. In general, the potential benefits of antiretroviral therapy (e.g., rise in the CD4 cell count, decline in the HIV RNA level) must be balanced against the potential risks of these therapies (e.g., toxicity, drug interactions, immune reconstitution syndrome/paradoxical worsening) (12).

Prognosis of Patients with Respiratory Failure

The outcomes and mortality from PCP-associated respiratory failure have changed during the course of the AIDS epidemic. From 1981 to 1985, only 14% of patients with PCP who were admitted to an ICU survived to hospital discharge. This percentage improved to 40% between 1986

TABLE 75.5
CONSIDERATIONS IN A PATIENT FAILING TO IMPROVE AS EXPECTED

Problem	Main diagnoses	Diagnostic approach	Action(s)
Worsening dyspnea and/or hypoxemia ^a	Progressive pneumonia	Chest radiograph	Change treatment
	Pleural effusion/empyema	Chest radiograph	Thoracentesis (diagnostic and therapeutic)
	Superimposed pneumonia	Chest radiograph	Evaluate and add treatment for new process
	Pneumothorax	Chest radiograph	Consult specialist for chest tube placement
Worsening cough	Pulmonary embolism	Chest radiograph—if unchanged, then spiral chest CT or ventilation-perfusion scan	Evaluation for source and anticoagulation
	Progressive pneumonia	Chest radiograph	Change treatment
	Superimposed pneumonia	Chest radiograph	Evaluate and add treatment for new process
	Airways disease	Chest radiograph	Trial of nebulized bronchodilators
	Persistent, new fever	Progressive pneumonia	Chest radiograph
New chest pain	Pleural effusion/empyema	Chest radiograph	Thoracentesis (at least diagnostic)
	Superimposed pneumonia	Chest radiograph	Evaluate and add treatment for new process
	Drug fever	Chest radiograph	Switch treatment
	Pneumothorax	Chest radiograph	Consult specialist for chest tube placement
	Pulmonary embolism	Chest radiograph—if unchanged, then spiral chest CT or ventilation-perfusion scan	Evaluation for source and anticoagulation
	Progressive pneumonia	Chest radiograph	Change treatment
	Superimposed pneumonia	Chest radiograph	Evaluate and add treatment for new process

^a Also consider nonpulmonary etiologies (e.g., cardiac). CT, computed tomography.

and 1988 but declined again to 24% from 1989 to 1991. The exact reasons for these changes are unclear. More recently, studies at multiple institutions have indicated that the survival of patients with PCP-associated respiratory failure may again be improving (13). Up-to-date outcomes data will be needed to help patients make decisions about life-sustaining treatments.

DISCHARGE ISSUES

Many drug toxicities first appear after 7–10 days of therapy. In patients who are discharged before this time, clinicians should describe the possible side effects to the patient and should ensure an adequate means of follow-up in the event that adverse effects do develop.

There are no published guidelines outlining when to discharge an HIV-infected patient with pneumonia. Each patient should be evaluated individually. In general, pulmonary disease should have improved to the point at which the patient can carry out daily activities (with supplemental oxygen if necessary), and other medical conditions should not pose significant risks to the completion of successful outpatient therapy. In certain instances, resources may permit the patient to complete a full course of intravenous therapy as an outpatient, either by returning to an outpatient infusion center or receiving home infusion

therapy supervised by a visiting nurse. Alternatively, some patients may complete their treatment course with oral medications, although the efficacy and timing of such a change have not been extensively studied.

PREVENTION OF PCP AND BACTERIAL PNEUMONIA

Patients with a CD4 cell count of 200/ μ L or less or a prior history of PCP should be given prophylaxis (6). The first-line prophylaxis regimen is trimethoprim-sulfamethoxazole (one double-strength tablet daily or thrice weekly, or one single-strength tablet daily). Alternative prophylaxis regimens include dapsone (100 mg daily), atovaquone (1,500 mg daily), and aerosolized pentamidine (300 mg via nebulizer monthly). Patients who are receiving trimethoprim-sulfamethoxazole for PCP prophylaxis may have a lower incidence of bacterial infections, although there may be an increased risk for development of drug-resistant bacteria. Patients with bacterial pneumonia are at risk for recurrent disease and patients who are cigarette smokers or injection drug users should be encouraged to quit. Ideally, the decision to quit will have been made during hospitalization, and appropriate referrals will have been made before discharge (14). In addition, pneumococcal vaccine is recommended if it has not been previously administered (6, 15).

COST CONSIDERATIONS AND RESOURCE USE

A number of cost-benefit analyses have examined the optimal approach to the management of patients with suspected PCP (empiric therapy vs. definitive diagnosis, sputum induction vs. bronchoscopy as the initial diagnostic procedure). There is no clear benefit of one approach over another. The choice of approach depends on a number of factors, including the availability of diagnostic procedures and their diagnostic sensitivity, the prevalence of PCP in a particular setting, and the prevalence of other pulmonary diseases that might also be diagnosed by one of the procedures.

KEY POINTS

- When evaluating an HIV patient with lung disease, recognize that the spectrum of illness is broad and includes both HIV-associated and non-HIV-associated conditions.
- Respiratory complaints are frequent in HIV-infected persons and increase in frequency as the CD4 cell count declines.
- The CD4 cell count is an essential piece of information. Each of the HIV-related pulmonary diseases usually develops at or below a characteristic range of CD4 cell counts.
- In many institutions, the most frequent pulmonary diseases seen are PCP and bacterial pneumonia. A careful history, physical examination, and review of the chest radiograph are often sufficient to differentiate between these two pneumonias.
- Specific guidelines for hospitalization and discharge of HIV-infected patients with pneumonia have not been developed and validated. In general, practical medical judgment is essential.

Complications of

HIV Disease

Christina M. Marra

INTRODUCTION

Prior to the advent of potent antiretroviral therapy, central nervous system (CNS) complications of HIV infection were seen in about 40% of infected patients in the developed world. Neurological complications of HIV are now less common but still occur. A working knowledge of the clinical manifestations, diagnosis, and therapy of these disorders is important for any physician who cares for HIV-infected persons. Although a bewildering array of possibilities is included in the differential diagnosis, *HIV-associated dementia*, *cryptococcal meningitis*, *toxoplasmosis*, and *progressive multifocal leukoencephalopathy (PML)* are the most common CNS complications. These typically occur in the setting of advanced immunosuppression, when the peripheral blood CD4 cell count is less than 200/ μ L. Patients with acute meningitis, including cryptococcal meningitis, and with acute CNS mass lesions, including those due to toxoplasmosis, may be ill enough to warrant hospital admission. Alternatively, HIV-associated dementia and PML are generally subacute progressive illnesses that can be diagnosed and managed on an outpatient basis. This chapter uses a generic algorithm (Figure 76.1) to outline the approach to meningitis, CNS mass lesions, and other causes of acute change in mental status in HIV-infected patients. A differential diagnosis is provided for each problem, with a focus on the most common entities that require hospital care.

MENINGITIS IN THE HIV-INFECTED PATIENT

Issues at the Time of Admission

Clinical Presentation

Although HIV-infected patients with acute meningitis may present with the typical symptoms and signs of fever, headache, stiff neck, vomiting, and clouding of consciousness (Chapter 70), they may also have less typical presentations. For example, patients with cryptococcal meningitis may lack meningeal signs and present primarily with fever or clouding of consciousness. Alternately, the symptoms and signs of meningitis in patients infected with bacteria such as *Streptococcus pneumoniae* or *Salmonella* species may be overshadowed by signs and symptoms of systemic infection.

Differential Diagnosis and Initial Evaluation

Many pathogens can cause meningitis in patients infected with HIV; the more common entities are listed in Table 76.1. By far, the most common are *Cryptococcus neoformans* and *Mycobacterium tuberculosis*. The diagnosis and management of cryptococcal meningitis present special challenges and considerations in the HIV-infected person. On the other hand, the diagnosis and management of tuberculous

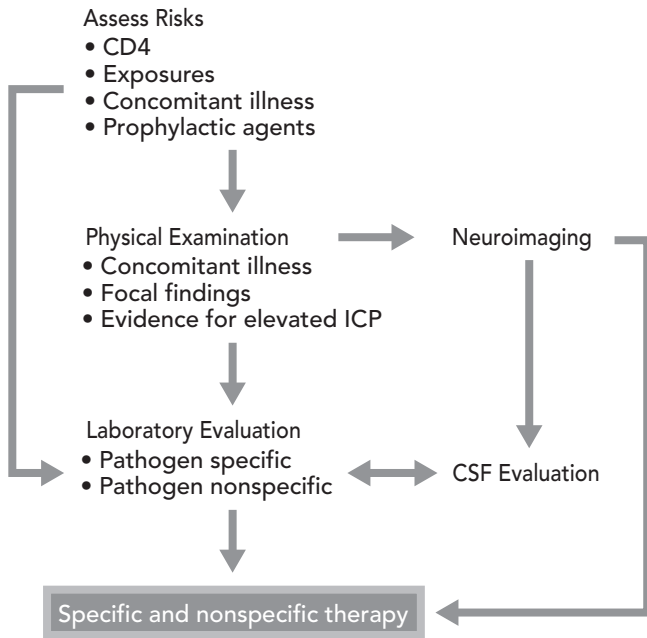

Figure 76.1 Diagnostic approach to HIV-infected patients with neurologic disorders. ICP, intracranial pressure.

meningitis do not differ significantly in HIV-infected and uninfected persons (1).

The first step in evaluating an HIV-infected patient with meningitis is to assess risk status. Risk assessment is based primarily on peripheral blood CD4 cell count but should also take into consideration PPD (purified protein derivative) status, exposure history, and any prophylactic therapies. Patients with CD4 cell counts below 200/ μ L are at greatest risk for opportunistic infections, such as crypto-

coccal meningitis. Meningitis caused by more aggressive pathogens, such as *M. tuberculosis*, can occur with less advanced immunosuppression. Patients with a positive PPD or who are currently being treated for pulmonary tuberculosis are at greatest risk for tuberculous meningitis. Traveling or living in the southwestern United States increases the risk for *Coccidioides* meningitis, and traveling or living in the midwestern United States increases the likelihood of *Histoplasma* meningitis. Finally, fluconazole for prevention of oral candidiasis is also effective in preventing cryptococcal meningitis, and prophylactic trimethoprim-sulfamethoxazole may decrease the risk for conventional bacterial infections.

The next step is to perform a directed physical examination that focuses on identification of extrameningeal sites of concomitant disease, and identification of focal neurologic abnormalities or evidence of raised intracranial pressure (Chapters 70 and 117). Patients with either of the latter two findings should undergo neuroimaging to evaluate the possibility of a focal brain lesion. Contrast-enhanced magnetic resonance imaging (MRI) is the study of choice, but if it is not available, contrast-enhanced computed tomography (CT) is usually adequate. The presence of a brain lesion may still be compatible with a diagnosis of meningitis. For example, cryptococcomas are relatively common in HIV-infected patients with cryptococcal meningitis. Tuberculomas may be found in patients with tuberculous meningitis or may develop during the course of therapy, and gummas or infarcts may be seen in patients with syphilitic meningitis. Cryptococcomas, tuberculomas, and gummas resolve with medical therapy and generally do not require surgical intervention. Findings on neuroimaging determine whether a patient can safely undergo lumbar puncture. Shift of brain structures away from the midline and compression of the fourth ventricle are contraindications to this procedure. Cisternal or sulcal effacement and loss of gray matter/white matter distinction are less absolute contraindications that require individualized assessment.

Every effort should be made to obtain cerebrospinal fluid (CSF) in HIV-infected patients with suspected meningitis so that appropriate therapy can be administered. The CSF profile of patients with bacterial meningitis is discussed in Chapter 70, and with tuberculous meningitis in Chapter 67. The CSF profile is similar in HIV-infected and uninfected patients who have conventional bacterial meningitis or tuberculous meningitis, but this is not the case with cryptococcal meningitis. HIV-infected patients with cryptococcal meningitis are more likely to have a CSF white blood cell count of less than 20/ μ L and are more likely to have a positive CSF culture. In general, CSF evaluation should always include bacterial, mycobacterial, and fungal cultures. CSF cryptococcal antigen should be assessed if the serum cryptococcal antigen test is reactive or the result is unknown, and the CSF VDRL test should be performed if the serum syphilis serologic tests are reactive or the results are unknown (p. 741). The need for CSF cytologic examination, polymerase chain reaction (PCR) assays for viruses, and specific antigen

TABLE 76.1
MOST COMMON ETIOLOGIES OF MENINGITIS IN HIV-INFECTED PATIENTS

Category of pathogen	Specific etiologies
Bacteria	<i>Mycobacterium tuberculosis</i> <i>Treponema pallidum</i> <i>Listeria monocytogenes</i> <i>Salmonella</i> species <i>Streptococcus pneumoniae</i> <i>Nocardia</i> species
Fungi	<i>Cryptococcus neoformans</i> <i>Coccidioides immitis</i> <i>Histoplasma capsulatum</i> <i>Candida</i> species <i>Aspergillus fumigatus</i>
Viruses	HIV Cytomegalovirus <i>Herpes simplex</i> type 2 Varicella-zoster virus
Noninfectious	Lymphomatous meningitis Drug-induced meningitis

(*Histoplasma*, *Candida*) or antibody (*Coccidioides*) tests should be individualized.

The initial laboratory evaluation of HIV-infected patients with suspected meningitis should always include blood cultures and testing for serum cryptococcal antigen. The serum cryptococcal antigen is sensitive but not specific for the diagnosis of cryptococcal meningitis. Similarly, a nonreactive serum fluorescent treponemal antibody absorption test (FTA-ABS) or *Treponema pallidum* particle agglutination test (TP PA) effectively rules out the diagnosis of syphilitic meningitis. A chest radiograph should be obtained; in some instances, the etiology of meningitis can be presumptively established from the findings on pulmonary evaluation.

Indications for Hospitalization

Hospital admission is generally required for all HIV-infected patients with acute meningitis. It is particularly appropriate for those with evidence of acute hydrocephalus, increased intracranial pressure, new seizures or new focal neurologic abnormalities, significant change in mental status, or hemodynamic instability. Patients with a more subacute or chronic presentation, normal neurologic examination findings, normal lumbar puncture opening pressure, and mild lymphocytic pleocytosis can often be managed as outpatients if they do not live alone. As for all neurologic presentations, the goals of hospitalization are to establish the correct diagnosis, initiate appropriate therapy, and stabilize the patient. In the absence of complications, this can usually be accomplished within 2–5 days for HIV-infected patients with meningitis.

Indications for Initial Intensive Care Unit Admission

Hemodynamic instability and increased intracranial pressure are indications for admission to the ICU. Some experts recommend ICU admission for all patients with suspected bacterial meningitis. Elevated intracranial pressure is an important cause of morbidity and mortality in HIV-infected persons with cryptococcal meningitis and may require serial lumbar punctures or continuous lumbar or ventricular drainage (2). Similarly, hydrocephalus can complicate the course of tuberculous meningitis and may require continuous ventricular drainage.

Initial Therapy

The choice of initial therapy is based on the results of initial CSF and laboratory analysis. If the CSF cryptococcal antigen test is reactive, therapy with intravenous (IV) amphotericin (0.7 mg/kg daily), with or without oral flucytosine (100 mg/kg daily in four divided doses), should be initiated (3). Similarly, if the CSF Gram stain or formula suggest bacterial meningitis, appropriate antibiotics should be administered

(see Tables 70.3 and 70.4 for antibiotic regimens). In many instances, the etiology of meningitis will not be known immediately, and empiric treatment must be instituted based on the most likely diagnosis. Once the etiology is determined, therapy can be tailored. Appropriate empiric therapy for suspected bacterial meningitis should be given as soon as possible and should neither be delayed by the need to obtain neuroimaging nor by the time required to obtain the results of CSF testing. The use of dexamethasone in HIV-infected patients with bacterial meningitis has not been studied but is reasonable in patients who are suspected to have pneumococcal meningitis (4). Dexamethasone should be given before or with the first dose of antibiotics (Chapter 70). Empiric therapy for tuberculous meningitis is appropriate when the likelihood of disease is high and no other etiology is apparent (see Chapter 67 for recommendations). A recent study shows that adjunctive treatment with dexamethasone improves survival in HIV-uninfected patients with tuberculous meningitis, but does not decrease disability (5). No benefit was demonstrated in HIV-infected patients in this study (5). Generally, empiric antifungal therapy is not administered when cryptococcal meningitis has been excluded.

Indications for Early Consultation

Neurologic or neurosurgical consultation is appropriate for assistance in managing patients with elevated intracranial pressure. Infectious diseases consultation should be considered for patients in whom the etiology of meningitis remains elusive, or for patients with less common etiologies, such as *Coccidioides*, *Histoplasma*, or *Candida*.

Issues During the Course of Hospitalization

The first hours of hospitalization should be devoted to beginning appropriate, often empiric, therapy and to completing necessary diagnostic tests. Therapy for presumed bacterial meningitis should be initiated in the emergency department. Therapy for presumed *M. tuberculosis* meningitis or for cryptococcal meningitis can generally be delayed until the results of diagnostic tests, such as the CSF profile, CSF cryptococcal antigen test, and chest radiograph, are available. Adjunctive therapies, such as antipyretics, antiemetics, and pain medications, and correction of electrolyte abnormalities or volume depletion should be tailored to the individual patient. Although volume overload should be avoided, there is no role for iatrogenic dehydration to treat elevated intracranial pressure because this could potentially increase the possibility of cerebral infarction, which can result from infectious arteritis or venous sinus thrombosis. Empiric anticonvulsants are indicated if there is increased intracranial pressure, because a seizure could further elevate pressure.

Vital signs should be assessed three to four times daily; the assessment should include determination of the level

of consciousness and screening for focal abnormalities. A nursing assessment and a home assessment should be performed in the first 24 hours after admission. Antibiotic regimens should be modified, if necessary, to cover organisms recovered from blood or CSF bacterial cultures. In most cases, antibiotic coverage for conventional bacteria can be discontinued at 48 hours if the cultures are negative. Patients who fail to improve or worsen by day 2 or 3 of hospitalization should be evaluated as outlined in Table 76.2.

Discharge Issues

By the third hospital day, patients who are neurologically stable or improving, are hemodynamically stable, can meet their fluid and nutritional needs by mouth, and can tolerate their antimicrobial therapy may be able to be discharged to complete their treatment at home or in a skilled nursing facility. The decision to discharge to home versus a more supervised setting depends on the frequency with which medication is administered, the degree of supervision required, and the patient's home situation. Generally, patients completing a course of therapy for acute meningitis should not be sent home if they live alone. Physician follow-up should be scheduled within the first week after discharge, and caregivers should be cautioned to contact the health care provider for worsening of symptoms and signs or development of new symptoms and signs, particularly focal neurologic abnormalities.

FOCAL CENTRAL NERVOUS SYSTEM LESIONS

Issues at the Time of Admission

Clinical Presentation

HIV-infected patients with focal CNS lesions typically present with mental status changes or focal neurologic

findings, including weakness and clumsiness. Seizures may occur in as many as one-third of patients. The clinical findings are generally not helpful in distinguishing one etiology from another, although there are a few caveats. Patients with CNS toxoplasmosis may be more likely to have fever. Patients with primary CNS lymphoma may be less likely to have focal findings because of the predominance of frontal lobe involvement. Patients with PML may be more likely to have visual field deficits because occipital lobe involvement is common.

Differential Diagnosis and Initial Evaluation

Central nervous system lesions associated with neuroimaging evidence of brain edema, mass effect, and contrast enhancement in patients infected with HIV are most commonly caused by toxoplasmosis or primary CNS lymphoma. Tuberculomas may be more common than primary CNS lymphoma in specific risk groups, such as IV drug users and persons from countries where tuberculosis is prevalent. Focal CNS lesions not associated with brain edema, mass effect, or contrast enhancement are most commonly due to PML; less commonly, these lesions may be associated with varicella-zoster encephalitis, stroke, or, rarely, an atypical primary CNS lymphoma. A CSF PCR that is positive for JC virus in this setting increases the likelihood of PML from 68%–99% (6). The diagnosis of PML may be more difficult to establish in patients who are receiving potent antiretroviral therapy. Such patients may have enhancing lesions on MR because of improved immune competence or an “immune reconstitution syndrome” (7). In addition, potent antiretroviral therapy decreases the amount of JC virus DNA in CSF, thus decreasing the diagnostic sensitivity of this test (8).

As in the case of meningitis, the first step in evaluating an HIV-infected patient with a focal brain lesion is to assess risk status. Patients with CNS toxoplasmosis typically have CD4 cell counts below 200/ μ L, whereas patients with pri-

TABLE 76.2

DIAGNOSTIC CONSIDERATIONS IN HIV-INFECTED PATIENTS WITH MENINGITIS WHO FAIL TO IMPROVE ON THERAPY

Reason	Diagnostic approach
Diagnosis incorrect; patient does not have meningitis or presumed etiology incorrect	Repeat neuroimaging and cerebrospinal fluid evaluation. Look carefully for other sources of infection.
Increased intracranial pressure	Repeat neuroimaging and lumbar puncture with measurement of opening pressure.
Hydrocephalus	Repeat neuroimaging.
Stroke	Repeat neuroimaging.
Metabolic derangement	Check appropriate laboratory values such as electrolytes, calcium, magnesium, and serum liver chemistries.
Iatrogenic	Check drug administration records.

mary CNS lymphoma or PML usually have lower CD4 cell counts, generally below 100/ μ L. Although there are no routine laboratory features that can predict the likelihood of primary CNS lymphoma or PML, 95% of patients with CNS toxoplasmosis have reactive serum anti-*Toxoplasma* immunoglobulin G. A nonreactive serology decreases the likelihood of CNS toxoplasmosis in a patient with a focal brain lesion from 78%–6% (6). Prior use of trimethoprim-sulfamethoxazole to prevent *Pneumocystis jirovecii* pneumonia (formerly *P. carinii*) also lowers the likelihood of CNS toxoplasmosis twofold to threefold (9).

Neuroimaging characteristics tailor the differential diagnosis. Contrast-enhanced CT is adequate for lesions associated with edema, mass effect, and enhancement, but MRI is superior for lesions that lack these characteristics. Because it is difficult to predict neuroimaging characteristics from clinical findings, proceeding directly to MRI is a more cost-effective approach. For patients who have lesions associated with edema, mass effect, and enhancement but a low likelihood of CNS toxoplasmosis, CSF should be examined if lumbar puncture can be performed safely. The PCR test for Epstein-Barr virus DNA in CSF is sensitive and specific for the diagnosis of primary CNS lymphoma. For patients who have nonreactive anti-*Toxoplasma* serology, the likelihood of lymphoma when a CSF PCR is positive for Epstein-Barr virus is 96%–98% (6).

Indications for Hospitalization

Patients with PML typically have a more subacute or chronic course than do patients with CNS toxoplasmosis or primary CNS lymphoma, and they can often be evaluated and managed as outpatients. Hospital admission is generally required for patients with suspected CNS toxoplasmosis or primary CNS lymphoma who have a depressed level of consciousness, significant mass effect, are too impaired to care for themselves safely, or do not have adequate living assistance. In the absence of complications, hospital stays of 2–5 days are typical for patients with mass lesions.

Indications for Initial Intensive Care Unit Admission

Obtundation, significant mass effect on neuroimaging, or frequent seizures are indications for admission to the ICU. These patients are at particular risk for brain herniation, which is the most acute risk of CNS toxoplasmosis and primary CNS lymphoma. They require frequent neurologic monitoring and may need neurosurgical intervention (see below).

Initial Therapy

In the past, an HIV-infected person who had a brain lesion associated with edema, mass effect, and enhancement had at least a 70% chance of having CNS toxoplasmosis. Be-

cause the prevalence of CNS toxoplasmosis was high, an HIV-infected patient with such a lesion was given a 2-week trial of toxoplasmosis treatment. The clinical and neuroimaging response to empiric therapy confirmed the diagnosis of CNS toxoplasmosis, and brain biopsy was reserved for patients who did not respond to the treatment trial. In recent years, the likelihood of CNS toxoplasmosis has decreased in patients with mass lesions associated with edema, mass effect, and enhancement, even when the anti-*Toxoplasma* serology is reactive (10).

An empiric treatment trial is now less appropriate for all HIV-infected patients with brain lesions associated with edema, mass effect, and enhancement. Patients appropriate for a toxoplasmosis treatment trial are those with a high likelihood of disease based on neuroimaging findings, reactive serum anti-*Toxoplasma* immunoglobulin G, and no prior use of trimethoprim-sulfamethoxazole for *Pneumocystis jirovecii* pneumonia (formerly *P. carinii*) prophylaxis. The results of PCR analysis of CSF can further define the likelihood of CNS toxoplasmosis. Initial therapy for toxoplasmosis includes pyrimethamine (100–200 mg PO load followed by 75–100 mg PO daily) and sulfadiazine (1.5–2.0 g PO four times daily). Adequate hydration must be maintained to avoid tubular crystallization of sulfadiazine with subsequent renal dysfunction. In patients who are allergic to sulfa medications, clindamycin (600–900 mg PO or IV) can be substituted for sulfadiazine. All treated patients should receive folinic acid (10–50 mg PO daily) to avert the marrow suppression caused by pyrimethamine.

In general, steroids should not be used in conjunction with a treatment trial because they can induce nonspecific clinical and neuroimaging improvement. However, a short course of steroids can be used in some instances to decrease edema and mass effect and thereby allow lumbar puncture to be performed safely. Empiric anticonvulsants should be given if there is significant brain edema or other evidence of elevated intracranial pressure. Patients with a low likelihood of CNS toxoplasmosis should not undergo a treatment trial. They should be referred for brain biopsy or, when the CSF PCR is positive for Epstein-Barr virus, for empiric radiation therapy.

In the era before the availability of potent antiretroviral therapy, the survival of HIV-infected patients with primary CNS lymphoma who have a good performance status and were treated with radiation therapy was 3–4 months. Today, patients with primary CNS lymphoma who respond to potent antiretroviral therapy may have prolonged survival (11). Figure 76.2 is a decision algorithm that addresses the diagnosis of focal CNS lesions.

Indications for Early Consultation

Patients admitted to the ICU because of concerns regarding brain herniation should undergo evaluation by neurosurgery for placement of an intracranial pressure monitor, a

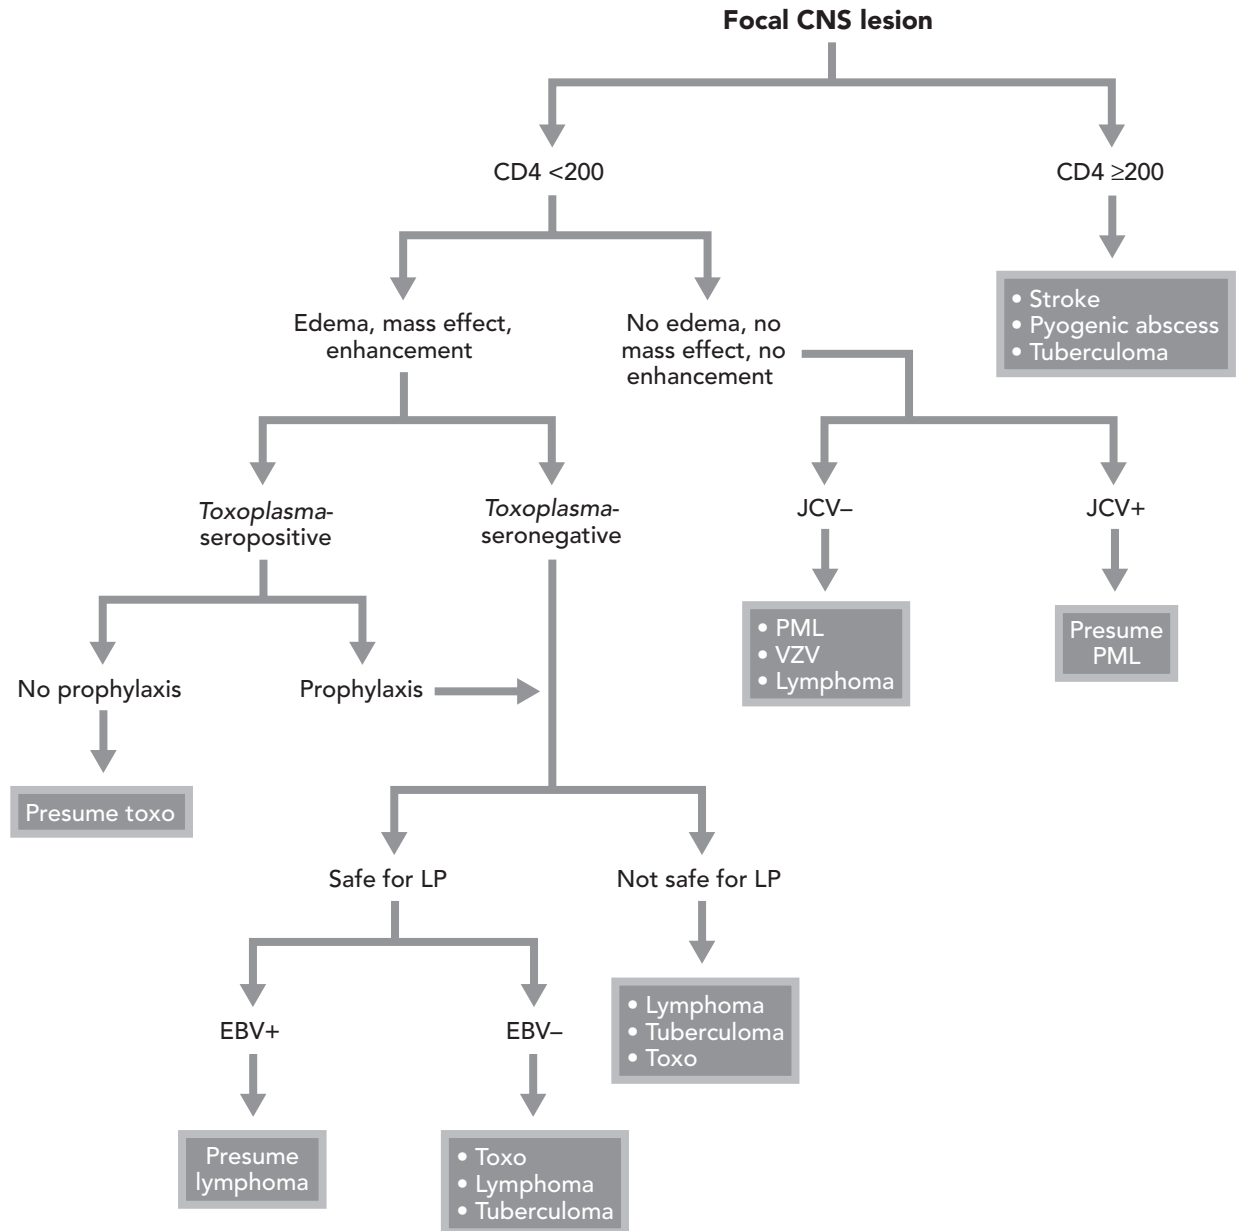

Figure 76.2 Suggested algorithm for the evaluation of HIV-infected patients with focal central nervous system lesions. *CD4*, peripheral blood CD4 lymphocyte count in cells per microliter; *CNS*, central nervous system; *EBV-*, Epstein-Barr virus DNA not identified in CSF by polymerase chain reaction; *EBV+*, Epstein-Barr virus DNA identified in CSF by polymerase chain reaction; *Edema, mass effect, enhancement*: lesion has edema, mass effect, and enhancement on neuroimaging; *JCV-*, JC virus DNA not identified in cerebrospinal fluid (CSF) by polymerase chain reaction; *JCV+*, JC virus DNA identified in CSF by polymerase chain reaction; *LP*, lumbar puncture; *No edema, mass effect, enhancement*: lesion does not have edema, mass effect, and enhancement on neuroimaging; *No prophylaxis*, patient is not taking trimethoprim-sulfamethoxazole; *PML*, progressive multifocal leukoencephalopathy; *Prophylaxis*, patient is taking trimethoprim-sulfamethoxazole; *Toxo*, CNS toxoplasmosis; *VZV*, varicella-zoster virus encephalitis.

CSF drainage procedure, or surgical resection (Chapter 117). A neurology consultation is appropriate for management of recurrent seizures (Chapter 118). An infectious disease consultation should be obtained to help devise an alternate treatment regimen if the patient is unable to tolerate the recommended therapy for CNS toxoplasmosis.

Issues During the Course of Hospitalization

The first hours of hospitalization should be devoted to completing the patient evaluation outlined above and initiating empiric therapy for CNS toxoplasmosis if this is determined to be the most appropriate course. As for patients

with meningitis, an assessment of vital signs, including directed neurologic evaluations, should be performed 3–4 times per day, and a nursing and home assessment should be obtained in the first 24 hours after admission. During the hospitalization, patients with focal neurologic abnormalities should have physical and occupational therapy assessments; speech therapy assessment is appropriate for patients with swallowing difficulties or speech deficits. Although a CNS toxoplasmosis treatment trial is usually continued for 10–14 days before efficacy is assessed, half of the patients with CNS toxoplasmosis improve clinically by day three of therapy, and most improve by day 7 (12). Failure to improve within the first week of treatment increases the likelihood of an alternative diagnosis, such as primary CNS lymphoma.

Discharge Issues

By the third hospital day, patients who are neurologically stable or improving and can tolerate their therapy may be able to be discharged to home or a skilled nursing or rehabilitation unit provided that continued neurologic follow-up is available. The decision to discharge to home versus a more supervised setting depends on the factors mentioned previously. Physician follow-up should be scheduled within the first one to two weeks after discharge, and caregivers should be cautioned to contact the health care provider in case of worsening of symptoms and signs, or the development of new symptoms and signs, particularly a change in the level of consciousness.

OTHER CAUSES OF ALTERED MENTAL STATUS

Issues at the Time of Admission

Clinical Presentation

The term *altered mental status* includes a spectrum of cognitive changes that range from confusion to delirium and dementia. Dementia does not cause acute changes in mental status and, as noted in the introductory section, HIV-associated dementia is a subacute disorder that can be diagnosed and managed on an outpatient basis. Not uncommonly, HIV-infected patients present with acute changes in mental status. They may be confused, with disorientation and misinterpretation of external stimuli or clouding of consciousness. Patients who are delirious may be disoriented and have hallucinations, illusions, or delusions. These symptoms often fluctuate.

Differential Diagnosis and Initial Evaluation

The differential diagnosis of an acute change in mental status includes infectious, structural, toxic, metabolic, and

other disorders (Table 76.3). Patients with underlying cognitive impairment may be more susceptible to changes in mental status caused by these problems. The suggested evaluations for meningitis and focal CNS lesions are provided above. Encephalitis in HIV-infected patients is relatively uncommon. Before the advent of potent antiretroviral therapy, a common cause of encephalitis in HIV-infected patients was cytomegalovirus (CMV). CMV encephalitis is now quite rare but should be considered in patients with CD4 cell counts below 75/ μ L who are not receiving antiretrovirals. The remaining entities are listed in Table 76.3; none is unique to HIV-infected patients (Chapter 115). The exception to this statement may be that HIV-infected patients are particularly susceptible to the toxic effects of medications, and because they may be taking many different medications at the same time, they are at increased risk for drug–drug interactions.

Again, the first step in evaluating an HIV-infected patient with acute change in mental status is to assess risk status in terms of the degree of immunosuppression. Consideration should also be given to any history of trauma, use of recreational drugs and prescription medications, and history of previous neurologic disease, including seizures. The physical examination should include a formal assessment of mental status—for example, the Short Portable Mental Status Questionnaire (Table 16.3) or the Mental Alternation Test (13). The Glasgow Coma Scale (Table 117.1) can be used for obtunded or comatose patients. Because the differential diagnosis for acute change in mental status is extensive, most patients, particularly those with a CD4 cell count below 200/ μ L, should undergo neuroimaging.

TABLE 76.3
MOST COMMON CAUSES OF ACUTE CHANGE IN MENTAL STATUS IN HIV-INFECTED PATIENTS

Category of process	Specific etiologies
Non-CNS infection	Pneumonia Bacteremia
CNS infection	Meningitis Cerebritis Abscess <i>Herpes simplex</i> encephalitis Varicella encephalitis
Structural	Head trauma Hemorrhage Tumor
Toxic encephalopathy	Recreational drugs Prescription medications
Metabolic encephalopathy	Electrolyte abnormalities Hepatic dysfunction Hypoxemia
Other	Seizure Psychiatric disease

CNS, central nervous system.

Cranial CT with and without contrast is the study of choice in this setting to exclude quickly a focal lesion such as abscess or hemorrhage, and to determine the safety of lumbar puncture. Lumbar puncture should be performed to evaluate the possibility of CNS infection in patients at greatest risk based on clinical presentation or a low CD4 cell count. CSF studies should include a cell count and determination of glucose and protein levels. The use of PCR to detect CMV in CSF is appropriate if the patient is at risk for CMV encephalitis (see earlier in this chapter). *Herpes simplex virus* (HSV) encephalitis has been uncommonly described in HIV-infected patients and may have fewer focal features than in immunocompetent patients. Encephalitis due to HSV type 2, rather than type 1, may be more common in HIV-infected patients. PCR to detect HSV DNA in CSF is 98% sensitive and 94% specific for the diagnosis of HSV encephalitis. Blood should be sent for assessment of electrolytes and renal and hepatic function. A urine toxicology screen and determination of blood levels of psychoactive medications can be helpful. In particularly perplexing situations, it is useful to have a family member or friend bring all the patient's medications to the hospital for review.

Indications for Hospitalization and Intensive Care Unit Admission

Hospital admission is generally required for all patients with acute onset of significant change in mental status. Patients who are completely alert but confused or delusional, or in whom symptoms are slowly evolving, may be able to be evaluated on an outpatient basis. Because the differential diagnosis is so extensive, an estimate of the usual duration of hospitalization cannot be provided. In addition to the criteria for ICU admission listed above, patients who do not open their eyes to voice or who are comatose should be admitted to an ICU.

Initial Therapy

The choice of initial therapy is based on the results of initial neuroimaging and of CSF and other laboratory analyses. Patients with HSV encephalitis should be treated with acyclovir (10 mg/kg IV every 8 hours). Neurosurgical consultation is appropriate for assistance in managing patients with intracranial hemorrhage or contusion who may require treatment to decrease intracranial pressure or surgical excision. Metabolic abnormalities should be corrected. Medication toxicity can be treated by withdrawal of the offending agent or in some cases (benzodiazepines or opiates) by administering a reversing agent.

Issues During the Course of Hospitalization

The first hours of hospitalization should be devoted to beginning appropriate therapy and completing the necessary diagnostic evaluation. Therapy for presumed HSV en-

cephalitis will often need to be initiated before the results of confirmatory tests are available. Assessment of vital signs and directed neurologic evaluations should be performed 3–4 times daily. As for most hospitalized patients, a nursing and a home assessment should be obtained in the first 24 hours after admission.

Discharge Issues

Because the differential diagnosis of acute change in mental status is so extensive, generalizations regarding expected hospital course are difficult to make. Broadly speaking, patients with reversible causes of toxic or metabolic encephalopathy can be expected to recover within 1–3 days and be discharged home. Patients with structural abnormalities or with encephalitis would be expected to have a more protracted course and to require rehabilitation, either in a skilled nursing facility or a rehabilitation unit, before eventual discharge home.

COST CONSIDERATIONS AND RESOURCE USE

Neurologic disease increases the length of stay and hospital costs for HIV-infected patients (14). The time required to establish a diagnosis is a likely contributor to increased costs. In addition, neurologic disease is more likely to result in discharge to an extended care facility, which suggests that HIV-infected patients with neurologic disease may be more severely ill than those without neurologic disease and thus require a longer length of stay. Given this information, means to increase the diagnostic accuracy of HIV-associated neurologic disorders could decrease the cost of hospital care. Neuroimaging is often considered to be a major contributor to the cost of neurologic care. Although the cost of cranial MRI can be as much as twice that of cranial CT, proceeding directly to the cranial MRI in selected patients may ultimately reduce costs because MRI often provides information that CT does not and thereby reduces the duration of hospitalization.

KEY POINTS

- HIV-associated dementia, cryptococcal meningitis, toxoplasmosis, and progressive multifocal leukoencephalopathy are the most common central nervous system disorders associated with HIV infection. All typically occur in the setting of advanced immunosuppression.
- The first step in evaluating an HIV-infected patient with a neurologic disorder is to assess the risk status of the patient based primarily on peripheral blood CD4 cell count, but also on the results of other laboratory tests, presence of concomitant illnesses, and administration of prophylactic therapies.

- Although HIV-infected patients with acute meningitis may present with the typical symptoms and signs of fever, headache, stiff neck, vomiting, and clouding of consciousness, they may also have less typical presentations. The most common causes of meningitis are *Cryptococcus neoformans* and *Mycobacterium tuberculosis*.
- Elevated intracranial pressure is an important cause of morbidity and mortality in HIV-infected patients with cryptococcal meningitis.
- Clinical findings are generally not very helpful in distinguishing one etiology of focal central nervous system lesions in HIV-infected patients from another.
- Central nervous system lesions associated with neuroimaging evidence of brain edema, mass effect, and contrast enhancement in patients infected with HIV are most commonly caused by toxoplasmosis and primary central nervous system lymphoma.
- Focal central nervous system lesions not associated with neuroimaging evidence of brain edema, mass effect, or contrast enhancement are most commonly caused by progressive multifocal leukoencephalopathy. However, mass effect and contrast enhancement may be seen in patients who develop PML shortly after beginning potent antiretroviral therapy as part of an "immune reconstitution syndrome."
- The differential diagnosis of acute change in mental status in HIV-infected patients includes infectious, structural, toxic, metabolic, and other disorders.

Signs, Symptoms, and Laboratory Abnormalities in Gastrointestinal Disease

Kenneth McQuaid

INTRODUCTION

Gastrointestinal symptoms and signs are common in the hospitalized patient. They are sometimes attributable to problems intrinsic to the gastrointestinal tract or may be indicative of a systemic disorder. When they are present on admission, the differential diagnosis of these symptoms and signs is lengthy. However, a complete history and physical examination focus on the diagnostic evaluation. Gastrointestinal symptoms that arise during hospitalization most commonly are caused by problems intrinsic to hospital treatment: medications, chemotherapy, nosocomial infections, and invasive procedures or surgery. In approaching hospitalized patients, physicians should first consider these nosocomial and iatrogenic factors while also keeping in mind that “outpatient disorders” may arise in the inpatient setting. In this chapter, the approaches to several common signs, symptoms, and laboratory abnormalities are addressed. The differential diagnosis, diagnostic considerations, evaluation, and management for patients

presenting to the hospital are discussed and contrasted with those for patients whose problems arise during a hospitalization.

ABDOMINAL PAIN OCCURRING DURING THE COURSE OF HOSPITALIZATION

Description and Differential Diagnosis

Common disorders resulting in abdominal pain that lead to hospitalization are discussed in the subsequent chapters of the gastroenterology section (e.g., acute pancreatitis in Chapter 86, and bowel obstruction in Chapter 88). The patient in whom abdominal pain develops *after* hospitalization presents a difficult challenge. In many instances, such patients are critically ill with a major medical problem or are in a postoperative recovery period. They may be unable to provide a history of their symptoms because of alterations in mental status or the need for assisted ventilation.

Abdominal pain presenting in the hospitalized patient can generally be assigned to one of the following categories.

Conditions Overlooked or Misdiagnosed on Hospital Admission

Patients who are elderly, have a psychiatric illness or altered mental status, have multiple comorbid medical illnesses, or are taking long-term analgesics or corticosteroids may not manifest typical symptoms or signs of acute surgical disease on admission and may be admitted to a nonsurgical service. The admitting diagnoses of “fever,” “gastroenteritis,” “sepsis,” “altered mental status,” “obstipation,” or “failure to thrive” may stem from undiagnosed intraabdominal conditions such as a perforated peptic ulcer, cholecystitis or cholangitis, diverticulitis, or appendicitis in patients reporting little or no initial abdominal pain. Significant pain may not become apparent until the disease progresses and complications (e.g., peritonitis or abscess) arise. In such cases, initial physical findings may be minimal, or the atypical location may confound the diagnostic impression.

Unrelated Conditions First Arising in the Hospital

Because physicians are trained to look for a “unifying diagnosis,” the possibility of a second, unrelated problem arising anew in the hospitalized patient often is not even considered. The presentation of common causes of abdominal pain such as acute cholecystitis, acute appendicitis, and perforated peptic ulcer may be atypical in the hospitalized patient. This may lead to a delayed diagnosis and complications.

Conditions Arising as a Direct Consequence of Problems Related to Critical Illness

A host of problems may arise in the gastrointestinal tract that are a direct consequence of critical illness (Table 77.1), such as the following:

Mucosal Ischemia

As a consequence of severe physiological stress, shunting of splanchnic blood flow may give rise to ischemic damage throughout the gastrointestinal tract. Patients at greatest risk are those with sepsis, shock, coagulopathy, major trauma, major central nervous system events, multiple organ failure, or those who are undergoing mechanical ventilation or major surgery. Many critically ill patients are unable to report abdominal symptoms because of altered mental status or sedation. Hence, these conditions commonly are overlooked until complications supersede. *Acalculous cholecystitis* may manifest with any combination of right upper quadrant pain or tenderness, fever, and leukocytosis in the postoperative or ICU patient. Symptoms or signs referable to the right upper quadrant com-

TABLE 77.1

CAUSES OF ABDOMINAL PAIN IN THE HOSPITALIZED PATIENT

Problems arising from physiological stress

Stress-related gastric or duodenal ulcers
Mesenteric ischemia
Ischemic colitis
Acalculous cholecystitis
Pancreatitis
Ileus
Acute colonic pseudo-obstruction (Ogilvie’s syndrome)
Acute adrenal insufficiency

Complications secondary to hospitalization

Postsurgical complications
Postprocedural complications
Clostridium difficile colitis
Medication-induced abdominal pain
Constipation
Pneumonia
Coronary ischemia

monly are not apparent or are overlooked until sepsis or cholangitis develops (Chapter 84). *Nonocclusive mesenteric ischemia* and *ischemic colitis* most commonly arise in patients with cardiogenic or hypovolemic shock that results in vasoconstriction or other compromise of the mesenteric arteries (Chapter 87).

Disruption of Intestinal Motility

Ileus and *acute colonic pseudo-obstruction (Ogilvie’s syndrome)* are due to reversible inhibition of intestinal motility that develops in patients who are critically ill or in a postoperative state. They are characterized by diffuse abdominal pain and distention (Chapter 88).

Acute Pancreatitis

Acute pancreatitis may occur in the hospitalized patient for a number of reasons. The medication list must be carefully reviewed for potential causative agents. Fasting patients are predisposed to the development of biliary sludge and small gallstones, which can cause acute pancreatitis. Ischemic injury to the pancreas may occur in patients who have had shock. Up to 8% of patients sustain overt pancreatitis after cardiopulmonary bypass, and significantly more have subclinical injury. Finally, acute pancreatitis may occur after other abdominal surgeries, even when the pancreas is not directly manipulated (Chapter 86).

Acute Adrenal Insufficiency

Adrenal crisis may occur in hospitalized patients with latent adrenal disease due to the stress of surgery, trauma, infections, or prolonged fasting. It may also occur in patients taking chronic adrenocorticoids if these medications are not continued in the hospital. Acute adrenal

insufficiency (Chapter 109) may also occur following injury to adrenals by hemorrhage, thrombosis, or infection. Patients may complain of nausea, vomiting, abdominal pain, and diarrhea. Signs of adrenal crisis include fever, hypotension, hypoglycemia, and hyponatremia.

Complications Arising as a Consequence of Hospitalization Or Intervention

Postprocedural Complications

In the hospital setting, patients may undergo a variety of abdominal procedures. Any patient complaining of abdominal pain within 24–48 hours of an invasive procedure should be presumed to have a complication until proved otherwise. A full description of these complications is beyond the scope of this discussion, but three broad categories should be considered: (a) bleeding (intraperitoneal, retroperitoneal, within solid organs, or within the bowel wall); (b) perforation of a hollow viscus; or (c) infection.

Inflammatory Colitis

Clostridium difficile-associated colitis develops in 1% of patients receiving antibiotics (see the section on “Diarrhea” later in this chapter). Some patients present with fever, abdominal distention, pain, tenderness, and leukocytosis with minimal or no diarrhea. Such cases may be confused with ileus or Ogilvie’s syndrome. *Neutropenic typhlitis* is an inflammatory process involving the cecum, ascending colon, and terminal ileum that occurs in some patients with profound neutropenia (<1,000 cells μ L) after they receive cytotoxic drugs. It may lead to bacterial invasion, perforation, and shock, and carries a mortality of 50%. Right lower quadrant cramping pain, fever, and watery or bloody diarrhea usually are present.

Abdominal Pain Induced by Medication

A host of medications can cause dyspepsia, including nonsteroidal antiinflammatory drugs (NSAIDs), iron, niacin, corticosteroids, oral antibiotics, lactulose, sorbitol, acarbose, theophylline, digoxin, and L-dopa. Acute opiate withdrawal should be considered in high-risk patients with cramping abdominal pain and diarrhea. Anticoagulation may be associated with spontaneous or post-procedure hemorrhage in the liver, spleen, bowel wall, peritoneal cavity, retroperitoneum, or abdominal wall, resulting in acute, often dramatic, abdominal pain.

Constipation

Constipation is common in the hospital setting because of alterations in diet, bed rest, medications, postoperative pain, and restricted access to private facilities. It may go unnoticed until abdominal distention and pain develop.

Other Medical Conditions

Pneumonia and *coronary ischemia* may present with pain in the epigastrium or upper quadrants. Pursuit of abdominal causes of pain in these cases may lead to serious delay in diagnosis and appropriate treatment.

Evaluation

The initial approach to the hospitalized patient with abdominal pain is similar to that in the outpatient setting. When possible, a history and physical examination should be repeated, with emphasis on the presence of abdominal symptoms that preceded hospital admission. The findings of abdominal distention, recent incision or puncture sites, hematomas, and the presence or absence of bowel sounds should be noted. Tympany and tenderness are suggestive of ileus or perforation. Attention should be paid to the presence of tenderness in the right upper quadrant (cholecystitis), right lower quadrant (Ogilvie’s syndrome or appendicitis), or left lower quadrant (ischemic colitis or diverticulitis). The finding of gross blood on digital rectal examination is suggestive of mesenteric ischemia or ischemic colitis.

Reports of all diagnostic and therapeutic procedures should be reviewed, and any complications noted. The medication list should be reviewed for antibiotics or other drugs that might cause abdominal pain. Anticoagulants increase the likelihood of an intra-abdominal or retroperitoneal hemorrhage.

Abdominal pain that develops in the hospitalized patient warrants further investigation. A complete blood cell count with differential, a urinalysis, and values for electrolytes, liver chemistries, and amylase should be obtained. A recent drop in hematocrit suggests intra-abdominal hemorrhage. Leukocytosis is nonspecific in the hospitalized patient, but a recent or continued rise suggests a serious cause of abdominal pain. The presence of an anion gap acidosis is worrisome for lactic acidosis caused by intra-abdominal abscess, sepsis, or ischemic bowel. Changes in liver chemistries, sometimes quite minor, may be indicative of calculous or acalculous cholecystitis, cholangitis, or both. Hyperamylasemia may point to acute pancreatitis.

A flat and upright or right lateral decubitus abdominal radiograph should be obtained in all hospitalized patients with abdominal pain to look for the presence of free intra-abdominal air. Increased gas throughout the small and large bowel suggests ileus. Acute obstruction of the large or small bowel can be distinguished from ileus by auscultation and abdominal radiographs. When the colon is predominantly dilated, Ogilvie’s syndrome, *C. difficile* colitis, and (in immunosuppressed patients) typhlitis should be considered. The presence of gas in the rectum helps to distinguish these from a distal large-bowel obstruction. Hypaque enema or colonoscopy is sometimes necessary to exclude mechanical large-bowel obstruction

(Chapter 88). Significant thickening of the colonic wall may be evident with ischemic colitis, pseudomembranous colitis, or typhlitis. Sigmoidoscopy or colonoscopy may be indicated when ischemic colitis or *C. difficile* pseudomembranous colitis is suspected. Constipation is evidenced by a large, stool-filled rectum and descending colon.

When the above fail to indicate the cause of abdominal pain, further imaging is required. For suspected cholecystitis, ultrasonography is preferred. In most other patients, abdominal computed tomography (CT) is the optimal study to evaluate the presence of small amounts of intraperitoneal air, intraabdominal abscess, retroperitoneal hemorrhage, intestinal ischemia, cholecystitis, pancreatitis, and appendicitis. In patients with suspected complications of an invasive procedure, it is also the study of choice.

Management

The appropriate management of the hospitalized patient with abdominal pain depends on the suspected etiology. If there is any question of a complication related to a procedure, the service that performed that procedure should be contacted. The patient should be aggressively volume-resuscitated as needed. Patients with sepsis or suspected intra-abdominal infection should be treated with broad aerobic and anaerobic antibiotic coverage (Chapter 64). Placement of a nasogastric tube is indicated for the patient with vomiting, ileus, acute colonic pseudo-obstruction, or bowel obstruction. For specific management of stress ulceration (Chapter 80), acalculous cholecystitis (Chapter 84), acute pancreatitis (Chapter 86), ileus and Ogilvie's syndrome (Chapter 88), and surgical emergencies (Chapter 87), refer to the chapter indicated.

NAUSEA AND VOMITING

When Presenting at the Time of Admission

Description and Differential Diagnosis

The medullary vomiting center receives stimulatory input from (a) vagal and splanchnic fibers from the gastrointestinal tract, (b) the vestibular system, (c) the chemoreceptor trigger zone (rich in serotonin and dopamine receptors), and (d) higher central nervous system centers. The causes of acute vomiting can be subsumed under these general categories (Table 77.2).

Chronic vomiting may be a consequence of gastroparesis, gastric outlet obstruction, intestinal dysmotility, central nervous system disorders, systemic disorders, psychogenic factors, and pregnancy. It is important to distinguish mechanical causes (which may require surgical therapy) from other causes. Vomiting immediately after meals may represent bulimia or other psychogenic factors, but it also occurs in patients with pyloric stenosis from peptic ulcer disease. The vomiting of undigested food between one and several hours after meals suggests gastroparesis, gastric outlet obstruction, or proximal small-bowel obstruction. Morning vomiting is typical of alcoholic gastritis, pregnancy, uremia, and increased intracranial pressure.

Evaluation

In patients with acute vomiting, the goal is to distinguish "surgical" from "medical" conditions. The acute onset of vomiting without significant abdominal pain is commonly

TABLE 77.2
CAUSES OF ACUTE NAUSEA AND VOMITING

Visceral afferent sensation	Hyperglycemia
Infections	Adrenal crisis
Viral gastroenteritis	Radiation therapy
Toxin-mediated food poisoning	Vestibular disorders
Acute systemic infections	CNS stimulation
Mechanical obstruction	Increased intracranial pressure
Extrinsic small bowel obstruction	CNS tumors
Intrinsic small bowel obstruction	Subarachnoid hemorrhage
Ileus	Subdural hemorrhage
Visceral pain or peritoneal irritation	Meningitis
Medications/irritants	Encephalitis
Stimulation of CTZ	Psychogenic
Chemotherapy agents	Other systemic conditions
Other medications	Myocardial infarction
Opioids	Hypercalcemia
L-dopa	Pregnancy
Systemic disorders	Acute fatty liver of pregnancy
Uremia	
Diabetic ketoacidosis	

CNS, central nervous system; CTZ, chemoreceptor trigger zone.

caused by “medical” conditions, such as infectious gastroenteritis, food poisoning, myocardial infarction, or medications. The acute onset of abdominal pain that is accompanied or followed by vomiting is typical of “surgical” conditions, such as acute pancreatitis, cholecystitis, appendicitis, perforated viscus, renal colic, or intestinal obstruction. Patients should be asked about recent changes in medications, food ingestion, viral symptoms, or similar illnesses in family members.

On physical examination, evidence of volume depletion should be sought. Abdominal distention suggests ileus or intestinal obstruction. A succussion splash may be present with gastric outlet obstruction or gastroparesis. The presence of severe abdominal pain or tenderness or signs of peritoneal irritation is indicative of a surgical condition and warrants urgent attention (Chapter 87). Hernial orifices and surgical scars should be carefully examined. Neurologic and fundoscopic examinations are mandatory to screen for increased intracranial pressure.

A complete blood cell count and values for electrolytes, glucose, liver chemistries, blood urea nitrogen, creatinine, and amylase should be obtained. Leukocytosis may suggest a “surgical” cause of vomiting but is also seen with viral gastroenteritis. Elevated liver chemistries or amylase may indicate hepatitis, cholecystitis, choledocholithiasis, or pancreatitis. A metabolic acidosis may be caused by renal insufficiency, adrenal insufficiency, and diabetic or alcoholic ketoacidosis. Prolonged vomiting may result in hypokalemia, metabolic alkalosis, hyponatremia or hypernatremia, and prerenal azotemia. In menstruating women, levels of urinary or serum β -HCG (human chorionic gonadotropin) should be determined.

A flat and upright abdominal radiograph should be obtained in patients with severe pain or in whom mechanical obstruction is suspected to look for free intraperitoneal air or dilated loops of small bowel. Aspiration of more than 200 mL of residual material via nasogastric tube in a fasting patient suggests gastric outlet obstruction, proximal small-bowel obstruction, or gastroparesis. The cause of gastric outlet obstruction is best determined by upper gastrointestinal endoscopy. In patients in whom mechanical obstruction is excluded by endoscopy or upper gastrointestinal series, gastroparesis can be demonstrated by a nuclear scintigraphic study showing delayed gastric emptying. Suspected pancreaticobiliary disease can be investigated with abdominal ultrasonography, CT, or endoscopic retrograde cholangiopancreatography (ERCP). Central nervous system symptoms warrant evaluation with magnetic resonance imaging (MRI) of the head.

Management

Management of the patient with vomiting is directed at the underlying disorder. Most cases of acute vomiting caused by infections or food poisoning are mild and self-limited, and they require no specific treatment. In patients with

severe vomiting, metabolic alkalosis and hypokalemia can develop. Intravenous (IV) 0.45% saline solution with potassium chloride (20 mEq/L) can be given to maintain hydration. A nasogastric tube for gastric decompression improves patient comfort and permits monitoring of fluid loss.

Medications that inhibit different neural inputs into the vomiting center may be given to control vomiting. Combinations of agents from several drug classes provide greater efficacy with less toxicity (Table 77.3).

When Nausea and Vomiting Appear During Hospitalization

Description and Differential Diagnosis

Vomiting in hospitalized patients has a limited differential diagnosis. The most common cause is ileus, a nonspecific condition associated with a number of medical and surgical conditions (Chapter 88). Most cases resolve within 3–5 days, and persistent symptoms should prompt evaluation for an undrained abscess or systemic infection. A number of medications can cause nausea (Table 77.2 and Chapter 80). Although nausea and vomiting are common in patients receiving chemotherapy or radiation therapy, other causes of vomiting related to malignancy should be considered, including brain metastases, malignant bowel obstruction, and electrolyte imbalances (especially hypercalcemia). Nausea and vomiting can be early symptoms of acute veno-occlusive disease or graft-versus-host disease in transplant recipients (Chapter 96). In immunocompromised patients, vomiting can reflect hepatic or gastrointestinal involvement with opportunistic infections; the presence of headache or central nervous system symptoms suggests meningitis or brain abscesses caused by opportunistic pathogens (Chapter 70).

Evaluation

The hospital course should be reviewed, with particular attention paid to the medication record. A temporal relationship between the initiation of medications and the onset of nausea and vomiting is noteworthy. Physical examination should note the presence of distention, bowel sounds, and focal or diffuse abdominal tenderness. Ileus and mechanical obstruction can be difficult to differentiate in patients in the postoperative period (Chapter 88).

Further evaluation includes complete blood cell count and determination of values for electrolytes, calcium, liver chemistries, and amylase. A flat and upright abdominal plain film helps distinguish ileus from mechanical obstruction. When the diagnosis is in question, a limited barium radiographic study or abdominal CT may be helpful. Imaging with abdominal ultrasonography or CT is also indicated in patients with suspected acalculous cholecystitis or intraabdominal infection. Upper gastrointestinal endoscopy

TABLE 77.3
COMMON ANTIEMETIC REGIMENS

	Dosage	Route
Serotonin (5-HT₃) antagonists		
Ondansetron	Postoperative: 8 mg or 0.15 mg/kg once daily Before chemotherapy: 32 mg 8 mg twice daily	IV IV PO
Granisetron	1 mg or 0.01 mg/kg 2 mg once daily	IV PO
Dolasetron	100 mg or 1.8 mg/kg once daily 100–200 mg once daily	IV PO
Dopamine antagonists		
Prochlorperazine	5–10 mg q4–6h 25 mg suppository every 6–8 hrs	PO, IM, IV PR
Metoclopramide	10–20 mg q6h 0.5–2 mg/kg q6–8h	PO IV
Trimethobenzamide	250 mg every 6–8 hrs 200 mg every 6–8 hrs	PO PR, IM
Antihistamines and anticholinergics		
Diphenhydramine	25–50 mg q4–6h	PO, IM, IV
Scopolamine	1.5 mg q3d	Patch
Sedatives		
Lorazepam	1–2 mg q4–6h	PO, IV
Dronabinol	5 mg/m ² q2–4h	PO

5-HT₃, 5-hydroxytryptamine.

is sometimes performed to exclude peptic ulcer disease and to diagnose opportunistic infections in immunocompromised patients and acute graft-versus-host disease.

Management

The management of vomiting in the hospitalized patient is similar to that for the patient presenting this symptom. The management of intestinal ileus is discussed in Chapter 88.

DIARRHEA

When Presenting at the Time of Admission

Description and Differential Diagnosis

Diarrhea is a common symptom that ranges in severity from a self-limited annoyance to a life-threatening illness. In sorting among the myriad causes, it is helpful to distinguish acute from chronic diarrhea, as the differential diagnosis, evaluation, and treatment are entirely different. With rare exceptions, chronic diarrhea is evaluated on an outpatient basis and therefore is not discussed in this section.

Diarrhea that is acute in onset and persists less than three weeks is most commonly caused by viral or bacterial

infections, bacterial toxins (“food poisoning”), parasites, or medications (Table 77.4). Similar illness in family members suggests an infectious origin. Recent ingestion of improperly stored or prepared food implicates food poisoning, especially if others have been similarly affected. Antibiotic use within the prior 1–2 months increases the likelihood of *C. difficile* colitis. All current medications (including over-the-counter medications), illicit drugs, nutritional and herbal supplements, alcohol, and caffeine should be reviewed, especially those started within the last 8 weeks. A careful travel history should be obtained. In elderly patients, acute cramping abdominal pain followed by bloody stools suggests ischemic colitis. Fecal impaction leading to pseudo-diarrhea should be considered in institutionalized or bedridden patients.

The nature of diarrhea helps to distinguish among different causes.

Noninflammatory Diarrhea

Watery, nonbloody diarrhea associated with periumbilical cramps, bloating, nausea, or vomiting suggests an enteritis caused by either a toxin-producing bacterium or other noninvasive agents that disrupt intestinal absorption or secretion. Prominent vomiting suggests viral enteritis or *Staphylococcus aureus* food poisoning. Although in most cases noninflammatory diarrhea in adults is mild, in some cases (e.g., infection with *Vibrio cholerae*) it leads to volu-

TABLE 77.4
MAJOR CAUSES OF ACUTE DIARRHEA
(LESS THAN 3 WEEKS DURATION)

Infections

Viral: rotavirus, Norwalk virus

Toxin-producing bacteria

—Preformed (ingested) toxin: *Staphylococcus aureus*, *Clostridium perfringens*

—Secretory enterotoxin: *Bacillus cereus*, enterotoxigenic *Escherichia coli*, *Aeromonas*, *Vibrio cholerae*

—Cytotoxin: enterohemorrhagic *E. coli* O157:H7, *V. parahaemolyticus*, *C. difficile*

Invasive bacteria: *Salmonella*, *Shigella*, *Campylobacter*, *Listeria monocytogenes*, *Yersinia enterocolitica*

Parasitic/protozoal: *Giardia*, amebiasis

Immunosuppression and HIV disease: cytomegalovirus, MAC, *Cryptosporidium*, microsporidia, *Isospora*, fungal

Medications

Ulcerative colitis

Ischemic colitis

Fecal impaction

MAC, *Mycobacterium avium* complex.

minous fluid loss and electrolyte imbalance. Because tissue invasion does not occur, fecal leukocytes are not present.

Inflammatory Diarrhea

The presence of fever and bloody diarrhea indicates colonic mucosal disruption as a consequence of direct bacterial invasion or cytotoxin production, inflammatory bowel disease, or ischemic colitis. Because such processes primarily involve the colon, diarrheal volume is small (<1 L/d) and is associated with lower abdominal cramps, urgency, and tenesmus. Although fecal leukocytes commonly are present, they may be absent (Table 77.5). *Escherichia coli* O157:H7, a toxigenic, noninvasive organism that can be acquired from contaminated beef or unpasteurized juice, has caused outbreaks of acute, often severe hemorrhagic colitis. It is the most common cause of infectious bloody diarrhea in adults and the most common cause of hemolytic uremic syndrome in children. In patients who have AIDS or are otherwise immunocompromised, cytomegalovirus infection can result in intestinal ulceration with watery or bloody diarrhea.

Enteric Fever

A severe systemic illness manifested by high fevers, confusion, and respiratory symptoms followed by abdominal tenderness, diarrhea, and rash can be caused by infection with *Salmonella typhi* or *S. paratyphi* and result in bacteremia and multiple organ dysfunction.

Evaluation

More than 90% of cases of acute diarrheal illness are mild and self-limited, responding within 5 days to simple rehy-

dration therapy or antidiarrheal drugs. In such cases, laboratory investigation is unnecessary because it usually is unrevealing and does not affect outcome. The isolation rate of pathogens from stool cultures is less than 3%. The goal is to distinguish patients with mild self-limited disease from those with serious illness. Patients with mild illness at presentation can be treated symptomatically without further stool studies or culture. If diarrhea persists or fails to improve within 10 days, stool should be sent for culture and ova and parasite evaluation.

Patients with signs of more severe illness manifested by any of the following require more aggressive evaluation: high fever ($\geq 38.5^\circ\text{C}$), bloody diarrhea, significant abdominal pain, and signs of volume depletion, tenesmus, or prolonged illness. Hospitalization is required for severe dehydration, abnormal mental status, suspected bacteremia, or marked abdominal pain. Peritoneal findings may signify the presence of enterohemorrhagic *E. coli* O157:H7 infection (patients are usually afebrile), enteric fever, or fulminant ulcerative colitis. An abdominal radiograph should be obtained in such patients to look for evidence of megacolon, perforation, or colonic thickening. Approximately 50% of patients with bloody or severe diarrhea requiring hospital admission have positive stool cultures for bacterial or parasitic pathogens.

Microscopic examination of the stool for fecal leukocytes is an easy, inexpensive test that helps distinguish inflammatory from noninflammatory diarrhea (Table 77.5). The presence of fecal leukocytes suggests an infectious diarrhea that warrants stool bacterial culture and ova and parasite determination, although results are sometimes positive in inflammatory bowel disease or ischemic colitis. Patients with mild-to-moderate diarrhea whose stool is negative for fecal leukocytes can be treated symptomatically.

TABLE 77.5

Noninflammatory diarrheas: fecal WBCs absent

Viral: rotavirus, Norwalk agent

Protozoal: *Giardia*, *Cryptosporidium*, *Cyclospora*, *Isospora*

Bacterial: *Staphylococcus aureus*, *Bacillus cereus*, *Clostridium perfringens*, enterotoxigenic *Escherichia coli*, *Vibrio cholerae*

Inflammatory diarrheas

1. Fecal WBCs usually present

Bacterial: *Shigella*, *Campylobacter jejuni*

Noninfectious: ulcerative colitis, Crohn's disease, radiation or ischemic colitis

2. Fecal WBCs variably present

Bacterial: *Salmonella*, *Yersinia enterocolitica*, *Vibrio parahaemolyticus*, *Aeromonas*, *Listeria monocytogenes*, *E. coli* O157:H7, *C. difficile*

3. Fecal WBCs absent: amebiasis, cytomegalovirus

WBC, white blood cell.

In most patients with severe acute diarrhea, the findings of flexible or rigid sigmoidoscopy are nonspecific and add little to the initial assessment. Infectious colitis cannot be distinguished from ulcerative colitis by sigmoidoscopy. In suspected ischemic colitis, the presence of sigmoid colitis with a normal-appearing rectum (rectal sparing) confirms the diagnosis. Sigmoidoscopy also can be helpful in assessing patients with symptoms of proctitis (tenesmus, rectal pain, bloody discharge), in which mucosal abnormalities are confined to the anorectum.

Management

Fluids and Diet

The majority of patients with mild acute diarrhea can be treated conservatively with oral fluids containing carbohydrates and electrolytes. Patients generally find it more comfortable to rest the bowel by avoiding high-fiber foods, fats, milk products, caffeine, and alcohol. However, oral intake of fluids and soft foods should be encouraged. In severe diarrhea, volume depletion can occur quickly, especially in children and the elderly. Oral rehydration is preferred to IV fluids because it is inexpensive, safe, and highly effective. Oral electrolyte solutions (e.g., Pedialyte) are commercially available. Fluids should be given at a rate of 50–200 mL/kg daily depending on hydration status. IV solutions may be necessary initially in patients with severe dehydration.

Symptomatic Therapies

Antidiarrheal agents can be used safely in mild diarrheal illness. Opioids reduce stool number and liquidity and control rectal urgency. They should not be used in patients with signs of severe colitis (high fever, severe pain, significant bleeding, tenderness) because of the possibility of exacerbating the illness. Loperamide is preferred because it does not cross the blood–brain barrier (4 mg initially, then 2 mg after each bowel movement; maximum, 16 mg/24 h). Bismuth subsalicylate (two tablets or 30 mL four times daily) is an effective treatment for diarrhea because of its antiinflammatory and antibacterial actions. Anticholinergics are contraindicated in acute diarrhea because they may (rarely) cause megacolon.

Antibiotic Therapy

Because more than 90% of patients with acute diarrhea have self-limited disease, empiric antibiotic treatment of all patients with acute diarrhea is not warranted. The exception to this is *traveler's diarrhea*, in which empiric treatment with loperamide and an antibiotic (trimethoprim-sulfamethoxazole or a fluoroquinolone) for 3–5 days markedly curtails the period of diarrhea. However, in patients with moderate-to-severe fever, bloody stools, or severe diarrhea, empiric treatment is recommended while stool bacterial cultures are pending. The choice of antibiotics depends on known local sensitivity patterns. The duration of treatment has not been

well defined, but five days is adequate in most cases. For patients with diarrhea and positive stool cultures, antibiotics are not recommended for nontyphoidal *Salmonella*, *Campylobacter*, *Aeromonas*, *E. coli* O157:H7, or *Yersinia* infection (except in severe or prolonged disease) because such therapy has not been shown to hasten recovery or reduce the period of fecal bacterial excretion.

When Diarrhea Appears During the Hospitalization

Description and Differential Diagnosis

Diarrhea is a common problem in hospitalized patients, occurring in up to 40% of patients in the ICU setting. Although many cases are mild, diarrhea can complicate nursing care, compromise nutrition by interfering with the administration of enteral feeds, and disturb fluid and electrolyte balance. Nosocomial diarrhea is associated with an increased incidence of other nosocomial infections, increased mortality, longer hospital stays, and higher hospital costs.

Diarrhea developing within the first three hospital days may be caused by any of the factors previously discussed. Thereafter, infectious diarrheas (other than those associated with *C. difficile*) are rare except in immunocompromised patients. The most common causes of diarrhea in the hospitalized patient are the following:

Antibiotic-Associated Diarrhea

Antibiotics account for more than half the cases of nosocomial diarrhea. In the majority of these cases, no pathogen can be identified. Alterations in colonic flora caused by antibiotics can lead to a decrease in colonic bacterial fermentation of fecal carbohydrates, resulting in an osmotic diarrhea, or to an increase in luminal fatty acids, resulting in secretory diarrhea.

Approximately 20% of cases of antibiotic-associated diarrhea are attributable to infection with *C. difficile*. It is estimated that 20% of hospitalized patients become colonized with *C. difficile*, and most remain asymptomatic. Standard infection control procedures, with hand washing between examinations and enteric precautions for patients with known infection, are important in preventing the nosocomial spread of *C. difficile*. Although most antibiotics have been associated with *C. difficile* disease, third-generation cephalosporins, ampicillin, and clindamycin are most commonly implicated. *C. difficile* is the major cause of nosocomial diarrhea, affecting between 1 in 100 and 1 in 1,000 persons receiving parenteral antibiotics. Most have mild-to-moderate watery diarrhea with lower abdominal cramps or tenderness. In a subset of patients, more severe colitis develops. The serum white blood cell count may be extremely high. Although some blood may be present, grossly bloody stools are unusual. Fulminant, life-threatening colitis characterized by lethargy, fever, tachycardia, abdominal pain, and distention occurs in a small number of

patients. Complications include hypovolemia, hypoalbuminemia from mucosal protein loss, and toxic megacolon. The development of toxic megacolon with paralytic ileus can result in a paradoxical decrease in diarrhea.

Enteral Feedings

Diarrhea occurs in more than one-fourth of patients receiving enteral feedings. Causes include high osmolality of the solution, rapid rate of infusion, intestinal ileus with rapid transit, intestinal villous atrophy with malabsorption, hypoalbuminemia, and bacterial contamination.

Other Infections

In immunosuppressed patients, diarrhea can be caused by infection with cytomegalovirus, fungi, or *Cryptosporidium*.

Other Causes

Milk is included routinely in hospital diets, despite a high prevalence of lactose intolerance. Medications administered in the hospital can cause diarrhea. Fecal impaction with pseudo-diarrhea occurs in patients with prolonged constipation. The acute onset of cramping abdominal pain followed by bloody stools should suggest the possibility of ischemic colitis in elderly patients. Chemotherapy may result in diarrhea beginning within 3–10 days of treatment. Acute graft-versus-host disease occurs after allogeneic bone marrow transplants and is manifested by skin rash, jaundice, abdominal pain, and profuse diarrhea.

Evaluation

A stool assay for *C. difficile* cytotoxin and an assessment of fecal leukocytes should be performed in all patients. Fecal leukocytes are present in more than half of patients infected with *C. difficile*, especially those with severe or pseudomembranous colitis. One negative cytotoxin test result does not exclude the diagnosis, as the sensitivity is only 80% when the first stool sample is examined.

Sigmoidoscopy is not helpful in most patients with nosocomial diarrhea. In patients with mild *C. difficile*-associated diarrhea, the mucosal appearance is usually normal. However, in cases of severe disease, there is a patchy or diffuse colitis with or without pseudomembranes. Therefore, in a patient who has profuse diarrhea or signs of toxicity but whose stool test result is negative for *C. difficile*, flexible sigmoidoscopy should be performed and the patient treated presumptively for *C. difficile* infection if colitis is found. In 10% of cases of severe *C. difficile*-associated colitis, mucosal changes are confined to the proximal colon and are missed by sigmoidoscopy. Sigmoidoscopy also helps diagnose ischemic colitis or cytomegalovirus colitis.

Evaluation for other causes of nosocomial diarrhea should be pursued after *C. difficile* infection has been excluded. Routine stool cultures should be performed in patients with immunosuppression, AIDS, or persistent diarrhea when fecal leukocytes are present. The medication

list must be reviewed and possible offending agents discontinued. Diarrhea caused by enteral feedings is suggested by the presence of an increased stool osmolality gap (>100 mOsm/L).

Management

Treatment of nosocomial diarrhea is directed at the underlying cause. In mild cases of antibiotic-associated diarrhea, symptoms usually improve without therapy within 2–3 days after discontinuation of the antibiotic. When *C. difficile*-associated diarrhea is persistent or severe, specific therapy is indicated. Metronidazole (250 mg orally four times daily for 10 days) is the drug of choice because of its high efficacy (>95%) and low cost. Diarrhea and fever begin to respond within 24–48 hours and resolve within 5–10 days. Failure to respond may be a consequence of ileus, perforation, or underlying colonic diseases, such as malignancy, inflammatory bowel disease, or ischemic colitis. Although vancomycin (125 mg orally four times daily) is equally effective, its use is discouraged because it is expensive and promotes the development of vancomycin-resistant organisms. It should be restricted to patients who fail initial treatment with metronidazole. Patients unable to take oral medications because of ileus and patients with severe colitis should be treated with IV metronidazole (500 mg every 6 hours) or with vancomycin given via nasogastric tube or retention enema (500 mg in 500 mL of saline solution every 8 hours). Seriously ill patients with fulminant or intractable symptoms may require colectomy for progressive deterioration, peritonitis, or perforation. After initial resolution, symptoms recur in 20% of cases. Most relapses respond to a second course of treatment. With recurrent relapses, prolonged antibiotic treatment with gradual tapering during 1–2 months may be successful.

Diarrhea associated with enteral feedings usually improves after a reduction in the rate of delivery of the enteral solution (Chapter 15). Iso-osmolar feeding solutions may be better tolerated than hyperosmolar formulations; however, further dilution of the enteral formulation is seldom helpful. Although no clear advantage has been demonstrated with formulations that contain extra fiber, they may benefit some patients. No clear benefit has been demonstrated for elemental or short-peptide enteral formulations. Opioids (loperamide or paregoric) can be useful, but should be avoided in patients with *C. difficile* colitis.

HEPATOMEGALY

The best means of determining liver size is ultrasonography or CT. Physical examination is neither sensitive nor specific in the detection of true enlargement. Half of the livers believed to be enlarged on physical examination are of normal size on ultrasonography. A nonpalpable liver with a percussion span of less than 12 cm in the midclavicular line

makes hepatomegaly unlikely. The liver edge is palpable 1–2 cm below the costal margin in approximately one-third of normal adults.

Description and Differential Diagnosis

It is important to distinguish true hepatomegaly from inferior displacement by the right hemidiaphragm. True hepatomegaly can be caused by either focal or diffuse liver disorders. Although this distinction is not always appreciated on physical examination, it is readily established with imaging studies.

Among patients with *diffuse enlargement*, the acute onset of right upper quadrant discomfort is suggestive of hepatic venous congestion or acute hepatitis. Hepatic venous thrombosis (*Budd-Chiari syndrome*) occurs most commonly with hypercoagulable states, renal or hepatocellular carcinoma, and collagen vascular disorders. It can present acutely with right upper quadrant pain and hepatomegaly, or subacutely-to-chronically with hepatomegaly, ascites, and portal hypertension. The presence of hepatomegaly in patients with active alcoholism suggests fatty liver, active hepatitis, or the development of hepatocellular carcinoma. Fatty liver also occurs with obesity or diabetes mellitus. The presence of renal insufficiency and congestive heart failure may suggest amyloidosis. Hemochromatosis can be associated with diabetes and congestive heart failure.

Focal hepatic lesions are caused by cysts, abscesses, and benign and malignant tumors. The presence of fever, right upper quadrant pain, and tender hepatomegaly suggests hepatic abscess. However, some patients present with nonspecific malaise, weight loss, and hepatomegaly. Many abscesses are secondary to biliary disease, intraabdominal infection, or bacteremia, but half have no obvious cause. Amebic abscesses occur in patients with a history of travel to endemic areas. Echinococcosis is rare in the United States, occurring principally in people from sheep-raising regions. Peliosis hepatis is associated with the use of anabolic steroids or with HIV infection and bacillary angiomatosis.

Cavernous hemangiomas, which occur in up to 7% of the population and are almost always asymptomatic, are the most common type of hepatic tumor. Hepatic adenomas occur predominantly in women using birth control pills. Most remain asymptomatic unless complicated by hemorrhage, which can cause a tender right upper quadrant mass or hemoperitoneum. The majority of patients with malignant hepatic tumors lose weight. More than 90% of cases of hepatocellular carcinoma occur in patients with underlying cirrhosis or chronic hepatitis B or C, and in immigrants from Africa or Southeast Asia. Metastatic disease should be suspected in patients with a history of malignancy.

Evaluation

Patients with diffuse hepatomegaly should be asked about any history, symptoms, or signs of liver disease. Comorbid

medical illnesses associated with diffuse hepatomegaly should be considered, including congestive heart failure, obesity, diabetes mellitus, and myeloproliferative disorders. Alcohol intake should be carefully assessed. Medication use should be determined.

Patients with focal hepatic lesions should be asked about fevers or chills and about travel history. A review of systems may suggest malignancy with possible hepatic metastases.

Physical examination should include a careful cardiac examination with a search for evidence of right-sided congestive heart failure. The degree of chest inflation and diaphragmatic excursion should be evaluated to exclude a low-lying liver caused by lung hyperinflation. Diffuse lymphadenopathy suggests lymphoma; regional lymph node enlargement suggests malignant disease with nodal and hepatic metastases. Signs of chronic liver disease should be carefully sought. Evidence of weight loss may point to chronic liver disease or metastatic malignancy. Feces positive for occult blood may indicate underlying gastrointestinal malignancy with hepatic metastases.

The liver size, contour, and texture and the presence of tenderness should be determined. Most diffuse liver disorders result in generalized enlargement. Significant tenderness indicates acute inflammation or acute distention (e.g., hepatic venous congestion). A tender, pulsatile liver is seen in tricuspid insufficiency. Cirrhosis leads to a firm, nontender liver with an irregular, nodular consistency. Depending on their size and location, focal liver lesions may or may not be palpable. Hepatic rubs or bruits occur in fewer than 10% of patients with hepatic tumors. The presence of concomitant spleen enlargement narrows the diagnostic considerations. *Hepatosplenomegaly* is most commonly caused by increased portal venous pressures but is also caused by infections and infiltrative disorders.

The extent of evaluation for hepatomegaly depends on the likelihood of underlying disease. It is reasonable to obtain a complete blood cell count and values for liver chemistries, prothrombin time, albumin, ferritin, iron, and transferrin saturation. When diffuse hepatomegaly is present, hemochromatosis is suggested by transferrin saturation above 50% and elevated ferritin levels. The evaluation of focal liver lesions must first distinguish cystic from solid tumors by means of ultrasonography or CT. Uncomplicated cysts require no further evaluation or treatment. In patients with hepatic abscesses, clinicians must distinguish between pyogenic and amebic infection. More than 90% of patients with amebic abscesses have positive serologic tests for *Entamoeba histolytica*. With pyogenic abscesses, diagnostic aspiration for culture under ultrasonographic or CT guidance is recommended before antibiotics are begun. Most benign liver tumors do not cause any significant abnormalities in liver chemistries. The vast majority of hemangiomas are asymptomatic and identified as incidental findings during the evaluation of abnormal liver chemistries by ultrasonography or CT. In such circum-

stances, they are problematic simply because they must be distinguished from malignant tumors. With metastatic liver disease or hepatocellular carcinoma, elevated alkaline phosphatase is common; however, liver chemistries are normal in half the cases, even in the presence of extensive liver involvement. A marked elevation in lactate dehydrogenase suggests hepatic infiltration by lymphoma or leukemia. Elevated levels of α -fetoprotein are seen in more than 70% of cases of hepatocellular carcinoma, but low levels do not exclude this cancer.

When hepatomegaly is thought to be secondary to hepatic venous congestion or other diffuse liver diseases, ultrasonography is an excellent means of evaluating liver size and excluding focal lesions. It also provides information about the presence of ascites, intra-abdominal varices, and splenomegaly. Ultrasonography with Doppler flow assessment is the preferred screening study to evaluate for hepatic venous thrombosis, and it is also the best study to distinguish cystic from solid liver lesions. Ultrasonography and CT are highly accurate in the diagnosis of hepatic abscess. Abdominal CT has an important role in the evaluation of focal benign or malignant liver lesions. In suspected metastatic disease, chest and abdominal CT may also identify the primary neoplasm. Based on the clinical history and CT or ultrasonographic appearance, most common hepatic focal lesions can be initially and reliably characterized as benign or malignant.

Percutaneous or transjugular liver biopsy is indicated in the evaluation of patients with unexplained diffuse hepatomegaly when the diagnosis cannot be established by other laboratory or imaging tests. Biopsies are particularly helpful in the diagnosis of diseases with diffuse hepatic involvement, such as non-alcoholic steatohepatitis, hemochromatosis, amyloidosis, or Wilson's disease. It also is helpful in the evaluation of patients with unexplained fever (especially the immunocompromised), suspected drug-induced hepatitis, and granulomatous liver disease. Fine-needle biopsy guided by ultrasonography or CT is useful in the evaluation of focal liver lesions.

Management

The extent of further evaluation and management depends on the initial findings and is beyond the scope of this chapter.

ABDOMINAL MASS

When Presenting at the Time of Admission

Description and Differential Diagnosis

An abdominal mass may be noted by the patient or the examining physician. Although the differential diagnosis for such lesions is lengthy, the etiology is determined readily

by history, examination, and imaging with CT or ultrasonography. It is important to distinguish masses within the abdominal wall from those that are intra-abdominal. Causes of abdominal wall masses include hernias, lymph nodes, lipomas, hematomas, and abscesses. Intra-abdominal masses include abscesses, hematomas, aneurysms, enlarged solid organs, and feces.

The following questions help to discriminate among abdominal masses. *How long has the mass been present?* A mass that suddenly appears is suggestive of a hernia, hematoma, or abscess. Hematomas are most common in patients with recent trauma or those who are using anticoagulants. A mass that is increasing in size is worrisome for malignancy, abscess, or pseudocyst. Conversely, one that is unchanged over months-to-years is likely to be benign. *Is tenderness or pain present?* Pain or tenderness suggests an infectious or inflammatory process or distention of a hollow viscus, such as the gallbladder or urinary bladder. Severe pain in the epigastrium or back suggests a ruptured aortic aneurysm. *Is there fever?* If so, an intra-abdominal abscess should be considered. *Are there other constitutional symptoms?* Most patients with a palpable malignancy or abscess report fatigue, malaise, and weight loss. *Are there other gastrointestinal symptoms?* Dysphagia, early satiety, or postprandial vomiting suggests a gastric malignancy. Jaundice may be a sign of malignant biliary obstruction caused by pancreatic carcinoma or cholangiocarcinoma. Chronic diarrhea may be caused by Crohn's disease, or it may be pseudo-diarrhea resulting from a nearly obstructing colonic carcinoma. Severe constipation can cause bulky, pliable abdominal masses.

Evaluation

Abdominal examination should include inspection for bulges, asymmetry, and surgical scars. Masses should be characterized by their location, size, consistency, mobility, pulsation, and the presence of tenderness. Masses within the abdominal wall are superficial and best palpated with a light touch. The linea alba, umbilicus, inguinal and femoral canals, and all surgical scars should be palpated carefully with the abdomen relaxed first and then tensed to look for evidence of hernias. Uncomplicated hernias are minimally tender; significant tenderness is worrisome for incarceration with strangulation. For abdominal wall masses, imaging studies typically are not needed. When uncertainty remains, abdominal ultrasonography or CT definitively characterizes the location.

Examination of intra-abdominal masses is best performed with deep palpation. In patients with a right upper quadrant mass, proper examination can distinguish hepatomegaly (discussed in the previous section) from a dilated gallbladder or renal mass. A soft, palpable, nontender gallbladder is noted with malignant obstruction of the biliary tract by pancreatic carcinoma or cholangiocarcinoma, which results in "painless" jaundice. Epigastric masses may be gastric carcinoma, pancreatic carcinoma, or pancreatic

pseudocyst. Left upper quadrant masses are caused by splenomegaly or renal disorders.

In the left lower abdomen, a nontender, doughy mass suggests a stool-filled colon. A tender mass in either the right or left lower abdomen is suggestive of an abscess from appendicitis or diverticulitis, especially if accompanied by fever. With Crohn's disease, a right lower quadrant mass may be an inflammatory reaction or abscess. Colonic malignancies are seldom palpable or tender upon abdominal examination unless extracolonic invasion is present. A distended urinary bladder may be confused with other abdominal masses; when in doubt, a catheter should be placed to ensure complete urinary drainage. A rectal examination should be performed to look for evidence of tenderness or fluctuance suggestive of abscess. Bimanual pelvic examination is required in all women to examine the uterus, adnexa, and pelvis. Large ovarian cysts may be palpable on abdominal examination and can be confused with an enlarged bladder. On pelvic examination, most ovarian tumors or cysts and uterine fibroids are nontender. The presence of adnexal pain and tenderness points toward a tubo-ovarian abscess or a hemorrhagic cyst. Abscesses felt on pelvic or rectal examination may also be caused by appendicitis or diverticulitis.

Most intra-abdominal masses warrant further evaluation. Laboratory studies should include a complete blood cell count and liver chemistries. A leukocytosis may indicate intra-abdominal abscess. Iron-deficiency anemia points toward a gastrointestinal malignancy with chronic intestinal blood loss. Elevated alkaline phosphatase and bilirubin indicate cholestasis, which can be caused by pancreatic or biliary cancer or metastatic liver disease. For a mass suspected to be stool, an abdominal radiograph confirms the diagnosis, and the mass should disappear after bowel cleansing. In most other patients, imaging with ultrasonography or CT of the abdomen is needed. Ultrasonography is excellent to screen for gallbladder and biliary tract distention, hepatomegaly or splenomegaly, renal cysts, ovarian or uterine cysts or masses, pancreatic pseudocysts, and abdominal aortic aneurysm. In patients in whom an abdominal mass is unequivocally present on examination, abdominal CT is the study of first choice, as it can distinguish between organomegaly, solid tumor, cyst, and abscess.

Management

The management of abdominal masses depends on the etiology and is beyond the scope of this discussion.

When an Abdominal Mass Appears During the Hospitalization

Description and Differential Diagnosis

The majority of abdominal masses that "appear" during hospitalization were present on admission but overlooked.

Therefore, the differential diagnosis is the same as in the patient presenting an abdominal mass. True masses arising *de novo* are unusual. Hematoma of the rectus sheath should be considered in patients receiving anticoagulants or subcutaneous injections. Intra-abdominal abscess should be suspected in patients with tenderness, fever, or leukocytosis. A large bladder secondary to acute urinary retention and a fecal mass secondary to constipation are common occurrences in the hospitalized patient.

Evaluation and Management

The evaluation and management of the hospitalized patient with an abdominal mass are the same as for the patient presenting at the time of diagnosis.

ABNORMAL LIVER CHEMISTRIES

When Presenting at the Time of Admission

Description and Differential Diagnosis

In the evaluation of the patient with possible liver disease, the history and physical examination are routinely supplemented by determination of liver chemistries. Although liver chemistry abnormalities are nonspecific, different types of hepatic and biliary disorders are associated with certain patterns of abnormalities (Table 77.6). By aiding the initial diagnostic impression, these patterns guide the course of subsequent evaluation with laboratory tests, imaging studies, and liver biopsy.

TABLE 77.6

CAUSES OF LIVER CHEMISTRY ABNORMALITIES

Hepatocellular pattern: aminotransferases >8 times normal; alkaline phosphatase <3 times normal (Chapter 82)

Cholestasis pattern: AST <3 times normal; alkaline phosphatase >2–3 times normal

1. Infiltrative liver disorders

Hepatic malignancy, metastatic or primary

Primary biliary cirrhosis

Infections: TB, MAC, *Candida*, other fungal infections, bacillary angiomatosis

Granulomatous hepatitis (drugs, infections, sarcoidosis)

2. Intrahepatic and extrahepatic biliary obstruction (Chapter 84)

Choledocholithiasis

Malignant biliary obstruction: pancreas, ampullary,

cholangiocarcinoma

Benign postoperative stricture

Oriental cholangiohepatitis

Primary sclerosing cholangitis

AST, aspartate aminotransferase; MAC, *Mycobacterium avium* complex; TB, tuberculosis.

Indicators of Hepatocellular Damage

Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are enzymes contained within hepatocytes. Normal serum values of AST and ALT are below 45 IU/L. Although AST can be released from other tissue, such as muscle, ALT is specific for liver injury. An elevation in AST or ALT reflects hepatocellular injury by factors such as viruses, toxins, ischemia, autoimmune disease, and drugs. An enzyme pattern in which the aminotransferase levels are increased to more than eight times normal and the alkaline phosphatase level to less than three times normal is indicative of significant hepatocellular damage. However, many serious causes of chronic hepatocellular injury cause only mild aminotransferase elevation.

The causes of a hepatocellular pattern may be considered according to the level of rise of AST and ALT. A more extensive discussion of the causes and management of acute hepatitis can be found in Chapter 82.

Indicators of Cholestasis

In response to stasis of bile flow, bile duct cells and canaliculi increase the production of alkaline phosphatase, leading to a rise in serum levels. Because alkaline phosphatase also may arise from bone and other organs, γ -glutamyl transpeptidase or 5'-nucleotidase levels are sometimes obtained to confirm the hepatic origin of an increased alkaline phosphatase. A small rise of serum alkaline phosphatase to less than 2–3 times normal is a nonspecific finding that can occur with almost any acute or chronic hepatic or biliary disorder. An increase to more than 2–3 times normal reflects significant cholestasis resulting from extrahepatic biliary tract obstruction, intrahepatic biliary tract obstruction, or infiltrative disorders (see below). The level of rise cannot be used to distinguish among these. Aminotransferase levels also are increased in cholestasis, but usually to less than three times normal.

Bilirubin

Unconjugated (“indirect”) bilirubin is the normal end product of the degradation of heme derived from hemoglobin and liver hemoproteins. Circulating unconjugated bilirubin is taken up by hepatocytes through a carrier-mediated mechanism, conjugated in the endoplasmic reticulum to a glucuronide, and secreted across the canalicular membrane into bile, the rate-limiting step in metabolism.

The serum bilirubin level reflects the amount of bilirubin delivered to the liver, the efficiency of hepatocyte bilirubin clearance, and biliary drainage. In normal persons, the serum bilirubin level is less than 1.2 g/dL, and 95% is unconjugated. An increase in pigment production from hemolysis or a resorbing hematoma leads to an increase in serum unconjugated bilirubin. Conditions that affect hepatocyte function, such as hepatitis, may decrease clearance, so that serum direct bilirubin is significantly increased. Obstruction of one hepatic duct or the presence of infiltrative disorders results in a minimal increase of serum conjugated

(“direct”) bilirubin because of increased excretion by the unobstructed portion of the liver, whereas obstruction of the common bile duct or diffuse hepatic infiltration cause a dramatic rise in bilirubin. With either hepatocellular dysfunction or cholestasis, both direct and indirect bilirubin increase, although the increase in direct bilirubin usually predominates. The levels of direct versus indirect bilirubin are of no value in distinguishing hepatocellular dysfunction from intrahepatic or extrahepatic cholestasis.

Typical Patterns of Alkaline Phosphatase and Bilirubin in Various Conditions

- *More than twofold to threefold rise in alkaline phosphatase with minimal increase in bilirubin:* This pattern is typical of partial biliary tract obstruction, infiltrative liver disorders, or partial biliary tract obstruction.
- *Increase of alkaline phosphatase and bilirubin:* This is most commonly caused by extrahepatic obstruction of the common bile duct by malignancy, postoperative strictures, choledocholithiasis, or sclerosing cholangitis. With choledocholithiasis, the bilirubin level may fluctuate but usually remains below 5 mg/dL; a level above 10 mg/dL is uncommon. Advanced infiltrative liver disorders also may cause a combined increase in alkaline phosphatase and bilirubin.
- *Increase in bilirubin with normal alkaline phosphatase:* An isolated increase in indirect bilirubin may be caused by increased pigment load in cases of hemolysis, recent transfusion, or resorbing hematoma. Gilbert’s disease is an autosomal dominant condition affecting 4% of the population; it is characterized by a mild increase in indirect bilirubin (<5 mg/dL), especially during fasting, sleep deprivation, or illness. Some drugs, such as HIV protease inhibitors, can cause isolated rises in either indirect or direct bilirubin through inhibition of bilirubin uptake or metabolism.

Evaluation

The evaluation of the patient with abnormal liver chemistries begins with a detailed assessment of risk factors for liver disease, including alcohol, intravenous drug use, blood transfusions, and prior hepatitis or jaundice. A record of all medications should be obtained, with special attention given to any started during the previous six months. Obesity and adult-onset diabetes mellitus are significant risk factors for steatohepatitis. A history of inflammatory bowel disease raises suspicion for sclerosing cholangitis. A benign stricture may develop after biliary tract surgery. A family history may raise suspicion of hemochromatosis (diabetes, heart failure), α_1 -antitrypsin deficiency (early-onset chronic obstructive pulmonary disease), or Wilson’s disease (neurologic, psychiatric disease).

Physical examination should note the presence of jaundice and icterus. The acute onset of jaundice with hepatic

tenderness in a patient without a prior history of liver disease suggests acute viral hepatitis A or B, alcoholic hepatitis, toxin exposure, or drugs. The presence of jaundice, right upper quadrant pain, and fever suggests acute cholangitis. An indolent onset of jaundice points toward chronic liver disorders, such as cirrhosis, or extrahepatic duct obstruction by malignancy. Physical findings of chronic liver disease suggest advanced disease, most commonly caused by alcohol or chronic viral hepatitis. Such findings include spider angiomas, palmar erythema, gynecomastia, muscle wasting, asterixis, and evidence of portal hypertension (Chapter 83). Evidence of right-sided congestive heart failure suggests hepatic congestion.

In patients with acute liver disease, a rise in the prothrombin time is an ominous finding indicating significant hepatic failure. Because of the long half-life of albumin (20 days), serum albumin is not a useful indicator of hepatic function in patients with acute hepatitis. In patients with chronic liver disease, an increase in the prothrombin time of more than three seconds above normal or a serum albumin level below 3 g/dL reflects significant liver dysfunction.

The evaluation of the patient with acute hepatitis is reviewed in Chapter 82. In patients with elevated aminotransferases, viral serologies for hepatitis B and C (and hepatitis A, if acute) and iron studies should be ordered. Alcohol, potentially hepatotoxic drugs, and toxins should be discontinued. If the etiology remains in doubt, other serologic tests, including those for antinuclear antibody, α_1 -antitrypsin, and ceruloplasmin, should be obtained. In patients with persistent aminotransferase abnormalities of uncertain etiology or whose physical examination suggests chronic liver disease, an imaging study is appropriate to look for evidence of chronic liver disease and to screen for primary or metastatic malignancy. α -fetoprotein should be determined in all patients with cirrhosis or chronic viral hepatitis to screen for hepatocellular carcinoma. Liver biopsy is indicated to evaluate the severity of chronic viral hepatitis, look for evidence of drug- or toxin-induced hepatitis, confirm alcoholic liver disease, and diagnose autoimmune hepatitis, hemochromatosis, or Wilson's disease.

The first goal in the evaluation of cholestasis is to distinguish, by means of abdominal ultrasonography, infiltrative liver disorders from disorders causing biliary obstruction (Chapter 84). The presence of dilation of the intrahepatic or extrahepatic biliary ducts confirms biliary obstruction. Biliary dilation may not be present in up to 20% of patients with acute biliary obstruction, especially those with cirrhosis. Therefore, if suspicion of an obstructive lesion is high (especially in patients with suspected cholangitis), ERCP should be performed to establish a definitive diagnosis even if ultrasonography does not demonstrate biliary dilation. In patients in whom there is no evidence of biliary obstruction, infiltrative disorders should be considered. Potential toxic medications should

be discontinued. An anti-mitochondrial antibody determination should be obtained if primary biliary cirrhosis is suspected. A liver biopsy usually is required for definitive diagnosis.

Management

The management of patients with liver chemistry abnormalities depends on the underlying etiology. The management of acute hepatitis is reviewed in Chapter 82. Either ERCP or biliary surgery is necessary to relieve extrahepatic biliary obstruction (Chapter 84).

When Liver Chemistry Abnormalities Appear During the Hospitalization

Description and Differential Diagnosis

The development of liver chemistry abnormalities in the hospitalized patient is a common event. Patients with chronic liver disease are susceptible to worsening of hepatic function in response to illness or major surgery. However, most hospitalized patients in whom liver chemistry abnormalities develop do not have underlying liver disease. The differential diagnosis of liver chemistry abnormalities in the hospitalized setting is limited.

Jaundice

The principal causes of jaundice in the hospitalized setting are increased pigment load, postoperative jaundice, multiple organ failure, total parenteral nutrition (TPN), acalculous cholecystitis, and veno-occlusive disease. Jaundice may follow massive transfusion, resorption of large hematomas after surgery, or severe trauma. Provided there is no intrinsic hepatic dysfunction, the serum indirect bilirubin level is increased but other liver chemistry values remain normal. In the patient with chronic liver disease, both direct and indirect bilirubin levels may rise because of the inability of hepatocytes to handle the need for increased bilirubin conjugation and secretion. Another cause of isolated hyperbilirubinemia is Gilbert's syndrome, which may develop in the setting of fasting or physiologic stress.

Jaundice may develop 2–10 days after a prolonged surgical procedure, especially when it has been complicated by hypotension or the need for transfusions. Bilirubin levels may rise from 10–30 mg/dL, with variable increases in alkaline phosphatase or aminotransferase levels. The etiology of postoperative jaundice is multifactorial. Hepatic ischemia caused by abdominal surgery, hypotension, or hepatic congestion associated with congestive heart failure may "stun" hepatocyte function. In the presence of this postoperative dysfunction, an increased pigment load resulting from transfusions or hematomas can cause profound jaundice. Postoperative infections, sepsis, or TPN can contribute to hepatocyte dysfunction and impaired bilirubin metabolism. Although halothane can cause hepatitis, it

now is seldom used, and problems with other inhalational anesthetics are rare. The evaluation of jaundice in the liver transplant patient is discussed in Chapter 85.

Cholestatic jaundice with hyperbilirubinemia and elevated alkaline phosphatase are common in multiple organ system failure and may precede other signs of organ dysfunction, such as acute respiratory distress syndrome (ARDS), hypotension, renal failure, and coagulopathy (Chapter 25). With improved techniques for the administration of TPN, acute hepatic toxicity is unusual in adults. Aminotransferase elevations are common within the first 1–2 weeks of TPN, but these episodes are usually mild and self-limited and require no specific therapy. A rise in alkaline phosphatase and bilirubin occasionally seen after 3–4 weeks of TPN may be attributable to excess total calorie administration or an improper ratio of glucose versus fat (Chapter 15).

Aminotransferase Elevation

Mild-to-moderate rises in aminotransferases in the hospitalized patient usually are caused by medications. The majority of drug reactions are idiosyncratic toxicities that may not develop for weeks to months after initiation of a drug. A causal relationship is often difficult to establish. Hypersensitivity reactions become apparent within 2–10 weeks and are accompanied by fever, eosinophilia, and rash. Marked aminotransferase elevations may be caused by ischemic hepatitis (“*shock liver*”) and usually normalize within one week.

Alkaline Phosphatase Elevation

The most common causes of increase are medications or TPN (discussed on p. 763).

Evaluation

Because chronic liver disease increases the risk for hepatic problems in the hospitalized setting, the prior medical history and risk factors for liver disease should be reviewed. A review of liver chemistries before hospitalization may reveal chronic abnormalities suggesting chronic hepatitis from drugs, alcohol, or virus. All medications taken before and during the hospitalization should be reviewed. The use of TPN should be noted and anesthesia records should be reviewed for episodes of hypotension, intraoperative blood loss, and type of anesthetic used. Review of the hospital record should note episodes of hypotension, sepsis, or arrhythmias that may have precipitated hepatic ischemia, and also the number of blood transfusions.

Physical examination should look for findings of chronic liver disease. Fever and right upper quadrant tenderness may indicate acalculous cholecystitis or sludge-induced cholangitis. In patients with congestive heart failure, tender hepatomegaly may suggest hepatic congestion. Fever with hepatomegaly may indicate infiltrative

fungal or bacterial infections, veno-occlusive disease, or graft-versus-host disease.

In the hospitalized patient with jaundice, the paramount goal is to distinguish “medical jaundice” from obstructive jaundice or acalculous cholecystitis. The former is treated with supportive medical care; the latter requires emergent drainage to preclude cholangitis. Therefore, in patients with an elevated direct bilirubin or alkaline phosphatase level, or in patients with nonspecific liver chemistry abnormalities and fever or leukocytosis, abdominal ultrasonography is vital to look for evidence of acalculous cholecystitis, biliary sludge, or choledocholithiasis. In patients with a cholestatic profile suggestive of infiltrative infection, a liver biopsy may be necessary.

Management

For patients with jaundice resulting from transfusions, surgery, or multiple organ failure, therapy is supportive. The jaundice *per se* is of no consequence and resolves gradually. When possible, TPN should be discontinued and enteral feedings begun at the earliest opportunity. Acalculous cholecystitis is discussed in Chapter 84. The management of drug-induced hepatitis associated with hypersensitivity or idiosyncratic reactions depends on the particular drug and the severity of the reaction. The drug should be discontinued in the presence of a hypersensitivity reaction (fever, eosinophilia), symptomatic hepatitis (malaise, fatigue, nausea, vomiting, jaundice), or aminotransferase levels persistently above three times normal values.

KEY POINTS

- Abdominal pain in the hospitalized patient is usually caused by physiologic stress (e.g., mesenteric ischemia), postsurgical or procedural complications, or *Clostridium difficile* colitis.
- In patients with acute vomiting, it is important to distinguish between “medical” and “surgical” causes.
- The fecal leukocyte test often helps separate noninflammatory from inflammatory causes of diarrhea.
- The physical examination for hepatomegaly is unreliable. Imaging studies may be needed to confirm the finding and to differentiate focal from diffuse hepatomegaly.
- Abnormal liver chemistries should be categorized as indicative of hepatocellular damage or of cholestasis.

Acute Gastrointestinal Bleeding

78

Jonathan P. Terdiman **Peter K. Lindenauer**

INTRODUCTION

Acute gastrointestinal bleeding is a common medical condition, accounting for some 350,000–500,000 admissions to acute care hospitals in the United States each year. Overall hospitalization rates and mortality rates for gastrointestinal bleeding have not changed over the past decade. Bleeding can occur in the upper or lower gastrointestinal tract. *Upper gastrointestinal bleeding* is defined as bleeding from the esophagus, stomach, and duodenum. *Lower gastrointestinal bleeding* occurs from a site distal to the duodenum, the most common being the colon. The majority of patients with gastrointestinal bleeding have a self-limited illness and uncomplicated hospital stay. Many patients are admitted to or remain in the hospital despite this very low risk for a poor outcome. However, a sizable minority of patients have further bleeding and complications. Rapidly distinguishing between low- and high-risk patients is essential if care is to be appropriate and cost-effective.

The annual incidence of upper gastrointestinal bleeding is approximately 150 per 100,000 adults in Western populations, affecting twice as many men as women. Upper gastrointestinal bleeding is very common in the elderly; a 20–30 fold increase in incidence is seen between the third and ninth decades of life. Likely as a consequence of this, most patients who present with upper gastrointestinal bleeding are found to have comorbid medical conditions that can play a key role in determining outcome. Between 5%–25% of patients with acute upper gastrointestinal bleeding are already hospitalized for the treatment of another illness.

Lower gastrointestinal bleeding requiring hospitalization is becoming more common, although it is still not as

common as upper gastrointestinal bleeding. The annual incidence has previously been reported at approximately 20 per 100,000 adults, but more recent reports place the figure at upwards of 100 per 100,000. Lower gastrointestinal bleeding is slightly more common in men and is overwhelmingly a disease of the elderly. The incidence of lower gastrointestinal bleeding increases more than 200-fold from the third to the ninth decade of life. In approximately 5% of cases, lower gastrointestinal bleeding occurs after hospital admission for another diagnosis.

Gastrointestinal bleeding stops spontaneously in approximately 80% of patients. However, both upper and lower gastrointestinal bleeding can result in considerable morbidity and mortality. The majority of patients with gastrointestinal bleeding require blood transfusions, and 2%–10% of patients require urgent surgery to arrest uncontrolled hemorrhage. The average length of stay varies but in general is approximately 4–7 days. Mortality rates between 2%–10% have recently been reported for patients admitted with gastrointestinal bleeding, translating into an overall mortality rate of approximately 20 per 100,000 in the general population. The mortality rate of patients in whom bleeding develops after admission to the hospital for another reason is over 20%.

Average hospital costs for gastrointestinal bleeding are more than \$5,000, with an estimated annual expenditure of more than \$2 billion in the United States. Most of the costs incurred are for hospital or ICU stays rather than for physician fees, blood products, medications, or diagnostic tests. Thus, a reduction in the rate of hospital admissions and length of stay has the greatest potential to reduce costs related to gastrointestinal bleeding.

DIAGNOSTIC AND THERAPEUTIC MODALITIES

A great deal of information about diagnosis and prognosis in patients with gastrointestinal bleeding can be obtained by a rapid and directed medical history, physical examination (including a rectal examination), nasogastric tube lavage, and simple laboratory evaluation. The information obtained from these simple steps can determine, with good accuracy, whether the source of bleeding is in the upper or lower gastrointestinal tract; it can also be used to gauge the severity of the event and to guide triage and the use of diagnostic tests and therapies. Key diagnostic tests employed in the patient with gastrointestinal bleeding are endoscopy, including esophagogastroduodenoscopy (EGD), sigmoidoscopy, and colonoscopy; technetium (Tc) 99m red blood cell scintigraphy (RBC scan); and mesenteric angiography. Other, less commonly employed diagnostic tools include barium radiographs, computed tomography (CT), magnetic resonance imaging (MRI), small-bowel endoscopy (enteroscopy), capsule endoscopy, and sodium pertechnetate (Tc) 99m scintigraphy (Meckel's scan).

A number of therapeutic modalities are also available. Ongoing bleeding can be terminated by a variety of invasive techniques, the most common of which involves the endoscopic delivery of hemostatic therapy. In nonvariceal hemorrhage, endoscopic therapy can be accomplished by thermal contact methods (heater probe, multipolar electrocoagulation) or by injection of the site of bleeding with a variety of substances, including dilute epinephrine and sclerosing agents such as alcohol. Less common forms of endoscopic therapy include injection of thrombin or fibrin glue, placement of hemostatic clips, argon plasma coagulation, or laser coagulation of bleeding lesions. Therapy is delivered to actively bleeding lesions, but prophylactic therapy is also delivered to nonbleeding lesions at high risk for rebleeding. In variceal hemorrhage, endoscopic therapy involves the injection of bleeding varices with sclerosing agents such as ethanolamine oleate, tetradecyl sulfate, or sodium morrhuate (sclerotherapy), or the ligation of varices with rubber bands. New forms of endoscopic therapy of variceal bleeding are being developed and include the injection of cyanoacrylate glue. Non-endoscopic therapies for nonvariceal gastrointestinal bleeding include directed intraarterial infusion of vasopressin after diagnostic angiography, embolization of bleeding lesions at angiography, surgical resection, or oversew of sites of bleeding. Refractory variceal hemorrhage can be terminated by the creation of a *transjugular intrahepatic portosystemic shunt* (TIPS). Surgical portosystemic shunting and liver transplant also terminate variceal bleeding, although emergency surgery for portal hypertension is rarely undertaken. Occasionally, balloon tamponade is used to treat ongoing variceal hemorrhage. Until recently, medical therapy was disappointing in its ability to stop ongoing gastrointestinal bleeding or prevent rebleeding. Several recent reports have

demonstrated the efficacy of proton pump inhibitors, and possibly octreotide (a synthetic analog of somatostatin), in the control of nonvariceal bleeding, and the use of somatostatin or octreotide is well established in the treatment of variceal bleeding.

UPPER GASTROINTESTINAL BLEEDING

Issues at the Time of Admission

Upper gastrointestinal bleeding can present in a variety of ways. *Hematemesis*, the vomiting of either red blood or material resembling "coffee grounds," is observed in approximately one-fourth of patients. Another fourth present with *melenas* alone, and a combination of the two is seen in the remaining half. *Hematochezia*, the passage of red stool, generally signifies a source of bleeding distal to the duodenum but is observed in as many as 15% of cases with upper gastrointestinal pathology, typically in the setting of massive hemorrhage. Most patients seek medical attention after witnessing blood in their vomitus or stool, but in some cases bleeding may be discovered only as part of an evaluation of syncope, chest pain, or fatigue.

Before the diagnosis of upper gastrointestinal bleeding can be made, it is important to exclude other causes of hematemesis or melena. These include bleeding from lesions of the oronasopharynx or respiratory tract. A directed history should focus on features that have been shown to predict etiology or influence outcome. Because peptic ulcer disease is the most common cause of upper gastrointestinal bleeding, a prior history of ulcers or dyspepsia should be sought. Other important historical features include portal hypertension, which predisposes patients to esophageal varices; and a history of coughing or retching, which is reported in as many as 50% of patients later found to have Mallory-Weiss tears. Medications and drugs that predispose to bleeding, such as nonsteroidal antiinflammatory agents (NSAIDs), anticoagulants, and alcohol, warrant review.

Other important historical items to review include the character of the bleeding and the presence of active comorbidities. "Red blood" hematemesis is a sign of active bleeding, and studies of prognosis have shown that the risk for rebleeding and death is higher among patients with this presentation than among those who present with "coffee grounds." Cirrhosis is the most important comorbidity to identify because it influences the differential diagnosis and identifies patients more likely to have a poor outcome. Other comorbidities shown to affect outcome adversely include renal failure, disseminated malignancy, cardiac ischemia, congestive heart failure, and sepsis.

Measurement of the vital signs is the most powerful way to evaluate severity of bleeding and lay a framework for appropriate risk stratification. Patients with shock and tachycardia benefit from aggressive resuscitation and early endoscopy. The remainder of the physical examination is of

relatively limited diagnostic value but can identify the presence and severity of comorbid conditions. The patient's overall appearance should be observed for signs of hypoperfusion or stigmata of chronic liver disease. An altered level of consciousness in the setting of upper gastrointestinal bleeding is associated with a high risk for aspiration, and the airway should be protected before endoscopy is performed. However, routine endotracheal intubation for airway protection during endoscopy for severe upper gastrointestinal bleeding does not lower mortality or cardiopulmonary complication rates (including aspiration pneumonia). A brief examination of the oronasopharynx can sometimes disclose a previously unsuspected source of bleeding, and examination of the heart and lungs will identify signs of congestive heart failure, pneumonia, or obstructive lung disease. The abdominal examination should note any focal tenderness, peritoneal irritation, or signs of advanced liver disease, such as ascites, splenomegaly, or caput medusae. The patient's stool should be classified as brown, black, or red. Brown stool can be observed early in the course of upper gastrointestinal bleeding, but as little as 50–100 mL of fresh blood will rapidly render it melanic. Hematochezia, although typically a marker of lower gastrointestinal bleeding, can be observed when intestinal transit times are increased, as in the setting of brisk bleeding.

In patients who present with gross rectal bleeding or melena, but no hematemesis, a nasogastric tube should be placed. The finding of a bloody nasogastric aspirate confirms an upper gastrointestinal source of bleeding and can help identify high-risk patients who might benefit from early endoscopy. A nonbloody aspirate does not rule out an upper gastrointestinal source; as many as 15% of patients have this finding. Nevertheless, the presence of a clear aspirate in a patient with melena is a marker of lower risk.

Resuscitation with isotonic fluids (0.9% saline solution or lactated Ringer's solution), infused at a rate proportional to the degree of hemodynamic instability, should begin as soon as the patient arrives in the emergency department. Patients with any high-risk clinical features, even those who do not require immediate volume replacement or transfusion, should have two peripheral intravenous catheters (≥ 18 gauge) placed in anticipation of rebleeding. Patients who present in shock should receive fluids as rapidly as possible until their hemodynamic status has improved or until complications of volume overload develop. Because cardiac ischemia is a common complication of hemorrhage, the hematocrit should generally be maintained above 25%. Patients with a history of coronary artery disease typically are transfused to maintain the hematocrit above 30%.

Initial laboratory evaluation includes a complete blood cell count, measurement of blood urea nitrogen and creatinine, serum liver chemistries and coagulation studies, and a complete set of serum electrolytes. An additional sample of blood should be sent for typing and cross-matching. Because the initial hematocrit can underestimate the magni-

tude of blood loss, management decisions should not be unduly influenced by its value. In the face of active bleeding, the clinician should anticipate rather than observe the nadir hematocrit and transfuse accordingly. In the setting of acute gastrointestinal bleeding, an elevated prothrombin time usually indicates advanced liver disease and should immediately raise the possibility of variceal hemorrhage. The utility of the routine chest radiograph is limited but may help identify patients with congestive heart failure or those with free air under the diaphragm. Abdominal films should be limited to patients with pain or distention. Because of the high incidence of ischemic complications, all patients 40 years of age or older and those with a history of coronary heart disease or congestive heart failure should undergo electrocardiography.

Indications for Hospitalization and Intensive Care

Historically, all patients with acute upper gastrointestinal bleeding have been admitted to the hospital for observation. Triage decisions have traditionally been based on clinical factors such as age, degree of hemodynamic instability, and character of the bleeding. Diagnostic/therapeutic endoscopy is carried out in the large majority of patients, usually on the day of or day after admission. Recently, this approach has been challenged by several studies in which clinical and endoscopic risk stratification was completed before admission (1, 2). By using such a strategy, it is possible to distinguish between patients who are likely to rebleed and require hospitalization, and those in whom the risk for rebleeding is negligible and who may be eligible for immediate or early discharge. Important clinical risk factors include advanced age, hemodynamic instability (shock or tachycardia), active red blood hematemesis, and major comorbidities such as congestive heart failure, cirrhosis, and end-stage renal disease. Endoscopic markers of high risk include actively bleeding ulcers, ulcers with visible arterial vessels, ulcers with adherent clots, and esophageal varices. Low-risk lesions include ulcers with a clean base, mucosal erosive disorders such as gastritis or duodenitis, and Mallory-Weiss tears (Table 78.1).

In one prospective study, a combination of similar clinical and endoscopic criteria was used to identify patients at low risk for further bleeding who could be safely managed in the outpatient setting. Approximately one-fourth of patients met the criteria and were discharged from the emergency department, and clinically significant rebleeding developed in less than 3% of patients managed in this way (1). An analysis of data from a nationwide audit of upper gastrointestinal bleeding in the United Kingdom estimated that the same strategy might have eliminated the need for admission in as many as 29% of patients (3), and subsequent studies from the United States have confirmed this finding (4). Thus, an initial strategy of immediate endoscopy for all clinically stable patients is warranted whenever this is available.

TABLE 78.1
PREDICTORS OF OUTCOME IN UPPER GASTROINTESTINAL BLEEDING

Clinical predictors of outcome	Endoscopic predictors of outcome
<ul style="list-style-type: none"> • Age >60 y • Hemodynamic instability <ul style="list-style-type: none"> Tachycardia Shock (SBP <100 mm Hg) • Comorbidities <ul style="list-style-type: none"> Cirrhosis Renal failure Metastatic cancer Congestive heart failure Cardiac ischemia Sepsis Encephalopathy • Hematemesis • Coagulopathy 	<ul style="list-style-type: none"> • Low-risk endoscopic findings <ul style="list-style-type: none"> Esophagitis Gastritis Duodenitis Mallory-Weiss tears Clean-based ulcers • High-risk endoscopic findings <ul style="list-style-type: none"> Active bleeding of any lesion Peptic ulcers with visible vessel or clot Esophageal/gastric varices

SBP, systolic blood pressure.

Advanced age, persistent tachycardia, severe anemia, and significant comorbidities all warrant admission to an acute care bed. Where immediate endoscopy is not available to complete risk stratification, admission for all patients with acute gastrointestinal bleeding is recommended. Patients with shock or unstable major comorbidities, especially advanced liver disease, renal failure, congestive heart failure, or cardiac ischemia, and those who require intubation for airway protection should be initially managed in the ICU. Therapeutic endoscopy should be performed when the patient has been fully resuscitated and when life-threatening conditions have been stabilized.

Initial Therapy

Endoscopy is the diagnostic “gold standard” and has been shown to be an effective method of achieving hemostasis and reducing mortality for patients with nonvariceal upper gastrointestinal bleeding (5) (Table 78.2). Endoscopic therapeutic techniques are able to achieve initial hemostasis in 80% of actively bleeding, nonvariceal lesions. Injection and thermal therapies have similar rates of success; a combination of the two modalities may be superior than either alone for patients with spurting hemorrhage.

Newer endoscopic therapies, such as hemostatic clipping, have not yet been convincingly demonstrated to be superior to the standard techniques. With endoscopic sclerotherapy or band ligation, it is also possible to achieve hemostasis in as many as 75%–80% of patients with variceal bleeding. In addition to performing therapeutic functions, endoscopy provides prognostic information that can be used to estimate a patient’s likelihood of rebleeding and mortality (Table 78.3) and assign an appropriate level of care. Population-based studies suggest that the clinical

TABLE 78.2
THERAPEUTIC ENDOSCOPY AND OUTCOME IN UPPER GASTROINTESTINAL BLEEDING

Therapy	Rebleeding odds ratio	Surgery odds ratio	Death odds ratio
Thermal	0.32	0.31	0.67
Laser	0.58	0.58	0.49
Injection	0.23	0.18	0.50
All	0.38	0.36	0.55

Odds ratios refer to the risk for rebleeding, requiring surgery, or dying, when the reference group (i.e., odds ratio of 1 for these negative outcomes) is drawn from similar patients who did not receive therapeutic endoscopy.

Adapted from Cook DJ, Guyatt GH, Salena BJ, et al. Endoscopic therapy for acute nonvariceal upper gastrointestinal hemorrhage: a meta-analysis. *Gastroenterology* 1992;102:139–148, with permission.

outcomes of high-risk patients who undergo endoscopy within 24 hours of admission are superior to those of patients in whom endoscopy is delayed, in great part because of the delivery of endoscopic therapy (6).

In addition, routine performance of a “second look” endoscopy in high-risk patients, may improve outcomes by detecting and treating persistent non-bleeding visible vessels. For patients at lower risk, early endoscopy can reduce the total duration of hospitalization by over 30% (Figure 78.1). This reduction is attributable to the delineation of low-risk features that allow for safe early discharge of patients (7).

Because endoscopy plays a central role in the diagnosis, treatment, and risk stratification of patients with upper gastrointestinal bleeding, early consultation with a skilled endoscopist is recommended for all patients. Consultation should be obtained after the initial resuscitation and evaluation have been completed. In many cases, patients will be found to be suitable candidates for immediate or early endoscopy.

Effective pharmacologic therapy for acute upper gastrointestinal bleeding has been challenging to identify. In recent years, the somatostatin analog octreotide has proved successful in controlling *variceal bleeding*, and may be as

TABLE 78.3

Figure 78.1 Unadjusted length of stay in patients who underwent endoscopy within 1 day of admission and those who did not, stratified by quintile of propensity of undergoing early endoscopy. Within each quintile of patients, length of stay was lower in patients who underwent endoscopy ($p < 0.0001$). (Adapted from Cooper GS, Chak A, Connors AF, et al. The effectiveness of early endoscopy for upper gastrointestinal hemorrhage, a community analysis. *Medical Care* 1998;36:462–474, with permission.)

good as or better than emergency endoscopic therapy for the initial control of bleeding. Its early and empiric use should be considered in patients with known cirrhosis or evidence of advanced liver disease. The combination of endoscopic therapy and octreotide has been demonstrated to reduce rebleeding rates better than either modality alone (8). The standard dose of octreotide is a 50-mg intravenous bolus followed by a continuous infusion at 50 mg/h. All patients found to have a variceal source of bleeding at endoscopy should remain on octreotide for 48–72 hours. The benefits of octreotide may extend beyond patients with varices to all those with nonvariceal upper gastrointestinal bleeding. In a meta-analysis, it appeared that the use of octreotide reduced rates of rebleeding by 27%–47% (9). These findings have not yet translated into widespread changes in clinical practice.

Despite numerous randomized controlled trials attesting to their ineffectiveness in the management of acute bleeding, H_2 receptor antagonists continue to be commonly used in this setting. *The use of these agents is not warranted.* However, proton pump inhibitors (PPIs) have become standard therapy for patients with high-risk upper gastrointestinal bleeding. Recent studies have demonstrated that the use of intravenous, or high dose oral, PPIs is effective at reducing rates of rebleeding, decreasing the need for blood transfusions, and decreasing length of hospital stay. Moreover, PPIs are cost-effective when used in patients that have received endoscopic therapy for nonvariceal bleeding (10, 11).

Both freshly frozen plasma and platelet concentrates are commonly used in the management of selected patients with upper gastrointestinal bleeding, but their efficacy is unproven. In general, patients with active bleeding and a significant coagulopathy should receive vitamin K and

freshly frozen plasma to reduce the prothrombin time to less than 1.5 times the midpoint of the institutional control. Patients with coagulopathy in the setting of advanced liver disease should receive vitamin K parenterally. Platelet transfusions should be reserved for actively bleeding patients who have platelet counts of less than $50,000/\mu\text{L}$ or have taken irreversible platelet inhibitors within three days of the bleeding episode. For details of managing coagulopathy, see Chapter 98.

Issues During the Course of Hospitalization

Determining the Need for Continued Hospitalization

Bleeding ceases spontaneously in 70%–80% of patients, but rebleeding remains a serious problem for a significant minority. Determining the need for continued hospitalization after the resolution of the initial episode of bleeding should be based on the patient's expected probability of rebleeding or death and on the management of any active comorbid conditions. A simplified scoring system based on clinical and endoscopic variables that can be used to predict rebleeding and mortality has been developed (Table 78.4 and Figure 78.2).

TABLE 78.4
SCORING SYSTEM FOR PREDICTING REBLEEDING AND MORTALITY

Variable	Score

Selection of patients for early discharge or outpatient care after acute upper gastrointestinal haemorrhage. *National Audit of Acute Upper Gastrointestinal Haemorrhage. Lancet* 1996;347:1138–1140, with permission.)

A growing body of literature has shown that treatment guidelines or clinical care pathways that incorporate the early discharge of stable patients with a low risk for rebleeding significantly reduce length of stay, save money, and do not lead to increased adverse outcomes (12, 13). An example of a guideline that combines local expertise and an evidence-based approach is shown in Table 78.5.

Refeeding

Patients should receive nothing by mouth until an endoscopy has been performed. Those found to have low-risk lesions can resume a normal diet immediately, whereas patients with moderate- or high-risk lesions should continue to have nothing by mouth for 24–48 hours.

Identification and Management of Rebleeding

A high degree of vigilance is required to detect rebleeding, because there may be a long delay between its onset and the appearance of overt blood. New hematemesis always indicates rebleeding and should prompt immediate action. In contrast, melena may persist for several days following an initial episode of bleeding. Marked changes in blood pressure, the development of tachycardia, or an unanticipated

decline in the hematocrit should prompt repeat nasogastric aspiration and generally a repeat endoscopy. The effectiveness of repeat endoscopy in patients with rebleeding peptic ulcers has been demonstrated, with repeat endoscopy leading to durable hemostasis in 75% of patients, reduced need for surgery, and reduced complication rates compared with an operation at the first episode of rebleeding. Nevertheless, surgical intervention is required in 2%–10% of patients with gastrointestinal bleeding. Surgical consultation is mandatory whenever rebleeding has been detected because of the high risk for serious complications.

Discharge Issues

Most patients with acute gastrointestinal bleeding will be suitable for discharge within 1–4 days following admission. Rebleeding and cardiopulmonary complications of bleeding, such as myocardial infarction or aspiration pneumonia, can significantly prolong the hospital course. Once bleeding has resolved, hemodynamic status has returned to normal, and the risk for rebleeding has fallen to an acceptable level, patients can be safely discharged provided that other comorbidities are stable. Melena in the absence of other signs of rebleeding is not an indication for continued hospitalization.

TABLE 78.5
CLINICAL AND ENDOSCOPIC RISK STRATIFICATION AND TRIAGE FOLLOWING ENDOSCOPY

	Moderate	48 h observation ^c	48–72 h observation ^c	ICU observation (48–72 h hospitalization)
	High	ICU observation (72 h hospitalization)	ICU observation (72 h hospitalization)	ICU observation (72 h hospitalization)

AVM, arteriovenous malformation.

^aMajor comorbid diseases include ischemic heart disease, CHF, acute renal failure, sepsis, disseminated malignancy, altered mental status, pneumonia, COPD/asthma.

^bPatients may be discharged following 23 hours of observation if there is no evidence of rebleeding, vital signs are normal, there is no further need for transfusion, and the hematocrit has remained stable at the target range.

^cIn general, the same criteria for discharge as noted above hold true. Given the moderate risk for rebleeding, current standard of practice is to observe these patients for a period longer than 24 hours.

Most patients are able to return home following acute gastrointestinal hemorrhage and can resume normal activities as tolerated. Patients discharged with anemia should be advised that they may experience fatigue and dyspnea on exertion for several weeks following discharge and may benefit from iron replacement. Patients should be instructed to contact their primary care physician or return to an emergency department if hematemesis recurs or if they notice hematochezia or melena. Routine follow-up with the primary care physician should be scheduled within 1–2 weeks, depending on the patient’s overall functional status.

Measures to prevent recurrent variceal bleeding and treat peptic ulcers and erosive mucosal disorders should be addressed at the time of discharge. Both nonselective β-blockers and a combination of β-blockers with long-acting nitrates have proved effective for the secondary

prevention of variceal bleeding. Patients with documented peptic ulcers should undergo biopsy or serologic testing for *Helicobacter pylori* infection and should be treated according to current regimens, since this has been demonstrated to reduce rates of future bleeding (Chapter 80). Patients should be counseled to avoid NSAIDs and aspirin-containing compounds and to abstain from alcohol. Proton pump inhibitors or misoprostol should be given to patients who must resume NSAIDs or aspirin to prevent ulcer recurrence, although neither therapy is entirely effective. Alternatively, NSAIDs that selectively inhibit cyclooxygenase-2 (COX-2) (e.g., celecoxib, rofecoxib) appear to cause fewer gastrointestinal problems than do traditional NSAIDs, but their use can still lead to gastrointestinal hemorrhage. Recent concerns about cardiac toxicity should also be factored into decision-making regarding COX-2 inhibitors (14).

LOWER GASTROINTESTINAL BLEEDING

Issues at the Time of Admission

Hematochezia is characteristic of lower gastrointestinal bleeding. Unfortunately, the presence or absence of hematochezia cannot be used to distinguish upper from lower gastrointestinal bleeding with certainty (see p. 768). Although melena usually implies a source of bleeding in the upper tract, it can occur when the source of bleeding is in the small bowel and occasionally when the source is in the right side of the colon.

The majority of episodes of lower gastrointestinal bleeding are painless, though mild lower abdominal cramps may accompany the passage of bloody stool. Painless bleeding is the norm with diverticula, vascular ectasias, neoplasms, and hemorrhoids. Marked abdominal pain and tenderness can occur when bleeding occurs in the setting of ischemia, as in ischemic colitis, or in association with bowel inflammation, as in an infectious colitis or inflammatory bowel disease.

Because the distinction between upper and lower gastrointestinal bleeding is not always possible at initial presentation, the initial approach to management is the same for all patients. Rapid evaluation of hemodynamic status is mandatory, and prompt volume replacement is essential. Patients with abnormal vital signs or with evidence of ongoing blood loss based on the continuing passage of blood per rectum require placement of a minimum of two large-bore peripheral intravenous catheters. As with upper bleeding, volume replacement with isotonic crystalloid solutions should commence immediately, and blood products should be infused as soon as they become available to correct any significant laboratory abnormalities. Recommendations with respect to the appropriate use of blood products are the same as for upper gastrointestinal bleeding.

During the initial resuscitation of the patient, a directed medical history should be taken and physical examination performed. The initial vital signs and the response of the vital signs to the initial resuscitative efforts are the most important determinants of the severity of the bleed. The patient should be asked about hematemesis, the location of any abdominal pain, and any previous history of gastrointestinal disease or hemorrhage, as this information may suggest the diagnosis and lead to a consideration of bleeding in the upper tract. It is important to inquire about past abdominal operations, especially previous repair of an abdominal aneurysm, as *aortoenteric fistula* is a rare but often fatal cause of lower gastrointestinal bleeding. As in patients with bleeding from the upper tract, the remainder of the history should be directed toward identifying active comorbid conditions that can complicate the hospital course. A complete list of medications should be obtained. During the physical examination, the clinician should look for evidence of decompensated cardiopulmonary and liver

disease, and the abdomen should be observed to determine if any significant focal tenderness or other abnormalities are present. Initial laboratory evaluation should be the same as for the patient with upper gastrointestinal bleeding, and a specimen should be sent to the blood bank for typing and cross-match. Bleeding caused by an inflammatory process is often associated with an elevated leukocyte count. Abdominal radiographs are not needed unless significant abdominal tenderness is present on physical examination.

A nasogastric tube aspirate should be obtained in all patients with clinically important bleeding in an attempt to distinguish upper from lower tract bleeding, even if the only overt manifestation of bleeding is hematochezia. A positive nasogastric aspirate for blood should trigger an endoscopic evaluation of the upper gastrointestinal tract. A negative nasogastric aspirate does not rule out an upper gastrointestinal bleed, although the presence of bile (without blood) makes an upper source very unlikely. Many experts support the rapid performance of upper gastrointestinal endoscopy in patients presenting with shock regardless of the results of nasogastric tube aspiration, especially in circumstances in which an operation is planned to treat lower tract bleeding when the site of bleeding has not been definitively identified.

In a patient presenting with hematochezia, careful inspection of the anorectum by digital examination and anoscopy is important. The examination may demonstrate a bleeding lesion, such as hemorrhoids or an anal fissure, which often can be treated at the bedside. Even if an anorectal source of bleeding is identified, most experts still recommend a complete evaluation of the lower gastrointestinal tract, although this may be performed electively.

Use of a flexible sigmoidoscope as part of the initial evaluation of patients presenting with clinically important hematochezia is widely recommended but is practiced routinely at few hospitals. It is unclear if the routine performance of urgent sigmoidoscopy at presentation would reduce admission rates and otherwise alter outcomes.

The list of possible sources of lower gastrointestinal bleeding is long, but colonic diverticulosis is the most common source and accounts for 20%–50% of cases. Other common sources of bleeding are colonic vascular ectasias, colonic neoplasms, colonic ulcers, colitis, and hemorrhoids. Small-bowel sources of bleeding are rare, accounting for fewer than 10% of cases of lower gastrointestinal bleeding.

Indications for Hospitalization and Intensive Care

Clinical risk stratification for patients with lower gastrointestinal bleeding is not as well defined as it is for those with upper gastrointestinal bleeding. A recent study identified seven clinical features that were predictive of severe lower gastrointestinal bleeding; tachycardia, low systolic blood

pressure, syncope, nontender abdominal examination, bleeding per rectum during the first four hours of evaluation, aspirin use, and more than two active comorbid conditions (15). In up to 80% of cases of bleeding from the lower tract, the bleeding stops spontaneously and does not recur. Outpatient evaluation of patients with self-limited hematochezia is possible if there is no evidence of hypovolemia. Anemia alone does not necessitate hospitalization if it seems likely that the blood loss has been chronic and the present transfusion requirement is not great. All patients with abnormal vital signs or who continue to pass blood per rectum require hospitalization. Hospitalization also is appropriate for patients with significant abdominal pain, tenderness, or fever, and for patients with active comorbid medical conditions. All patients with a history of previous aortic surgery should be hospitalized, even if it appears that the bleeding has stopped, as an aortoenteric fistula may present with a self-limited "herald" bleed before an exsanguinating hemorrhage. The indications for hospitalization in patients with hematochezia are summarized in Table 78.6.

A subset of patients with lower gastrointestinal bleeding requires ICU admission. Patients in shock and or with massive hematochezia should be admitted to the ICU initially. The severity of other comorbid conditions should be taken into account during triage decisions.

Diagnosis

In light of the possible difficulties of distinguishing upper from lower gastrointestinal bleeding on clinical grounds, upper gastrointestinal endoscopy should be performed if any doubt remains, especially in the setting of a clinically severe bleed. Unfortunately, there is presently no standardized diagnostic and therapeutic approach to the patient with clinically important lower gastrointestinal bleeding. The specific diagnostic sequence is determined in part by the clinical status of the patient and the rate and pattern of bleeding, but also by local experience and expertise of the treating physicians. Massive bleeding often starts and stops

spontaneously, thereby frustrating diagnostic efforts. In up to 20% of patients with clinically important lower gastrointestinal bleeding, a definitive diagnosis is never established.

Colonoscopy, technetium (Tc) 99m red blood cell scintigraphy, and selective mesenteric angiography are the most commonly employed diagnostic tests in the evaluation of lower gastrointestinal bleeding. *Colonoscopy* is the procedure of choice whenever bleeding has stopped. At colonoscopy, diverticula, vascular ectasias, neoplasms, ulcers, and areas of inflammation can be seen with good sensitivity. Because many of these lesions are common in the population at large, establishing the causal bleeding site in the absence of active bleeding may be difficult. The diagnostic evaluation of patients with ongoing or recurrent lower gastrointestinal bleeding remains controversial. Some experts support the performance of an RBC scan as the first test, whereas others recommend mesenteric angiography. Still other experts favor emergency colonoscopy after a rapid colonic purge as the initial test of choice. *RBC scintigraphy* can localize a site of gastrointestinal bleeding when rates of bleeding are as low as approximately 1 unit every 2–4 hours. Ideally, scintigraphy can detect and localize the site of bleeding with sensitivity five times greater than that of angiography. Scintigraphy cannot establish a specific diagnosis and has no therapeutic potential, but it can direct further diagnostic and therapeutic interventions, such as angiography or surgery, should they become necessary. In clinical practice, a great deal of controversy exists regarding the value of the RBC scan. *Selective visceral angiography* can localize the site of bleeding when the rate of bleeding is approximately 1 unit hourly. Even when angiography does not show extravasation of contrast into the bowel lumen, it may be diagnostic of abnormalities suggestive of a site of bleeding, such as a vascular ectasia.

Mesenteric angiography also has therapeutic potential (e.g., embolization of bleeding vessels and intraarterial infusion of vasoconstrictors such as vasopressin). Unfortunately, angiography has an associated morbidity of approximately 10%, including arterial thrombosis and dye-induced acute renal failure. Although angiography can be both diagnostic and therapeutic in patients with lower gastrointestinal bleeding, its precise role and value have not been established clearly. Some investigators argue that colonoscopy should be the test of choice for lower gastrointestinal bleeding, even when the bleeding is ongoing. In their hands, colonoscopy is technically possible in this setting after a rapid purge, and the diagnostic yield of this approach is far greater than that of angiography (>80% vs. <20%). In addition, colonoscopy does permit the delivery of endoscopic therapy to selected lesions, including actively bleeding diverticula, or those with a visible vessel (16). However, precise identification of the bleeding diverticulum remains uncommon, even with early colonoscopy. In one study, colonoscopy reduced rates of angiography

TABLE 78.6

INDICATIONS FOR HOSPITALIZATION IN PATIENTS WITH HEMATOCHZIA

Abnormal vital signs
Continued passage of blood per rectum
Severe anemia (i.e., Hb <8 g/dL)
Fever, leukocytosis
Abdominal pain, tenderness
Unstable comorbid conditions
Suspicion of upper tract bleeding
Previous aortic surgery

Hb, hemoglobin.

from 50% to less than 5%, and the need for emergency surgery from 20% to less than 5%. Length of stay in the ICU was reduced by a mean of two days and the total hospital stay by at least three days, which resulted in a large reduction in the cost of services (17). Early colonoscopy (within 24 hours) also has been associated with a shorter length of hospitalization, primarily attributable to earlier delineation of low-risk stigmata rather than to the delivery of endoscopic therapy to high-risk lesions (18).

Other diagnostic tests are occasionally used in patients with lower gastrointestinal bleeding. Those with significant abdominal pain or tenderness may benefit from abdominal and pelvic CT. In patients with a previous history of aortic aneurysm or aortic surgery, the combination of CT and endoscopy beyond the duodenum is the best method of diagnosing an aortoenteric fistula. Aortogram is not as useful a test for this diagnosis. If a site of bleeding is suspected in the small bowel based on scintigraphy or angiography, an endoscopic examination of the small bowel with an

enteroscope is appropriate. The newest generation of scopes can examine the small intestine to approximately 100 cm beyond the ligament of Treitz. Lesions such as vascular ectasias and ulcers can be detected and, if need be, treated. Recently video capsule endoscopy has been introduced as a new method of detecting bleeding lesions in the small intestine beyond the reach of the enteroscope (19). If bleeding has stopped, a *small-bowel contrast study*, such as an enteroclysis, can be used to look for small-bowel pathology, such as ulcers, diverticula, Crohn's disease, or neoplasms. In young patients with lower gastrointestinal bleeding of obscure origin, a *Meckel's scan* should be performed.

A recommended diagnostic algorithm for patients with hematochezia is presented in Figure 78.3.

Therapy

As more than 80% of episodes of lower gastrointestinal bleeding spontaneously stop and do not recur, specific

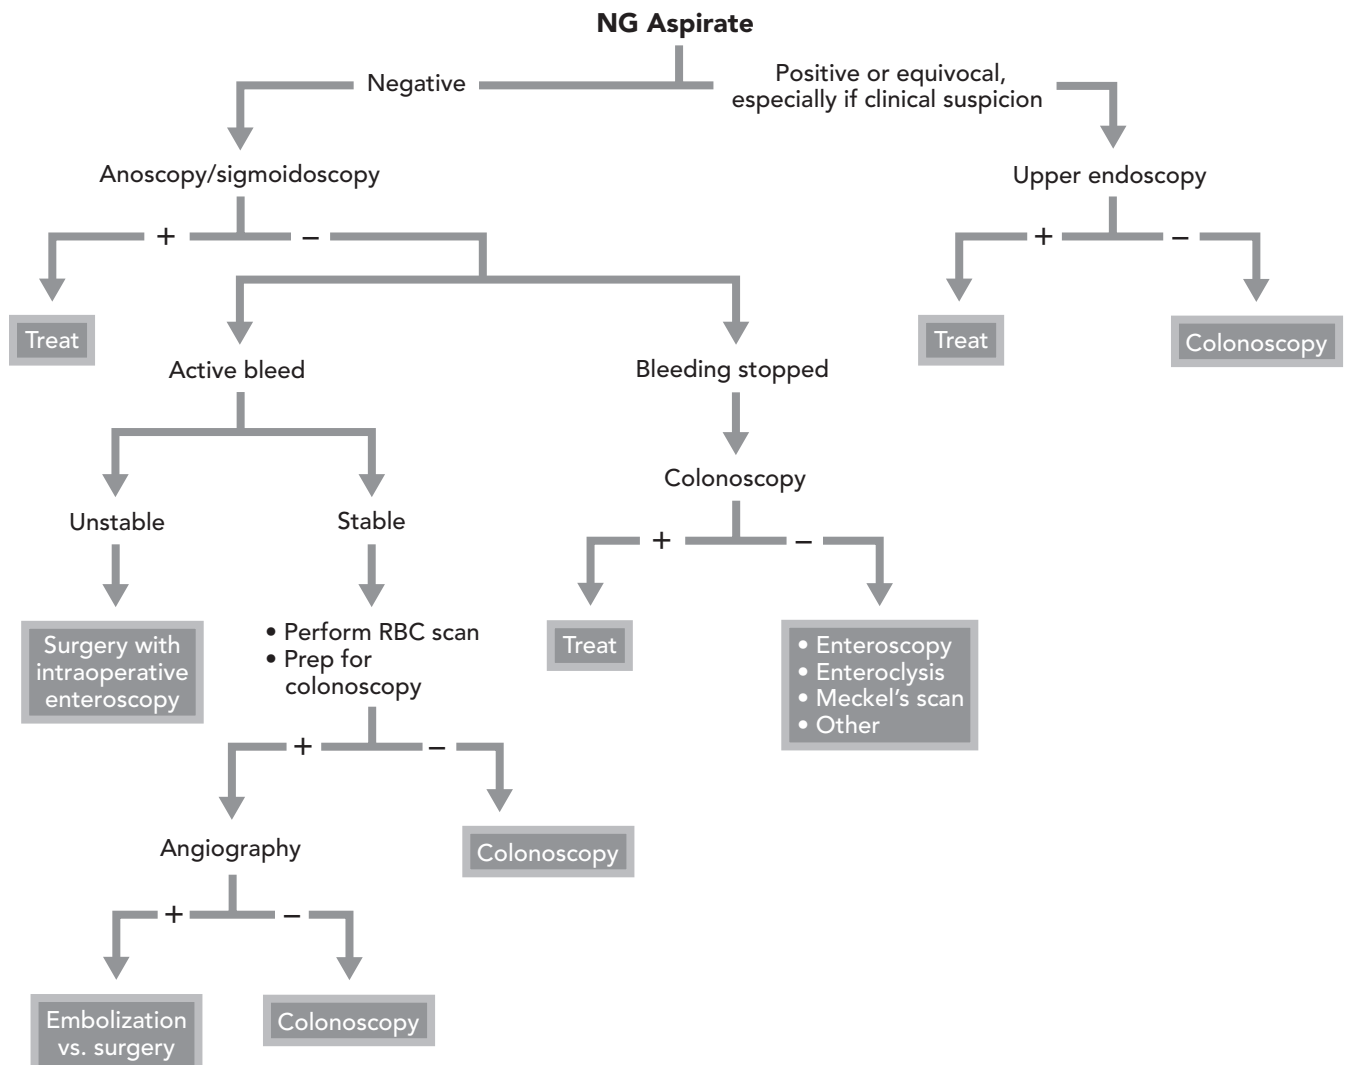

Figure 78.3 Diagnostic algorithm for patients with hematochezia.

therapy to arrest hemorrhage is generally not needed. Therapeutic maneuvers primarily are supportive. Medical therapy has been disappointing in its ability to arrest ongoing bleeding, prevent recurrent bleeding, and improve outcomes.

Endoscopic therapy is preferable to angiographic or surgical therapy if it is possible, and it may be possible in a significant fraction of cases of lower gastrointestinal bleeding. However, large controlled trials to evaluate the use of endoscopic therapy in lower gastrointestinal bleeding and define patients who would benefit from such therapy have not been performed. The type of therapy chosen depends on the lesion encountered. For bleeding vascular ectasias, thermal contact methods are the treatment of choice, whereas for ulcers and bleeding after polypectomy, either thermal contact methods or injection therapy can be employed. Bleeding polyps can be removed endoscopically, and bleeding from larger neoplasms can sometimes be stopped temporarily by epinephrine injection until definitive surgical therapy can be undertaken. Investigators have reported successful endoscopic treatment of bleeding diverticula with epinephrine injection or thermal contact methods (16).

Angiographic treatment of lower gastrointestinal bleeding is possible. Intraarterial infusion of vasopressin can arrest bleeding in up to 90% of cases, although bleeding will recur in as many as 50%–70% of cases on withdrawal of therapy. Small studies have demonstrated the efficacy and safety of subselective embolization of bleeding vessels, although concerns about the risks for intestinal infarction remain.

Surgical resection of bleeding lesions remains a viable therapeutic approach for patients with persistent lower gastrointestinal hemorrhage. Rarely, patients present with massive hematochezia, and attempts to fully resuscitate the patient and establish the location of the site of bleeding are impossible. Such patients require urgent surgical intervention to control the bleeding and prevent exsanguination. Intraoperative endoscopy can be attempted to localize the bleeding site if it is not obvious at laparotomy. Total abdominal colectomy is often undertaken if no site of bleeding can be localized in the operating room. Complication and rebleeding rates following this procedure are significant. Fortunately, this form of intervention is rarely required.

Much more commonly, patients have bleeding that starts, stops, and then starts again. The site of bleeding may or may not have been documented by previous diagnostic studies. The role of surgery in the management of these patients is not defined. Decisions about the need for and timing of surgical intervention are based on factors such as the number of episodes of rebleeding, total volume of blood transfused, clinical severity of each episode, and the patient's operative risk. Because the management of clinically important lower gastrointestinal bleeding is complex, gastroenterologic and surgical consultation should be obtained at the time of hospitalization in all patients.

Issues During the Course of Hospitalization

In the majority of cases, lower gastrointestinal bleeding stops and does not recur, and the hospital course is uncomplicated. Many patients may be eligible for early discharge once they are resuscitated. Risk assessment in lower gastrointestinal bleeding is based mostly on expert opinion, as large prospective studies exploring the relationship of clinical presentation, medical history, and endoscopic diagnosis to outcome have not been undertaken.

In our opinion, assessment of the clinical history and endoscopic diagnosis can be used to predict outcome and determine the need for ongoing hospitalization in patients with lower gastrointestinal bleeding (Table 78.7). Patients with high-risk features should be observed in the ICU for at least 24 hours and should remain in the hospital for at least 72 hours. Moderate-risk endoscopic findings include nonbleeding colonic ulcers, vascular ectasias that can be endoscopically treated, and bleeding polyps that can be endoscopically resected. Patients with these endoscopic findings and without high-risk clinical features should be observed in the hospital but can be given a regular diet. The optimal duration of inpatient observation is unclear, but it probably is safe to discharge these patients if there has been no sign of active bleeding for more than 24 hours. Low-risk endoscopic findings include bleeding hemorrhoids and mild colitis. In the absence of high-risk clinical features, such patients are appropriate for immediate discharge.

A difficult situation arises when no diagnosis can be established after conventional endoscopy of the upper and lower tract. A small bowel source of bleeding should be suspected, and these patients should remain in the hospital for further diagnostic evaluation. If no diagnosis is established, patients should be observed in the hospital for a minimum of 48–72 hours for rebleeding.

TABLE 78.7

CRITERIA THAT HELP IDENTIFY HIGH-RISK PATIENTS WITH LOWER GASTROINTESTINAL BLEEDING WHO REQUIRE ONGOING HOSPITAL OBSERVATION

Clinical criteria

- Presentation with shock
- Ongoing abnormality of vital signs
- Transfusion requirement of >3–4 units of blood on a single day
- Recurrent episodes of bleeding during hospital stay
- Persistent fever, abdominal pain or tenderness, leukocytosis
- Unstable comorbid conditions

Endoscopic criteria

- Diverticulum with active bleeding, visible vessel, or adherent clot
- Severe ischemic colitis
- Cancer
- Colonic ulcer with active bleeding, visible vessel, or adherent clot

During hospital observation, clinicians should be watching carefully for an exacerbation of comorbid medical conditions and for evidence of rebleeding. Passage of dark blood or melena per rectum does not necessarily indicate rebleeding. An assessment of the vital signs and the hematocrit will aid in the diagnosis of rebleeding. Passage of bright red blood indicates that bleeding has resumed. Appropriate management for an episode of rebleeding is not well defined and requires a case-by-case approach.

Discharge Issues

Patients are eligible for discharge after an appropriate interval of observation if bleeding has not recurred, the vital signs are normal, further transfusion is not required, and any comorbid medical conditions are stable. During a follow-up period of several years, a significant minority of patients requires readmission for further bleeding and a significant minority die, although death is rarely related to acute lower gastrointestinal bleeding. Of cases of diverticular bleeding in which surgical resection is not performed, bleeding recurs in approximately 10% by one year and in 25% by four years. Of patients admitted for their second diverticular bleed, approximately 50% have further bleeding after discharge. The rate of rebleeding requiring readmission for other diagnoses has not been well defined.

No ongoing medical therapy after discharge has been demonstrated to reduce rates of rebleeding or to improve long-term outcomes. Lower gastrointestinal bleeding is associated with aspirin and NSAID use. Whenever possible, these medications should be discontinued permanently or resumed in the lowest possible dose after an interval of several months. The risk associated with resumption of anticoagulants is unclear and must be determined on an individual basis.

GASTROINTESTINAL BLEEDING DEVELOPING IN THE HOSPITALIZED PATIENT

Gastrointestinal bleeding is a frequent and morbid complication of hospitalization. Patients in whom nosocomial bleeding develops are at very high risk for poor outcome and have a mortality rate upward of 30%. Most of this mortality is secondary to a deterioration of the patient's overall medical condition rather than to uncontrolled bleeding. Bleeding tends to occur after a prolonged hospital stay and is more likely to occur in patients with more severe underlying illnesses. Risk factors include ICU admission during the hospital stay, the need for mechanical ventilation, and coagulopathy. However, the majority of patients with nosocomial gastrointestinal bleeding are not in the ICU at the onset of bleeding. Duodenal ulcer disease is the most common source of this bleeding (Chapter 80). Preventive

medical therapy (such as administration of intravenous proton pump inhibitors) is imperfect, as the majority of patients in whom bleeding develops have been receiving some form of prophylaxis. In general, the approach to the diagnosis and management of patients with nosocomial gastrointestinal bleeding is the same as for patients admitted with primary gastrointestinal bleeding.

COST CONSIDERATIONS AND RESOURCE USE

Evidence-based guidelines, management algorithms, and clinical care pathways show great promise in directing appropriate resource utilization for patients with gastrointestinal bleeding. Risk stratification data are available that will permit a more rational approach to admission decisions. It is estimated that up to 25% of admissions for upper gastrointestinal bleeding can be averted and care delivered in the outpatient setting without sacrificing safety. Several prospective studies basing admission decisions on clinical criteria and results of upper gastrointestinal endoscopy performed before hospital admission have validated this approach to care. Routine risk reassessment during the course of the hospital stay also aids in the early discharge of admitted patients, once again without compromising safety. Implementation of a risk assessment guideline at one institution decreased the mean length of stay for upper gastrointestinal bleeding from 4.6–2.9 days without any differences noted in complications, patient health status, or patient satisfaction measured one month after discharge (12). Similarly, in another study, implementation of a clinical care pathway for both upper and lower gastrointestinal bleeding reduced length of stay from 5.3–3.5 days without an increase in adverse outcomes (13).

KEY POINTS

- Gastrointestinal bleeding is a common medical condition, accounting for some 500,000 hospitalizations annually in the United States. Despite advances in medical and endoscopic therapy, mortality rates remain in the range of 2%–10%.
- Initial resuscitation should consist of prompt and adequate volume replacement and careful attention to airway management.
- Triage from the emergency department should be guided by an assessment of the patient's risk for further bleeding or death based on clinical risk assessment.
- Early endoscopy is recommended for all patients with acute upper gastrointestinal bleeding. Patients judged to be at low clinical risk may be suitable for immediate endoscopy and may be candidates for outpatient management.

- High-dose proton pump inhibitors are beneficial in high-risk upper gastrointestinal bleeding. Octreotide has been shown to improve short-term outcomes in patients with variceal hemorrhage.
- Clinical and endoscopic information can be combined to predict outcome and suggest an optimal length of stay for patients with upper gastrointestinal bleeding. The use of clinical practice guidelines or clinical care pathways based on these criteria has been shown to reduce length of stay without compromising clinical outcomes.
- In comparison with the approach to patients with upper gastrointestinal bleeding, the diagnostic and therapeutic approach to patients with lower gastrointestinal bleeding is not well standardized. Early colonoscopy may prove to be the best strategy to improve outcome and reduce costs.
- The likelihood of recurrent bleeding after discharge can be reduced by measures such as eradication of *Helicobacter pylori* in peptic ulcer disease, administration of nonselective β -blockers in patients with esophageal varices, and avoidance of aspirin and nonsteroidal anti-inflammatory drugs in all patients.

Esophageal Disorders

79

Asyia Ahmad James C. Reynolds

INTRODUCTION

Despite the relatively simple function of the esophagus, disorders involving it are a common source of patient symptoms, morbidity and mortality. The main function of the esophagus is the movement of an oral bolus into the stomach without allowing significant regurgitation back into the esophagus. Swallowing, the essential function of the esophagus, can be divided into three main phases. In the oral phase, food is masticated, lubricated with saliva, and passed to the back of the mouth. In the pharyngeal phase, food is passed to the pharynx and subsequently across the upper esophageal sphincter into the cervical esophagus. As the bolus is rapidly propelled to the pharynx, the nasal cavity and the trachea are protected by the soft palate and vocal cords, respectively. In the esophageal phase, food is propelled down the esophagus and through the gastroesophageal junction as the lower esophageal sphincter relaxes. A variety of esophageal disorders can occur if any part of this swallowing process is disrupted.

Most esophageal disorders present with symptoms of dysphagia, odynophagia or atypical chest pain. An outpatient evaluation is generally sufficient, and a thorough history and examination often suggest a diagnosis and aid the diagnostic strategy. Hospitalization is rarely required for acute esophageal disease, but complaints due to the esophagus are common among hospitalized patients. This chapter describes diagnostic and therapeutic strategies for a variety of esophageal conditions that are commonly encountered in the hospitalized patient.

DYSPHAGIA

Dysphagia is the sensation of food sticking as it passes from the mouth to the stomach. Dysphagia can be differentiated into two distinct clinical syndromes. *Oropharyngeal dysphagia* is the inability to adequately transfer food from the oropharynx into the cervical esophagus. Oropharyngeal

dysphagia is the result of dysfunction of the upper esophageal sphincter or the oropharyngeal muscles and is commonly referred to as "transfer dysphagia." *Esophageal dysphagia* is a disturbance in the function of the esophagus itself. The differential diagnosis of this type of dysphagia is diverse and largely depends on differentiating mechanical causes from those related to motility disorders.

History is an important part of the evaluation of dysphagia. Patients will often point to the sternal notch as the site where food "gets stuck." While this may accurately describe the location in oropharyngeal dysphagia, patients with esophageal disorders often incorrectly localize their symptoms to this location. In contrast, patients who identify their symptoms as originating lower in the substernal region are usually accurate in pointing to the site of the pathology. Nasal regurgitation, coughing, or aspiration strongly suggest transfer dysphagia. Disorders of the oropharynx and proximal esophagus are often due to neuromuscular disorders of striated muscles. Symptoms of esophageal dysphagia are more varied and depend on the underlying etiology. For example, chronic heartburn suggests a benign cause such as a stricture. Advanced age, a history of weight loss, or heavy tobacco or alcohol use increase the risk of a malignant cause for the dysphagia. Dysphagia to solids suggests a mechanical obstruction, while dysphagia to both solids and liquids implies a functional or motility impairment as the cause. The constant sensation of a lump in the throat that is unaffected by swallowing is not dysphagia but "globus." Globus is most often due to GERD (gastroesophageal reflux disease, which is discussed later in this chapter), not hysteria (as had been taught for years). In summary, although characterization of symptoms is helpful, this assessment alone lacks adequate sensitivity or specificity in determining the cause of dysphagia.

The initial evaluation should be based on symptoms (Figure 79.1). A patient with oropharyngeal dysphagia should have a thorough evaluation for underlying abnormalities of the central nervous system, peripheral nerves and muscles. In addition, anatomical investigation

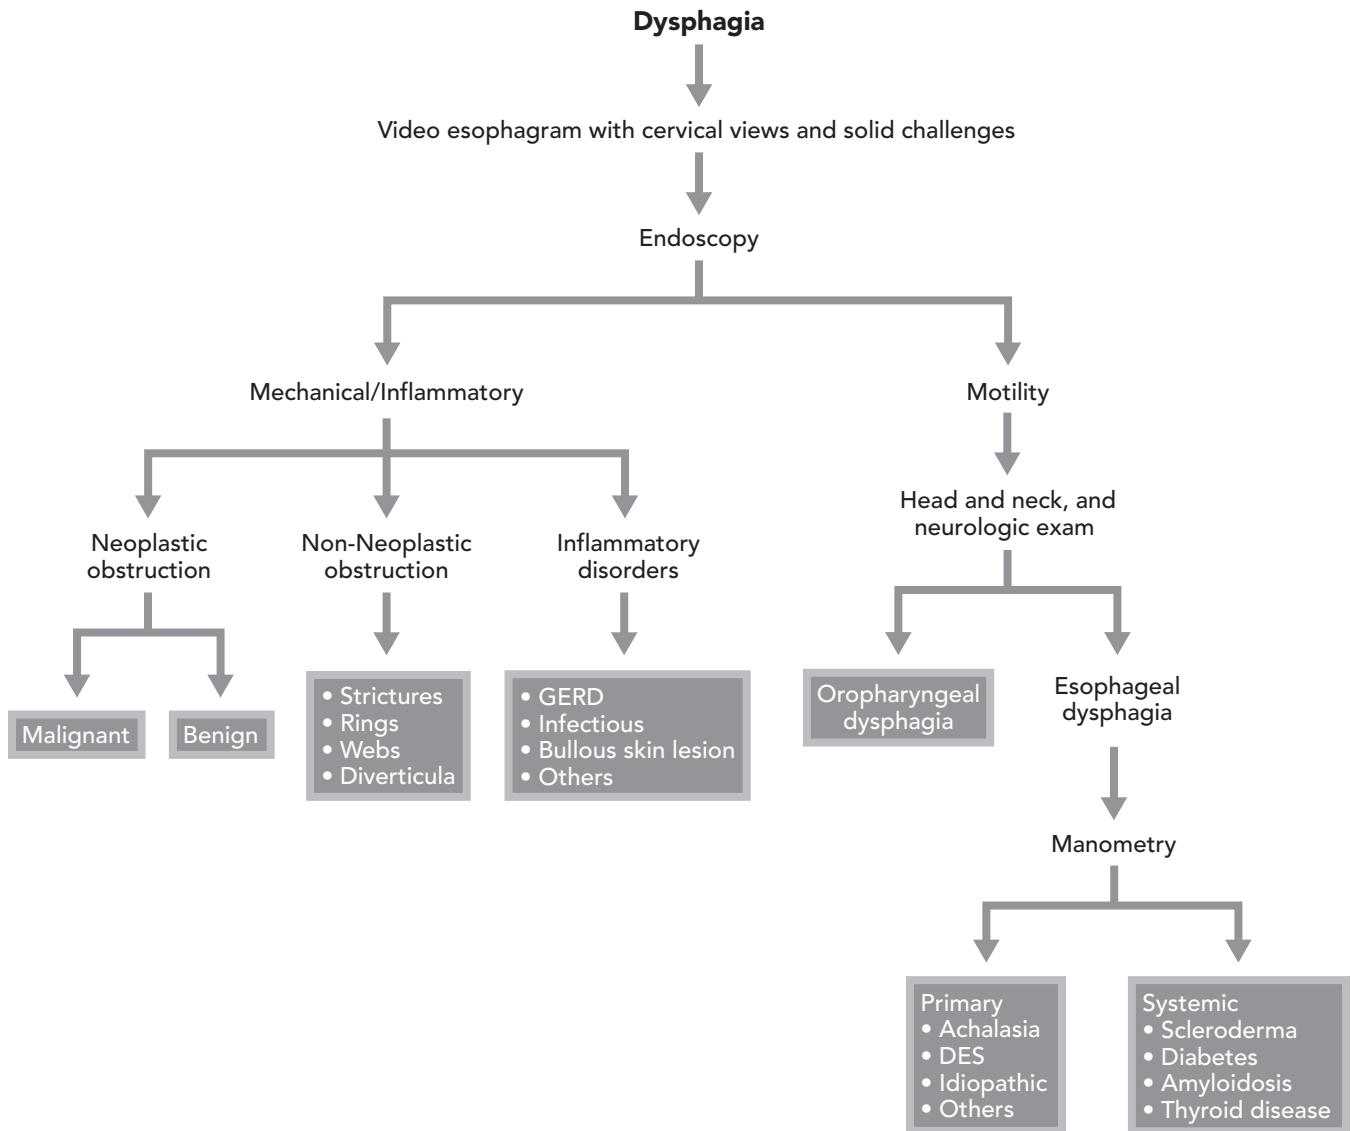

Figure 79.1 Approach to dysphagia. DES, diffuse esophageal spasm; ENT, otolaryngologic; GERD, gastroesophageal reflux disease.

of the hypopharynx and cervical esophagus, as well as a radiographic study of swallowing, should be completed. Causes of esophageal dysphagia can be divided into two categories. The evaluation of patients with symptoms implicating a mechanical cause for dysphagia should begin with a barium study to delineate the anatomy of the esophagus. Most will also require an upper endoscopy. Endoscopy provides a means to obtain biopsies for definitive diagnosis and for therapeutic maneuvers, including esophageal dilation. Patients with symptoms suggesting a functional cause for dysphagia should also undergo endoscopy. When endoscopy is negative, an esophageal manometry study should be performed to assess the adequacy of esophageal peristalsis and lower esophageal function.

Benign Esophageal Stricture

The majority of benign esophageal strictures are peptic in origin. The remainder occur as a complication of surgery (or from caustic toxin ingestion), pill esophagitis, infection, or radiation esophagitis. Another cause of a narrowed esophagus, a *Schatzki's ring*, is a fixed circumferential mucosal fold located at the squamocolumnar junction. Patients with strictures usually complain of progressive dysphagia to solid food and have a long-standing history of heartburn and/or ingestion of antacids. Barium swallow or upper endoscopy may reveal a smooth tapered narrowing, usually within the lower third of the esophagus. Biopsy and brush cytology of the strictured area can rule out underlying cancer.

The mainstay of treatment is esophageal dilation. In addition, an aggressive antireflux regimen with a proton pump inhibitor is warranted and has been shown to decrease the need for recurrent dilations (1). Unlike Schatzki's ring, in which quick disruption of the ring is required, gradual stretching is needed in peptic stricture. Stretching is usually accomplished by beginning with dilators of a diameter matching the size of the stricture. Patients may be dilated up to three successive sizes in one session and may have to return for further dilations (2).

Esophageal Carcinoma

Over 90% of all esophageal cancers are either adenocarcinoma or squamous cell carcinoma. Adenocarcinoma is more commonly diagnosed in Caucasian males with a long-standing history of GERD. These patients may have underlying Barrett's mucosa in which the carcinoma develops. The incidence of esophageal adenocarcinoma has risen since the 1970s; during the 1990s, it surpassed the incidence of squamous cell cancer (3). Squamous cell esophageal cancer is more likely to develop in African Americans who may have other risk factors such as tobacco and alcohol use, previous achalasia, or lye ingestion (4). Symptoms of esophageal cancer include progressive dysphagia to solids and rapid weight loss. A barium swallow that shows an ulcerated, irregular mass in the esophagus suggests esophageal cancer, and an upper endoscopy with biopsy is diagnostic. Staging of the tumor includes CT scanning of the chest. Endoscopic ultrasound can identify approximately 25% of patients who would otherwise be inaccurately staged (5). Surgery with esophagectomy remains the standard of care for localized tumors, while tumors with lymph node invasion or distant metastasis are treated with a regimen of chemotherapy and radiation. In aggressive obstructing tumors, esophageal stents can be placed for palliation, allowing oral intake to continue. Despite recent advances in surgical techniques and chemoradiation, prognosis in cases of esophageal cancer remains poor, with fewer than 25% of patients surviving 5 years (6).

Achalasia

Achalasia is an esophageal motility disorder characterized by loss of peristalsis in the esophagus and failure of the lower esophageal sphincter to relax. Although the cause is unknown, viruses, environmental factors and autoimmune mechanisms have been implicated as playing a role. Presentation of this disorder occurs equally in both genders and usually manifests with symptoms of dysphagia to both solids and liquids. Although dysphagia is the most common complaint, nocturnal regurgitation, chest pain with eating, and pulmonary complications are also seen. Long-term esophageal complications such as *Candida* esophagitis and squamous cell carcinoma may complicate the course. With

advancing disease, dietary restrictions, social isolation, and malnutrition affect this population. Evaluation for achalasia includes barium studies, chest radiographs, upper endoscopy, and esophageal manometry. A barium swallow may reveal delayed esophageal transit or a dilated esophagus which tapers distally to give a "bird beak" appearance (7). There may be evidence of an air-fluid level in the mediastinum or signs of chronic aspiration on chest radiographs. Endoscopy may suggest achalasia in a patient with a tight lower esophageal sphincter (LES) and a dilated esophagus, but a definitive diagnosis can only be made by esophageal manometry. Characteristic findings on manometry include simultaneous esophageal contractions, a LES that fails to relax, and intraesophageal pressures that exceed gastric pressure. When simultaneous contractions are of high amplitude and associated with chest pain, the descriptive term "vigorous achalasia" is used.

Once the diagnosis is made, it is important to distinguish primary achalasia from secondary achalasia or pseudoachalasia. Secondary achalasia can be caused by malignancy, either by direct extension into the lower esophagus, as seen in cancer of the gastric cardia, or as a paraneoplastic phenomenon. An unusual cause is Chagas disease, an infection caused by *Trypanosoma cruzi*. Finally, extrinsic compression on the lower esophagus can mimic achalasia.

In primary achalasia, there is no treatment to reverse the degeneration of the neurons, so treatment merely aims to improve symptoms. Medications such as nitrates or calcium channel blockers have been used with limited success. Endoscopic treatment consists of botulinum injection or pneumatic dilation of the lower esophageal sphincter. Botulinum injection is a safe procedure than can relieve symptoms of dysphagia, but its effects are short-lived, with a mean duration of response of 16 months, at most (8). Patients generally require repeat injections, making this a costly procedure. Thus, botulinum injection is reserved for patients who cannot undergo pneumatic dilation. In contrast, a single pneumatic dilation can provide effective therapy in most patients. After a second dilation, 85%–90% of patients will enjoy long-term relief (9). The complications associated with pneumatic dilation include local bleeding, hematoma formation, and esophageal perforation, which occur in approximately 5% of patients. Despite these risks, pneumatic dilation is the most cost-effective treatment in healthy patients (10). Those patients who have a poor response to medical and endoscopic treatment may benefit from a surgical myotomy, with which up to 90% of patients achieve good results (11).

In secondary achalasia, treatment with dilation may be inappropriate, and it is important to determine the true cause for the abnormality. Clues that are helpful in recognizing secondary achalasia include an ulcerated or asymmetric lower esophageal sphincter seen on endoscopy or radiographic studies, significant weight loss, rapid onset of symptoms, and older age of onset.

Esophageal Spasm

Esophageal spasm is an intermittent, simultaneous, non-peristaltic contraction of the esophagus that occurs during more than 10%, but less than 100%, of swallows. Symptoms can include intermittent dysphagia to either liquids or solids or chest pain with eating. Diagnosis is difficult since spasm occurs intermittently and may not be visualized by diagnostic studies. Barium studies may show a corkscrew-shaped esophagus or tertiary contractions, but these findings are only suggestive. Manometry confirms spasm in fewer than 5% of patients (12). Provocation studies with edrophonium or other acetylcholinesterase inhibitors may reproduce the symptoms of chest pain and suggest the diagnosis. If chest pain coincides with spasms, a definitive diagnosis of diffuse esophageal spasm (DES) can be made.

Treatment of these patients is often difficult. It is important to ensure that the patient does not have underlying cardiac disease as the cause of the symptoms. For symptoms related to esophageal spasm, agents such as nitrates, calcium channel blockers, anticholinergic drugs, and antidepressants can be tried. Anticholinergic agents, including hyoscyamine, provide relief in patients with spasm; however, they do have side effects such as dry mouth, constipation, and blurred vision. Side effects can be reduced by prescribing short-acting sublingual hyoscyamine products. Antidepressants improve symptoms in approximately 50% of patients, regardless of motility findings (13). In refractory DES, pneumatic dilation or surgical myotomy may provide relief but is rarely used.

Systemic Diseases with Esophageal Involvement

Many systemic diseases that cause multi-organ dysfunction and lead to hospitalization also involve the esophagus. These are listed in Table 79.1. One systemic disease with frequent esophageal involvement is scleroderma. The condition is most common in women in their 20s to 40s; gastrointestinal involvement may occur in up to 90% of these patients (14). Esophageal involvement is characterized by

decreased lower esophageal pressures and low-amplitude peristalsis, which causes symptoms of dysphagia to solids and liquids, as well as severe reflux. Peptic strictures and Barrett's esophagus are dangerous complications that may occur in these patients. Treatment is based on behavioral modifications and an aggressive antireflux regimen. In addition, patients should be taught to eat slowly to compensate for the absence of ordered peristalsis.

ODYNOPHAGIA

Odynophagia is the sensation of pain during swallowing. It almost always results from a disorder that leads to mucosal disruption. The etiology of odynophagia is diverse. In immunocompromised patients, infectious etiologies such as *Candida*, *Herpes simplex virus (HSV)* and cytomegalovirus (CMV) must be considered. In some patient populations, other causes such as chronic reflux, radiation, and pill-induced damage are more commonly seen.

Infectious Esophagitis

Patients with organ transplants, neutropenia, cancer, and AIDS are particularly susceptible to infectious esophagitis. However, patients with diabetes, motility disorders such as achalasia, those on steroids, and alcoholics are also at increased risk. The most common infectious causes of esophagitis is *Candida*. Patients with *Candida* esophagitis usually present with dysphagia, but they may also complain of severe chest pain and odynophagia. On examination, oral thrush may be present, but *its absence does not exclude Candida* as the cause for the symptoms. Barium studies may reveal an esophagus with a foamy or shaggy appearance. Ulceration or masses are unusual, and their presence should suggest another etiology. Endoscopy is often performed in patients who fail to appropriately respond to empiric therapy; when performed, it may reveal characteristic white plaques. Diagnosis can be confirmed

TABLE 79.1
SYSTEMIC DISEASES WITH ESOPHAGEAL INVOLVEMENT

by esophageal brushings with cytology or biopsies with histology. The latter is also helpful in ruling out other opportunistic infections. Treatment is with fluconazole 100 mg orally daily, or other appropriate anti-fungal agents, for 14 days. Patients with severe dysphagia, or those who fail initial therapy, need to be hospitalized for intravenous anti-fungal therapy with fluconazole, caspofungin, or amphotericin B.

Viruses such as cytomegalovirus (CMV) and *Herpes simplex* (HSV) are also important causes of infectious esophagitis. HSV esophagitis is seen in both the HIV and organ transplant population, and much less commonly in the immunocompetent host. Patients generally present with odynophagia. Barium studies reveal small discrete mucosal ulcerations without surrounding mucosal involvement. Endoscopy is necessary to confirm the presence of HSV. Treatment in patients who can tolerate oral medications consists of acyclovir 400 mg three times a day. In patients who cannot tolerate oral medications, intravenous acyclovir at 5–10 mg/kg every 8 hours can be used.

CMV esophagitis is more common than HSV in the AIDS population. Symptoms mainly consist of odynophagia. Barium studies may reveal deep ulcerations. Endoscopy with biopsy is needed for diagnosis. Treatment consists of ganciclovir intravenously, with an induction dose of 5 mg/kg every 12 hours for 2 weeks followed by a maintenance dose. Foscarnet can also be used in to treat CMV esophagitis; however, side effects such as electrolyte abnormalities and nephrotoxicity can occur. For patients with mild disease, oral valganciclovir at a starting dose of 900 mg twice daily is an option.

Other Causes of Odynophagia and Esophagitis

An often overlooked cause of odynophagia is *pill esophagitis*. Patients with pill-induced ulceration usually present with severe odynophagia or chest pain. It is important to obtain a thorough history, since patients with acute odynophagia may have received only one dose of the offending medication. Agents most commonly responsible include alendronate, tetracycline, quinidine, NSAIDs, and potassium. Pills may become temporarily lodged above the aortic indentation or at a stricture of the esophagus. Endoscopy may reveal circumferential ulceration in the mid- or distal-esophagus. Treatment is symptomatic, the offending agent is discontinued, and patients are instructed to take medications while in the upright position, drinking a 4- to 8-ounce glass of fluid both before and after taking the medication.

Radiation esophagitis may also cause odynophagia in patients undergoing radiation for head and neck cancers. Esophageal damage occurs in 40%–50% of patients, despite adequate shielding. In patients receiving concomitant chemotherapy, radiation injury to the esophagus may be more severe. Treatment may include sucralfate or a mixture

of Mylanta and viscous lidocaine; both regimens appear to have similar efficacy. If odynophagia is severe, radiation treatment may have to be postponed and intravenous nutrition may be required.

GASTROESOPHAGEAL REFLUX DISEASE

Gastroesophageal reflux disease (GERD) results when the passage of stomach contents back into the esophagus causes symptoms or mucosal disease. Heartburn is a burning sensation behind the sternum after meals, especially when recumbent. This symptom alone has a high predictive value for diagnosing GERD. Symptoms such as a bitter taste in the back of the mouth, belching, nausea, dysphagia, and regurgitation are also common. Complaints such as chronic laryngitis, cough, hoarseness, and asthma can also be attributed to chronic GERD. Cohort studies reveal that GERD symptoms occur in almost 50% of patients at least once a month and approximately 20% at least once a week (15). Overall, Americans spend billions of dollars each year for medications to treat GERD.

Although transient reflux episodes occur normally, GERD leads to symptoms or mucosal injury as a result of impairment of normal esophageal defenses. Peptic stricture is a costly sequela of severe GERD (particularly if not treated with effective anti-reflux therapy). It may cause extensive esophageal narrowing and the need for repeat esophageal dilations. In addition, chronic GERD may lead to the development of Barrett's metaplasia or dysplasia. Once Barrett's is detected, patients need to undergo regular endoscopic surveillance in order to detect esophageal adenocarcinoma, which develops in approximately 0.5% of Barrett's patients per year (16).

Although GERD can cause erosive esophagitis, non-erosive GERD is a common cause of symptoms and can lead to an impaired quality of life. Patients with non-erosive esophagitis have the same severity of symptoms, reduction in quality of life, and utilize equal amounts of antireflux medications as patients with erosive esophagitis. Surprisingly, some patients with severe erosive esophagitis seen on endoscopy have minimal symptoms of heartburn and are only diagnosed incidentally.

Treatment Options for Gastroesophageal Reflux Disease

Nonpharmacologic Treatments

Lifestyle modifications are often recommended as the first step in treating reflux symptoms. These are listed in Table 79.2. Elevation of the head of the bed has been shown in prospective trials to be an effective maneuver. Avoidance of foods high in fat content or that may affect lower esophageal sphincter relaxation can be helpful. Lastly,

TABLE 79.2**NONPHARMACOLOGIC TREATMENTS OF GASTROESOPHAGEAL REFLUX****Avoidance of injurious medications**

Agents that impair sphincter tone
 Anticholinergics
 Progestins
 Calcium channel antagonists
 Nicotine
 Theophylline
 Agents that cause mucosal injury
 Aspirin
 Alendronate
 Nonsteroidal antiinflammatory agents
 Tetracycline
 Potassium supplements

Dietary measures

Reduce fat intake
 Reduce meal size
 Limit foods that impair sphincter function
 Caffeine
 Chocolate
 Peppermint

Life-style modifications

Stop smoking
 Limit alcohol intake
 Avoid tight garments
 Remain upright after eating
 Elevate head of bed

medications that reduce esophageal contractile force or that irritate the esophageal mucosa should be avoided if possible. If these medications cannot be avoided, they should be taken with an adequate amount of fluid to prevent injury to the esophagus.

Pharmacologic Therapy

There are three main approaches to the initial treatment of reflux. The *step-up approach* starts with the least costly measures. In patients who do not respond to initial treatment or who have breakthrough symptoms, medications of increasing efficacy are recommended until symptoms are relieved. This approach is appropriate only in patients with uncomplicated mild-to-moderate GERD.

The first step in this approach consists of lifestyle modifications and the nonpharmacologic interventions listed in Table 79.2. Patients should limit excess fat intake and lose weight if necessary. Smoking cessation is another important component of therapy. It not only improves GERD symptoms but decreases the incidence of peptic ulcer disease and various cancers. Concurrent medications should be carefully scrutinized, since specific medications known to reduce lower esophageal sphincter pressure can worsen GERD. Even with strict compliance with the above guidelines, most patients will remain symptomatic and need to proceed to step two. At this point, pharmacologic therapy with a histamine-2 receptor blocker (H₂RA) is initiated. Additionally, the prokinetic agent metoclopramide has been helpful in patients with mild GERD and symptoms of dyspepsia and bloating. If symptoms persist despite the above measures, step three consists of discontinuing the H₂RA and starting a proton pump inhibitor (PPI). While this *step-up approach* is commonly used, it has been shown to be the most costly due to repeated office visits and unnecessary testing. For this reason, clinicians increasingly favor the *step-down approach*.

The *step-down approach* begins with the use of a PPI, the best acid-suppression medication for GERD. This en-

hanced acid suppression leads to faster symptom relief, improved quality of life, and a greater percentage of patients achieving mucosal healing. In addition, this class of medications is the treatment of choice for GERD-related complications such as esophageal ulceration and strictures. PPIs may also play a substantial role in improving poorly controlled asthma, chronic cough, and laryngitis due to GERD. Once symptoms have been controlled for several months, patients may be switched to a less expensive, less potent medication such as a prokinetic agent or H₂RA. Although the step-down approach may reduce costs, 60%–80% of patients will require PPI maintenance therapy to remain symptom free.

Finally, the *on-demand approach* provides PPI therapy on an as needed basis. This approach is appropriate and cost-effective for patients who do not have esophagitis or esophageal ulcers. Studies using omeprazole have demonstrated only a 29% failure rate at 6 months in patients following this routine (17). Patients who do not respond to medical therapy may choose to undergo surgical fundoplication. Recommendation for surgery must be made after careful evaluation as recent studies show limited long-term benefit of this intervention. Furthermore, cost analysis reveals medical therapy to be more cost-effective (18).

SPONTANEOUS ESOPHAGEAL RUPTURE (BOERHAAVE'S SYNDROME)

Boerhaave's syndrome (or spontaneous esophageal rupture) is a full-thickness tear of the esophagus in the absence of prior instrumentation. Patients often have a preceding history of retching or vomiting, although any maneuver that increases intraabdominal pressure can precipitate esophageal rupture. The most common site for rupture is in the distal posterolateral esophagus. The patient may complain of chest, back, or abdominal pain; while others have symptoms of odynophagia, dysphagia

or nausea. On physical examination, patients may appear acutely ill, with hypotension, tachycardia or fever. Signs of a pleural rub or decreased breath sounds should be sought. Chest or abdominal radiographs usually suggest the diagnosis by revealing pneumomediastinum or a left-sided pleural effusion.

Treatment of this syndrome is primarily surgical. Patients should be adequately resuscitated and promptly placed on intravenous antibiotics. Individuals with small tears in the esophagus which are not associated with complete perforation can be treated conservatively with antibiotics and close in-hospital observation.

COST-EFFECTIVENESS AND RESOURCE UTILIZATION

Esophageal disorders rarely require hospitalization. Exceptions include chest discomfort where cardiac causes must be ruled out. In this case, early PPI therapy may relieve symptoms of reflux esophagitis, allowing for shorter hospitalization stays. In addition, patients with poor oral intake secondary to radiation or infectious esophagitis may need to be hospitalized for intravenous fluids and antibiotics. Patients with esophageal rupture usually require urgent hospitalization for intravenous resuscitation, antibiotics, and emergency surgery.

Other esophageal conditions can be adequately evaluated and treated in the office. Patients with peptic stricture and achalasia may need repeat dilation. This can normally be done on an outpatient basis. Rarely do complications from these procedures require hospitalization. Early recognition of symptoms of esophageal cancer may lead to early diagnosis and shorter hospitalization stays if surgery is required. Lastly, suspected motility disorders should be thoroughly evaluated with barium studies, endoscopy, and esophageal manometry before complications develop. By following these recommendations, early treatment strategies can be implemented in a cost-effective manner.

KEY POINTS

- Gastroesophageal reflux disease (GERD) is the most common esophageal disorder in hospitalized patients. It is a cause of esophageal cancer, atypical chest pain, asthma, chronic cough, chronic laryngitis, and tracheal stenosis.
- All patients with GERD should be counseled in lifestyle modification, avoiding precipitating medications, and dietary measures. Most will also benefit from the use of a proton pump inhibitor.
- Odynophagia is most commonly caused by reflux or infections, both of which can be effectively treated once a specific diagnosis is made.

- Achalasia is an important treatable cause of dysphagia, angina-like chest pain, and recurrent aspiration. Botulinum toxin is an important new treatment of achalasia, but pneumatic dilation is generally more effective over the long term.
- Dysphagia should be promptly evaluated to identify treatable causes and recognize cancer at its earliest stages.

Peptic Ulcer Disease and Stress-Related Mucosal Disease

80

Brennan M. R. Spiegel Gareth S. Dulai

INTRODUCTION

Epidemiology

Peptic ulcer disease (PUD) and gastritis are two of the most commonly reported gastroenterologic disorders in hospitalized patients, accounting for more than 600,000 hospitalizations per year in the United States. PUD alone is the primary diagnosis in more than 450,000 hospitalizations per year, with an average hospital stay of four days and an annual mortality rate of 1.74 per 100,000 persons. Gastritis is the primary diagnosis for nearly 200,000 hospitalized patients per year, with an average hospital stay of four days and an annual mortality rate below 1 per 100,000 persons (1, 2).

Infection of the gastric mucosa with the Gram-negative bacillus *Helicobacter pylori* and the use of nonsteroidal anti-inflammatory drugs (NSAIDs) are the two most important causes of PUD. As many as 33 million people in the United States consume prescription and over-the-counter NSAIDs on a long-term basis, and the prevalence of NSAID use is increasing in lockstep with the aging of the American population. Epidemiologic data indicate that NSAID consumption increases the odds of developing an ulcer or ulcer-related complication by 3–6 times, depending on age. The prevalence of *H. pylori* infection in the population varies by age, but more than 50% of Americans older than 60 years are infected. Thus, millions are at risk for PUD and its complications. However, most endoscopic ulcers do not lead to clinically significant complications such as dyspep-

sia, ulcer hemorrhage, or ulcer perforation. In fact, data indicate that fewer than one-third of endoscopic ulcers lead to these relevant outcomes (3). The lifetime risk for symptomatic ulceration in those with chronic *H. pylori* infection is estimated to be 15% (3), and the annual risk for clinically significant ulceration in long-term users of NSAIDs is 1%–3% (4–6).

A number of factors associated with increased risk for PUD have been identified. In particular, the risk of developing NSAID-related GI complications is highest in patients using concurrent aspirin, coumadin, or steroids; patients with a previous history of an ulcer hemorrhage; and patients over 65 (7). Bacterial factors, such as the degree of cytotoxin A expression, and host factors, including the age at infection, genetic background, and degree of gastric acid secretion, may play a role in determining the risk for subsequent PUD among persons with *H. pylori* infection.

Accumulating data indicate that there may be a synergistic effect between NSAID use and *H. pylori* status. Specifically, meta-analysis reveals that *H. pylori* infection increases the risk of endoscopically detected ulcers in NSAID users by three and one-half fold compared to *H. pylori*-negative NSAID users. In addition, the risk of ulcer hemorrhage increases six-fold when both factors are present (8). In contrast, at least two case-control studies have found no evidence of an interaction between these risk factors (9, 10), and additional data indicate a protective effect of *H. pylori* on PUD in NSAID users (11). It is difficult to generalize these findings because the studies are limited by significant

variations between study populations, definitions of NSAID use, and evaluated outcomes. Although data are conflicting, the weight of the evidence appears to support the notion that *H. pylori* and NSAIDs are likely to be at least additive, and possibly synergistic, risk factors for PUD (8).

Definition of Syndromes

Peptic ulcer disease and gastritis represent patterns of mucosal response to injury. *Peptic ulcers* are breaks in the gastroduodenal mucosa that occur as a result of an imbalance between mucosal defense mechanisms and mucosal irritants. Whereas the diagnosis of PUD is made by endoscopic or radiographic visualization, the diagnosis of gastritis is, by strict definition, based on the histologic finding of gastric mucosal inflammation. In practice, however, the term gastritis has been used to refer to a variety of endoscopic appearances, such as erythema of the stomach, that correlate poorly with actual histologic findings. Of the three major types of gastritis (erosive and hemorrhagic, nonerosive or chronic, and distinctive), it is primarily the erosive and hemorrhagic variety that are of any immediate clinical consequence in the hospitalized patient. The principal clinical consequence of erosive and hemorrhagic gastritis is upper gastrointestinal hemorrhage.

Because the diagnosis of erosive and hemorrhagic “gastritis” is most often made on the basis of endoscopic visualization without biopsy, and because the biopsy when performed does not show prominent inflammation, the preferred terms for this disease entity are either erosive and hemorrhagic “gastropathy” or simply subepithelial hemorrhage. Erosive and hemorrhagic gastropathy occurs primarily in response to stress, use of NSAIDs, and alcohol. *Stress-related gastropathy* is the most important type of gastropathy in hospitalized patients and is therefore the only type considered in this chapter.

Duodenal ulcers are more than twice as common as gastric ulcers. Among patients with PUD who are not taking NSAIDs, 90%–100% of those with duodenal ulcers and 60%–90% of those with gastric ulcers are infected with *H. pylori*. NSAID use is a more frequent cause of gastric ulcers but may cause duodenal ulcers as well. Both types of ulcers occur more commonly in the elderly, reflecting the increasing prevalence of NSAID use and *H. pylori* infection with increasing age. Erosive and hemorrhagic gastropathy, in contrast, tends to occur diffusely in the stomach without any known age-specific trend in prevalence.

Current Trends

Within the past two decades, a paradigm shift has occurred in the approach to the diagnosis and therapy of PUD. It is now recognized that most PUD is not caused primarily by oversecretion of acid, but rather by *H. pylori* infection, the

consumption of NSAIDs, or both. Management of PUD, therefore, has shifted from maintenance of remission with antisecretory therapy, to cure through identification and elimination of *H. pylori* infection and discontinuation of NSAIDs, use of co-therapy, or use of anti-inflammatory/analgesic agents with decreased ulcerogenic potential.

This chapter presents a rational approach to therapeutic decision making in hospitalized patients with uncomplicated PUD, with an emphasis on recent developments in care. Because gastropathy is a relatively uncommon cause of morbidity in the hospitalized patient, a short section is devoted to strategies for prophylaxis.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation and Differential Diagnosis

The most common symptom associated with uncomplicated PUD is chronic or recurrent pain or discomfort in the upper abdomen, referred to as *dyspepsia*. Dyspepsia affects more than 25% of the general population but rarely results in hospitalization. Although only 10%–30% of patients with dyspepsia who present for medical evaluation have PUD, a history of dyspepsia can be elicited in up to 50%–70% of patients with uncomplicated PUD. The remaining patients present with atypical symptoms or with “silent ulcers.” The latter, who may present with complications of PUD, are commonly the elderly and those with NSAID-associated PUD. In numerous studies, discrimination of symptoms and symptom complexes has not been shown to be sensitive or specific for the presence of uncomplicated PUD. However, the presence of “alarm” features, such as weight loss, anemia, and dysphagia, are associated with a high probability of serious underlying pathology.

Complicated ulcer disease may present with acute, severe abdominal pain with guarding and rebound tenderness that suggest posterior penetration or perforation. Weight loss, early satiety, recurrent emesis, and a succussion splash on examination may indicate gastric outlet obstruction. A history of melena, hematochezia, or hematemesis may indicate acute or subacute gastrointestinal hemorrhage.

A wide range of disorders can present with dyspepsia or severe abdominal pain. Unfortunately, studies of dyspepsia are largely limited to the outpatient population and may not be directly applicable to hospitalized patients. Of outpatients presenting with dyspepsia, only one-third are found to have an underlying organic etiology, including erosive esophagitis, peptic ulcers, or, rarely, gastric cancer. In contrast, two-thirds of patients with dyspepsia have no discernible organic pathology and are said to have “functional dyspepsia.” A subset of these patients may have undiagnosed non-erosive reflux disease.

Occasionally, biliary or pancreatic disease can mimic PUD. However, both entities tend to have classic presentations that are readily distinguishable from those of PUD. Classic cholecystitis (Chapter 84) causes episodes of acute, severe pain that often localize to the right upper quadrant. Pancreatitis (Chapter 86) tends to be associated with episodes of acute, severe pain in the left upper quadrant that radiates to the back. Rare causes of dyspepsia may include Crohn's disease, medications, systemic metabolic abnormalities, celiac disease, and intestinal ischemia. Intestinal ischemia (Chapter 87) should always be considered given its significant consequences, especially in patients with severe cardiovascular disease. In the "typical" case, however, intestinal ischemia presents with one or more warning signs, such as intestinal angina or weight loss.

Risk Stratification and Indications for Hospitalization

Patients presenting with symptoms suggestive of PUD may be divided into two groups: (1) those suspected of having uncomplicated PUD, and (2) those suspected of having complicated PUD. Patients with uncomplicated PUD require hospitalization mainly for debilitating symptoms that cannot be controlled on an outpatient basis, such as pain or inability to maintain adequate nutrient intake. The decision to admit the patient with suspected uncomplicated PUD hinges on the patient's nutritional status, comorbidities, reliability, and on the provider's clinical judgment.

In contrast, hospitalization of the patient with complicated PUD is generally straightforward. Patients with suspected perforation or penetration require prompt surgical evaluation and admission to an ICU. Those with suspected obstruction, or who have evidence of dehydration or are at risk for further complications such as aspiration should be admitted for observation and diagnostic evaluation. The triage of patients with upper gastrointestinal hemorrhage is addressed in Chapter 78.

Diagnostic Evaluation

Complicated Peptic Ulcer Disease

Patients with suspected complicated PUD require rapid evaluation. Important historical risk factors include the patient's age, prior history of PUD, active comorbid conditions, and use of NSAIDs, alcohol, anticoagulants, tobacco, or corticosteroids. A complete physical examination should include an assessment of vital signs, with particular attention paid to evidence of volume depletion. Laboratory tests to obtain a complete blood cell count and values for coagulation parameters, liver chemistries, electrolytes,

amylase, blood urea nitrogen, and serum creatinine should be routine. Elderly patients and those with pre-existing cardiovascular morbidities should receive a baseline electrocardiogram, especially if gastrointestinal hemorrhage is suspected. Patients with suspected perforation require both supine and upright radiographs of the abdomen to rule out pneumoperitoneum. If an "acute abdomen" is present or if perforation is suspected clinically, early surgical consultation is mandatory. Those with suspected hemorrhage should be managed according to the strategies outlined in Chapter 78. In particular, data indicate that early endoscopy within 12–24 hours improves patient outcomes and reduces length of stay *versus* delayed endoscopy, suggesting that early endoscopy should be a routine component of care for patients admitted with suspected ulcer complications (12). Patients with suspected gastric outlet obstruction require upright or decubitus radiographs of the abdomen to rule out distal small-bowel obstruction and placement of a nasogastric tube for decompression.

Uncomplicated Peptic Ulcer Disease as a Primary Diagnostic Consideration

The management of patients hospitalized principally for the evaluation of uncomplicated PUD has not been extensively evaluated, and current guidelines or decision aids are not available. Given the high physical, mental, and financial burden of continued medical uncertainty in the hospitalized patient, rapid and definitive diagnosis and treatment are warranted. A suggested algorithmic approach to diagnose patients hospitalized primarily for evaluation and treatment of suspected uncomplicated PUD begins with a referral for early upper gastrointestinal panendoscopy (Figure 80.1).

Endoscopy is a safe and accurate means of confirming or excluding the major organic causes of dyspepsia, including PUD, reflux esophagitis, and cancer, by direct visualization and biopsy of the gastrointestinal mucosa. With an experienced endoscopist, the procedure has a sensitivity and specificity for PUD of nearly 100%. Endoscopy allows further diagnostic evaluation with gastric biopsy to rule out *H. pylori* infection and cancer, and a number of studies have shown that patients prefer upper gastrointestinal endoscopy to upper gastrointestinal radiography.

Double-contrast upper gastrointestinal radiography is an acceptable, although much less sensitive (50%–60%) and slightly less specific (90%–100%), alternative when endoscopy is not readily available (13). Although the direct cost of radiography may be less than that of endoscopy, radiography does not allow targeted biopsy of gastric ulcers to rule out cancer, nor does it facilitate invasive testing for *H. pylori* or accurately exclude reflux esophagitis. Moreover, whereas endoscopy can be performed at the bedside of

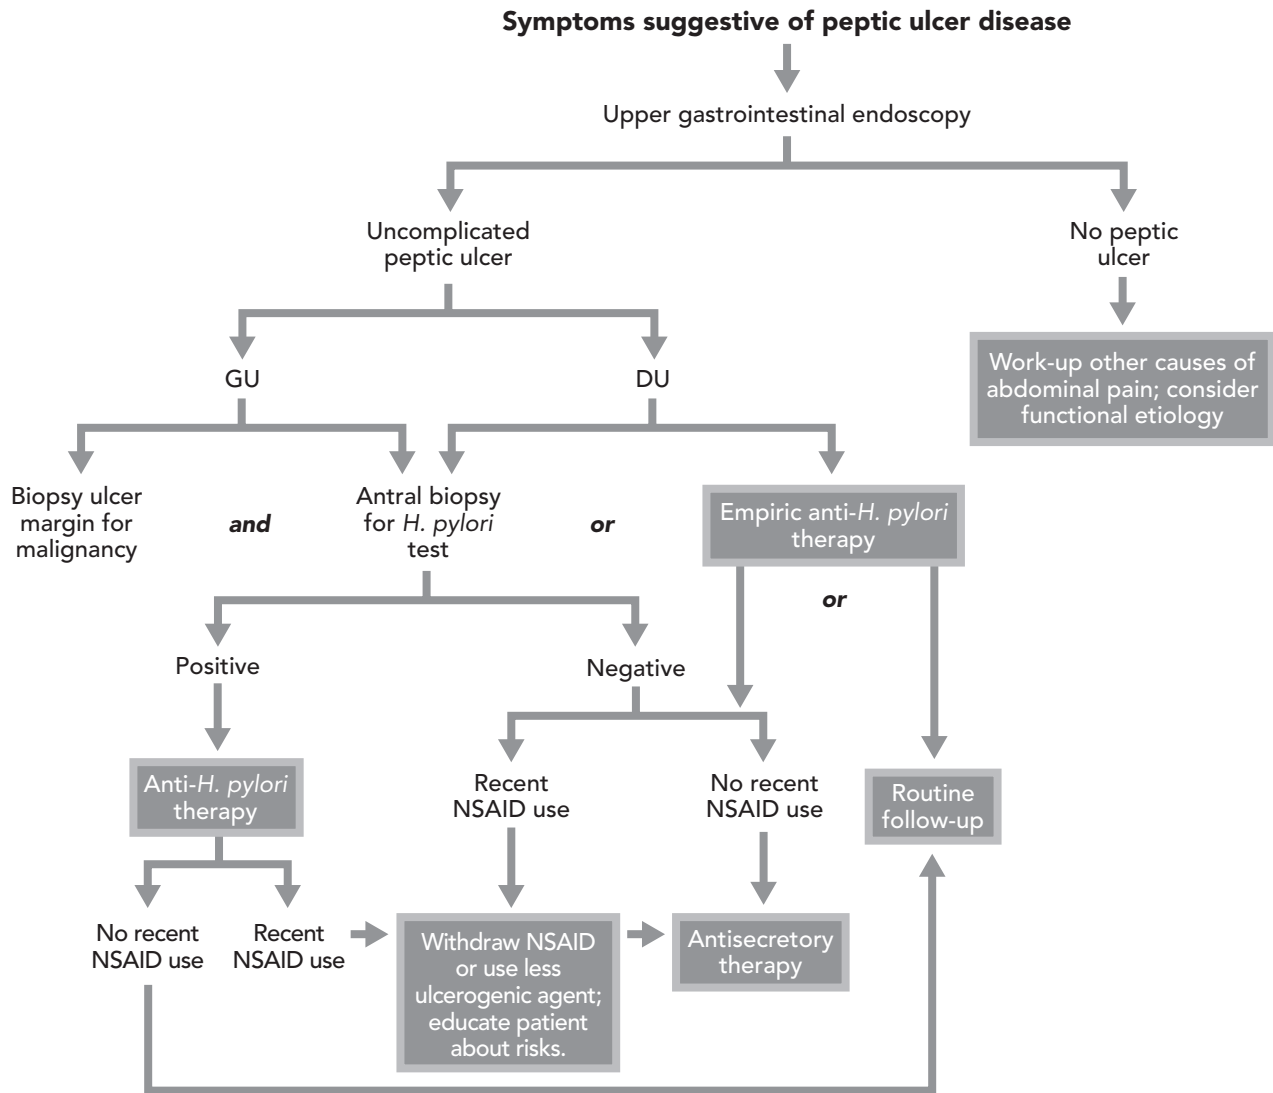

Figure 80.1 Algorithm for the management of patients with suspected peptic ulcer disease. DU, duodenal ulcer; GU, gastric ulcer; NSAID, nonsteroidal anti-inflammatory drug.

critically ill patients, radiography requires that the patient be able to cooperate with simple maneuvers and be suitable for transfer to the radiology suite. Finally, endoscopy may be precluded for days after radiography because of retained contrast, which also may damage the endoscope. For all of these reasons, endoscopy is the initial study of choice for the diagnosis of uncomplicated PUD in hospitalized patients.

Once PUD is confirmed by direct endoscopic visualization (preferably performed within the first 12–24 hours of admission), biopsy specimens should be taken from the antrum and midbody along the greater curvature to exclude *H. pylori* infection. Cost-effective analysis suggests that anti-*H. pylori* therapy may be given empirically without *H. pylori* testing, given the high pretest probability of *H. pylori* infection in patients with uncomplicated duodenal ulcers who deny NSAID use. Under these circumstances, treatment might still be warranted even in the presence of a negative

diagnostic test because the pre-test likelihood of *H. pylori* is very high (Chapter 6). If a gastric ulcer is present, biopsy specimens should be taken for *H. pylori*, as above, and also from the ulcer margin to exclude malignancy. A rapid urease test for *H. pylori* should be performed with antral biopsy specimens. The remaining specimens should be mounted and fixed for confirmatory histologic review in the event that the rapid urease test result is negative. If PUD is confirmed by radiography instead of endoscopy, a noninvasive test for *H. pylori* infection should be performed.

Diagnostic Tests for *Helicobacter pylori*

Determining which *H. pylori* testing method to employ is critical to implementing any evidence-based algorithm for PUD management. In patients with simple dyspepsia, noninvasive tests such as serology, carbon-labeled breath tests, and stool antigen tests have been shown to be more cost-

effective than invasive tests requiring endoscopy (e.g., the rapid urease test or histology), and these are recommended for the diagnosis of *H. pylori* infection in ambulatory patients with dyspepsia. The stool antigen test, in particular, is an effective means of confirming cure following anti-*H. pylori* therapy (14). Deciding which noninvasive test to use may depend on variable local factors, such as availability, institutional test characteristics, and costs (15). In patients with a low prevalence (30%–50%) of *H. pylori* infection, such as a young ambulatory patient with simple dyspepsia, non-invasive testing should be undertaken only if it is decided *a priori* to treat in the event of positive test results (because the false-positive rate may be up to 21%). In patients hospitalized for evaluation of possible PUD, gastric biopsy with rapid urease test or histological evaluation is an accepted means of testing for *H. pylori* because they are already committed to early endoscopic evaluation.

Peptic ulcer disease in the absence of *H. pylori* infection and NSAID consumption presents a diagnostic challenge. The most common causes include false-negative *H. pylori* test results and surreptitious NSAID use. The clinician must also be cognizant of other medications that contain NSAID ingredients, including various herbal preparations, Alka Seltzer®, Anacin®, Bufferin®, Pepto Bismol® liquid, Darvon®, and Percodan®. Recent use of antibiotics, bismuth, or antisecretory agents, or recent upper gastrointestinal hemorrhage may cause false-negative results when tests for *H. pylori* that rely on the load of organisms are used, such as the carbon-labeled breath test or rapid urease test of biopsy specimens. Serology may be the test of choice in these situations. Given the high pretest probability of *H. pylori* infection in PUD patients who deny NSAID use, an initial negative test result for *H. pylori* has a low negative predictive value. Therefore, a second confirmatory test or empiric anti-*H. pylori* therapy may be warranted, especially in the case of recurrent or complicated PUD.

Biopsy specimens from *H. pylori*-negative and NSAID-negative PUD patients should be reviewed for evidence of malignancy, Crohn's disease, sarcoidosis, eosinophilic gastroenteritis, or viral infection. A history of recent radiation therapy, chemotherapy, or "crack" cocaine use may provide clues to other specific etiologies. In an appropriate setting, such as the presence of multiple ulcers in unusual locations, fasting serum gastrin levels should be ordered to rule out Zollinger-Ellison syndrome. Serum calcium should be checked to exclude hyperparathyroidism. Further workup for exceptional cases is beyond the scope of this chapter.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Initial Therapy and Monitoring

The general management of patients with uncomplicated PUD should include intravenous administration of fluids

for those who are unable to tolerate oral intake or who show evidence of intravascular volume depletion. There is little evidence to support the efficacy of routine antisecretory therapy before a definitive diagnosis has been made.

Vital signs should be monitored routinely every 6–12 hours. A daily assessment of symptoms and abdominal examination should be performed. Patients with dyspepsia in the setting of uncomplicated PUD may not become asymptomatic once antisecretory therapy is initiated. Scant data exist to define the appropriate length of in-hospital therapy before discharge. Medicare data from 2002 reveal an average hospital stay of four days for patients with a discharge diagnosis of PUD (2). However, a hospital stay of one to two days after the diagnosis is made should not be considered unusual in patients without significant comorbidity. We recommend that patients be discharged once their symptoms can be controlled on an outpatient basis. Patients whose symptoms increase in severity or who develop new symptoms or signs of complication will require longer hospitalization with gastroenterologic or surgical consultation.

Specific Therapy

This section emphasizes the management of uncomplicated PUD. A discussion of specific endoscopic and surgical therapeutic strategies employed in the management of complicated PUD is beyond the scope of this chapter.

Conventional Ulcer Therapy

Although more than 50% of ulcers heal spontaneously within 8 weeks, the addition of acid-inhibitory therapy with either H₂-receptor antagonists (H₂RAs) or proton pump inhibitors (PPIs) increases the speed of healing and the absolute percentage of healed ulcers at 8 weeks. PPI therapy for 8 weeks results in healing rates above 90%. However, an ulcer recurs within 1 year in 10% of those who continue on maintenance antisecretory therapy and in 80% of those who withdraw from therapy (3). Conventional ulcer-healing doses of H₂RAs (daily or in divided doses) include 800–1,200 mg of cimetidine, 300 mg of ranitidine, 40 mg of famotidine, or 300 mg of nizatidine for 4–8 weeks. Ulcer-healing doses of PPIs are 20 mg daily of omeprazole or esomeprazole, 30 mg daily of lansoprazole, 20 mg daily of rabeprazole, or 40 mg daily of pantoprazole for 4–8 weeks. Gastric ulcers may require 12 weeks for complete healing.

Anti-*Helicobacter pylori* Therapy

Curing *H. pylori* infection reduces the recurrence rate of PUD to less than 10% at one year, without the need for maintenance antisecretory therapy. The re-infection rate after successful eradication of *H. pylori* is less than 1% annually,

though it is higher in patients with concurrently infected family members or other ongoing environmental exposures. National guidelines currently recommend anti-*H. pylori* therapy for all infected patients with PUD (3). Adequate eradication requires combination therapy that includes at least two antibiotics and an antisecretory agent. Issues that may influence the choice of therapy for the individual patient include efficacy, cost, compliance, and antibiotic resistance. There are several 10–14 day anti-*H. pylori* regimens that have been approved by the U.S. Food and Drug Administration (Table 80.1). In addition, recent data indicate that regimens lasting only 3–5 days may achieve eradication rates equivalent to longer regimens (16). Because there are only limited data supporting these foreshortened regimens, they have not yet become standard care.

Given adequate compliance and limited metronidazole resistance, a bismuth-based regimen improves outcomes at a lowest cost. However, because compliance is often poor, a PPI-based regimen may be the preferred choice because it requires taking fewer pills at less frequent intervals for a shorter period of time. In patients who have previously received metronidazole or clarithromycin therapy, or in geographic regions with known metronidazole or clarithromycin resistance, a regimen utilizing amoxicillin or tetracycline is preferred.

Despite initial concern, prior treatment with a PPI does not appear to influence the success or failure of subsequent antibiotic therapy. The principal benefit of *H. pylori* eradication for these patients lies in preventing recurrence of PUD, since *H. pylori*-associated ulcers heal on antisecretory therapy alone. Therefore, eradication regimens need not be instituted immediately.

Management of Peptic Ulcer Disease Induced by Nonsteroidal Antiinflammatory Agents

Patients with PUD who have been taking NSAIDs should discontinue these drugs if possible. Acetaminophen should be substituted for NSAIDs if only analgesia is required. The patient who discontinues NSAIDs should receive a standard course of healing antisecretory therapy with an H₂RA or a PPI. Although the degree of interaction between *H. pylori* and NSAIDs in PUD pathogenesis remains unclear, routine testing for *H. pylori* infection is recommended in patients with NSAID-associated PUD. All patients with documented *H. pylori* infection should receive a course of eradication therapy.

Management options for patients with NSAID-associated PUD who require chronic NSAID therapy include use of either a cyclooxygenase-2 (cox-2) selective inhibitor (known as a “coxib”), or a traditional non-selective NSAID with a co-prescribed PPI. Emerging data suggest that the latter option may be preferred in the majority of patients at high-risk for gastrointestinal complications of NSAID (17). First, despite the significant relative risk reduction in GI complications afforded by coxibs, their absolute risk reduction (compared with NSAIDs) is less than 1% for clinically-significant ulcer complications—an absolute reduction that does not offset their increased costs versus generic NSAIDs (17). Second, prospective studies in high-risk patients indicate that coxibs do not provide additional risk reduction for ulcer complications when compared with the NSAID + PPI combination. Third, cost-effectiveness analysis reveals that the coxib strategy is more expensive, yet less effective, than the NSAID + PPI

TABLE 80.1
FDA APPROVED ANTI-*H. PYLORI* REGIMENS

Regimen	Duration (d)	Efficacy (%)
Omeprazole 40 mg qd + clarithromycin 500 mg tid for 14 d, then omeprazole 20 mg qd for 14 d	28	88–94
Ranitidine bismuth citrate (RBC) 400 mg bid + clarithromycin 500 mg tid for 14 d, then RBC 400 mg bid for 14 d	28	71–75
Bismuth subsalicylate 525 mg qid + metronidazole 250 mg qid + tetracycline (TCN) ^a 500 mg qid for 14 d; + H ₂ RA for 28 d	28	77–82
Lansoprazole 30 mg bid + amoxicillin 1 g bid + clarithromycin 500 mg bid for 14 d	14	73–83
Lansoprazole 30 mg tid + amoxicillin 1 g tid for 14 d ^b	14	35–67
Omeprazole 20 mg bid + clarithromycin 500 mg bid + Amoxicillin 1 g bid for 10d	10	83–91
Lansoprazole 30 mg bid + Clarithromycin 500 mg bid + Amoxicillin 1g bid for 10 d	10	81–84
Esomeprazole 40 mg bid + Clarithromycin 500 mg bid + Amoxicillin 1 g bid for 10d	10	77–85

H₂RA, histamine₂ receptor antagonist.

strategy in high-risk patients. Fourth, whereas data reveal that the use of concurrent aspirin attenuates the relative gastrointestinal protective effects of coxibs, PPIs are highly effective in minimizing aspirin and other NSAID-related gastropathy. These data, combined with increasing concerns about cardiovascular safety of coxibs (18) (which led to the withdrawal of rofecoxib from the market), suggest that the purported gastrointestinal benefits of coxibs may not offset their additional risks and higher cost compared to the NSAID + PPI combination. Misoprostol may be an acceptable alternative to PPI co-therapy in selected patients. If possible, patients found to have an NSAID-related ulcer should receive a full healing course of anti-secretory therapy before initiating further NSAID therapy.

Patients with NSAID-negative and *H. pylori*-negative ulcers in whom no other etiology is immediately discernible should receive a course of healing antisecretory therapy. Consideration should be given to repeated *H. pylori* testing versus an empiric course of *H. pylori* eradication therapy. Those patients with complicated or recurrent disease should continue to receive maintenance antisecretory therapy indefinitely.

Prophylactic Therapy for Stress-related Mucosal Disease

There is an increasing consensus that stress-related erosive and hemorrhagic gastropathy, or “gastritis,” is a less common cause of significant hemorrhage in hospitalized patients than previously thought. This trend possibly reflects the improved classification and identification of other endoscopic entities that can account for upper gastrointestinal hemorrhage. It may also reflect a decrease in the incidence and severity of gastropathy as a consequence of improved care for high-risk patients, such as the widespread use of rapid resuscitation, early enteral nutrition, and stress gastropathy prophylaxis. In this regard, the most significant recent change in the management of gastropathy has been the recognition that prophylactic therapy should be targeted to specific high-risk populations.

Although uncommon, clinically significant gastrointestinal hemorrhage from stress-related mucosal disease in a critically ill patient is associated with a 50% mortality rate when it occurs. Clinically significant upper gastrointestinal hemorrhage will develop in approximately 1%–2% of critically ill patients. Risk factors for clinically significant hemorrhage include mechanical ventilation, coagulopathy, head trauma, burns over more than 30% of the body, a history of recent PUD or gastrointestinal bleeding, and organ transplants. Of these, *48 hours of mechanical ventilation* and the presence of a *coagulopathy* are independent risk factors. The best available evidence suggests that the incidence of significant bleeding in patients without these factors is only 0.1% (19).

Multiple studies have demonstrated the efficacy of prophylactic therapy in decreasing the risk for bleeding, although an effect on mortality has not been convincingly demonstrated. H₂RAs, antacids, sucralfate, PPIs, and misoprostol have all been evaluated as prophylactic therapy. Initial studies suggested that prophylaxis with sucralfate reduced the rate of nosocomial pneumonia and death. Although the results of various studies are conflicting, the best available evidence suggests that, in comparison with sucralfate, H₂RAs provide a greater reduction in the risk for clinically significant bleeding, with no difference in mortality (20). The best candidates for prophylactic therapy may include ICU patients with uncorrected coagulopathies and those requiring sustained mechanical ventilation. H₂RAs are currently the preferred form of prophylactic therapy.

Recently, intravenous (IV) PPIs (pantoprazole, esomeprazole) have become available for inpatient use. Although IV PPIs have shown effectiveness in minimizing recurrent hemorrhage following endoscopic hemostasis of bleeding peptic ulcers, there are limited data regarding their use in stress ulcer prophylaxis. Physiologic data clearly indicate that IV PPIs produce more potent and longer-lasting acid inhibition than H₂RAs, and this finding suggests that IV PPIs might provide equal or superior clinical outcomes in stress ulcer prophylaxis than H₂RAs. In particular, recent data indicate that IV PPIs are capable of rapidly raising and maintaining intragastric pH in critically ill patients who cannot receive enteral feedings (21). Despite these suggestive physiological data, there are currently no randomized trials that have demonstrated a benefit in clinically relevant outcomes for IV PPIs over IV H₂RAs for stress ulcer prophylaxis. In light of this shortcoming, H₂RAs may remain the agents of choice for many practitioners.

ISSUES AT DISCHARGE

Clinicians should be aware of several of the more common drug interactions and side effects of ulcer therapy. Potentially significant drug interactions include those of PPIs and clarithromycin with other drugs metabolized by cytochrome P-450 pathways. Cimetidine can act as an anti-androgen, has well-known effects on the metabolism of warfarin and phenytoin, and can decrease renal excretion of theophylline, lidocaine, and other cationic drugs. Sucralfate can decrease the absorption of a variety of drugs, cause hypophosphatemia, and result in constipation. Antisecretory therapy of any type can decrease absorption of itraconazole and ketoconazole, and may increase the risk for nosocomial pneumonia in ICU patients. Misoprostol is an abortifacient and should not be given to women of childbearing age. In addition, it may cause crampy abdominal pain, nausea, and diarrhea in a dose-related fashion. Antibiotic therapy may result in gastrointestinal symptoms such as nausea, diarrhea, or, rarely, pseudomembranous colitis. Metronidazole can cause a disulfiram-like reaction to alcohol, and clar-

ithromycin can cause dysgeusia. Bismuth subsalicylate results in reversible darkening of the tongue and stool.

Patients should be educated about expected side effects of therapy, the importance of compliance, and specific symptoms that might warrant a phone call to the physician or an office visit. A list of NSAIDs and common over-the-counter preparations that contain NSAIDs should be given to patients, along with specific education about the ulcer risks of NSAIDs. Symptoms worthy of evaluation include the “warning symptoms” of potentially complicated PUD, in addition to uncontrolled or increasing pain.

Patients with uncomplicated PUD require office follow-up in 1–2 weeks, followed by repeat endoscopy in 8–12 weeks to document healing and confirm *H. pylori* eradication. Patients with uncomplicated PUD may be seen within 2–4 weeks. Repeat endoscopy for confirmation of *H. pylori* eradication is not recommended in uncomplicated PUD.

QUALITY-OF-CARE CONSIDERATIONS AND RESOURCE UTILIZATION

Clinical practice guidelines already exist for the management of hospitalized patients with bleeding PUD (Chapter 78) and for ambulatory patients with dyspepsia. Similar strategies must be designed for the management of hospitalized patients with uncomplicated PUD. Such approaches should favor early endoscopy as the key step in diagnosis and disposition (15). Patients with uncomplicated PUD based on initial evaluation might fall into a low-risk category of patients who could be safely discharged from the emergency department or shortly after admission. Rapid diagnosis and institution of appropriate therapy should result in good, cost-effective outcomes.

KEY POINTS

- Most peptic ulcers are caused by *H. pylori* infection or nonsteroidal anti-inflammatory drug use and can be cured by eradicating *H. pylori* or eliminating the use of these drugs, respectively.
- Clinical practice guidelines and pathways for uncomplicated PUD require further development, evaluation, and implementation if the quality of care provided to patients hospitalized with this common condition is to improve.
- Strategies that utilize early endoscopy facilitate rapid diagnosis and therapy and should result in efficient, cost-effective care with improved outcomes.
- Gastritis, better referred to as gastropathy, is a relatively unusual cause of significant morbidity in hospitalized patients.
- Patients at high risk for the development of stress-related gastropathy (particularly those with coagulopathy or who are receiving prolonged mechanical ventilation) should receive appropriate prophylactic therapy.

Inflammatory Bowel Disease

81

Stephen B. Hanauer Sunanda V. Kane

INTRODUCTION

The group of (idiopathic) inflammatory bowel diseases (IBDs) includes four disorders: ulcerative colitis (UC), Crohn's disease (CD), microscopic colitis, and collagenous colitis. This discussion is limited to the first two diagnoses. Ulcerative colitis and Crohn's disease are identified by a composite of non-specific clinical, endoscopic, and histologic characteristics (Table 81.1). There is no pathognomonic feature for either, and these diseases need to be distinguished from inflammatory disease caused by infections, ischemia, or drugs.

Ulcerative colitis was first described in 1859; by 1909, a detailed account of the disease and its natural history had been published. Crohn's disease is more recently known. It was first described as ileitis in 1913. In the late 1950s to 1960s, the potential for panenteric involvement or confinement to the colon became recognized. IBD is found worldwide, with the highest incidence in the United States, United Kingdom, Northern Europe, and Australia. The overall incidence of ulcerative colitis has remained steady during the past few decades: 3–15 cases per 100,000 annually, with a prevalence ranging from 50–80 cases per 100,000. The incidence and prevalence for Crohn's disease are similar, although the incidence has risen during the past 20 years. Any age group may be affected by IBD, with the peak incidence in the second and third decades and another peak in the elderly. The male-to-female ratio is near unity, and whites with IBD outnumber African-Americans and Asians four-fold. Risk for the development of IBD increases in people who have a family member affected with ulcerative colitis or Crohn's disease.

The specific etiologies of ulcerative colitis and Crohn's disease are unknown. Current theories implicate a genetic

predisposition, with numerous potential environmental triggers initiating an overly exuberant mucosal immunoinflammatory response. Neither specific pathogens nor consistent luminal factors have been identified. To date, the only differentiating etiologic factor in IBD is the smoking history; cigarette smoking is protective against the development of ulcerative colitis and is detrimental to the course of Crohn's disease. Eighty percent of adult patients with ulcerative colitis are nonsmokers, and 80% of adults with Crohn's disease smoke cigarettes. Recently, two independent teams of researchers described the first candidate gene in Crohn's disease, but it will be years before this discovery has direct clinical impact.

Ulcerative colitis is an idiopathic disorder primarily involving the superficial mucosal layer of the large intestine. The inflammatory process begins in the rectum and extends to a proximal margin that varies between persons. Approximately 30% of patients have disease limited to the rectum and another third to the left side of the colon; only about 20% have extensive disease involving the entire colon (pan-colitis). The extent of inflammation does not necessarily correlate with the severity and course of the disease. The primary symptom of ulcerative colitis is rectal bleeding, because the rectum is involved in all patients. The severity of disease depends on the extent of colon involved. Many patients with ulcerative proctitis present with constipation but frequent or urgent passage of blood or mucus. Abdominal pain is uncommon. In severe colitis, the inflammation extends to deeper layers, with serosal inflammation and destruction of the circular and longitudinal muscles. This thinning of the colonic wall may lead to colonic dilation and toxic megacolon.

Eighty percent of patients have intermittent attacks throughout their lifetime, and 10%–15% experience a

TABLE 81.1**DIFFERENTIATING CHARACTERISTICS FOR ULCERATIVE COLITIS (UC) VS. CROHN'S DISEASE (CD)**

	Clinical presentation	Endoscopic features	Radiologic findings	Histologic changes
UC	Bloody diarrhea Tenesmus Cramping	Diffuse pattern Circumferential Small ulcers	Extends proximally Fine ulcerations	Crypt abscesses Mucosal infiltrate

chronic, continuous course. Only about 10% present with fulminant colitis necessitating colectomy during the first attack. With current medical therapies, life expectancy is normal. Long-term disease does, however, increase the risk for colorectal cancer. This increased risk begins after 10 years of disease, and the risk is higher for patients with more extensive disease. The increased risk is the rationale for colonoscopic surveillance beginning 10 years after the onset of colitis, with multiple biopsy specimens taken from throughout the colon to identify epithelial dysplasia.

At endoscopy, the colonic mucosa is diffusely edematous and granular (instead of glistening), and it displays a spectrum of vascular changes ranging from a loss of the normal pattern to frank hemorrhage. Microscopic changes include an inflammatory infiltrate within the mucosa and neutrophilic infiltration of the epithelium, particularly the crypts. This inflammatory infiltration may lead to cryptitis, microabscesses, and architectural distortion of the glands.

Crohn's disease differs from ulcerative colitis in that the inflammatory changes are transmural (rather than superficial) and can involve any part of the alimentary tract, from the mouth to the anus. Crohn's disease typically affects the ileum, colon, and perianal region. Approximately 30%–40% of patients have isolated small bowel involvement, 40%–55% both small bowel and colonic involvement, and 15%–25% have isolated colitis.

Crohn's disease exhibits two predominant patterns: fibrostenotic-obstructing and penetrating-fistulizing. Macroscopically superficial ulcers (aphthae) may enlarge and coalesce into linear or irregularly shaped ulcers outlining areas of normal mucosa ("cobblestone" appearance). Because the disease is transmural, the bowel wall thickens and becomes fibrotic, stiff, and stenotic. Deep ulcers penetrate serosa, with development of fistulous tracking to adjacent loops of bowel, urinary bladder, vagina, or perineum. Symptoms of Crohn's disease are diverse and are determined by the disease location and severity within the involved segments. Because of its transmural nature, Crohn's disease often is associated with abdominal pain, obstruction, fevers, and malabsorption.

This chapter outlines the management issues for both acute ulcerative colitis and Crohn's disease. Despite significant overlap between the presentation and therapeutic principles, there is sufficient dissimilarity to warrant separate discussions. Most patients can be managed on an outpatient basis, and transitions between outpatient and inpatient status and vice versa are important milestones for patients with these diseases. Appropriate outpatient follow-up once the acute attack is resolved is important and will be addressed.

ULCERATIVE COLITIS

Issues at the Time of Admission

Clinical Presentation

Most patients with mild-to-moderate ulcerative colitis have had chronic symptoms with gradual progression and are managed as outpatients (1). Patients who have more than 6–10 urgent, bloody, or liquid stools, including nocturnal bowel movements, with mucopus and cramping require hospitalization. Such patients often have anorexia, nausea, vomiting (particularly with severe cramping during bowel movements), fever, dehydration (tachycardia, orthostasis) and prostration.

Patients with moderate ulcerative colitis who fail to improve with outpatient management also should be hospitalized. These patients may be less acutely ill but present with persistent diarrhea and rectal bleeding. They may have additional complications of colitis, including iron-deficiency anemia, anemia of chronic disease, hypoalbuminemia, and osteoporosis.

Important aspects of the physical examination include assessment of hemodynamics and volume status, and the abdominal examination. Patients are usually pale and orthostatic. Unusual patients may be febrile or toxic. Abdominal tenderness, especially rebound tenderness, implies transmural extension of superficial colitis to the

serosa. Bowel sounds are usually hyperactive, but colonic dilatation may result in distention and hypoactive or high-pitched bowel sounds. There usually is no significant perianal disease, even in patients with a history of prolonged diarrhea and straining. Extraintestinal manifestations can include ocular inflammation (episcleritis or iritis), large joint arthritis, erythema nodosum, or pyoderma gangrenosum (Table 81.2).

Differential Diagnosis and Initial Evaluation

The differential diagnosis of bloody diarrhea includes enteric infections, ischemia, radiation, other forms of IBD, and drugs (including nonsteroidal anti-inflammatory agents, gold, penicillamine, and chemotherapy). Most infectious colitis is acute and self-limited, but some cases may be fulminant and associated with systemic complications (e.g., *Escherichia coli* 0157:H7 infection with thrombotic thrombocytopenic purpura and renal failure). It is worth noting that in patients with a known diagnosis of ulcerative colitis, an exacerbation can be precipitated by an intercurrent infection, food poisoning, or antibiotic-associated diarrhea. Stool cultures for *Salmonella*, *Shigella*, *Campylobacter*, *Clostridium difficile*, amoebae, *E coli*, and, in the proper context, *Schistosoma*, cytomegalovirus, and atypical mycobacteria must be considered. It is important to alert the laboratory that the diarrhea is bloody, so that appropriate media can be used to identify *E. coli* 0157:H7. *C. difficile* infection is particularly common and should be sought by cytotoxin assay (Chapter 77).

Laboratory tests include a complete blood count with differential and platelets, coagulation studies, and a basic metabolic profile including liver chemistries. The erythrocyte sedimentation rate is nonspecific but can be useful to follow patients through the hospital course. Assessment of protein (albumin), calcium, and iron stores is important to define the overall nutritional status and replacement needs. A flat and upright abdominal radiograph is essential to rule out free air or dilatation of colon or small intestine. The proximal extension of colitis can be estimated by the absence of feces and haustra distal to the margin of disease (or

throughout the colon). If the transverse colon is dilated to more than 6 cm, *toxic megacolon* is considered to be present (Table 81.3). Contrast barium studies are contraindicated in acute colitis, as the insufflation can cause perforation. Likewise, aggressive attempts at colonoscopy are contraindicated. A limited proctoscopic or flexible sigmoidoscopic examination can define the presence of colitis, and a subsequent abdominal radiograph will outline the proximal extension of colonic wall involvement. If necessary in an acute presentation, labeled white blood cell scans may help define the extent of colonic inflammation and exclude small-bowel disease.

Indications for Initial Intensive Care Unit Admission

Patients presenting with hypotension, profuse bleeding requiring multiple transfusions, an acute abdomen, or altered mental status should be admitted to an intensive care setting. Patients with concurrent liver failure secondary to primary sclerosing cholangitis also require admission to the ICU.

Initial Therapy

Patients presenting with evidence of volume depletion require intravenous (IV) fluid resuscitation until the pulse and blood pressure stabilize. It is important to include extra potassium (20–40 mEq/L) to replete losses from diarrhea and corticosteroid therapy. Other electrolyte disturbances, such as hypomagnesemia and hypophosphatemia, should be corrected with IV (not oral) supplements. Transfusions of packed red blood cells are indicated when the hematocrit is below 25% and bleeding is persistent. Administration of fresh frozen plasma is essential if there is evidence of clotting dysfunction.

The mainstay of pharmacologic therapy for the patient with a severe case of ulcerative colitis is IV steroids. Appropriate regimens include hydrocortisone (100 mg every 6 hours), methylprednisolone (16 mg every 6 hours), or dexamethasone (6–8 mg twice a day). The authors prefer a continuous infusion of 40 mg of methylprednisolone during a 24-hour period because this provides constant delivery of steroids. Doses higher than 60 mg of prednisone (or equivalent) have no added efficacy and can contribute to complications. In the setting of severe acute colitis, no oral therapy for colitis (i.e., aminosalicylates, azathioprine, 6-mercaptopurine) has been shown to add any benefit as an adjunct to corticosteroids. Rectal administration of hydrocortisone enemas can be helpful for patients with tenesmus if they are able to retain the small (60 mL) volume.

Analgesics are limited to acetaminophen and tramadol. Antispasmodics or antidiarrheal agents may be prescribed for patients with stable or improving colitis, but they should be avoided in the acute setting because they reduce peristalsis. Opiates are contraindicated because they can paralyze colonic musculature and precipitate toxic megacolon. Nonsteroidal anti-inflammatory drugs worsen colitis and should also be avoided. Low doses of benzodiazepines at bedtime may help the patient sleep.

The role of antibiotics in acute ulcerative colitis is controversial. In severe colitis, antibiotics have no additional value over steroids. However, in fulminant colitis or toxic megacolon, antibiotics are advocated to prevent transmigration and systemic bacteremia. Thus, in the presence of peritoneal findings, fever, tenderness, profound leukocytosis, or colonic dilation, we recommend broad-spectrum coverage with a combination of a second-generation cephalosporin, metronidazole, or a fluoroquinolone, in addition to an aminoglycoside. This regimen will also cover the patient for possible emergent surgery. The antibiotics are discontinued after 48 hours except when an infectious complication has been confirmed or surgery is pending.

Many patients are anorectic and do not wish to eat (fearing postprandial tenesmus or cramping). If patients are not vomiting and desire food, they may be allowed to consume liquids or a low-residue diet. Patients who present with toxic manifestations, high fever, or abdominal tenderness should have nothing by mouth until they improve. Patients

with persistent vomiting and evidence of an ileus should be treated with nasogastric suction. Most patients with severe fulminant ulcerative colitis require parenteral nutritional support until they begin ingesting a full diet. Even those who are able to eat are often unable to consume the calories necessary to meet the additional catabolic demands associated with acute inflammation, corticosteroids, and protein exudation from the colon. Either peripheral or parenteral nutrition should supplement the oral intake to meet protein and caloric needs (Chapter 15).

Indications for Early Consultation

It is reasonable to request a gastroenterologic consultation for any patient hospitalized for the treatment of ulcerative colitis (2). The disease is relatively rare, and few patients are hospitalized with severe cases. Furthermore, the morbidity and mortality of ulcerative colitis can be greatly minimized by expert management. Despite the contraindication for full colonoscopy in the acute setting, a limited endoscopic study can assess the nature of intestinal bleeding. Finally, if the diagnosis is in question, a gastroenterologist can help define and then narrow the differential diagnosis. Surgical consultation at admission is warranted for patients presenting with fulminant colitis or toxic megacolon and for patients who fail to improve or who deteriorate within the first days of treatment (3).

Issues During the Hospital Course

The highest priority is to resuscitate an acutely ill, volume-depleted patient and rule out acute toxic megacolon and perforation (4). Frequent monitoring of vital signs and physical examinations during the first 24–48 hours are essential to detect early signs of deterioration. High doses of steroids can mask abdominal signs and fever. Tachycardia or a change in mental status may be the only signs of perforation. It is important to remember that acute perforation, which tends to involve the left side of the colon, can occur without being preceded by toxic megacolon.

In the absence of toxic megacolon, bowel movements should become less frequent within the first 36–48 hours. Each bowel movement may still be bloody and of liquid consistency. By the third full hospital day, the patient should be demonstrating improvement, with few bowel movements, less blood and urgency, and less anorexia. The therapeutic goal is for the patient, within 5–7 days, to have fewer than five movements a day and no fever, cramping, urgency, or nocturnal bowel movements. When a patient reaches this goal, the clinician can switch to 10 mg of oral prednisone four times daily to simulate the continuous delivery of IV steroids. At this point, the patient can be advanced to a low-residue diet with no limit on the number of calories consumed.

For patients who do not respond to 5–7 days of IV steroids, *cyclosporine* can be used as adjunctive therapy (5,

6). Initial dosing is 2–4 mg/kg over 24 hours as a continuous infusion. It is imperative that the patient's serum cholesterol is documented first because cyclosporine binds to cholesterol, and a cholesterol level below 120 mg/dL can lead to higher cyclosporine serum levels and increase the risk for toxicity (grand mal seizure). Blood levels should be monitored every 2–3 days and kept in a range of 200–400 mg/dL. Dosing adjustments should be based on either serum levels or patient side effects.

The therapeutic goals for IV cyclosporine are the same as those cited above. Patients can be switched from parenteral to oral cyclosporine when they are having formed bowel movements without blood or rectal urgency (this usually takes 5–10 days). The oral dose is twice the final IV dose in two doses. For example, a 70-kg patient with normal cholesterol who required 140 mg IV over 24 hours in the acute setting would be converted to 140 mg twice daily as an oral regimen.

If the patient has not improved within the first 2–3 days of cyclosporine therapy, another abdominal film should be obtained. If a megacolon is present, patients should receive nasogastric suction for decompression and frequent turning to aid in mobilization of air (patients should not spend more than two hours at a time in the prone position). If the findings on the repeated film are unremarkable, consider alternate diagnoses (Table 81.4). If the patient is on antibiotics, send stools for *C. difficile* toxin assay. Make certain that the patient has not been given any nonsteroidal agents for headache, fever, or pain, and that all electrolyte abnormalities have been corrected.

TABLE 81.4
CONDITIONS TO CONSIDER IF THE PATIENT FAILS TO IMPROVE

Inflammatory bowel disease-related

New fistula formation
Abscess formation
Obstruction
Perforation
Premature feeding challenge

Medication-related

Opiate withdrawal
Nonsteroidal anti-inflammatory agent use
Clostridium difficile infection secondary to antibiotics
Opportunistic infection secondary to immunosuppressants

Miscellaneous

Ischemia
Catheter infection
Thromboembolic event
Premenstrual syndrome or menses
Alternate etiologies of diarrhea: fat malabsorption, bile salt-induced colonic secretion, bacterial overgrowth, or factitious diarrhea

If the colitis symptoms are improving yet the patient is not doing well clinically, consider manifestations of immunosuppression: oral candidiasis or herpes simplex lesions can cause odynophagia, and fevers can be caused by opportunistic infection. Leukocytosis with a left shift is expected because of the steroids, but the presence of more than 20% immature cells is worrisome. If a gastroenterologist was not initially consulted, one should be when the patient has not improved and IV cyclosporine is being considered.

Continued bleeding or a blood transfusion requirement of more than 6 units within a 48-hour period is a poor prognostic sign; surgery should seriously be considered and is clearly indicated for the patient who worsens despite 24–48 hours of steroids and cyclosporine. Other poor prognostic signs after 48 hours of therapy include more than nine bowel movements a day, persistent tachycardia, fevers above 38°C, and abnormal radiographic findings. It should be pointed out that the option of surgical intervention ought to be discussed with patients who have severe ulcerative colitis even before it becomes necessary because of deterioration.

Discharge Issues

At discharge, the patient should be tolerating a low-residue diet and oral medications, have a stable hematocrit, and have no further need for transfusions. There should be adequate home support for the patient to engage in basic activities of daily living. The follow-up appointment should be about 1 week after discharge, with appropriate contact numbers in case of relapsing symptoms. The patient should be counseled about the risks of overexertion, dietary indiscretion, and medication non-adherence (Figure 81.1).

Oral prednisone should be continued at stable doses from discharge until the outpatient follow-up visit. If the patient was treated with cyclosporine, oral cyclosporine is continued along with trimethoprim-sulfamethoxazole three times weekly to prevent pneumocystis infection. Maintenance therapy with an aminosalicilate can be added at discharge (7). Additional education regarding the importance of adherence with maintenance therapy, follow-up, and drug monitoring are essential. The patient should be informed about the risk of nonsteroidal anti-inflammatory agents exacerbating colitis. At the first outpatient visit, the drug regimen is reviewed and, if cyclosporine has been used, trough blood levels are obtained. Many of these patients will be treated subsequently with long-term azathioprine or 6-mercaptopurine as supplemental maintenance therapy, in addition to an aminosalicilate. Over several months, first corticosteroids are tapered, then cyclosporine. The patient should be maintained on a long-term aminosalicilate (and azathioprine/6-mercaptopurine if cyclosporine has been used).

For ulcerative colitis (UC):	
<input type="checkbox"/>	1. Is there minimal to no blood with bowel movements?
<input type="checkbox"/>	2. Is the patient having nocturnal bowel movements?
<input type="checkbox"/>	3. Is the patient able to pass gas without having to use the toilet?
<input type="checkbox"/>	4. Is the patient tolerating oral intake?
<input type="checkbox"/>	5. Is the patient on appropriate doses of medications (steroids, aminosalicylates)?
<input type="checkbox"/>	6. Does the patient have emergency phone numbers and a follow-up appointment?
For Crohn's disease (CD):	
<input type="checkbox"/>	1. Is the patient having significant pain with oral intake?
<input type="checkbox"/>	2. Can the patient sleep through the night without a bowel movement?
<input type="checkbox"/>	3. Is the patient free of obstructive symptoms to allow adequate oral intake?
<input type="checkbox"/>	4. If no to the preceding question, does the patient have adequate intravenous access to allow for parenteral fluids/nutrition?
<input type="checkbox"/>	5. Does the patient have emergency phone numbers and follow-up appointments?

Figure 81.1 Checklist for hospital discharge

CROHN'S DISEASE

Issues at the Time of Admission

Clinical Presentation

Crohn's disease requiring hospitalization can present in several ways: refractory diarrhea, abdominal pain, bleeding, abdominal abscess, or obstruction. Volume depletion is common in the setting of nausea and vomiting resulting from obstruction or diarrhea. Fever, anorexia, and malnutrition are also common. On examination, abdominal tenderness may be localized or diffuse. There may be evidence of distention, an inflammatory mass, or frank abdominal or perianal abscess.

Differential Diagnosis and Initial Evaluation

The differential diagnosis for an acute flare of Crohn's colitis, like that for ulcerative colitis, includes infectious colitis, the use of nonsteroidal anti-inflammatory agents, antibiotic-related diarrhea, acute diverticulitis, and ischemia. Other acute processes such as appendicitis, pelvic inflammatory disease, lower lobe pneumonia, or acute hepatitis must be distinguished from a flare of Crohn's disease with small bowel involvement. Free perforation is uncommon and is more likely to occur as the first presentation of Crohn's disease than as a complication of an exacerbation. This is because transmural inflammation results in a "sticky" serosa, and the patient's own omentum usually will patch any chronic serosal leak. The transmural extension then results in thickened mesentery, an inflammatory mass of bowel wall

and mesentery, or localized fistula formation (e.g., enteroenteric, enterocolonic, or enterovesicular). In the patient with bowel obstruction, the differential diagnosis is between inflammatory obstruction secondary to a narrowed lumen and mechanical obstruction from a fibrotic stricture or adhesions from previous surgery. The acuity of the obstruction preceding inflammatory symptoms (abdominal pain, fevers, weight loss, diarrhea) and recent dietary history (consumption of hard roughage, such as nuts, celery, mushrooms) will assist in the differential diagnosis. Initial evaluation requires a thorough history to differentiate acute versus chronic symptoms. A complete physical examination should include a rectal examination and close inspection of the perianal region to rule out fistula or abscess. If the patient has diarrhea, the stool should be examined for fecal leukocytes, enteric pathogens, and *C. difficile*. Blood work should include a complete blood count with differential, chemistry panel, and cultures if the patient is febrile.

Flat and upright abdominal radiographs will rule out acute obstruction or ileus. In the presence of an abdominal mass and fever, ultrasonography or computed tomography of the abdomen and pelvis are indicated to rule out an abscess necessitating surgical consultation or percutaneous drainage.

Indications for Hospitalization

Hospitalization is indicated if the patient is unable to maintain adequate hydration or nutrition because of protracted diarrhea. It is also indicated for acute hemorrhage and severe abdominal pain or vomiting. Finally, patients presenting with fever, a tender abdominal mass, or

evidence of an abdominal, pelvic, or perianal abscess should be admitted.

Indication for Intensive Care Unit Admission

Admissions to the ICU for Crohn's disease are rare and related to complications such as septic shock, intractable hemorrhage, or profound metabolic derangement.

Initial Therapy

Repletion of intravascular volume and electrolytes with IV fluids and blood products is paramount. Patients already receiving steroid therapy should receive stress doses of IV steroids (e.g., 200–400 mg of hydrocortisone or 40–60 mg of prednisone) to overcome relative adrenal insufficiency. In patients without prior steroids, glucocorticoids are withheld until infectious complications (abscess, perforation) have been ruled out. The initial distinction between fever secondary to the disease or to complications may be difficult until blood cultures and imaging studies are completed. Once infection has been excluded, it is safe to begin IV glucocorticoids (e.g., 16 mg of methylprednisolone every six hours, 100 mg hydrocortisone every 6 hours, or 6–8 mg of dexamethasone every 12 hours). *Sulfasalazine has no role in the treatment of a severe flare of Crohn's disease.* Antibiotics play more of a role in acute Crohn's disease than in ulcerative colitis. They are employed to treat the inflammatory disease or as an adjunct to prevent systemic seeding from an infectious focus (e.g., abscess). After appropriate cultures of blood, urine, and aspirates of fluid collections, broad-spectrum antibiotics (e.g., a second generation cephalosporin, a combination of an aminoglycoside and metronidazole, or a fluoroquinolone and metronidazole) are commonly employed for patients with abdominal pain and tenderness.

Once acute infection has been ruled out, an infusion with *infliximab* to treat severe inflammatory disease may be considered (8). *Infliximab* is administered as a 5 mg/kg IV infusion given over two hours. If the patient has received *infliximab* previously but not in the last eight weeks, premedication with acetaminophen 650 mg orally and 50 mg IV diphenhydramine to prevent an acute infusion reaction is warranted.

Pain is more prevalent in Crohn's disease than in ulcerative colitis because of transmural inflammation that involves pain receptors on the serosa and peritoneum. Patients presenting with pain should receive nothing by mouth and be placed on bowel rest. The pain of Crohn's disease usually abates when the patient is not eating. Opiate tolerance and seeking are not infrequent in patients with chronic Crohn's disease and should be considered when pain is the predominant symptom in the absence of inflammatory components (e.g., fever, leukocytosis, abdominal mass). If the patient has been receiving opiate analgesia before admission, gradual tapering may be necessary to avoid withdrawal symptoms. If the patient

is not able to eat, parenteral nutrition should be initiated and later tapered when the patient tolerates an advancing diet.

Indications for Early Consultation

Because of the complex and varied nature of Crohn's disease and its therapy, gastroenterologist consultation should be obtained for most patients. A surgical team should also be consulted for patients with obstructive symptoms, an inflammatory mass, an abscess, or profuse hemorrhage. Consultation from an anesthesiologist or a pain service should be considered in patients receiving opiate analgesia outside the perioperative period. A nutritional support consultation is warranted for patients receiving parenteral nutrition or elemental diets, and for those with metabolic complications, short-bowel syndrome, or specific nutritional issues. Psychiatric or psychology/social work services can provide short-term emotional support, help manage acute psychosocial complications, and deliver ongoing outpatient counseling for adaptive problems related to chronic illness.

Issues During the Course of Hospitalization

The initial key management decision concerns whether the patient has an immediate indication for surgical intervention (9). If not, then the goal is to resolve acute inflammatory symptoms and work toward a stable maintenance regimen that minimizes the use of prolonged steroids and opiate analgesics. Indications for surgical exploration include the following: obstruction lasting more than 48 hours; unremitting fever; increasing abdominal pain, distention, rebound tenderness, or leukocytosis; and free intraperitoneal air. Likewise, an abscess that is not amenable to percutaneous drainage requires operative intervention.

In the absence of obstruction, ileus, or abscess, bowel rest and corticosteroids should alleviate abdominal pain and diarrhea. When the patient is pain-free after a period of bowel rest, then a trial of oral intake is initiated. An elemental diet is usually tolerated as well as total parenteral nutrition and represents a conservative approach to refeeding. Conversely, there is no advantage to a "clear liquid diet," which is commonly hyperosmotic and thus aggravates diarrhea. Patients can be advanced to low-residue diets with or without lactose, according to their history of milk intolerance. If lactose tolerance is an issue, lactose-free diets are started, with an evaluation of lactase deficiency deferred to a later date. Patients with significant ileal disease or who have had an ileal resection have an impaired ability to absorb fat and should be prescribed a low-fat diet to minimize diarrhea. At discharge, the patient should be able to tolerate sufficient calories from a low-residue diet to meet nutritional demands, and be able to perform most activities of daily life independently. There should be no need for opiates for pain

control. Many patients may have “noninflammatory” symptoms of abdominal cramping or loose bowel movements that can be managed with anticholinergic antispasmodics or antidiarrheal agents (e.g., loperamide).

If the patient is not improving or is worsening, additional considerations include new fistula or abscess formation, opiate withdrawal, thromboembolic events, nonsteroidal drug-related diarrhea, *C. difficile* infection, and mechanical obstruction from adhesions or a fibrotic (rarely neoplastic) stricture. Fat malabsorption, bile salt-induced colonic secretion, or small bowel bacterial overgrowth can cause diarrhea in the absence of active inflammation of Crohn’s disease. Persistent abdominal pain or distention, fever, or leukocytosis warrant repeated imaging with plain films or computed tomography, blood cultures, and a reassessment of the medication profile.

When patients with IBD are hospitalized for an unrelated problem, they should be maintained on their oral maintenance medication if possible. In the setting of other infectious illness, antibiotic or nonsteroidal drug exposure, or dietary alterations, it is not uncommon for inflammatory bowel symptoms to intensify. If the patient’s disease remains stable, no gastroenterology consultation is necessary. If, however, the patient becomes symptomatic, must take nothing by mouth, has a new medical problem, or needs new medications, gastroenterology consultation is warranted.

Discharge Issues

The goal of inpatient management of Crohn’s disease is to relieve pain, diarrhea, and inflammatory complications and allow resumption of a normal quality of life and social functioning with adequate oral intake to support metabolic demands. If the patient requires prolonged parenteral nutrition or antibiotics, appropriate IV access should be secured, and teaching and nursing arranged before discharge. At 7–10 days after discharge, follow-up should be coordinated with the primary treating physician (usually a gastroenterologist) and the requisite consultative teams (e.g., pain service, psychiatry, social work). If a patient has become deconditioned or requires specific rehabilitation services, then transfer to a short-term rehabilitation facility should be considered.

COST CONSIDERATIONS AND RESOURCE USE

A single study looking at the cost issues in inflammatory bowel disease estimated that in 1990, national health care expenditures were \$1.2 billion to \$1.4 billion (10). The primary component driving the cost of care was hospitalization. In Crohn’s disease particularly, surgical costs are the main driver of overall hospital costs (11). Therefore, the optimal means of reducing the costs of IBD is to minimize the need for hospitalization, and in Crohn’s disease, surgery. Early flares should be recognized and treated aggressively

before the patient’s condition deteriorates. A patient should be educated regarding the importance of maintenance therapy to avoid disease exacerbations, the exogenous factors that aggravate disease activity (nonsteroidal agents, antibiotics, cigarette smoking), and the role of diet in controlling symptoms. The use of home nursing to administer parenteral nutrition, iron, or antibiotics can decrease the number of hospital days. Another key management tool is an “integrated approach” (sometimes referred to as “disease management”) to outpatient care (12).

KEY POINTS

- Frequent physical exams within the first few days are essential for patients hospitalized with acute flares of ulcerative colitis or Crohn’s disease.
- Crohn’s disease can manifest in many ways, including diarrhea, bleeding, obstruction, severe abdominal pain, and abscess or fistula formation.
- Early gastroenterology and surgical consultation for either diagnosis is appropriate.
- If the patient is not responding to standard therapy, consider alternate diagnoses, such as infectious colitis or a complication of inflammatory bowel disease, such as abscess formation.
- If the patient is not responding to initial therapy, stop and redirect management. Patients with ulcerative colitis may benefit from adjunctive cyclosporine in addition to steroids, and patients with Crohn’s disease may require antibiotics, infliximab, or surgery.
- When a patient shows improvement, advances should be slow and methodical.

INTRODUCTION

Fulminant hepatic failure (FHF), the appearance of severe liver injury with rapid onset of encephalopathy and profound coagulopathy in a previously healthy individual, remains one of the most challenging conditions faced by hepatologists today (1, 2). Of the approximately 2,000 cases of FHF in the United States each year, acetaminophen overdose and idiosyncratic drug reactions are the most common causes, followed by infection with hepatitis A and B viruses, poisoning, and Wilson's disease. The cause remains unknown in approximately 20% of cases (3, 4). Although acute viral hepatitis accounts for a significant proportion of FHF cases in most industrialized countries, FHF is an uncommon complication of viral hepatitis (3).

Despite advances in medical treatment of complications, the mortality rate of FHF continues to be very high (50%–90%) (1, 2). Liver transplantation (Chapter 85) achieves survival rates averaging 65% (5) and has been used increasingly as an alternative to conservative medical management. Accurate early prognostication is crucial. Indeed, patients likely to recover spontaneously must be identified so that they are not subjected to the operative risk of and the long-term immunosuppression from an unnecessary liver transplant. On the other hand, patients in whom remission is unlikely should be transplanted before complications make surgical rescue impossible (6).

The principle challenges in the care of patients with FHF are making the correct diagnosis of severe acute hepatitis, accurately and promptly identifying patients at high risk for liver failure, and recognizing the major complications (7) that should prompt liver transplantation.

Fulminant hepatic failure was defined in 1970 as a potentially reversible condition caused by severe liver injury,

in which there is no prior history of hepatic disease and in which encephalopathy develops within eight weeks of the onset of illness. Though widely used, this definition was limited by the difficulty in determining the onset of the illness and the lack of a standard measure of the severity of hepatic failure. Newer classifications (1, 2, 6) emphasize: (a) the development of encephalopathy (which portends a worse prognosis); (b) the severity of hepatic failure, assessed by the prothrombin time and factor V level (higher prothrombin time and lower factor V level indicate worse prognoses); (c) the interval between the onset of jaundice and the development of encephalopathy (worst is 8–28 days); and (d) age (worse if younger than 10 years or older than 40 years).

In addition to patients with FHF, another group of patients suffers liver failure 60 days to six months after the initial injury. The cause of this delayed presentation is often "non-A, non-B" hepatitis. This *late-onset hepatic failure* tends to occur in older patients and has a very high mortality rate despite a relatively low likelihood of cerebral edema (8). In contrast, the rapidly progressive liver failure associated with hepatitis A and B viruses and drugs frequently is associated with cerebral edema but carries a lower mortality rate.

Etiology

Causes of FHF are listed in Table 82.1. For years, the most frequently identified cause was *viral hepatitis*. Newer data highlight the increasing importance of acetaminophen overdose (4) (Chapter 121). When no obvious viral or toxic cause can be implicated (approximately 20% of cases), liver failure is thought to be multifactorial. "Mutant hepatitis B viruses," "occult hepatitis B," unusual hepatitis viruses such as togavirus, cytomegalovirus, Epstein-Barr

TABLE 82.1
CAUSES OF FULMINANT HEPATIC FAILURE

Viral Hepatitis	Drug-induced Hepatitis	Other Causes
Hepatitis A–G	Acetaminophen	Metabolic (Wilson’s disease, Reye’s syndrome, galactosemia, sickle-cell disease)
Hepatitis non-A, non-G	Halothane	Poisoning (<i>Amanita</i> mushroom, other)
<i>Herpes simplex</i> virus	Isoniazid	Autoimmune hepatitis
Herpesvirus 6	Methyldopa	Budd-Chiari syndrome or veno-occlusive disease
Cytomegalovirus	Tetracycline	Partial hepatectomy
Epstein-Barr virus	Valproic acid	Jejuno-ileal bypass
Varicella zoster	Nicotinic acid	Massive neoplastic infiltration
Adenovirus	Phenytoin	Hyperthermia
		Giant-cell hepatitis
		Primary graft non-function
		Acute fatty liver of pregnancy

virus, and the recently discovered hepatitis E, C, and G viruses all have been considered as potential causes.

Prognosis

Several models have been proposed to aid in the early identification of those patients with a very poor prognosis who require liver transplantation for survival (6) (Table 82.2). King’s system, which separates patients with acetaminophen toxicity from all others, has been validated

TABLE 82.2
FULMINANT HEPATIC FAILURE: CRITERIA FOR LIVER TRANSPLANTATION

Patients with acetaminophen-induced fulminant hepatic failure

pH <7.30 (irrespective of stage of encephalopathy)
or
PT >100 s (INR > 6.5) and serum creatinine >3.4 mg/dL in patients with stages III or IV encephalopathy

Patients with other causes of fulminant hepatic failure

PT >100 sec (irrespective of stage of encephalopathy)
or
Three of the following (irrespective of stage of encephalopathy):

- Age <10 or >40 y
- Etiology: non-A non-B hepatitis, halothane hepatitis, idiosyncratic drug reactions
- Duration of jaundice before onset of encephalopathy >7 d
- PT >50 s (INR >3.5)
- Serum bilirubin >17.5 mg/dL

INR, International Normalized Ratio; PT, prothrombin time.

prospectively in a number of centers worldwide and is the most commonly used.

With the exception of some rare causes of severe acute liver failure (Table 82.3), no effective medical therapy is available, and the guiding principles in the care of patients with FHF include: (a) prevention of complications, (b) identification and avoidance of aggravating factors (Table 82.4), (c) supportive management in an intensive care unit, and (d) early transfer to a liver transplant center (5–7).

The severity of acute viral hepatitis is generally age-dependent. Patients over age 50 have the most severe disease, while infection in children is usually asymptomatic or, if symptomatic, non-icteric. Pregnancy is not associated with an increased severity of disease and there is no increase in fetal loss or fetal abnormalities.

ISSUES AT THE TIME OF ADMISSION

Typical Clinical Presentation

The course of acute viral hepatitis is similar regardless of the responsible agent (Table 82.5) and can be divided into four phases: incubation, prodromal, icteric, and convalescent (3). Nonspecific constitutional symptoms of the respiratory and gastrointestinal tracts may develop during the prodromal phase. These symptoms include malaise, fatigue, myalgia, anorexia, nausea, vomiting, diarrhea, and mild abdominal discomfort. Less common prodromal symptoms include fever, headache, and arthralgias.

Most patients seek medical attention with the development of *jaundice*. When jaundice begins, fever typically declines and systemic symptoms begin to subside. Physical examination may be unrevealing or may identify tender hepatomegaly (generally mild), splenomegaly, and

TABLE 82.3
SPECIFIC THERAPIES IN ACUTE HEPATITIS

Condition	Therapy	Doses
Hepatitis B	Lamivudine (controversial)	100 mg daily (adjusted for renal insufficiency)
Acetaminophen-induced hepatitis	N-acetylcysteine within 36 hours of ingestion ^a (Chapter 121)	140 mg/kg followed by 70 mg/kg every 4 h for 68 h, total of 17 doses
Budd-Chiari syndrome	Portal vein decompression	Emergency mesocaval or mesoatrial shunt, or transjugular intrahepatic portosystemic shunt
Veno-occlusive disease	Anticoagulation	See Chapter 98
Wilson's disease	D-penicillamine	300 mg/d (increase to 1,500–2,400 mg/d)
Autoimmune hepatitis	Steroids	Prednisolone: 1–2 mg/kg/d intravenous
Acute fatty liver of pregnancy	Early delivery	
<i>Herpes simplex</i> or cytomegalovirus hepatitis	Acyclovir or ganciclovir	Ganciclovir: 5 mg/kg every 8h intravenous; Acyclovir: 5–10 mg/kg/three times daily intravenous
Carbon Tetrachloride poisoning	N-acetylcysteine	
<i>Amanita</i> mushroom poisoning	Penicillin G and silymarine Early massive rehydration	Penicillin G: 40×10^6 units/day + silymarine: 50 mg/kg/day

^a N-acetylcysteine may improve survival rate even when the administration is delayed 72 hours after overdose.

TABLE 82.4
COMPLICATIONS OF FULMINANT HEPATIC FAILURE

Complication	Management	Therapy
Encephalopathy	Head computed tomography scan to rule out brain complications Consider neurology consultation	Avoid sedative-hypnotics Recognize and treat potentially reversible factors Lactulose (30–120 mL/d orally/rectally) Flumazenil (still experimental therapy with transient benefits) Neomycin is not recommended
Cerebral edema	Intracranial pressure monitoring	Keep head elevated Avoid aggravating conditions (head motion, hypoxemia, hypercapnia, fluid overload) Mannitol Pentobarbital
Coagulopathy	Regular monitoring of prothrombin time, platelet count	Vitamin K Fresh frozen plasma and platelet transfusion therapy for active bleeding or before invasive procedures; do not give prophylactically simply for elevated fibrin degradation products
Infection	Surveillance cultures If ascites, diagnostic paracentesis Chest radiograph	Low threshold for antibiotics Change intravascular catheters every 72 h Pulmonary toilet
Stress ulcerations	Intragastric pH monitoring	Histamine ₂ antagonist
Renal failure	Regular laboratory monitoring (creatinine, BUN, urinary sodium, glomerular filtration)	Combination loop diuretics and albumin Low-dosage dopamine Avoid nephrotoxic drugs
Hypoglycemia	Glucose monitoring every 4 h until stabilization	Continuous or intermittent hemodialysis 5–10% dextrose solutions (occasionally 25–50% solutions) should be started on admission
Metabolic acidosis	Arterial blood-gas monitoring	Bicarbonate replacement or hemodialysis
Respiratory failure	Arterial blood-gas monitoring	Intubation if encephalopathy stages III and IV
Gastrointestinal bleeding	Intranasal/oral examination to rule out bleeding gums Endoscopy	Somatostatin (100 mg bolus followed by 50 mg/h); no β -blockers in the acute setting Sclerotherapy or banding of varices Balloon tamponade if uncontrolled bleeding
Multiorgan failure	Invasive hemodynamic monitoring	Supportive

BUN, blood urea nitrogen.

MAIN FEATURES OF VIRAL HEPATITIS

	HAV	HBV	HCV	HDV	HEV
Transmission	Fecal-oral, outbreaks	Sexual, parenteral, vertical	Parenteral, sexual, vertical	Sexual, parenteral	Fecal-oral, outbreaks
Incubation (in days)	15–45	30–180	15–160	30–180	14–60
Symptoms					
Fever	Common	Uncommon	Uncommon	Common	Common
Nausea, vomiting	Common	Common	Uncommon	Common	Common
Arthralgia, rash	Uncommon	Common	Uncommon	Uncommon	Common
Jaundice	Common in adults	Variable	Uncommon	Common	Common
Severity of acute hepatitis	Mild (depends on age)	30% icteric	Very mild	Severe	Variable (severe in pregnancy)
Frequency of hepatic failure	0.1%	0.1–1%	0.1%	5% coinfection 20% superinfection	1–2% (10–20% during pregnancy)
Frequency of chronicity	Never	1–10% adults 90% newborns	80%	5% if coinfection with HBV 95% if superinfection	Never
Acute diagnosis	Anti-HAV IgM	HBsAg, anti-HBc IgM	Anti-HCV, HCV RNA	Anti-HDV IgM / IgG, HDV RNA	Anti-HEV IgM, HEV RNA

HAV, hepatitis A virus; HBV, hepatitis B virus; etc.

lymphadenopathy. In the icteric phase, jaundice may be associated with pruritus and skin excoriations. Suspicion of hepatic failure is based on identification of the triad of jaundice, dark urine, and systemic symptoms. Although there are no pathognomonic laboratory abnormalities associated with viral hepatitis, rising aminotransferase values identify the development of hepatocellular necrosis. Aminotransferase values, which start rising during the prodromal phase (before elevations in bilirubin and alkaline phosphatase levels), usually peak at levels greater than 1,000 unit/L. There appears to be little correlation between the degree of aminotransferase elevation and prognosis. Prolonged prothrombin time, however, does signify worsening hepatic function and a poor prognosis.

Atypical Clinical Presentation

Cholestatic Hepatitis

Cholestatic hepatitis is characterized by marked pruritus and chemical evidence of intrahepatic cholestasis, with elevations of serum alkaline phosphatase and serum bilirubin levels (usually in excess of 15 mg/dL), but no substantial hepatocellular disease. Despite their jaundice, these patients generally feel and do well.

Fulminant Hepatic Failure

FHF complicates viral hepatitis in less than 5% of the cases. Hepatitis A rarely may lead to FHF (0.1% of acute cases). The risk is higher in older patients and in those with underlying

chronic liver disease (9). Hepatitis B is the most common viral cause of FHF (50%–70% of virus-related cases). The low risk of developing FHF with acute hepatitis B virus infection (0.1%–1.0% of acute hepatitis B cases) is increased by infection with mutant strains or coinfection with hepatitis delta virus. Hepatitis C alone is a rare cause of FHF, but hepatitis C virus infection may contribute to hepatic failure in association with other viruses. By definition, patients with FHF have some degree of *cerebral dysfunction*, which may range from subtle personality changes to deep coma (Table 83.4). Jaundice is generally present; its absence may lead to an erroneous diagnosis of a psychotic episode, drug overdose, or septicemia. Other disorders that may masquerade as hepatic encephalopathy must be excluded. Laboratory investigations usually clarify the diagnosis.

Differential Diagnosis and Initial Evaluation

In patients presenting with severe acute hepatitis, an in-depth history including questions to assess suicidal ideation or surreptitious ingestion of toxins (including mushrooms or unusual herbal medicines) must be obtained. A rigorous examination also should be performed to look for incipient encephalopathy, which may be an early indicator of liver failure. Thereafter, neurologic status should be assessed frequently. If mental status worsens, intubation for airway protection must be considered. The physician also should search for signs of underlying chronic liver disease (such as spider nevi or palmar erythema), which is a risk factor for a severe course of acute hepatitis.

Because of the considerable overlap in the clinical symptoms, signs, and biochemical laboratory tests, serologic testing is needed to establish a specific diagnosis (Table 82.5). Useful laboratory tests include measurement of aminotransferases, total bilirubin, alkaline phosphatase levels, and prothrombin time. Evidence of a prolonged prothrombin time (INR of 1.5 or greater or prothrombin time of 17 seconds or longer), should raise concern regarding the potential development of FHF and should prompt continuous monitoring. These laboratory tests should be followed every 12 hours initially and then daily. If a coagulopathy is present, neither vitamin K nor fresh frozen plasma should be administered unless there is overt bleeding, as no benefit has been proven from these interventions, and therapy could mask the progression of the coagulopathy. Other useful tests include arterial blood-gas, creatinine, and hematocrit measurements. Ultrasound may be used to exclude biliary pathology in cholestatic forms of hepatitis.

Assessing the severity of the episode is essential for prompt referral to a transplant center (Table 82.2). In patients with signs of severe disease, information that is useful to the transplant center includes (a) *patient characteristics*, with special emphasis on height and weight, other medical problems that might preclude liver transplantation, social and psychological profile, and information about substance abuse; (b) *basic laboratory tests and measurements*, including complete blood counts with differential, platelet counts, electrolytes, serum aminotransferases, alkaline phosphatase, bilirubin, albumin, amylase, blood type, prothrombin time, arterial blood gases, urinalysis, and urine output; (c) *bacteriologic and serologic data*, including blood, urine, and ascitic fluid cultures, hepatitis B surface antigen, hepatitis B core IgM antibody, hepatitis A virus IgM antibody, hepatitis C virus antibody, and HIV serology; and (d) *imaging information*, including abdominal Doppler ultrasound, chest radiograph, and brain imaging results if indicated, electrocardiogram, and electroencephalogram.

Indications for Hospitalization

In the vast majority of cases, acute viral hepatitis is self-limited and most patients do not require hospitalization. Simple advice includes elimination of alcohol intake and discontinuation of potentially hepatotoxic medications. There are no mandatory dietary modifications. Sedatives and opiates should be avoided. Cholestyramine is the drug of choice for pruritus. There are certain clinical and biochemical characteristics that suggest a more complicated course and should lead to hospitalization (Table 82.6).

Indications for Early Consultation

Virtually all patients whose hepatitis is severe enough to require admission would benefit from a consultation by a

TABLE 82.6
ACUTE SEVERE HEPATITIS: INDICATIONS FOR HOSPITALIZATION

Serious underlying medical condition
Advanced age
Pregnancy
Treatment with hepatotoxic medication or immunosuppressive drugs
Underlying chronic liver disease
Malnutrition
Severe vomiting precluding adequate oral intake
Features suggestive of fulminant liver failure such as hepatic encephalopathy
Patients presenting with ascites
Laboratory findings of prolonged PT (>50% over the normal range), low serum albumin, hypoglycemia, or serum bilirubin >20 mg/dL
Any sign of gastrointestinal bleeding

PT, Prothrombin time.

hepatologist. In addition, patients with acute viral hepatitis and elevated creatinine, recent surgery, pregnancy, and HIV infection should be seen by a specialist.

Indications for Intensive Care Unit Admission

Any patient suspected of having FHF should be admitted to an ICU for monitoring for and treatment of complications (Table 82.6).

ISSUES DURING THE COURSE OF HOSPITALIZATION

There are no specific treatments for severe acute viral hepatitis. The use of lamivudine in the patient with acute hepatitis B is controversial; there are no randomized trials to guide this decision. Those rare acute causes of hepatitis with effective treatment are listed in Table 82.5. The highest priority during a hospitalization for acute viral hepatitis is thus *early recognition of FHF*. Avoidance of potential aggravating factors (such as electrolyte imbalance, nosocomial infections, and use of sedatives) and treatment of any complications (Table 82.4) are the key elements of successful management. Treatments that should be continued in patients with acute severe hepatitis include insulin in those with insulin-dependent diabetes (lowering the daily dosage to maintain blood glucose levels above 200 mg/dL), IV quinine in patients in whom falciparum malaria is suspected (i.e., travelers returning from endemic areas), and appropriate hormonal therapy in those with adrenal or thyroid insufficiency. Periodic assessments of neurologic status should be performed. In addition, information that ultimately could contraindicate liver transplantation should be assessed (Table 82.7) in case trans-

TABLE 82.7
CONTRAINDICATIONS TO URGENT LIVER TRANSPLANTATION IN CASE OF FULMINANT HEPATIC FAILURE

Severe irreversible brain damage
Active alcohol/drug abuse
Septic shock (bacterial infection is not a contraindication)
Severe cardiopulmonary disease
Acquired immunodeficiency syndrome
Severe hemorrhagic pancreatitis
Severe adult respiratory distress syndrome
Widespread thrombosis of portal and mesenteric veins
Sustained elevation of ICP >50 mm Hg
Cerebral perfusion pressure <40 mm Hg for >2 h

ICP, Intracranial pressure.

plantation is necessitated by worsening FHF. Attempts should be made to determine the cause, if it is still unknown at admission. Daily blood and urine cultures should be performed and broad-spectrum antibiotic therapy begun if there is any reasonable suspicion of active infection. It is important to remember that in severe forms of acute hepatitis, the classic signs of infection (such as fever, leukocytosis, or positive blood cultures) may be absent. An unexplained decrease in blood pressure or in urinary output, worsening hepatic encephalopathy, or development of severe acidosis should suggest sepsis (Chapter 26) and prompt the initiation of antibiotics and ICU admission. Liver function should be assessed frequently—initially every 12 hours, then daily. If prothrombin time or factor V levels are altered 50% or more out of the normal range, a hepatologist should be consulted. Finally, renal and pulmonary function should be measured daily so that complications can be recognized early.

DISCHARGE ISSUES

Once the prothrombin time has reached a plateau and begun to decrease, medical status has normalized, and other complications have resolved, the patient may be discharged from the hospital. Jaundice will still be present at this time; it may persist for as long as 4–6 weeks. Within two weeks of the onset of jaundice, the enlarged liver and spleen begin to shrink, pruritus resolves, and a sense of well-being returns. *Chronicity*, characterized by persistently abnormal liver function, is a major feature of hepatitis C virus infection (>80%) and to a lesser extent (1%–10%) of hepatitis B virus infection.

There are no specific measures to initiate upon discharge. The primary physician should assess laboratory values for chronicity. Any potential hepatotoxic medication should be avoided, as should alcohol. Follow-up by a primary physician should be scheduled within 2–3 weeks of

discharge, with an earlier visit scheduled for older patients or those with underlying comorbidities.

Precautions against percutaneous and sexual transmission are recommended for patients with hepatitis B or C for as long as there is virus present in the serum. Patients should abandon these precautions only if and when the virus clears from their sera (and virus is cleared only rarely in hepatitis C). By the time a patient with hepatitis A is discharged, no additional precautions are required, as the shedding of virus in feces precedes the development of acute disease.

SEVERE NONVIRAL ACUTE HEPATITIS

Although a viral agent is the most common cause of acute hepatitis, some cases are related to other causes, including drugs and metabolic or autoimmune disorders. Clinical symptoms at presentation are indistinguishable from acute viral hepatitis, with jaundice being the most prominent feature. Some features may point toward a particular cause (10–12) (Table 82.8). Criteria for admission are the same as for viral hepatitis, and efforts should be directed at detecting signs of liver failure and defining the cause (Figure 82.1).

Alcoholic Hepatitis

Most alcohol abusers remain asymptomatic and may develop cirrhosis silently if they continue drinking. A minority have episodes of acute alcoholic hepatitis. Although the course of alcoholic hepatitis is similar to that of viral hepatitis, some features help differentiate the two entities (Table 82.8). If, after initial evaluation, the clinician remains unable to distinguish between alcoholic hepatitis and a surgical process such as *cholecystitis*, a liver biopsy is preferable to laparotomy, which is associated with a high mortality rate among acutely ill patients. Typically, liver biopsy reveals swollen hepatocytes, inflammation with polymorphonuclear leukocytes, macrovesicular fat, and Mallory's bodies. In the patient at high risk for bleeding, liver biopsy may be performed via the transjugular route.

The management of patients with alcoholic hepatitis depends upon the severity of disease. Most patients with mild-to-moderate alcoholic hepatitis recover spontaneously following abstinence from alcohol and the provision of sufficient nutrition (Chapter 15) and vitamins (particularly folic acid). Patients with *severe alcoholic hepatitis*, defined by the presence of encephalopathy or a discriminant function (calculated as $4.6 [\text{prothrombin time} - \text{control time in seconds}] + \text{serum bilirubin [in micromoles per liter]} / 17$) greater than 32 and without gastrointestinal bleeding or bacterial infection derive a short-term benefit from treatment with corticosteroids (40 mg of methylprednisolone daily for four weeks) (13). Patients require intensive nutritional support, lactulose for encephalopathy, frequent checks of glucose, and close observation for infection

TABLE 82.8
FEATURES CHARACTERISTIC OF DIFFERENT CAUSES OF NONVIRAL ACUTE LIVER FAILURE

Disease	Main Characteristics
Acute fatty liver of pregnancy	Third trimester, associated with preeclampsia, hyperuricemia, hyperleukocytosis, mild increase of aminotransferase and bilirubin values
Alcoholic hepatitis	Consistent ingestion history, pain and tenderness, fever and hepatomegaly, AST higher than ALT with neither over about 600 International Units, normal ultrasound, leukocytosis and left shift, mild elevation of serum alkaline phosphatase, signs of chronic alcoholism
<i>Amanita</i> mushroom poisoning	Consistent ingestion history (lethal dose is approximately three medium-sized mushrooms), prominent abdominal cramps, vomiting, and diarrhea after a symptom-free interval of at least five hours
Budd-Chiari syndrome, veno-occlusive disease	History of chemotherapy or irradiation, bone-marrow transplantation; rapid onset of ascites, abdominal pain
Drug-induced hepatitis	Consistent ingestion history, absence of any other cause, hypersensitivity syndrome (cutaneous rash, fever, eosinophilia)
Ischemic hepatitis	History of hypoxia (septic or hemorrhagic shock, myocardial infarction, arrhythmias), coexistent renal failure, profound increase of serum aminotransferase values (>100 times normal) with moderate increase of bilirubin, improvement with treatment of the cause
Wilson's disease	Age <30 years, family history, Kayser-Fleischer ring, Coombs-negative hemolytic anemia, high levels of urine copper, very low concentration of serum ceruloplasmin
Autoimmune hepatitis	Young people (particularly women), presence of antiorganelle (anti-smooth muscle, anti-liver and kidney microsome type 1, antinuclear) antibodies. Giant-cell hepatitis (syncytial cells) may be a histological feature.

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

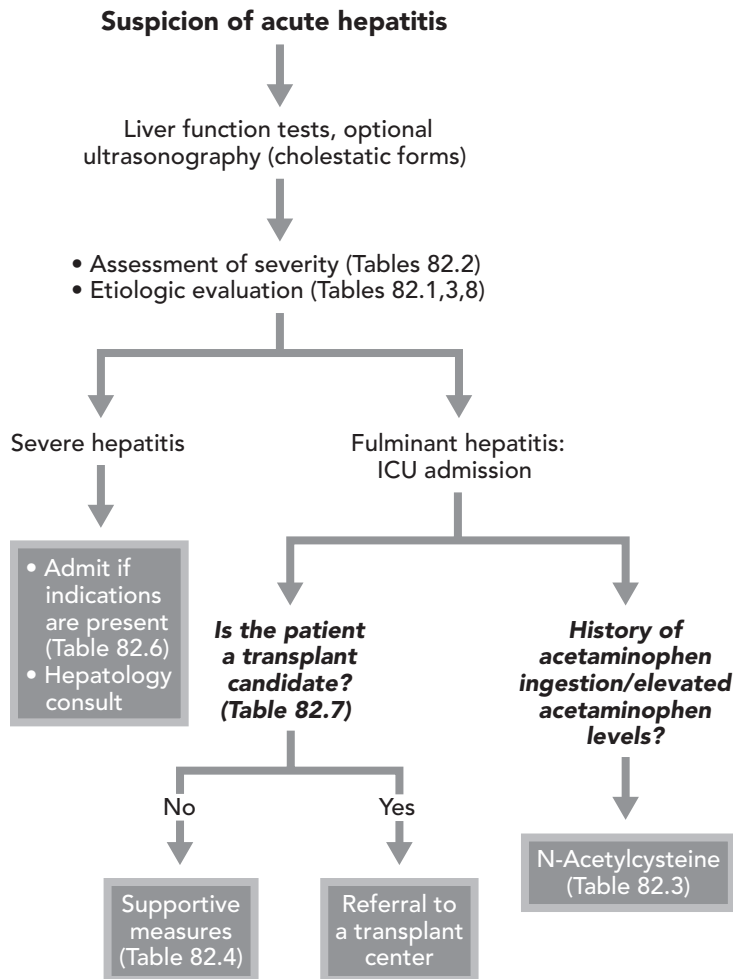

Figure 82.1 Management of acute hepatitis.

(including spontaneous bacterial peritonitis). These patients often benefit from the involvement of experienced hepatologists (Chapter 83).

Generally, serum bilirubin and albumin measurements and prothrombin time improve during the first 2–3 weeks of treatment, and patients may be discharged home to finish the six weeks of steroid therapy. Follow-up by a primary physician should be scheduled within one week of discharge.

The mortality rate among patients with severe alcoholic hepatitis is high, exceeding 60% in some series. The role of hepatic transplantation is still uncertain (Chapter 85). Although corticosteroids produce a short-term benefit in the small subset of severely ill patients with no bacterial infection or gastrointestinal bleeding, long-term survival is not improved. Because the prognosis of these patients is determined largely by their ability to remain abstinent from alcohol, careful long-term monitoring and appropriate counseling are important.

Acetaminophen Overdose

Acetaminophen is the most widely used nonprescription analgesic in the USA. If used according to package recommendations, there is very little risk of liver injury. However, it is a common putative cause of acute liver failure because of its recognized dose-related hepatotoxicity, its easy availability, and its frequent administration in the face of other cofactors, such as alcohol use, opiates, and starvation (5). Of all patients with FHF, those with acetaminophen-related liver failure have the best chances of spontaneous recovery with supportive care. However, clinicians should be aware of the rapidity with which liver injury evolves. Since outcome is unpredictable, early transfer to a transplantation unit should be considered. The monitoring should include repeated (twice daily) measurements of serum creatinine and prothrombin time, two main prognostic factors. N-acetylcysteine (NAC) is the main antidote (Table 82.3), with survival rate being related to the rapidity of its administration (6). NAC may induce nausea and occasionally cardiac arrhythmias.

COST CONSIDERATIONS AND RESOURCE USE

In considering the most cost-effective strategy for the management of acute liver failure, one needs to consider several variables, including the expected survival of patients with and without transplantation and the expected costs associated with transplantation. In 1996, the average charges for liver transplantation in the first year were \$314,500, with an estimated annual follow-up charge of an additional \$29,100. Because many transplant programs compete for contracts on the basis of both costs and outcomes, accept-

ing “difficult patients”, such as those with severe acute liver failure, may provide a disadvantage to a program in the current health care marketplace.

KEY POINTS

- Acute viral hepatitis is, in the vast majority of cases, a self-limited and benign disease with complete recovery and restoration of liver function. Most patients do not require hospitalization.
- Because severe acute hepatitis can evolve into FHF, patients with features suggesting a more severe course and significantly impaired synthetic function should be hospitalized for monitoring.
- Fulminant hepatic failure (defined as spontaneous encephalopathy or biochemical evidence of advanced hepatocellular dysfunction) is an indication for ICU admission.
- The major markers of unfavorable outcome in patients with FHF include encephalopathy, a prolonged prothrombin time, or a diminished factor V level.
- Patients with severe alcoholic hepatitis without infection or bleeding derive a short-term benefit from corticosteroid therapy.
- Early contact with a liver-transplant program is mandatory if the disease follows a severe or atypical course. Liver transplantation remains the best therapeutic approach in patients with low likelihood of spontaneous recovery.

Cirrhosis and Its Complications

83

Don C. Rockety

INTRODUCTION

Persistent liver injury leads to the clinical and pathologic entity known as cirrhosis. Although hepatic injury can be caused by a number of infectious or metabolic processes, the eventual clinical outcomes are identical, namely a histologic lesion consisting of bridging fibrosis with regenerative nodules. This scarring process leads to hepatocellular dysfunction and portal hypertension, each with attendant clinical sequelae and manifested as liver failure, hepatic encephalopathy, variceal hemorrhage, and ascites. Progressive hepatocellular dysfunction results in hepatic encephalopathy and liver failure; portal hypertension is the cause of ascites and variceal hemorrhage.

The complications of cirrhosis highlighted above are often life threatening. For example, the mortality rate of patients during the first episode of acute esophageal variceal hemorrhage is approximately 35%. Further, the 1-year mortality rate of patients with cirrhotic ascites approaches 50%. These poor outcomes underscore the severity of the underlying disease process. This chapter focuses on the major complications (ascites and spontaneous bacterial peritonitis [SBP], hepatic encephalopathy, and hepatorenal syndrome) in patients with known or presumed cirrhosis. Acute hepatitis, fulminant liver failure (Chapter 82), and acute variceal hemorrhage (Chapter 78) are reviewed elsewhere.

Portal Hypertension

Portal hypertension is the major complication of cirrhosis. The portal system is normally a low-pressure system. Portal hypertension occurs if the pressure in this system exceeds the pressure in the inferior vena cava by more than 5 mm Hg.

Collateral vessels (varices) form as the vascular system attempts to equalize the pressure between the portal and systemic circulation. The most common and clinically relevant sites in which collaterals form are in the esophagus and stomach. Elevated portal pressure results from increased intrahepatic resistance and/or increased flow through the portal venous system. Increased resistance probably occurs first and is followed by an increase in flow. Both increased resistance and flow are potential therapeutic targets.

Although portal hypertension most commonly results from cirrhosis (which leads to so-called "sinusoidal portal hypertension"), prehepatic portal hypertension (e.g., caused by portal or splenic vein thrombosis) and post-hepatic portal hypertension (caused by cardiac disease or hepatic vein occlusion) must be considered in all patients. Altered portal hemodynamics contributes not only to varix formation but also to ascites formation. The mechanism of ascites formation is not entirely understood but is most likely related to derangement of the neurohumoral axis that regulates sodium and water excretion.

Practical Approach to the Patient with Cirrhosis

When approaching the patient with possible cirrhosis, it is important to search for evidence of chronic liver disease. Clinical signs of cirrhosis include the following: spider angiomas, distention of abdominal wall veins, ascites, splenomegaly, muscle wasting, Dupuytren's contractures (especially with ethanol-associated cirrhosis), gynecomastia and testicular atrophy in males, and palmar erythema. However, it is important to emphasize that even in patients with histologic cirrhosis, these physical signs may not always be present. Laboratory data provide further clues to the

presence of cirrhosis as well as to the severity of the disease. In particular, the prothrombin time, bilirubin, albumin are important. These tests are important components of the Childs-Pugh classification (Table 85.1) and therefore are also used to help assess the severity of the liver disease. Additionally, the platelet count has proven to be a useful predictor of the presence of clinical portal hypertension (a low platelet count is caused by portal hypertension, splenomegaly, and sequestration of platelets in the spleen).

The cause of cirrhosis should be determined in all patients. An overview of initial evaluation is shown in Figure 83.1. The differential diagnosis of cirrhosis includes other diseases that may cause portal hypertension or ascites. All patients must have a careful cardiac examination, especially for constrictive pericarditis, because this disease easily can be mistaken for primary hepatic disease with portal hypertension. The nephrotic syndrome also can be misconstrued as cirrhosis. Ultrasound or computed tomography findings can suggest cirrhosis when portal hypertension is present. However, imaging tests are inadequate when an assessment of parenchymal architecture is required. Liver biopsy is the gold standard for assess-

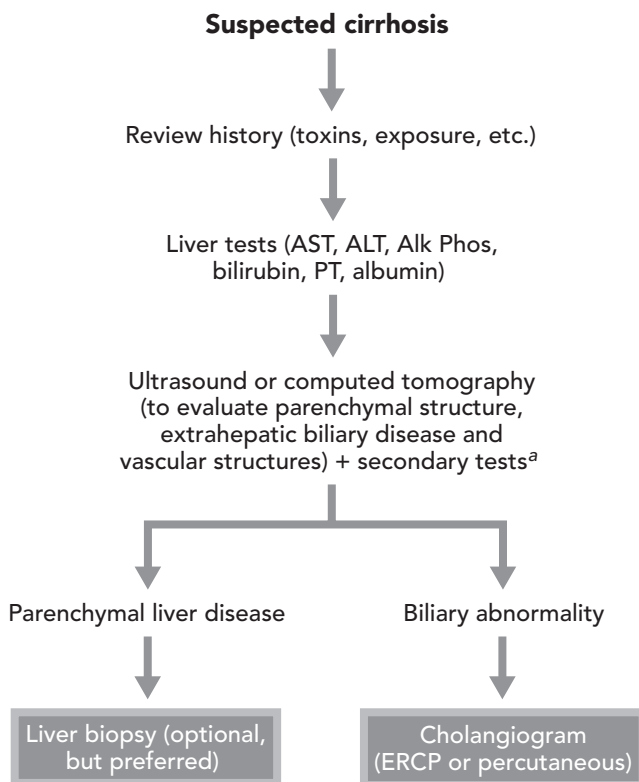

Figure 83.1. Evaluation of patients with suspected cirrhosis. Evaluation follows as outlined in the algorithm. ^aSecondary tests include the following: hepatitis serologies (B/C), iron studies (ferritin and iron saturation for hemochromatosis), copper studies (ceruloplasmin, urinary copper excretion, or slit-lamp examination if the patient is young or has neuropsychiatric disease), antinuclear antibody (autoimmune hepatitis), antimitochondrial antibody (primary biliary cirrhosis). *Alk Phos*, alkaline phosphatase; *ALT*, alanine aminotransferase; *AST*, aspartate aminotransferase; *ERCP*, endoscopic retrograde cholangiopancreatography; *PT*, prothrombin time.

ment of hepatic architecture and in some instances is required to document and assess the extent of hepatic disease. In situations in which the diagnosis is unclear, a hepatologist should be consulted.

Although many patients (up to 40%–50%) with cirrhosis are asymptomatic, once a complication of cirrhosis becomes clinically evident, an accelerated clinical course usually ensues. Generally, the underlying severity of liver disease dictates the clinical course. For this reason, it is imperative to assess the functional status of patients with liver disease early in their course. The presence of hepatic encephalopathy indicates severe hepatocellular dysfunction. Hepatocyte function is also judged by measurement of the prothrombin time, because hepatocytes synthesize clotting factors. An elevated prothrombin time in the absence of malnutrition or obstruction of the biliary system strongly suggests severe functional impairment. The serum albumin level also is used to judge hepatocellular function. In a patient with known liver disease, ascites strongly suggests portal hypertension and is also a sign of advanced disease. Such data allow a rapid assessment of the patient's clinical state and should be sought upon admission to the hospital. Child's classification, or the *Child-Pugh score* (Table 85.1), is a semiquantitative assessment of these and other factors that readily allows clinical ascertainment of the patient's clinical status, a discussion of prognosis with the patient, and a common ground for review of the literature. Recently, the *MELD (model for end-stage liver disease)* scoring system has been used to help assess the severity of liver disease. This quantitative scoring system calculates a single number based on the patient's bilirubin, prothrombin time, and creatinine and, unlike the Child-Pugh score, does not rely on subjective assessments, such as the degree of encephalopathy or the severity of ascites. Nonetheless, the Child-Pugh system remains useful for assessing the severity of the underlying liver disease. For example, the 1-year survival of patients with Child-Pugh class C disease is less than 50%.

Once a patient with cirrhosis presents with a complication, an assessment should be made as to patient's suitability for liver transplantation (Chapter 85). This is because the prognosis of the cirrhotic patient in the face of one of the known complications of cirrhosis is generally very poor, and the 5-year survival rate with transplantation approaches 70%. Consultation with an experienced hepatologist should be pursued early.

ASCITES

Ascites is defined as an abnormal accumulation of fluid in the peritoneal cavity. The most common cause is portal hypertension, but primary peritoneal disease should be considered initially, at least once, in all patients. In patients with a tense collection of abdominal fluid, the diagnosis of ascites is straightforward. However, patients with small or moderate degrees of ascites often present a diagnostic dilemma. The physical examination is notori-

ously unreliable for detection of up to 5 L of fluid in the abdominal cavity. Thus, if there is any question as to the presence or absence of ascites, ultrasound should be performed because it is extremely reliable, relatively simple, and inexpensive.

Issues at the Time of Admission

An important consideration in the care of patients with ascites is determining whether admission is required. Patients should be considered strongly for admission if they present with fever, abdominal pain, volume depletion or severe volume overload, altered mental status, or severe hyponatremia (<115 mEq/L). These clinical features often suggest spontaneous bacterial peritonitis (see below).

Additionally, it is imperative to determine the cause of ascites. Although the majority of patients admitted to the hospital with ascites have liver disease and portal hypertension underlying their ascites, other causes must be excluded (Table 83.1). For this reason, all patients with new-onset ascites should undergo diagnostic paracentesis. Diagnostic paracentesis is performed with a large (16-gauge) catheter with or without local anesthesia. Paracentesis can be performed in either the lower quadrant or the midline; the left lower quadrant is probably the safest. In general, the measurement of the ascites fluid albumin level is mandatory in patients undergoing diagnostic paracentesis, and the result is used to measure the *serum-ascitic fluid albumin gradient*. Diseases with a portal hypertensive basis have a high gradient (>1.1 g/dL); those associated with primary peritoneal disease (e.g., tuberculous peritonitis or carcinomatosis) have a low gradient. It is important to emphasize that a high gradient is present in patients with mixed processes (i.e., portal hypertension and a peritoneal disorder). Ascitic fluid WBC has become the gold-standard test for the diagnosis of SBP (see later in this chapter) and, therefore, is required in all patients in whom this diagnosis is possible. The clinical situation dictates the use of other diagnostic tests. For example, amylase level may be useful in patients with a history of pancreatitis to exclude pancre-

atic ascites, triglyceride measurements should be obtained in those with cloudy fluid to exclude chylous ascites, and cytology is important if malignancy is a possibility.

Issues During the Course of Hospitalization

An algorithm for diagnosis and management of ascites is shown in Figure 83.2. Because sodium retention is a key element in cirrhotic ascites, sodium restriction is a highly effective—but poorly complied with—therapy for patients with ascites. Upon admission to the hospital, sodium intake initially should be restricted to 1,000 mg/d (44 mmol/d). Sodium can be restricted to as low as 250 mg/d; however, upon discharge, patients rarely comply with this degree of sodium restriction, and thus it is more realistic to institute a more lenient degree of restriction. Diuretics are used to promote additional sodium loss. Diuresis usually is begun with spironolactone (100 mg/d). If spironolactone alone is ineffective, furosemide usually is added (beginning at 20 mg/d). After diuresis has been induced (a target level is 500–1,000 mL/d in those with peripheral edema, and no more than 500 mL/d in those without edema), sodium restriction and diuretic dose may be tailored to appropriate outpatient levels. During sodium restriction and diuretic therapy, renal function and electrolyte levels should be monitored closely. All patients with elevated creatinine levels should have a careful analysis of urine and a formal creatinine clearance performed. Serum creatinine must be interpreted with caution, as it correlates poorly with renal function in cirrhotic patients. Patients with ascites often have impaired water excretion, and thus hyponatremia is common. Diuretics often compound the problem, although the pathogenesis of hyponatremia in this setting is unclear. Free water restriction is not always necessary in patients with ascites, particularly in those without hyponatremia. However, in patients with hyponatremia, free water restriction at a level of 1 to 1.5 L/d usually is required.

Approximately 20% of patients have ascites that is seemingly refractory to sodium restriction and diuretics. Although this is often because of poor compliance, these patients present difficult management problems. *Large-volume paracentesis* (5–10 L at a time) is effective for short-term removal of fluid and provides rapid symptomatic relief. Although large-volume paracentesis is generally safe, it is associated with functional changes in hemodynamics and plasma renin activity, and it can be complicated by renal impairment, dilutional hyponatremia, and hepatic encephalopathy. Controversy surrounds the use of volume expanders immediately after large-volume paracentesis. Use of intravenous albumin (8 g per liter of ascitic fluid removed) prevents many of the hemodynamic alterations associated with paracentesis and represents a sensible adjunct to large-volume paracentesis. Unfortunately, intravenous albumin is extremely expensive and, moreover, does not alter outcome compared with other less effective volume expanders such as dextran-70 or polygeline (1). If volume expansion is deemed essential, albumin is still the preferred agent despite its cost.

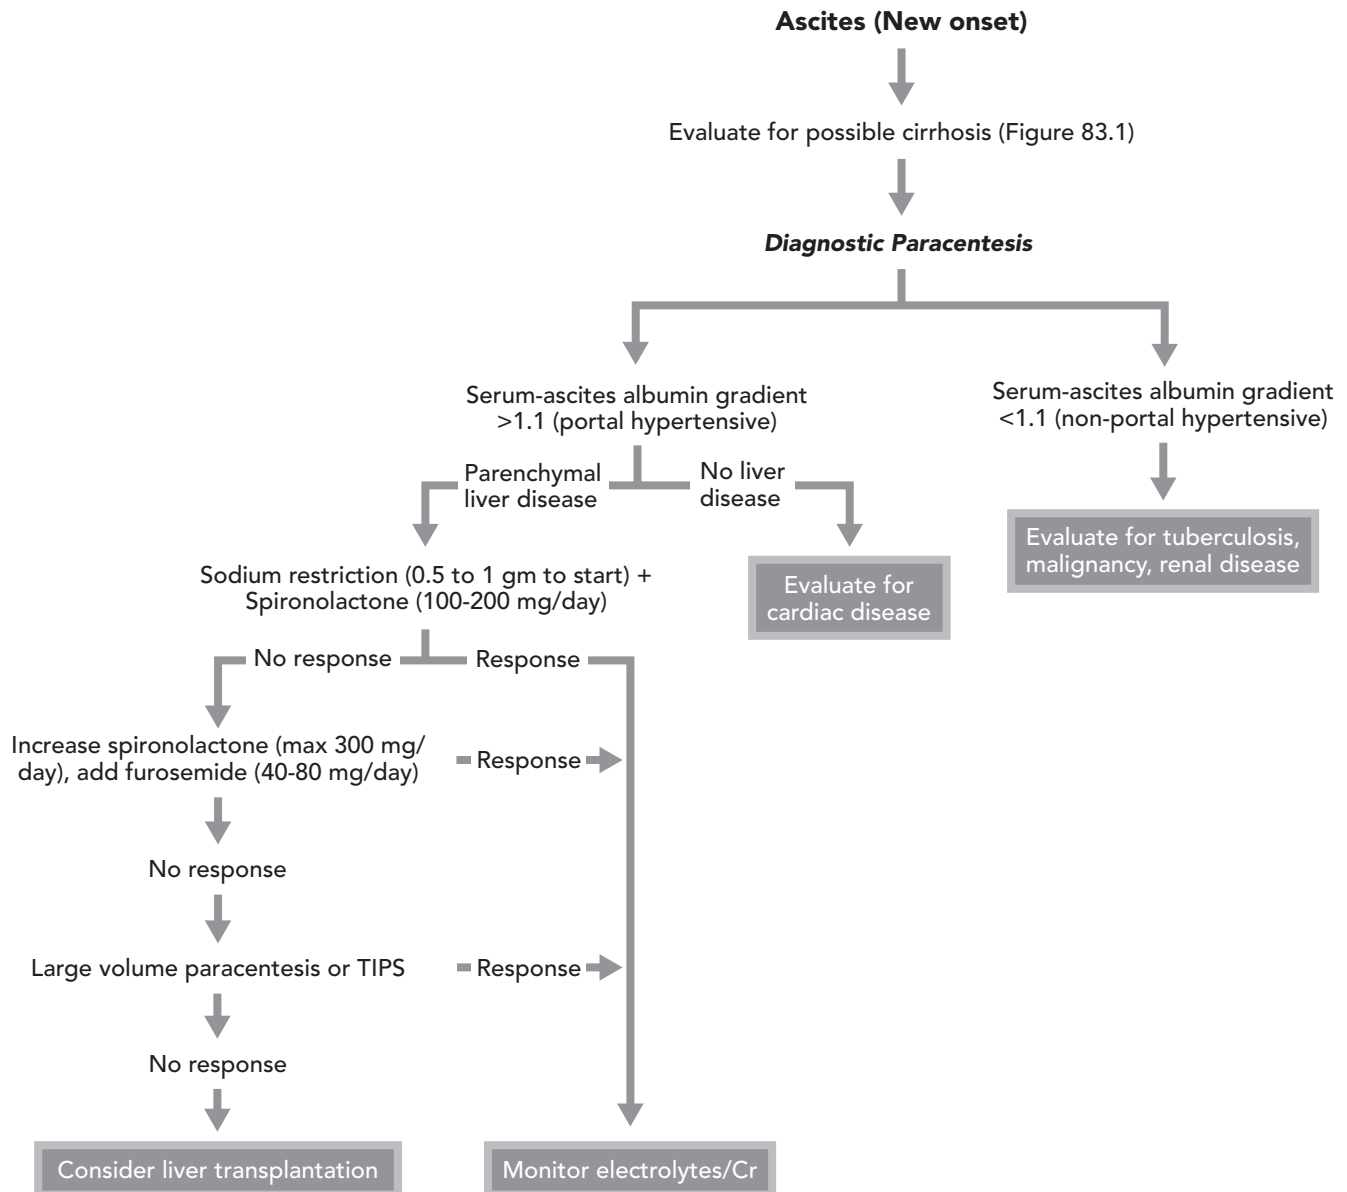

Figure 83.2 Evaluation and treatment of ascites. Cr, creatinine; TIPS, transjugular intrahepatic portosystemic shunt.

Peritoneovenous shunting can be highly effective for treatment of refractory ascites. This intervention leads to increases in glomerular filtration rate and decreases in serum aldosterone and plasma renin activity. However, frequent complications, including shunt occlusion, low-grade disseminated intravascular coagulopathy, and sepsis, have dampened enthusiasm for this procedure. Moreover, in a randomized controlled trial, peritoneovenous shunting did not result in increased survival compared with large-volume paracentesis or standard diuretic therapy (2). Finally, because peritoneovenous shunting may lead to recurrent SBP, venous thrombosis, and peritoneal fibrosis, the use of peritoneovenous shunting is not recommended in patients who are or may become candidates for liver transplantation.

The *transjugular intrahepatic portosystemic shunt* (TIPS) is an effective management strategy for some patients with

refractory ascites (3). TIPS is performed via a transjugular approach and creates a shunt from the portal vein to the central venous system (Figure 83.3). A TIPS behaves like a side-to-side portocaval shunt. In selected patients, a TIPS results in resolution of ascites or a significant reduction in diuretic requirements, and appears to be associated with an apparent improvement in nutritional status (4). However, complications are common (Table 83.2). Additionally, patients undergoing a TIPS require careful follow-up because of the high incidence of shunt stenosis. Finally, in randomized trials of TIPS versus medical management in patients with refractory ascites, results have varied, but the consensus view is that TIPS does not improve the mortality rate compared with large-volume paracentesis (5, 6). Thus, although TIPS can be highly effective therapy for certain patients with refractory ascites, caution is required, and a

Figure 83.3 Radiographic example of TIPS. A TIPS is by creating a tract from the portal vein to the central venous drainage of the liver. Panel **A**. shows the portal venous anatomy in a patient with clinical portal hypertension and ascites prior to TIPS; prior to TIPS placement, varices are prominent. In **B**. varices are absent after the shunt is successfully created and portal pressure is dramatically reduced. Placement of a successful shunt results in correction of the hepatic venous pressure gradient. TIPS, transjugular intrahepatic portosystemic shunt. (Images courtesy of Paul Suhocki, M.D., Duke University Medical Center).

hepatologist should be involved in all cases prior to this intervention for patients with refractory ascites. TIPS is not recommended in certain patients with advanced liver disease, such as those with elevated bilirubin (greater than 5 mg/dL) or elevated prothrombin time (INR >2.5). The use of TIPS in patients with varices is covered in Chapter 78.

Liver transplantation (Chapter 85) is highly effective for treatment of ascites. However, this therapy generally is reserved for patients who are severely incapacitated or who have had serious complications such as recurrent spontaneous bacterial peritonitis, hepatic hydrothorax, or functional renal impairment caused by diuretics. Hepatology input is required for consideration of liver transplantation.

The length of hospitalization generally depends on the severity of the ascites, and often the degree to which electrolyte or renal abnormalities dominate the clinical picture. Because continued hospitalization often is mandated by such renal and electrolyte problems, hospital stays are usually long, on the order of 3–5 days.

In summary, most patients with cirrhotic ascites can be managed with a combination of sodium restriction and diuretics. Given the poor long-term prognosis of patients once they have developed ascites, a decision should be made as to whether the patient is a liver-transplant candidate. If the patient is a transplantation candidate, treatment should focus on minimizing complications that might preclude transplantation. Large-volume paracentesis is probably the best initial approach. However, in patients with preserved renal function and without encephalopathy, a TIPS should be considered early. Unlike surgical shunting, this procedure does not alter the later ability to perform transplantation. The cost of TIPS maintenance in this situation also is minimized by

the finite time period for which it is required. In patients who are not transplant candidates, management is much more difficult, but therapeutic options remain the same.

Discharge Issues

The most critical aspect of care for the patient with ascites is optimization of sodium balance, fluid intake, diuretics, electrolytes, and renal function. Overly aggressive diuresis may contribute to development of hepatorenal syndrome in some patients. Therefore, electrolytes and volume status must be monitored carefully as patients make the transition from the inpatient to the outpatient setting. It is imperative that patients be discharged on a reasonable diuretic regimen, and that they have follow-up within 1 week after discharge. Significant changes in the diuretic regimen close to the time of discharge are strongly discouraged.

Chronic oral antibiotic therapy should be considered for all patients with ascites, as this intervention reduces the risk of subsequent SBP (7). Several regimens exist, the best of which appear to be trimethoprim-sulfamethoxazole or ciprofloxacin given as a single daily dose or 3 times per week. All patients with cirrhosis should receive vaccination against hepatitis A. They should also be vaccinated against hepatitis B, if hepatitis B is not the cause of their disease and they are not already immune.

SPONTANEOUS BACTERIAL PERITONITIS (SBP)

SBP is a common complication in patients with liver disease and ascites. SBP is defined as infection of preexisting ascitic fluid in the absence of an intraabdominal primary infection. The diagnosis of SBP rests upon analysis of ascitic fluid. The diagnosis is established in the setting of an elevated polymorphonuclear leukocyte (PMN) count (>250 PMNs per cubic millimeter) in the presence of a positive culture for bacteria. Variants of SBP include "neutrocytic" ascites, in which a high PMN count is present but bacteria are not identified, and "bacterascites," in which the PMN count is low but bacteria are isolated from ascitic fluid.

Issues at the Time of Admission

The clinical presentation of SBP is highly variable. The classic presentation is with fever or abdominal pain. Some patients may be minimally symptomatic, at least initially, and any abrupt clinical change (e.g., worsening encephalopathy) in the patient with liver disease should raise suspicion for SBP. Furthermore, approximately 33% of patients with infected ascites present to the hospital without symptoms or signs of SBP; the prevalence of SBP at the time of hospital admission of patients with ascites is about 25%. Thus, a high index of suspicion for all patients with cirrhosis and

ascites is required to make this diagnosis, and those with ascites who require hospitalization should probably undergo diagnostic paracentesis.

A positive ascitic fluid culture is required to make a definitive diagnosis of SBP. However, the culture is imperfect because of its low sensitivity (which can be improved by inoculating 10 mL of ascitic fluid into blood-culture bottles) and the long lag time before results are known. Thus, the PMN count in ascitic fluid has become used widely for the diagnosis of SBP. The differential diagnosis of SBP is relatively limited; the main alternative diagnosis is secondary peritonitis. An extremely high PMN count ($>5,000/\mu\text{L}$) should raise the possibility of secondary peritonitis caused by a perforated viscus or other intraabdominal process. Further diagnostic studies (including abdominal computed tomography scan) are required in this setting.

Although most patients with SBP require hospitalization, there is a small subgroup of patients who may be able to be managed in the outpatient setting. These patients usually are relatively well compensated clinically, compliant, and present without evidence of sepsis. Consultation with a specialist and assurance of close follow-up are required if outpatient management is being contemplated.

Issues During the Course of Hospitalization

Without appropriate therapy, the mortality rate of SBP is high. Antibiotics are the cornerstone of therapy. Recent studies have suggested that selected patients can be treated with short courses of antibiotics and even with outpatient regimens (see above). Antibiotics are tailored to the specific organisms typically isolated from ascitic fluid. Because this process appears to result from translocation of bacteria from bowel to ascitic fluid, the most frequently isolated organisms are enterobacteriaceae. Gram-positive cocci, including *Streptococcus pneumoniae* and *Enterococcus* species, are also common. Anaerobes are rarely isolated.

The best initial antibiotic choice is a parenteral third-generation cephalosporin, such as ceftriaxone or cefotaxime. β -lactam/ β -lactamase combinations also provide excellent coverage with little toxicity. Aminoglycosides should be avoided because of renal toxicity. The clinical response to antibiotics is usually good. If patients do not respond within 48 hours, other processes (Table 83.3) should be considered. If specific culture results are available, antibiotic coverage should be changed accordingly. The optimal duration of therapy for SBP is unknown but should be tailored to the individual clinical scenario. Generally, a 5-day course is adequate, some of which may be in the form of oral antibiotics. Repeat paracentesis may be an important tool in determining the length of antibiotic therapy. In patients with definite clinical improvement, a repeat paracentesis is usually not necessary, although some clinicians prefer to switch to oral antibiotics after the PMN count is below $250/\mu\text{L}$. On the other hand, repeat paracentesis is essential in patients with an atypical course or in

TABLE 83.3**CONSIDERATIONS IN PATIENTS FAILING TO IMPROVE AFTER EMPIRIC THERAPY FOR SPONTANEOUS BACTERIAL PERITONITIS (SBP)**

Did patient really have SBP?	Reason for failure	Recommended approach
Yes	Resistant organism (<i>Enterococcus</i> , <i>Pseudomonas</i>)	Microbiologic tests, change coverage
Yes	Nonbacterial pathogen (tuberculosis, fungus)	Repeat history for risk factors, microbiologic tests
Yes	Concomitant other infection	Further examination, urinalysis, chest radiograph, blood cultures
No	Secondary peritonitis (perforation)	Abdominal computed tomography, colon evaluation, surgical consultation
No	Other process (malignancy)	Review history and physical, specific tests

those who have persistent symptoms or signs. It is also helpful in those with bacterascites (a positive culture, with low PMN count) and a benign clinical course. In general, repeat paracentesis should be performed liberally in patients with SBP because it can help assess response to therapy. Intravenous albumin (1.5 mg/kg at the time of diagnosis, followed by 1.0 mg/kg daily) is an expensive intervention but does improve renal function and mortality in patients with SBP, and should be considered (8).

The length of hospitalization depends on the severity of illness. In patients with uncomplicated SBP, hospitalization is generally short (2–3 days). In patients with severe SBP or those with SBP and another problem such as variceal hemorrhage or hepatic encephalopathy, hospitalization is often much longer (5–7 days).

Discharge Issues

A complete course of appropriate antibiotics should be completed or planned at the time of discharge. Patients with SBP usually should receive chronic prophylactic antibiotics because one episode of SBP identifies the patient who is at risk for further episodes. If appropriate, vaccination against hepatitis A and B should be provided.

HEPATIC ENCEPHALOPATHY

Hepatic encephalopathy is common in patients with chronic liver disease and is a frequent indication for hospital admission. Its diagnosis is based on the presence of specific neurologic symptoms and signs in patients with advanced liver disease (Table 83.4). Importantly, the diagnosis of hepatic encephalopathy also requires exclusion of other causes of encephalopathy.

Issues at the Time of Admission

Although the diagnosis of encephalopathy as a clinical entity is straightforward, a differential diagnosis of the cause of encephalopathy in patients with known liver disease must be formulated in all cases. It is critical to consider metabolic encephalopathy (i.e., Wernicke-Korsakoff syndrome, hypoglycemia, electrolyte disturbances, ethanol intoxication), central nervous system infection, and structural lesions such as subdural hematoma. An ammonia level may be helpful in patients with a previous history of abnormal ammonia levels. However, this test must be interpreted with caution because its sensitivity and specificity are imperfect. In contrast, *cerebrospinal fluid glutamine levels*

TABLE 83.4**STAGES OF ENCEPHALOPATHY**

Stage	Symptoms	Signs
Subclinical	Impaired work, personality changes	Impaired psychomotor testing
I	Mild confusion, agitation, apathy	Fine tremor, asterixis
II	Drowsiness, lethargy, disorientation	Asterixis, dysarthria
III	Sleepy but arousable, marked confusion	Hyperreflexia, hyperventilation
IV	Coma	Decerebrate posturing, oculocephalic reflexes intact

have a high sensitivity and specificity for hepatic encephalopathy.

Reversible predisposing factors, such as gastrointestinal bleeding, infection, increased dietary protein level, use of sedative drugs, and renal failure, also must be identified and corrected in patients with hepatic encephalopathy. In the majority of patients, hepatic encephalopathy results from noncompliance with a prescribed medical regimen. In patients with ascites, diagnostic paracentesis is essential. Head computed tomography (to exclude subdural hematoma) and lumbar puncture should be considered strongly in patients with atypical symptoms or signs.

Issues During the Course of Hospitalization

The management of hepatic encephalopathy centers on correction of factors that precipitate or induce the altered mentation and decreasing production of toxins that result from enteric bacterial metabolism of nitrogenous compounds. Thus, sedative drugs should be discontinued, and infection, bleeding, and electrolyte abnormalities should be corrected. To remove toxins, dietary protein is restricted and enteric bacteria are killed or their products purged. In patients with mild encephalopathy, dietary protein should be restricted to less than 40 g/d; in those with severe encephalopathy, dietary protein should be eliminated. In patients with severe encephalopathy, treatment entails aggressive lactulose therapy. Lactulose is given at a dose of 30 mL every two hours until diarrhea begins. If patients cannot take oral medications because of disorientation, a nasogastric tube is recommended. Once diarrhea occurs, the lactulose schedule should be modified based on response and stool output. Two to four loose stools per day are optimal, and profuse diarrhea should be avoided. Neomycin can be added (1–2 g every 6 hours) or may be used as a substitute for lactulose; it is unknown whether the combination of lactulose plus neomycin is more effective than either alone. Patients who do not respond to lactulose or neomycin within 24 hours must be reassessed carefully, and the issues raised in Table 83.5 should be readdressed.

The length of hospital stay for patients with hepatic encephalopathy often depends on the underlying cause. In

patients hospitalized because of simple noncompliance, hospital stays are short (1–2 days). In those with severe underlying processes, however, hospital stays are longer (5–7 days).

Discharge Issues

Patients should be discharged only after their mental status has cleared and after a stable dosage of lactulose (or neomycin) has been achieved. Patient education is essential: all patients should be seen by a dietitian with expertise in liver-related diseases and placed on an appropriate diet. Follow-up and compliance are important. Thus, precise discharge instructions to the patient and care providers are essential. If appropriate, patients with cirrhosis should receive vaccination against hepatitis A and B.

HEPATORENAL SYNDROME

The hepatorenal syndrome is a common and extremely problematic complication of cirrhosis. It is characterized by intense activation of the renin-angiotensin-aldosterone system, with pronounced vasoconstriction of the renal circulation, which results in marked reduction of renal blood flow and glomerular filtration rate. The hepatorenal syndrome has been subtyped into two categories, which are likely to differ mechanistically and require divergent therapies. Type I is characterized by rapidly progressive deterioration in renal function, defined by a doubling of the serum creatinine to a value of more than 2.5 mg/dL or a 50% reduction of creatinine clearance to a level less than 20 mL/min in less than two weeks. Type II is characterized by a more moderate and slowly progressive reduction of glomerular filtration rate. One common thread in both forms of hepatorenal syndrome is the presence of vasoconstrictive compounds (including endothelin 1 and angiotensin II) in the afferent renal circulation.

Issues at the Time of Admission

The diagnosis of hepatorenal syndrome is established in the patient with rising creatinine and oliguria by documen-

TABLE 83.5

CONSIDERATIONS IN PATIENTS FAILING TO IMPROVE AFTER EMPIRIC THERAPY FOR HEPATIC ENCEPHALOPATHY

Does the patient really have hepatic encephalopathy?	Reason for failure	Recommended approach
Yes	Inadequate treatment	Increase lactulose, add neomycin
Yes	Worsening liver function	Evaluate for transplantation, specialist consultation
No	Electrolyte abnormalities	Check sodium, calcium; correct abnormalities
No	Subdural hematoma or other structural lesion	Careful examination and/or head computed tomography
No	Meningitis	Review history and physical, lumbar puncture

tation of low urinary sodium (<10 mEq/L) in the absence of intravascular volume depletion. Acute tubular necrosis (Chapter 100) resulting from contrast dye, nonsteroidal anti-inflammatory agents, or aminoglycosides is important to exclude; such patients often have high urine sodium levels. Because hypovolemia is often difficult to differentiate from hepatorenal syndrome, a volume challenge of at least 1 L of colloid is required, and in some instances central pressure monitoring is indicated. Obstruction and intrinsic renal disease also must be excluded; therefore, ultrasound and examination of the urine sediment are also important.

Issues During the Course of Hospitalization

Treatment is generally unsatisfactory, and prognosis is extremely poor. It is imperative to identify and discontinue potentially nephrotoxic compounds. Attention to volume is the most critical aspect of management. Intravascular volume depletion should be reversed if present; volume repletion is often best performed in an intensive care unit setting with central venous pressure monitoring. Medical therapy is generally ineffective, although there are some data indicating that the combination of prolonged ornipressin (a vasopressin-like peripheral vasoconstrictive substance) and plasma volume expansion with albumin may result in suppression of vasoconstrictor activity, improvement in glomerular filtration rate, and reversal of the hepatorenal syndrome (9). Another report suggested that the combination of midodrine and octreotide may reverse type I hepatorenal syndrome (10). TIPS, hemodialysis, and portocaval shunts have been reported to lead to reversal of hepatorenal syndrome in some cases, but controlled data to support their use are not available. Although liver transplantation may be appropriate in some instances, and the 3-year survival approaches 60% in patients with hepatorenal syndrome who undergo transplantation, many of these patients have extremely difficult postoperative courses. Hepatology and nephrology input is essential.

Discharge Issues

Unfortunately, the vast majority of patients with type I hepatorenal syndrome who do not undergo liver transplantation die. For those with type II hepatorenal syndrome, careful attention to volume status and electrolytes is essential. Consultation with a palliative care service is appropriate for patients who do not improve and who are not transplant candidates (Chapter 19).

COST CONSIDERATIONS AND RESOURCE USE

Care of patients with cirrhosis is extremely costly because of the severity of the underlying disease process. Complications requiring hospitalization in this patient population lend themselves to long and often complicated stays. In-

deed, a number of clinical findings preclude discharge (Table 83.6). Because of the degree of chronic debilitation in many of these patients, efforts to encourage ambulation and improve nutrition early in the hospital course are imperative. Patient education is particularly critical in all patients with cirrhosis and its complications. Because these disorders are chronic and generally not reversible, patient education (Figure 83.4) improves compliance and reduces cost by decreasing the need for future hospitalization.

In patients with esophageal varices or ascites, hospitalizations and cost can be reduced by prophylactic therapy. For example, *prophylactic antibiotics* in patients with ascites reduce the risk of SBP and thus of hospitalization. Additionally, *β-blockers* reduce the risk of future variceal hemorrhage and should be considered in all patients, especially those with large varices (Chapter 78). A detailed discussion of the prophylactic management of varices is beyond the scope of this chapter, but options include sclerotherapy, banding, and TIPS. Each technique has important advantages and disadvantages. In patients randomized to TIPS or sclerotherapy, TIPS is associated with a lower rate of rebleeding but no mortality advantage. Banding appears to be safer and more effective than sclerotherapy, but this technique has not been directly compared to TIPS.

Finally, a recent study found that, in patients with chronic hepatitis B and advanced liver disease, continuous treatment with lamivudine significantly reduced the rate of hepatic decompensation and progression to hepatocellular carcinoma (11).

TABLE 83.6
HIGH-RISK CRITERIA THAT HELP IDENTIFY PATIENTS NOT READY FOR DISCHARGE

Ascites

Sodium <120 meq/L
Fever or abdominal pain
BUN:creatinine >25:1 ratio
Rising creatinine or declining urine output
Major changes in diuretic regimen within previous 24 h
Altered mental status
Deteriorating liver function
Persistent tense ascites

Variceal hemorrhage

Persistent melena
Systolic blood pressure <90 mmHg, heart rate >120/min
Altered mental status
Deteriorating liver function

Hepatic encephalopathy

Persistent alteration in mental status
Unstable lactulose or neomycin regimen
Deteriorating liver function

BUN, blood urea nitrogen.

Cirrhosis

Your doctor has diagnosed you with cirrhosis. Cirrhosis is a scarring process of the liver caused by many years of injury to the liver (this can be caused by a virus, alcohol, too much iron or copper, an autoimmune disease, or a disease of the bile ducts). You may also have one of the many complications of cirrhosis which include ascites, intestinal bleeding, or encephalopathy. Ascites is a condition in which too much fluid accumulates in the abdomen. This can make you uncomfortable and/or can lead to infections. Treatment for this is usually done by removing fluid either with fluid pills or a needle. Intestinal bleeding occurs when veins in your stomach or esophagus rupture. This can be prevented by putting small bands on the veins or by taking medication that reduces the pressure in them. Encephalopathy refers to clouded thinking or confusion. This is caused because the liver can not clear out bad toxins from the system. It is treated by removing toxins from the intestinal tract with medicine (usually lactulose).

Follow-up Care

Follow-up with your physician is essential to your ongoing care. An appointment has been scheduled with:

Dr. _____

Phone number _____

Date _____ Time _____

If you develop fever, shaking chills, vomiting, confusion, black stools, or abdominal pain or redness, you should call your doctor or go to the clinic or emergency room. Because your doctors are trying to control your liver disease with medicines, it is imperative that you take your medicine exactly as prescribed. If your doctor has advised you to avoid salt and water, it is also important that you follow this advice.

Figure 83.4 Sample patient discharge instructions for cirrhosis and its complications.

KEY POINTS

- Development of complications of portal hypertension or evidence of hepatocellular dysfunction herald an accelerated course that typically is associated with substantial morbidity and mortality rates.
- Ascitic fluid albumin and white count with differential are required in those undergoing diagnostic paracentesis.
- The cornerstone of management of ascites is careful adjustment of diuretics, fluid, and electrolytes. Most cases do not require other interventions such as TIPS.
- The diagnosis of spontaneous bacterial peritonitis is often subtle and may be manifested by low-grade

fever, change in mental status, or general clinical deterioration.

- Spontaneous bacterial peritonitis and gastrointestinal bleeding must be excluded in the patient with new or worsening hepatic encephalopathy.
- Aminoglycosides and all potential nephrotoxins should be avoided in cirrhotic patients.
- Patients with a new diagnosis of cirrhosis or any of its complications should be referred early for consideration of liver transplantation.

Disorders of the Biliary System

84

Douglas B. Nelson Paul Druck Martin L. Freeman

INTRODUCTION

Extrahepatic biliary-tract disease is most commonly associated with gallstones or neoplasia. Less common causes include inflammatory conditions such as primary sclerosing cholangitis, chronic pancreatitis, trauma or surgical injury, congenital anomalies, parasitoses, and primary infectious diseases such as HIV. Gallstone disease is by far the most common cause; it is estimated that 20 million adults in the United States have gallstone disease, and approximately 600,000 cholecystectomies are performed annually (1). Gallstones are composed primarily of cholesterol, as a result of cholesterol supersaturation of bile (75% of cases), or pigment, as a result of excessive secretion of bilirubin coupled with bacterial deconjugation of soluble glucuronides (25% of cases). In the absence of bile-duct abnormalities, the majority of gallstones form in the gallbladder. Epidemiologic correlates of cholesterol gallstones include advancing age, gender (female predominance prior to menopause), obesity, and race (increasing prevalence from African-American to Caucasian to Native-American). Pigment stones are associated predominantly with advancing age, cirrhosis, chronic hemolytic states, and chronic biliary-tract infections and are relatively more common in Asians (2).

Disorders of the biliary system most commonly become manifest as a result of obstruction, and the clinical presentation varies with the level of the obstruction. Figure 84.1 shows the relevant anatomy of the biliary tract. Bile canaliculi join to form progressively larger bile ductules and then bile ducts. Anatomically, segmental bile ducts coalesce into the right and left hepatic ducts, which then unite to form the common hepatic duct. The junction of the cystic duct, communicating with the gallbladder and the common hepatic duct, forms the common bile duct. The

pancreatic duct merges for a short but variable distance with the common bile duct at its terminus to empty into the duodenum at the ampulla of Vater.

Most gallstones reside in the gallbladder without causing symptoms (approximately 20% of patients develop symptoms within 15–20 years). However, stones that impact at any point from the cystic duct to the pancreaticobiliary junction can produce a variety of clinical symptoms and syndromes (Figure 84.1). The pathophysiology of gallstone-associated biliary-tract disease may involve contractile dysfunction of the gallbladder or cystic duct obstruction (*biliary colic*), cystic duct obstruction with infection of gallbladder or its contents (*acute cholecystitis*), common bile-duct obstruction (*pain, obstructive jaundice, or pancreatitis*), or bile-duct obstruction with superimposed infection (*acute cholangitis*). The pathophysiology of *acalculous cholecystitis* has not been elucidated fully.

Traditionally, *biliary colic* (episodic right upper quadrant or epigastric visceral-type pain with radiation to the subscapular area, often accompanied by nausea) has been attributed to transient obstruction of the cystic duct or neck of the gallbladder by a gallstone. This generally occurs postprandially and is relieved after a few hours when the obstructing stone returns to the gallbladder or passes into the common bile duct. Less commonly, the syndrome may be produced by transient common bile-duct obstruction or by gallbladder dysfunction as demonstrated by gallbladder emptying studies.

If the stones persist in obstructing the gallbladder, *acute cholecystitis* may occur. Acute cholecystitis is characterized pathologically by an acute inflammatory infiltrate of the gallbladder wall with thickening, arterial and venous dilation and engorgement, and occasionally areas of ischemic necrosis. Such necrotic foci may cause gallbladder

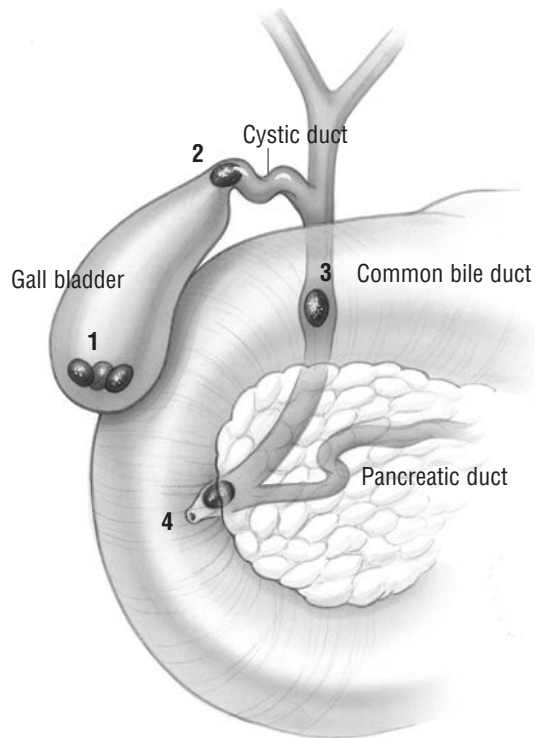

Figure 84.1 Illustration of biliary-tract anatomy, with obstruction caused by gallstones at various sites and their associated clinical manifestations. **1.** Gallstones in gallbladder; asymptomatic in most cases, unless impacted in neck or cystic duct. **2.** Gallstone in cystic duct; biliary colic if transiently obstructed; acute cholecystitis if impacted and infected. **3.** Gallstone in common bile duct; pain, jaundice, or abnormal liver chemistries, with or without cholangitis, if obstructing; may be minor or no symptoms if nonobstructing. **4.** Gallstone in distal bile duct (common channel with pancreatic duct); gallstone pancreatitis in some cases; may impact transiently, or pass into duodenum asymptotically.

perforations, which usually are contained by adjacent adherent viscera and omentum to produce pericholecystic abscesses. Uncommonly, the perforations may be free (uncontained) and produce generalized peritonitis. In 40%–60% of cases, the bile is infected with enteric organisms. If there is progression to frank suppuration, *empyema of the gallbladder* occurs. Necrosis of the gallbladder may occur (*gangrenous cholecystitis*), and if the gallbladder is infected with gas-producing organisms, air may be visible within its wall on abdominal film, computed tomography (CT), or ultrasound (*emphysematous cholecystitis*). Long-standing obstruction may lead to reabsorption or degradation of bilirubin, producing colorless bile (*hydrops of the gallbladder*). Pathogenetic mechanisms of cholecystitis include bacterial invasion of the gallbladder wall, irritation caused by lysolecithin produced by action of phospholipase on bile phospholipids, and mucosal ischemia secondary to gallbladder distention.

Total parenteral nutrition (TPN)-associated cholecystitis is not a consequence of TPN administration but of the underlying fasting state that precipitates the use of TPN. Fast-

ing has been shown to rapidly lead to the development or progression of gallbladder sludge and stones, which may result in calculous (obstructive) cholecystitis. When this occurs in a postoperative or critically ill patient, the classic signs and symptoms of cholecystitis may be obscured by the underlying disorder(s), leading to a delay in diagnosis. TPN-associated cholecystitis is distinct from acalculous cholecystitis, which also may occur in a critically ill patient.

In postoperative, post-trauma, and other critically ill patients, "*acute acalculous cholecystitis*" may occur in the absence of stones or obstruction of the cystic duct. This condition is distinguished pathologically from acute calculous cholecystitis by arterial occlusions, lack of venous filling, and widespread necrosis of gallbladder wall and vessels. These findings, when combined with the strong association with hypotension, use of vasoconstrictor agents, Gram-negative sepsis, and positive pressure ventilation, support the role of splanchnic ischemia as the precipitating cause. Because of this pathophysiology, acalculous cholecystitis may occur in the absence or presence of gallstones. If stones pass into or form within the common bile duct, obstruction to bile outflow may occur, and this may lead in turn to *acute cholangitis*. The pathophysiology of acute cholangitis requires two components: bacterial colonization of biliary tract and increased pressure within the biliary tract because of obstruction. Bacterial colonization of the normally sterile biliary tract is thought to occur through one of three pathways: from duodenal reflux through an incompetent sphincter of Oddi, from an infected gallbladder, or from the portal venous system. The similarity between the microbiology of acute bacterial cholangitis and that of normal colonic bacterial flora suggests the latter as the most likely source. Bacteria entering the portal venous system from the intestine gain access to the biliary tree through the hepatic parenchyma. Under normal circumstances, flow of bile prevents colonization; however, obstruction caused by bile stones, strictures, or tumors may result in bacterial proliferation and infection. With increased bile-duct pressure resulting from obstruction, large quantities of bacteria can enter the systemic venous circulation, resulting in the clinical syndrome of sepsis.

Biliary tract obstruction is most commonly caused by *choledocholithiasis*, which accounts for 60%–80% of cases. Malignant biliary strictures can lead to obstruction at various levels of the extrahepatic and intrahepatic biliary tree, but they rarely cause cholangitis. However, in patients with malignant biliary obstruction, occlusion of endoscopically- or percutaneously-placed biliary stents and stenosis of surgical bypass anastomoses often do result in cholangitis. Other principal causes of biliary obstruction include benign strictures from inflammatory conditions, extrinsic obstruction caused by chronic pancreatitis, bile-duct injury resulting from biliary-tract surgery, or stenosis of surgical biliary-enteric anastomoses. Uncommon causes of obstruction

include congenital choledochal cysts, pancreatic pseudocyst, chronic parasitic infestation, and AIDS cholangiopathy.

ACUTE CHOLECYSTITIS

Issues at the Time of Admission

Approximately 15% of patients harboring gallstones develop acute cholecystitis. The syndrome often begins with symptoms indistinguishable from ordinary biliary colic, which precedes the acute episode in 60%–70% of cases. Unlike biliary colic, which rarely lasts for more than a few hours, the symptoms of acute cholecystitis are unrelenting. As many as 70% of patients are afebrile on presentation; the remainder have low-grade fever. Marked right upper quadrant tenderness is almost always present and helps distinguish acute cholecystitis from biliary colic. *Murphy's sign* (inspiratory arrest during right upper quadrant palpation) is typical but not pathognomonic. With more advanced disease and development of peritonitis in the right upper quadrant, there may be pain on light palpation, movement, or coughing. A mass may be palpable, representing a distended gallbladder or a phlegmon. Diffuse abdominal tenderness or high fever are more consistent with other abdominal pathologies. Only 60% of patients present with leukocytosis, generally between 12,000 and 15,000 white blood cells/ μL (3). Mild elevation of the serum bilirubin concentrations in the range of 2–5 mg/dL may occur, although levels above 3 mg/dL suggest the presence of common bile duct stones. Mild asymptomatic hyperamylasemia in the absence of pancreatitis accompanies cholecystitis in approximately 15% of cases (4).

The differential diagnosis of acute cholecystitis includes all conditions that cause right upper quadrant or right hypochondrium pain and tenderness. This includes acute cholangitis or bile-duct obstruction caused by common bile duct stones. Clinical distinction between cholecystitis and choledocholithiasis can be quite difficult, and rarely do they coexist in the same patient. The distinction is important because, in general, stone disease of the gallbladder is treated surgically, while common bile duct stones are treated primarily endoscopically, if expertise is available. Common bile duct stones generally are suggested by elevations of liver enzyme levels and by ductal dilation on imaging studies. Perforated gastric or duodenal ulcers (Chapter 80) typically cause very abrupt onset of symptoms, are associated with more diffuse upper abdominal tenderness, and cause pneumoperitoneum visible on upright chest films. Acute viral hepatitis (Chapter 82) generally has a gradual onset, often with nongastrointestinal prodromal symptoms, and usually is associated with dramatic rises (10- to 20-fold) in serum aminotransferases. Acute pancreatitis (Chapter 86) is distinguished by more tenderness to the left of midline than in acute cholecystitis, and by marked elevations in serum amylase and lipase. Other

diagnoses to consider include appendicitis, pyelonephritis, gonococcal perihepatitis, and acute hepatomegaly from right ventricular failure.

The two principal diagnostic imaging studies for suspected acute cholecystitis are ultrasound and radionuclide cholescintigraphy. Sonographic findings consistent with acute cholecystitis include gallbladder wall thickening or edema, pericholecystic fluid, gallstones impacted in the neck of the gallbladder or cystic duct, and air in the gallbladder wall. The absence of these findings does not rule out cholecystitis, nor does the simple presence of gallstones indicate gallbladder inflammation. Ultrasound has approximately 90% sensitivity and 80% specificity for acute cholecystitis (5). The so-called “sonographic Murphy's sign” (point tenderness over the sonographically visualized gallbladder fundus) may be more useful; it has approximately 90% overall diagnostic accuracy if gallstones are present. Ultrasound is the preferred initial study in patients with upper abdominal pain suspected of having biliary-tract disease, because it is easily performed, readily available, and inexpensive. In addition, it can provide useful information about the common bile duct, pancreas, and right kidney.

Radionuclide imaging may be required if ultrasound is nondiagnostic. Radionuclide cholescintigraphy can demonstrate cystic duct occlusion, present in almost all cases of acute calculous cholecystitis. Sensitivity and specificity have been reported to be as high as 97% and 95%, respectively (5). False positives (nonvisualizing gallbladder) are more frequent with prolonged fasting, chronic alcoholism, severe chronic cholecystitis, and unsuspected prior cholecystectomy. False negatives (visualized gallbladder in the presence of acute cholecystitis) may be seen in acalculous cholecystitis. The key principle is that *radionuclide imaging assesses the patency of the cystic duct, not the presence or absence of inflammation*.

CT scanning has comparable sensitivity and specificity to ultrasound for the signs of acute cholecystitis but is substantially less sensitive for the detection of gallstones in the gallbladder. In addition, CT is more expensive and requires intravenous contrast. The utility of CT scanning lies primarily in excluding other intra-abdominal pathology when ultrasound and cholescintigraphy are nondiagnostic.

Indications for Hospitalization and ICU Admission

Acute cholecystitis requires inpatient treatment. If the diagnosis remains in question, hospitalization is still appropriate, as most of the other conditions that can be confused with acute cholecystitis also require hospitalization. ICU admission is appropriate for monitoring and resuscitation of hemodynamically unstable patients. Patients with severe or destabilized comorbid conditions, especially coronary artery disease, left ventricular failure, or pulmonary impairment, also may require intensive care.

Initial Therapy

During evaluation for suspected acute cholecystitis, intravenous fluids should be administered to correct hypovolemia, if present, and to provide maintenance volume thereafter. The patient should be given nothing by mouth, and if abdominal distention or vomiting occur, nasogastric suction should be initiated. Surgical consultation should be obtained within 24 hours of making the diagnosis, or sooner if there is diagnostic uncertainty, presence of severe symptoms (either of sepsis or local inflammation), or progressive or diffuse peritonitis. Finally, analgesics should be administered if necessary, once the diagnosis has been confirmed. Morphine should be avoided as it causes sphincter of Oddi spasm. Intravenous antibiotic therapy should be started and selected for activity against the organisms typically implicated (i.e., Gram-negative rods, anaerobes, and enterococci) (Chapter 64). Patients who are severely ill, diabetic, or immunosuppressed or have failed initial therapy should receive either broader-spectrum single-agent therapy, such as piperacillin-tazobactam or imipenem, or multiagent regimens, such as ampicillin-gentamicin-

metronidazole. Third-generation cephalosporins and aztreonam lack activity against enterococci, and their use as single agents is controversial.

Issues During the Course of Hospitalization and Discharge Issues

Approximately 75% of patients improve significantly with the therapy previously described; the remainder have persistent symptoms or suffer recurrence within the first 6–8 weeks (Table 84.1). Of those who initially resolve, more than half will experience recurrences within the subsequent five years. Accordingly, *cholecystectomy is definitive therapy*. Several randomized prospective trials have demonstrated that prompt cholecystectomy performed during the initial admission has equivalent risk and long-term outcome as an “interval cholecystectomy” (performed a few weeks later). Early cholecystectomy avoids recurrences during the interval of observation, results in a shorter total length of hospital stay, and incurs lower costs (6). Preoperative preparation with antibiotics has been

TABLE 84.1

DIAGNOSTIC CONSIDERATION IN PATIENTS FAILING TO IMPROVE AFTER HOSPITALIZATION FOR ACUTE CHOLECYSTITIS

If the patient is being medically managed prior to cholecystectomy

Complication	Action
Persistent or worsening sepsis, development of peritonitis	Proceed to cholecystectomy
Empyema	Proceed to cholecystectomy
Perforation or cholecystoenteric fistula/gallstone ileus	Proceed to cholecystectomy
Suspicion of common bile duct obstruction	Consider ERCP

If patient is post-surgical cholecystectomy

Complication	Action
Prolonged ileus	Obtain plain films of abdomen
Bile leak	Obtain RUQ ultrasound or computed tomography to detect biloma Obtain radionuclide cholescintigraphy to detect bile leak Perform ERCP to confirm diagnosis and perform sphincterotomy/place biliary stent to close bile leak Percutaneous drainage of biloma if collection is large or infected Surgery occasionally necessary to treat severe leak
Bile-duct stricture	Perform ERCP to diagnose and stent stricture Surgical choledochojejunostomy may be required
Bleeding	Obtain computed tomography scan or angiography Consider reexploration or angiographic therapy
Wound infection	Antibiotics Consider re-exploration, debridement for severe cases

ERCP, endoscopic retrograde cholangiopancreatography; RUQ, right upper quadrant.

shown to reduce septic complications of cholecystitis. Thus, optimal management of acute cholecystitis consists of prompt diagnosis, stabilization, and amelioration of fever and septicemia with intravenous antibiotics, followed by prompt cholecystectomy. Emergency cholecystectomy is rarely indicated, but is appropriate for diffuse peritonitis, severe or unimproving sepsis without concomitant common bile duct obstruction, or gas in the gallbladder wall (i.e., emphysematous cholecystitis suggesting gangrene of the gallbladder). *Laparoscopic cholecystectomy* has become the preferred approach, although there are cases in which contraindications to laparoscopy, technical difficulties, or limited local experience require laparotomy.

Specific postoperative complications of cholecystectomy include intra-abdominal fluid collections, bile-duct or adjacent viscous injury, retained common bile duct stones, and wound infection or dehiscence. The incidence of all complications after elective open cholecystectomy is approximately 20%, compared with 8% for laparoscopy. Severe complications (<1% incidence) are comparable. For acute cholecystitis, the complication rates are slightly higher, primarily because of an increase in septic complications.

After cholecystectomy, the occurrence of jaundice, sepsis, increasing or diffuse abdominal pain or tenderness, purulent or bilious wound drainage, unexplained tachycardia, or respiratory compromise strongly suggests a local abdominal complication and should be investigated thoroughly. Abdominal ultrasound and CT are appropriate initial studies and permit directed percutaneous drainage of intra-abdominal collections. Endoscopic retrograde cholangiopancreatography (ERCP) or percutaneous transhepatic cholangiography are usually required for diagnosis of bile-duct injury and, in some cases, may provide definitive therapy. When bile leakage from the cystic duct stump or other sites occurs, endoscopic stenting or biliary sphincterotomy is usually definitive in closing the leak.

The average hospital stay, including preoperative and postoperative recovery, is about 4 days for elective cholecystectomy with open technique versus 1–2 days for the laparoscopic technique. For acute cholecystitis, postoperative hospital stays average 5–7 days for open cholecystectomy and generally less for the laparoscopic technique, but the extent of right upper quadrant inflammation is often the critical factor.

Acute Cholecystitis in the Critically Ill

Acute cholecystitis may complicate the course of unrelated medical or surgical illness in approximately 1.5% of critically ill patients. In a postoperative setting, cholecystitis is acalculous in approximately 50% of cases; in post-trauma or burn patients this figure exceeds 90% (7). Often the etiology of cholecystitis in a critically ill patient is unclear preoperatively, and it may remain so postoperatively if

gallbladder necrosis is advanced. Mortality rates for cholecystitis in the critically ill exceed 50% in some series, because of the compromised condition of the susceptible patients as well as possible delays in diagnosis due to the absence or lack of specificity of classic signs of cholecystitis.

Ultrasound is the preferred initial test to evaluate suspected cholecystitis in critically ill patients. Positive findings include gallbladder wall thickening or edema, pericholecystic fluid, and intramural gas. Ascites or biliary sludge can contribute to exaggerated estimates of gallbladder wall thickening, however. The presence or absence of gallstones is only of marginal diagnostic significance. CT has comparable accuracy for detecting these abnormalities but requires transport of the patient to the radiology department. Radionuclide scanning is of limited utility, as negative results (i.e., visualization of the gallbladder) are common in acute acalculous cholecystitis, and positive results are not diagnostic in patients after prolonged lack of oral intake.

Ultrasound-guided *percutaneous cholecystostomy* is an important diagnostic and therapeutic tool. For the patient strongly suspected of having acute cholecystitis but at excessive risk for general anesthesia or surgery, bedside percutaneous cholecystostomy produces clinical improvement in 56%–94% of patients, with fewer than 10% having serious complications (bleeding, leakage of purulent bile with peritonitis, and catheter dislodgement) (8). Endoscopic transpapillary stenting of the cystic duct has been described as a potential alternative to percutaneous cholecystostomy, particularly in patients with coagulopathy or ascites in whom percutaneous approaches carry substantial morbidity (9). After nonsurgical drainage and recovery from the critical illness, cholecystectomy can be performed with more acceptable risk.

ACUTE CHOLANGITIS

Issues at the Time of Admission

The initial presentation of cholangitis can be variable, ranging from mild abdominal pain and fever to septic shock. The classic clinical presentation of cholangitis (commonly known as *Charcot's triad*) is comprised of right upper quadrant abdominal pain, fever, and jaundice. However, these findings are present in only 20%–70% of cases (10). The additional findings of hypotension and mental status changes have been described as *Reynold's pentad*, which is associated with a grave prognosis. Elderly patients are more likely to present with severe cholangitis and often with atypical features. Abdominal pain usually is present (80%–90%), although this can be absent in the elderly or the critically ill. Fever is present in 90%–100% of cases.

Laboratory examination can be variable in patients with acute cholangitis. Leukocytosis is present in 90% of cases;

however, with overwhelming sepsis the leukocyte count can be low. Although clinical jaundice is seen 60%–90% of the time, serum liver chemistry test results almost always are elevated. The pattern of liver enzyme abnormalities is to some degree dependent on the cause and chronicity of the obstructive process. The level of hyperbilirubinemia is generally greater in cases of cholangitis complicating malignant biliary obstruction (because of a gradual onset of high-grade obstruction) than in cases of calculous disease. Serum alkaline phosphatase levels usually are elevated in chronically obstructed patients but may be normal or near-normal in patients with acute obstruction caused by impacted stones. Aminotransferase levels also usually are elevated, but to varying degrees. In most instances, aminotransferase levels are less than two times the upper limits of normal. On occasion, patients presenting with acute common bile duct obstruction caused by gallstones may have dramatic elevation in aminotransferases (500–1,000 IU), which can be confused with viral hepatitis. However, the acute nature and severity of the pain should raise the concern of biliary-tract obstruction, and the markedly elevated aminotransferase levels rapidly fall within 24 hours. In general, the clinical presentation of acute right upper quadrant pain, fever, and abnormal liver chemistry tests, especially in older patients and in those without epidemiologic risk factors for acute viral or alcoholic hepatitis, strongly suggests the presence of extrahepatic biliary-tract disease.

The differential diagnosis of acute right upper quadrant abdominal pain, fever, and abnormal liver chemistries includes penetrating or perforating peptic ulcer disease (Chapter 80), pancreatitis (Chapter 86), appendicitis (Chapter 87), pyelonephritis (Chapter 68), gonococcal perihepatitis (Fitz-Hugh-Curtis syndrome), and conditions of acute liver enlargement resulting in painful stretching of the hepatic capsule (Chapter 82), including acute viral hepatitis, acute alcoholic hepatitis, and right heart failure. As mentioned previously, a common clinical error is the confusion of acute cholangitis with acute cholecystitis. At times, the distinction can be difficult and, rarely, these conditions may occur simultaneously. Both can present with fever and right upper quadrant abdominal pain. Although mild hyperbilirubinemia can occur with acute cholecystitis, it rarely exceeds 3 mg/dL. In general, elevated bilirubin levels should trigger suspicion of common bile duct obstruction. Although dilatation of the common bile duct on an ultrasound or CT scan supports the diagnosis of bile-duct obstruction, it is absent in up to one-third of patients with documented common bile duct stones.

Although not diagnostic of cholangitis, approximately 15% of gallstones are calcified and are apparent on plain films, raising the level of suspicion for calculous disease of the biliary tract. An ileus may be present on plain films, although it is nonspecific. Acute suppurative cholangitis is not associated with the presence of free intraperitoneal air, and this finding should point to another diagnosis. Air in the gallbladder wall may indicate emphysematous cholecystitis.

The most useful initial study is ultrasonography because it provides substantial information, is easily obtained (even at the bedside in critically ill patients), and is relatively inexpensive. Gallbladder stones are detected with a high degree of sensitivity and specificity, and the presence of calculous disease suggests a possible cause. However, ultrasound is much less accurate in identifying stones within the common bile duct. Because of overlying bowel gas, the distal duct is poorly visualized, and as a result ultrasound is able to visualize stones in the common bile duct in only about 10% of cases. Dilatation of the common bile duct suggests biliary obstruction but is present in only approximately 75% of cases of confirmed choledocholithiasis.

Radionuclide cholescintigraphy is rarely helpful in the setting of suspected common bile-duct obstruction; its value lies in the diagnosis of cystic-duct obstruction. There are few specific CT scan features of cholangitis because bile-duct stones and gallbladder stones seldom can be imaged directly, and biliary dilation is less reliably identified than by ultrasound. However, CT may be of value in excluding alternative causes of sepsis, such as suppurative cholecystitis, and may provide other evidence as to the cause of biliary obstruction and sepsis, such as malignant-appearing masses in the pancreas, porta hepatis, or liver.

Recent and promising alternatives for diagnosis of biliary obstruction include endoscopic ultrasound and magnetic resonance cholangiopancreatography (11). The role of these diagnostic modalities in the setting of acute cholangitis is limited, but they may be of value in high-risk patients in whom more traditional diagnostic tests fail to reveal the cause of the patient's illness.

ERCP is the procedure of choice both for diagnosis and therapy of bile-duct obstruction. Once the bile duct is cannulated selectively, removal of stones or drainage of other obstructing lesions can be performed. *Percutaneous transhepatic cholangiography* is an alternative in patients with dilated bile ducts in whom ERCP is technically unsuccessful because of surgical anatomy, or if available endoscopic expertise is limited.

Indications for Hospitalization and ICU Admission

All patients with suspected biliary obstruction and fever should be admitted promptly to the hospital. Indications for hospitalization and ICU admission are similar to those for acute cholecystitis.

Initial Therapy

Initial measures are aimed at stabilizing the patient until the biliary tract can be definitively decompressed. The patient should be given nothing by mouth. Intravenous fluids are administered for volume resuscitation and to correct any electrolyte imbalance, and central venous access is established for patients in shock. Approximately one-third of

patients presenting with cholangitis have coagulopathy, and correction of this should be initiated promptly in anticipation of a procedure (Chapter 98). Severely ill patients may require ventilatory support prior to definitive therapy.

Medical therapy does not substitute for drainage of an obstructed biliary tree but can stabilize a patient to allow a safer, more elective decompression procedure. Broad-spectrum antibiotic therapy should be initiated after blood cultures have been drawn. The microbiology is similar to that for acute cholecystitis. In severely ill patients or those with prior biliary-tract surgery, definitive coverage for anaerobes is recommended (12) (Chapter 64).

Urgent decompression of the biliary tract is indicated for treatment of cholangitis and should be performed as soon as is feasible. Seventy to 85 percent of patients with cholangitis respond to appropriate intravenous antibiotics with improvement in fever and abdominal pain, such that the decompression procedure can be done semi-electively within 72 hours. If complicated by hypotension or mental-status changes, decompression should be performed emergently, although not before vigorous medical resuscitation is performed. Endoscopic drainage of the obstructed biliary tract is the treatment of choice for cholangitis, depending upon local expertise and availability (13). ERCP involves endoscopic cannulation of the common bile duct and re-

moval of stones with baskets or balloon catheters (Figure 84.2), or internal stenting to bypass and relieve the obstruction. Alternatives for stone removal in patients with severe coagulopathy include extraction after balloon dilation of the sphincter or temporary decompression by stenting alone. Biliary drainage for obstructing stones or strictures can be established quickly by placing one or more internal stents above the level of obstruction, with more definitive endoscopic or other procedures deferred until the patient is more stable. For many patients, the initial endoscopic procedure is definitive. Procedural success rates range from 80%–98%, with complete duct clearance of stones at the first procedure in 80%–95% of cases, depending on local expertise, technical complexity, and comorbidity. The procedural morbidity rate, including cardiorespiratory events, bleeding, pancreatitis, perforation, or worsened sepsis in the event of a failed procedure, is approximately 5%–10%, with a direct procedure-related mortality rate of less than 1% (14). Gastric surgery or intestinal strictures may make ERCP difficult or impossible.

Percutaneous transhepatic drainage involves placement of a percutaneous catheter through the hepatic parenchyma into the dilated biliary tree. The procedural morbidity rate ranges from 7%–35%, with complications including sepsis, bleeding, bile leak, and fistula. The mortality rate from percutaneous transhepatic drainage in the setting of

Figure 84.2. Endoscopic retrograde cholangiograms showing multiple stones in a dilated common bile duct **A**, and a cleared duct after endoscopic biliary sphincterotomy and subsequent stone extraction with a balloon catheter **B**.

cholangitis has been reported as high as 5%–16%. Unlike ERCP, the procedure is contraindicated in the presence of coagulopathy, and it often requires subsequent surgery or ERCP for definitive therapy in the setting of choledocholithiasis. The absence of ductal dilatation may make percutaneous transhepatic drainage difficult or impossible. Surgical decompression usually is reserved for those patients failing the procedures previously described. The morbidity rate ranges from 40%–60%, and the mortality rate from 10%–40%.

In general, the initial approach to suspected cholangitis and other biliary obstruction should involve ERCP. A randomized, controlled trial of endoscopic versus surgical management of acute suppurative cholangitis showed that endoscopic drainage was significantly safer (approximately three-fold lower mortality rate) (13). For malignant obstruction, a randomized controlled trial showed that endoscopic drainage is safer than percutaneous drainage (15).

Issues During the Course of Hospitalization

Table 84.2 shows a critical pathway for acute cholangitis. After successful decompression of the common bile duct, many patients experience an immediate and dramatic clinical improvement, occasionally by the end of the proce-

dure. Abdominal pain usually resolves within 24 hours. Not uncommonly, patients experience an elevated temperature after instrumentation of the biliary tract in acute cholangitis, even after successful drainage and stone extraction. However, this usually resolves within 24–48 hours. Improvement in leukocytosis usually occurs within 2–4 days. After successful decompression of an obstructed biliary tree, elevated serum bilirubin levels should begin to improve within 24 hours, but may take up to a week or more to completely normalize. Patients with marked elevation and particularly those with malignant obstruction may take even longer to normalize their bilirubin levels.

Failure of clinical parameters to improve suggests a number of possible causes. Failure of the bilirubin level to fall, or of signs of sepsis to improve, suggests incomplete drainage resulting from residual bile-duct stones, edema at the site of the biliary sphincterotomy due to manipulation or local thrombus, malfunctioning of an endoprosthesis, or a separate cause such as concomitant cholecystitis or intrahepatic cholestasis resulting from sepsis. Complications after ERCP may result in deterioration as well. These include cardiorespiratory problems, such as aspiration pneumonia, cholangitis, pancreatitis, perforation, or hemorrhage from the sphincterotomy site. Hemorrhage usually presents as upper gastrointestinal bleeding but is sometimes delayed up to a week or more after the procedure,

TABLE 84.2

CRITICAL PATHWAY: ACUTE CHOLANGITIS

	Admission	Post-ERCP/PTBD day one (usually hospital day 2–4)	Post-ERCP/PTBD day two (usually hospital day 3–5)
Tests	Abdominal radiograph RUQ ultrasound CBC/differential Electrolytes Liver panel Coagulation studies Blood cultures	CBC Liver panel Check blood culture results	CBC Liver panel
Medical Therapy	Intravenous antibiotics Intravenous fluids Correct coagulopathy Gastroenterology consultation to perform prompt biliary decompression after stabilization ^a	Discontinue intravenous fluids If not improving, consider: Repeat ERCP Surgical consultation Nongastrointestinal source	Convert to oral antibiotics
Nursing	Vital signs Oxygen saturation	Vital signs Assist with activities of daily living	Vital signs Assist patient with activities of daily living and begin counseling family
Nutrition	NPO	Clear liquids if pain-free	Advance as tolerated
Discharge planning	Begin addressing	Discuss cholecystectomy	Make follow-up appointment

^a Septic patients should undergo *immediate* biliary drainage after stabilization.

CBC, complete blood count; ERCP, endoscopic retrograde cholangiopancreatography; NPO, nothing by mouth; PTBD, percutaneous transhepatic biliary drainage; RUQ, right upper quadrant.

especially in patients with coagulopathy or those placed on anticoagulation after the procedure. Trauma to the sphincterotomy site from multiple stone extractions during ERCP or localized thrombus can lead to edema, resulting in biliary obstruction and recurrent bacteremia. In instances in which a biliary stricture or incomplete clearance of bile-duct stones has required placement of a stent or nasobiliary tube, recurrence of symptoms may signal obstruction, malfunction, or dislodgement of the stent. Failure to improve within a reasonable period of time may force a repeat procedure to assess adequacy of decompression. In those cases in which the findings of ERCP were not suggestive of cholangitis, consideration should be given to nongastrointestinal sources of fever. In addition, the possibility of post-procedural aspiration pneumonia should be considered. Post-ERCP pancreatitis also can be a complication, and its onset can be delayed over 24 hours.

Discharge Issues

The optimal duration of antibiotic therapy for bacteremia associated with cholangitis has not been determined. Commonly, intravenous antibiotics are continued until the patient has become afebrile, and sometimes for an additional 1–2 days. Conversion to an oral antibiotic with suitable spectrum then can be instituted for a total duration of 7–10 days. One recent study has suggested that even shorter durations of post-procedure antibiotic therapy (3 days) may be appropriate after successful endoscopic drainage of the biliary tract (16).

Although endoscopic sphincterotomy and clearance of common bile duct stones represents definitive treatment of the index episode of cholangitis, cholecystectomy commonly is recommended for most patients who have intact gallbladders containing stones because of the risk of subsequent cholecystitis. However, in elderly patients, or those whose comorbid medical conditions place them at high risk for surgery, the gallbladder may be left intact after endoscopic treatment of common bile duct stones. The natural history of gallbladders containing stones and left *in situ* after endoscopic sphincterotomy for bile-duct stones is variable. A large review suggested a subsequent requirement for cholecystectomy in this group of approximately 2%–3% per year, with the majority occurring within the first two years (17). Several randomized controlled trials comparing strategies of cholecystectomy and “watchful waiting” have suggested that, while a significant proportion of patients managed expectantly may ultimately require cholecystectomy, the non-surgical approach results in no increase in significant complications or mortality (18, 19). Discussions among the patient, primary care physician, gastroenterologist, and surgeon are appropriate at this time or at follow-up appointments regarding the risks and benefits of elective cholecystectomy.

COST CONSIDERATION AND RESOURCE USE

Important determinants of cost and resource use in the management of acute cholecystitis are the number of diagnostic modalities utilized, the choice among various antibiotic regimens, the use of the ICU, the promptness of surgical consultation and possible cholecystectomy, and the length of the postoperative stay. A strategy of delayed cholecystectomy offers no clinical advantages over prompt cholecystectomy (after resuscitation) and is more expensive.

In general, the most cost-effective approach to acute cholangitis involves rapid resuscitation and early definitive procedural intervention without unnecessary delays for additional imaging studies such as CT scans, especially if the diagnosis is clear on clinical grounds.

KEY POINTS

- With few exceptions, treatment is not indicated for asymptomatic cholelithiasis.
- Acute cholecystitis is a serious intra-abdominal infection, which can be life-threatening if not treated. Diagnosis is made utilizing clinical, ultrasound, or radionuclide scan data.
- Appropriate treatment of acute cholecystitis includes intravenous fluids, antibiotics, and prompt cholecystectomy. Prolonged treatment with antibiotics followed by discharge and interval cholecystectomy offers no clinical advantages and is more costly.
- Acute cholecystitis complicating critical illness may be calculous or acalculous in etiology, is associated with a high mortality rate, and may be treated by cholecystectomy, percutaneous cholecystostomy, or endoscopic transpapillary gallbladder drainage.
- Cholecystitis must be differentiated from cholangitis. In patients with right upper quadrant pain and fever, elevated serum bilirubin levels should suggest cholangitis rather than cholecystitis.
- Patients with cholangitis should be stabilized with intravenous fluids, antibiotics, and correction of electrolyte and coagulation disturbances.
- ERCP is the procedure of choice for diagnosis and treatment of cholangitis.

Liver Transplantation

85

Raphael B. Merriman

INTRODUCTION

Liver transplantation has revolutionized the management of end-stage liver disease and acute liver failure since its inception more than four decades ago (1). Data from the United Network for Organ Sharing (UNOS) registry, which operates the Organ Procurement and Transplantation Network (<http://www.optn.org>), reports that in 2003, patients had a 1-year survival rate of 88.1% and a 5-year survival rate of 74.3%. Improvements in patient survival reflect advances in surgical and anesthetic techniques, patient selection, and pre- and post-operative management, including the development of more effective immunosuppressive and antimicrobial agents. Liver transplantation (LT) continues to be challenged by organ shortages and prolonged waiting list times. The most significant recent development in liver transplantation in the United States was the 2002 implementation of an allocation policy based on the Model for End-stage Liver Disease (MELD) and the Pediatric End-stage Liver Disease score (PELD). This policy now preferentially directs livers to patients with the most imminent risk of death.

This chapter provides a review of general surgical principles, indications for transplantation, and the evaluation of patients for liver transplantation. The management of the patient after liver transplantation will be outlined and the common complications will also be reviewed.

SURGICAL PRINCIPLES

A suitable donor organ is matched to a recipient with a compatible ABO blood type. Typically, the surgical procedure is divided into the hepatectomy phase, the anhepatic phase, and the reperfusion phase. The typical biliary reconstruction involves a direct duct-to-duct reanastomosis (choledochocholedochostomy), although occasionally, when the recipient duct is diseased (e.g., primary sclerosing

cholangitis) or unsuitable, a choledochoduodenostomy is performed using a Roux-en-Y anastomosis. Stenting of the biliary anastomosis with externalization of bile via a T tube is now infrequently employed.

Modern liver surgery is based upon the functional segmental anatomy of the liver (Figure 85.1); the eight segments are based on the distribution of the portal veins. This is especially relevant when segmental grafts are employed, as in adult and pediatric living liver donation and split liver transplantation. For example, a right hepatectomy involves the resection of segments V, VI, VII, and VIII. Hepatic venous drainage begins as the central veins join to form the right, middle, and left hepatic veins, which empty into the suprahepatic inferior vena cava. Donor organ preservation has been enhanced by the use of University of Wisconsin (UW) cold storage solution. Knowledge of the common anatomic variations in the hepatic artery is essential, especially for successful donor hepatectomy. Radiologic determination of portal vein patency is important for operative planning because an obstructed portal vein will require a venous graft to bypass or reconstruct the occluded portal vein segment.

PATIENT SELECTION FOR LIVER TRANSPLANTATION

Prognostic Models and Prioritization for Organ Allocation

Policies related to organ allocation significantly impact patient selection for transplantation and have recently undergone major changes. The success of LT led to a marked disparity between the number of patients on the LT waiting list and the number of donor livers available for transplantation in the United States. The most common indications for LT are hepatitis C, alcoholic liver disease, and hepatocellular carcinoma (HCC). As of February 2005,

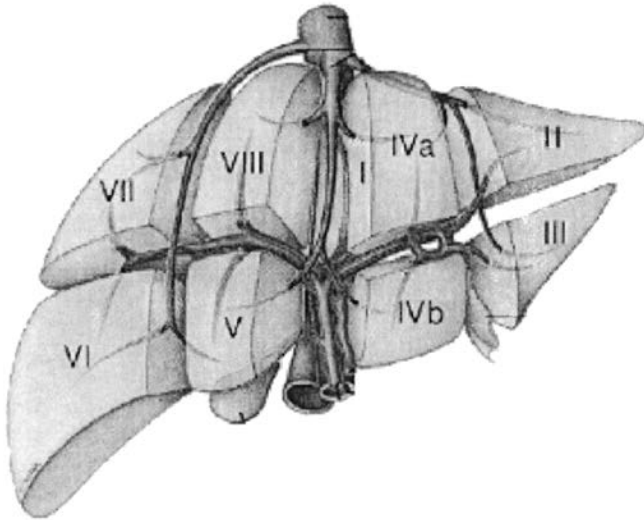

Figure 85.1 Functional anatomy of the liver.

17,678 patients were on the liver transplantation waiting list, while the total number of liver transplants in 2004 was only 5,136. *The Child-Turcotte-Pugh (CTP) score* (Table 85.1) is still used by UNOS to determine a patient's eligibility to be listed for LT. A CTP score of at least 7 is the minimum needed to be listed; this score reflects a predicted 1-year risk of death of at least 10%. Patients with fulminant hepatic failure (Chapter 82) who are highest risk for short-term mortality are classified separately and listed with the highest priority (Status I).

For patients without fulminant hepatic failure, the criteria for transplantation have changed. Prior to February 2002, the two major determinants of liver allocation were waiting time and CTP score. The former often did not reflect the medical need for transplantation, while the latter has subjective components that can be overestimated. In response to the clear need for an improved allocation policy, in March 2002 UNOS began using the MELD score as the basis for prioritizing organ allocation (1). Interestingly, the MELD prog-

nostic score was initially developed to predict short-term prognosis after transjugular intrahepatic portosystemic shunt (TIPS). Subsequently, the score was validated as an accurate predictor of pretransplantation short-term mortality from end-stage liver disease. The MELD score has the advantage of relying on objective and readily available standardized laboratory tests: serum creatinine, bilirubin, and INR (2). The PELD score has been adapted for organ allocation in children; it also accounts for age and growth failure. Policy developers recognized that the MELD score would not serve all candidates equally well and, therefore, introduced exceptions for certain conditions (e.g., HCC, hepato-pulmonary syndrome, portopulmonary hypertension, and familial amyloidosis) by assigning a higher initial score. Since the introduction of the MELD/PELD scores, the number of patients waiting for LT has decreased, with an increase in the number of patients who undergo LT for HCC (3). Unfortunately, the MELD/PELD system has its own shortcomings that will require further modifications over time.

Contraindications and Controversies

The contraindications to LT are generally not evidence-based, and it should therefore not be surprising that they are controversial, reflect local practice and culture, and constantly evolving. Broadly, they can be divided into two categories (Table 85.2). *Absolute contraindications* are conditions for which the results of LT are so poor that it is difficult to justify the use of the limited donor organ pool. *Relative contraindications* negatively affect survival, but not to such a degree that LT should never be considered. Many of these relative contraindications, in particular, are controversial. For example, early reports on the outcome of LT in patients with HCC were unfavorable because of a high incidence of tumor recurrence. However, data emerged indicating that patients with early stage HCC (stage I and II) have excellent results following LT, comparable to patients with non-HCC disease (4). In HIV-infected patients on highly active anti-retroviral therapy (HAART),

TABLE 85.1
CHILD-TURCOTTE-PUGH CLASSIFICATION

Feature	Points		
	1	2	3
Hepatic encephalopathy	None	Controlled	Not controlled
Ascites	None	Controlled	Not controlled
Total bilirubin (mg/dL)	<2	2–3	>3
Prothrombin time (secs prolonged)	0–3	3–6	>6
Albumin (gm/dL)	>3.5	2.8–3.5	<2.8
Childs Class A:	5–6 points		
Childs Class B:	7–9 points		
Childs Class C:	10–15 points		

TABLE 85.2
CONTRAINDICATIONS TO LIVER
TRANSPLANTATION

Absolute Contraindications

Severe, irreversible comorbidities
 Severe portopulmonary hypertension (mean pulmonary arterial pressure (PAP) ≥ 45 mmHg)
 Extrahepatic malignancy (excluding some skin cancers)
 Extensive hepatocellular carcinoma (including vascular invasion and lymph node involvement)
 Severe and uncontrolled systemic infection
 Multiorgan failure
 Active alcohol or substance abuse
 Advanced cardiac disease
 Severe, uncontrolled psychiatric disease
 Noncompliance
 Extensive portal vein and mesenteric vein thromboses

Relative Contraindications

HIV seropositivity
 Moderate portopulmonary hypertension (mean PAP ≥ 35 mmHg)
 Severe hepatopulmonary syndrome (PaO₂ ≤ 50 mmHg)
 Cholangiocarcinoma
 Morbid obesity (Body Mass Index ≥ 40 kg/m²)
 Advanced age (≥ 70 years)
 Recurrent hepatitis C in a transplanted liver

end-stage liver disease related to hepatitis C and B is the most common cause of death. Preliminary data suggest that solid organ transplantation in such patients, if well selected and performed in experienced centers, is both feasible and effective (5). Transplantation for cholangiocarcinoma has also been performed in selected centers employing experimental treatment protocols. Severe obesity may be associated with cirrhosis related to non-alcoholic fatty liver disease, and LT in this increasingly prevalent patient population presents unique surgical and postoperative management challenges. The allocation of organs to patients with alcoholic liver disease was once frowned upon, but is now less controversial. Survival rates after LT in patients with this history are second highest, trailing only patients with cholestatic liver disease. Rates of rejection, disease recurrence, and re-transplantation are generally lower in patients with isolated alcoholic liver disease than for other etiologies. Rates of recidivism or relapse are highly variable, depending on method of evaluation. Most programs report an alcohol use relapse rate of 15%–30% over the first 2–3 years. A minimum of six months of documented sobriety with proven rehabilitation is required by most transplant programs.

Evaluation of the LT Candidate

Evaluation of potential LT recipients involves a multidisciplinary approach, typically including evaluation by

a transplant hepatologist and surgeon, an addiction specialist, social-services personnel, nurse coordinators, financial counselors, and other specialist consultants according to patient needs (Table 85.3). Although usually occurring in the outpatient setting, rapidly deteriorating end-stage liver disease or acute liver failure will demand an expedited inpatient evaluation. The initial assessment involves a thorough history and physical examination, with an emphasis on the presence of complications related to chronic liver disease, assessment of co-morbidities and possible contraindications to transplantation, the potential recipient's current functional status, any history of ongoing or prior substance abuse, duration and reliability of abstinence, and risk of recidivism. The past medical and surgical history (especially hepatobiliary surgery or TIPS) guide further evaluation of surgical and postoperative risk. The patient meets with experienced transplant social workers, who evaluate the current and likely post-transplant level of family and other social support. The candidate also undergoes liver imaging (either ultrasonography with Doppler interrogation, multiple phase thin-cut spiral CT, or magnetic resonance imaging) that includes assessment of patency of the portal vein and other vascular structures and screening for HCC. The laboratory evaluation includes ABO typing and measurements of the serum albumin, total bilirubin levels, and prothrombin time. Other disease-specific assays are obtained if not previously performed. If no absolute contraindications are identified and the patient meets the minimal criteria for LT listing, the patient is listed. Many institutions make listing decisions at a multidisciplinary evaluation conference. Subsequently, a second phase of more invasive testing is initiated, often directed by symptoms or comorbidity. It includes a battery of infectious disease serologies, gynecologic evaluation and mammography for women, and screening tests for cardiopulmonary and renal disorders.

Evaluation of the Living Donor

Until 1989, all LTs used a cadaveric donor organ. Since the introduction of living donor transplants that year, the proportion of living donor transplants has grown steadily, from 1% in 1993 to 6% in 2004. Some of the unique features of the evaluation of a living liver donor deserve particular mention.

Transplantation of part of a liver from an adult into a child has been practiced for more than 15 years. The basic operation (a left lateral segmentectomy) is relatively predictable and has a low risk when done at experienced centers. In contrast, adult-to-adult living donation, which began about a decade ago, usually involves a more substantial operation, usually consisting of a right hepatectomy in the donor (6). Typically, potential donors are between 21 and 55 years of age, have a compatible blood

TABLE 85.3
EVALUATION OF THE LIVER-TRANSPLANT CANDIDATE

Consultations	Hepatologist Liver transplant surgeon Cardiologist, for recipients >50 years old Gynecologist (Pap test [all], mammography [recipients >40 years old]) Addiction specialist, if history of substance abuse Anesthesiologist, if needed Medical social worker evaluation Transplant coordinator Financial counselor
Pathology	Review biopsy, if available
Radiology	Liver imaging with sonography or CT and assessment of portal vein patency
Cardiopulmonary	Arterial blood gas Electrocardiogram Echocardiogram Cardiac stress test, when appropriate Chest radiograph, posteroanterior and lateral
Laboratory tests	ABO blood type, antibody screen HIV serology Chronic hepatitis panel: HBsAg, HBcAb, and anti-HCV; HBV-DNA and HBeAg for patients who are HBsAg-positive Hepatitis B immunity (HBsAb) Hepatitis C genotype and viral load (using an amplified, PCR-based assay) if anti-HCV positive Cytomegalovirus antibody, RPR Alpha fetoprotein Iron, transferrin saturation, and ferritin Thyroid function tests Prostate specific antigen assay for men \geq 50 years old Complete blood cell count, electrolytes, creatinine, blood urea nitrogen, alkaline phosphatase, total bilirubin, aminotransferases, albumin, prothrombin time, creatinine clearance estimate, if indicated Urinalysis and microscopy Random urine/blood toxicology screening (where appropriate)

Anti-HCV, antibody against hepatitis C virus; *HBcAb*, hepatitis B core antibody; *HBeAg*, hepatitis B e antigen; *HBsAb*, hepatitis B surface antibody; *HBsAg*, hepatitis B surface antigen; *HBV-DNA*, hepatitis B virus DNA; *HIV*, human immunodeficiency virus; *RPR*, rapid plasma reagin.

type, and are free of comorbid diseases. Currently, there is little standardization in the evaluation of donors and in the operative procedure, making it very difficult to assess the risks of complications and death to donors. However, the morbidity attributable to surgical resection in donors of grafts for adult recipients has been reported to be as high as 50% (6), substantially higher than that of donors of grafts for children. The most serious potential consequence is death caused by an intra-operative complication or postoperative liver failure. The donor should provide detailed informed consent and must be offered an opportunity to decline. In many programs, potential donors see a physician who is not part of the transplantation team, and in some programs, the potential donor is also evaluated by an ethicist. The evaluation places special emphasis on accurate determination of acceptable hepatic, biliary, and vascular anatomy; it may involve selective use of invasive procedures such as liver biopsy, cholangiography, and arteriography.

Evaluation of Selected Organ Systems

Pulmonary Evaluation

The differential diagnosis of pulmonary symptoms and gas-exchange abnormalities in patients with chronic liver disease is broad; efforts should focus on determining whether the severity of pulmonary dysfunction precludes LT and identifying conditions (such as hepatopulmonary syndrome and some cases of portopulmonary hypertension) that may reverse with transplantation. *Hepatopulmonary syndrome* (HPS), characterized by arterial hypoxemia ($\text{PaO}_2 \leq 70$ mmHg or alveolar-arterial gradient of >20 mmHg), occurs in as many as 15% of patients with chronic liver disease. It is caused by intrapulmonary vasodilation, and it results in impaired oxygenation (7). Symptoms include dyspnea and platypnea. An examination may reveal orthodeoxia and central cyanosis. Pulmonary function testing is usually unhelpful; arterial blood gases confirm hypoxia.

Contrast-enhanced echocardiography following the injection of agitated saline is a sensitive method to detect intrapulmonary shunting; bubbles detected early within the left atrium correlate well with the presence of pulmonary arteriovenous communications. Technetium^{99m}-macroaggregated albumin scintigraphy is definitive but rarely required to confirm the diagnosis. Measuring the PaO₂ on 100% oxygen also provides useful information, as it usually normalizes in patients with HPS. Failure to exceed a PaO₂ of 200 mmHg on 100% oxygen implies the likely presence of significant true shunts and precludes LT at most centers, unless gas exchange can be improved by embolization of those larger true shunts. HPS is associated with increased postoperative morbidity and need for mechanical ventilation, with substantially increased mortality (>30%) when the HPS is severe and the PaO₂ is <50 mmHg. Consequently, patients with a diagnosis of HPS are usually awarded a higher MELD exception score to facilitate earlier transplantation.

Portopulmonary hypertension, defined by a mean pulmonary arterial pressure (mPAP) >25 mmHg, occurs in up to 2% of patients with cirrhosis and portal hypertension (7). Patients may be asymptomatic or present with exertional dyspnea. Chest pain and syncope are late features. Contrast-enhanced echocardiography assesses right and left heart function and anatomy and usually provides noninvasive estimates of pulmonary artery pressures. Other common causes of pulmonary hypertension must be excluded (Chapter 59). Echocardiographic features suggestive of right-ventricular compromise may be sufficient to exclude a patient from consideration for LT. If a borderline, uncertain, or elevated pulmonary artery pressure (mean PAP ≥25 mmHg or systolic PAP ≥40 mmHg) is demonstrated, patients should undergo right-heart catheterization for direct pulmonary pressure measurement and assessment of the effect of vasodilator therapy. Prostacyclin vasodilator therapy improves survival in primary pulmonary hypertension, but the longer term effect on portopulmonary hypertension is less clear and may be dose limited by the associated thrombocytopenia. Experience with bosentan, an endothelin-1 receptor antagonist, is limited and uncertain in portopulmonary hypertension, in part related to reports of associated hepatotoxicity.

Cardiac Evaluation

Cardiac evaluation of the LT candidate should include directed history (specifically assessing the risk factors for atherosclerosis) and physical examination, electrocardiography, and echocardiography. These tests screen for potential ischemic cardiac disease, arrhythmias, left-ventricular dysfunction, and the consequences of hepatopulmonary syndrome and portopulmonary hypertension. High cardiac output associated with a low systemic vascular resistance is common among patients with decompensated chronic liver disease. Thus, the presence of an ejection fraction <60% suggests underlying ventricular dysfunction and warrants further investigation. All men over age 35 and

women over age 45 should undergo noninvasive coronary artery disease evaluation (dobutamine echocardiography or dipyridamole-thallium testing). Candidates with abnormal noninvasive studies, multiple ischemic heart disease risk factors, or an ejection fraction of less than 60% should undergo coronary angiography (Chapter 36).

CARE OF THE HOSPITALIZED PATIENT

First Four Days Following Liver Transplantation

Surgery and the Immediate Perioperative Period

Initial assessment of hepatic function begins in the operating room. Prompt and homogenous reperfusion and a soft allograft texture correlate with good function, whereas a poorly functioning graft may reperfuse slowly or become hard and edematous. During the immediate postoperative period, metabolic recovery of the liver, as measured by clearance of acid (lactate) and the associated metabolic acidosis and glucose production, serves as a gauge of allograft function. Typically, the recipient with a well-functioning graft develops a mild metabolic alkalosis. Prompt recovery from anesthesia, as well as normalization of the hepatic dependent coagulations factors (II, VII, IX, and X), as reflected in normalization of prothrombin time, are additional measures of successful engraftment. However, use of fresh frozen plasma and recombinant Factor VIIA may be necessary in the immediate postoperative period, especially if difficulty is encountered in achieving hemostasis. Patients with severe preoperative hepatic encephalopathy may take days to improve, even with a well-functioning graft. With successful engraftment, serum aspartate aminotransferase and alanine aminotransferase activities usually peak within the first 24–48 hours and decline to levels within four times normal by seven days after LT. As discussed later in this chapter, persistent elevation of the serum aminotransferases after LT is often an ominous marker for allograft dysfunction.

Complications arising in the immediate postoperative period may be categorized into three types: (a) *technical problems* related to the recipient operation, such as intra-abdominal hemorrhage and hepatic artery thrombosis, (b) *primary nonfunction of the allograft*, including primary nonfunction, preservation injury, and acute rejection, and (c) *medical complications*, such as fever, altered mental status, and renal insufficiency.

Technical Postoperative Problems

Intra-abdominal hemorrhage in the early postoperative period is characterized by hypotension, tachycardia, abdominal distension with high-output bloody abdominal drainage, decreasing urine output, and a falling hematocrit

level. Coagulopathy should be corrected and patients should be transfused to keep the hematocrit above 25%. Approximately 10% of recipients require early reoperation for control of hemorrhage. Hemodynamic instability or a transfusion requirement of more than 5–8 units of packed red blood cells in the first 24 hours are the usual indications for early operative reintervention.

Hepatic artery thrombosis (HAT) occurs in 7% of all adult transplants, usually within the first 30 days. Risk factors include small hepatic artery size, complex anatomy, the use of extension grafts for arterial anastomosis, prolonged ischemia time, and a hypercoagulable state. A marked elevation of levels of the serum aminotransferases ($>1,000$ IU/L), accompanied by evidence of hepatic allograft dysfunction, should prompt urgent abdominal Doppler ultrasonography and direct arteriography to confirm hepatic artery occlusion. If HAT is identified very early after LT, immediate angioplasty or reanastomosis may avoid the long term sequelae. The benefit of thrombolysis as a sole therapy or in conjunction with revascularization is unclear. Established HAT is associated with later ischemic biliary stricturing (as the bile ducts are supplied exclusively by this vessel), almost invariably necessitating later retransplantation. Once HAT is excluded in the patient with postoperative dysfunction, liver biopsy may be useful (Figure 85.2).

Primary Nonfunction of the Graft

Primary nonfunction of the hepatic allograft reflects a variety of insults, including damage inflicted by donor-related

disease, harvesting (donor hepatectomy), or cold preservation, as well as reperfusion injury. Primary nonfunction is characterized by rapid and marked elevations of the serum aminotransferases ($>2,000$ IU/L), rapid development of severe metabolic acidosis, hepatic synthetic failure, and ultimately multiorgan failure. The diagnosis is made on clinical grounds after exclusion of HAT. Urgent retransplantation (and even hepatectomy while awaiting a suitable graft) is the only treatment; without this, death generally follows within 72–96 hours. Patients with primary nonfunction of the allograft require ICU-level care; management is similar to that for a patient with acute liver failure (Chapter 82). Patients with severe allograft dysfunction typically require ventilatory support until retransplantation is feasible. Prophylactic broad-spectrum antibiotic therapy is warranted to prevent sepsis. If retransplanted in time, patient recovery is rapid and similar to that of patients transplanted for fulminant hepatic failure.

Postoperative Medical Complications

Fever in the immediate postoperative period should be approached in the same manner as fever in any postsurgical patient, with a few exceptions. More than 50% of LT recipients will experience one or more episodes of infection in the postoperative period. The most common infections in the first days after orthoptic LT are bacterial (8). Risk factors include prolonged anesthesia and anhepatic time, duration of surgery, and amount of blood products given. These

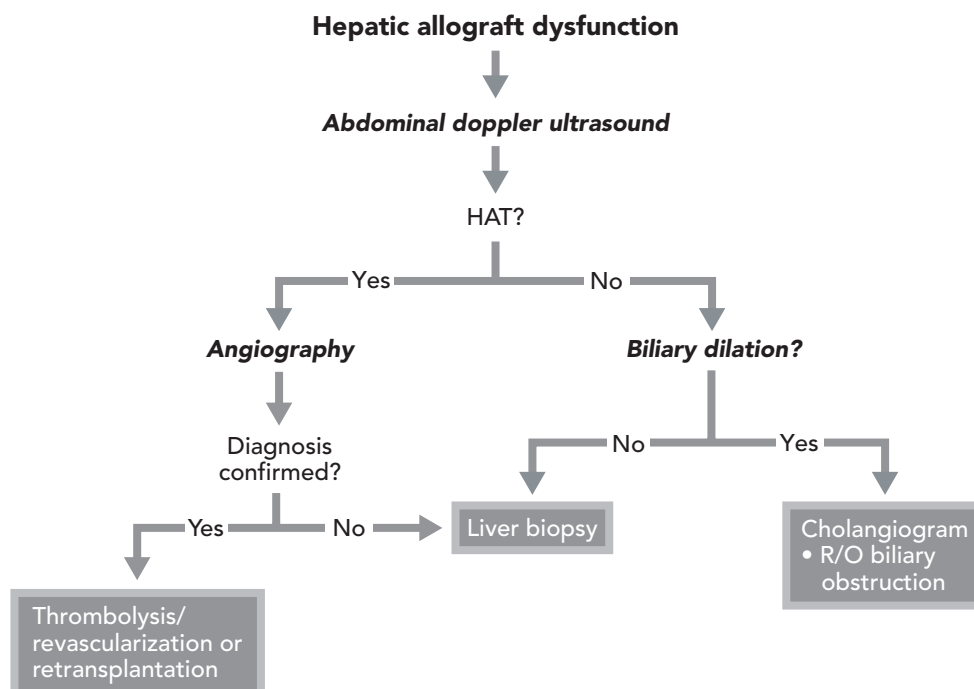

Figure 85.2 Algorithm for the evaluation of hepatic allograft dysfunction. *HAT*, hepatic artery thrombosis; *R/O*, rule out.

infections often are related to technical complications during the recipient operation and include pneumonia, liver abscess, and cholangitis. Vancomycin-resistant *Enterococcus* has emerged as an important nosocomial pathogen in LT patients.

Altered mental status in the immediate postoperative period is common and may result from residual or ongoing hepatic encephalopathy, poor clearance of analgesic or anesthetic medications, perioperative stroke, electrolyte and metabolic abnormalities, or drug toxicity. Central nervous system infections are rare during this time; therefore, lumbar puncture is not routinely indicated. Initial evaluation should include CT or magnetic resonance imaging, and possibly electroencephalography, to exclude seizure activity. Metabolic and electrolyte abnormalities should be corrected and may require temporary renal replacement therapy; potentially contributing psychotropic drugs should be discontinued. Central pontine myelinolysis may occur and should be included in the differential diagnosis. Idiosyncratic immunosuppressive-related neurotoxicity, especially caused by cyclosporine and tacrolimus, can result in a spectrum of neurologic deficits including seizures or coma (9). Predisposing factors include hypomagnesemia and hypocholesterolemia. Magnetic resonance imaging of the brain reveals a variety of changes, from reversible T2 prolongation in the occipital white matter to hemorrhagic infarcts. Treatment includes discontinuation of the medication and supportive care, including physical and speech therapy, as needed. Residual motor and speech impairments may result.

Renal insufficiency occurs frequently after orthotopic LT, may be either acute or chronic, and is usually multifactorial. It often requires hemodialysis (10). Pretransplant

renal impairment caused by hepatorenal syndrome, acute tubular necrosis precipitated by excessive diuresis or gastrointestinal bleeding, or specific disease-related conditions such as glomerulonephritis may all contribute to postoperative renal dysfunction. Pretransplant renal failure requiring dialysis (except hepatorenal syndrome) or associated with sepsis appear to be associated with a worse post-transplant outcome. Direct calcineurin inhibitor (e.g., cyclosporin or tacrolimus) vascular toxicity is the most common cause of renal insufficiency; primary allograft nonfunction, and hypovolemia resulting from intraoperative or postoperative hemorrhage and hypotension, also contribute. The routine use of low-dosage dopamine (1–3 mcg/kg/min) intraoperatively has not been shown to reduce the incidence of renal insufficiency after LT. The need for hemodialysis in the postoperative period has been associated with an increased mortality rate. Maintaining an adequate volume status, avoiding nephrotoxic antibiotics, withholding cyclosporine and tacrolimus early in the postoperative course, and closely monitoring serum drug levels may facilitate recovery of renal function.

Five to Thirty Days After Orthotopic Liver Transplantation

Presentations with Fever and/or Graft Dysfunction

Fever

Fever (Figure 85.3) occurring during this time frame warrants an inpatient evaluation. In the absence of liver function test abnormalities, an investigation for opportunistic

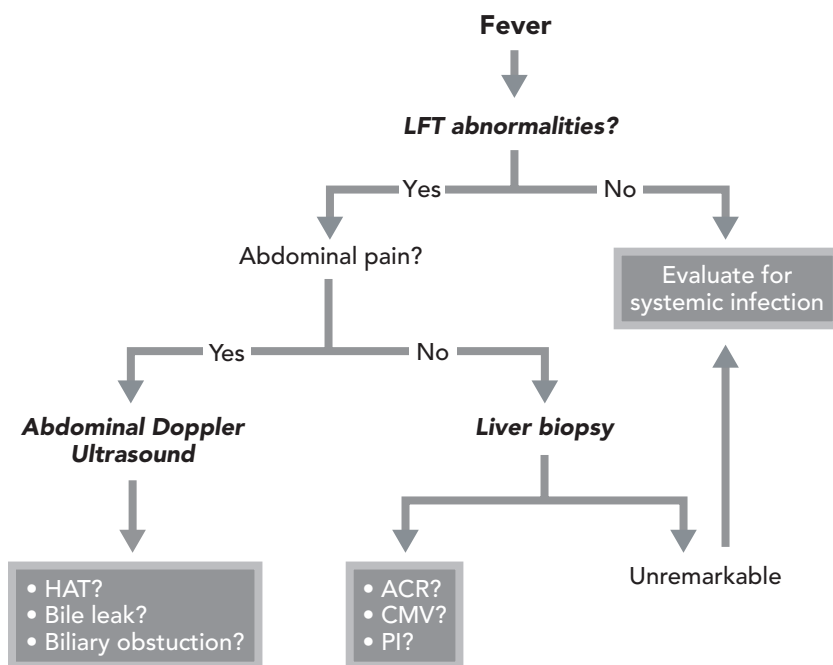

Figure 85.3 Algorithm for the evaluation of fever following liver transplantation. ACR, acute cellular rejection; CMV, cytomegalovirus infection; HAT, hepatic artery thrombosis; LFT, liver function test; PI, preservation injury.

infection should be initiated (Chapter 63). If liver tests are abnormal, it is important to determine whether the patient has localizing symptoms or signs. Differentiating fever and jaundice caused by biliary tract disorders from that caused by acute cellular rejection or viral infection may be challenging. Doppler ultrasonography enables evaluation of hepatic artery patency as well as identification of biliary dilatation and intra-abdominal bile collections (*bilomas*). If ultrasonography does not reveal biliary or vascular abnormalities, a liver biopsy should be performed, with an assessment of the biopsy specimen for acute cellular rejection or cytomegalovirus (CMV) infection.

Bile Leak

Abdominal or shoulder pain in the setting of fever and jaundice may indicate the presence of a *bile leak*, the most common biliary complication occurring during the first postoperative month. It may occur in up to 10% of recipients (11). Bile leaks are particularly common after adult-to-adult living donor transplantation, either in the recipient or the donor (7). Once a bile leak is suspected, cholangiography is indicated to identify the site of leakage. The mode of cholangiography will depend on the type of bile duct anastomosis. Most leaks can be managed successfully by the placement of a stent across the site of leakage (12). Nonanastomotic leaks, such as may occur from the cut surface of a living donor or split graft, may require endoscopic or surgical correction, depending upon the anatomy. It is also important to drain any intra-abdominal bile collections; this usually can be accomplished nonsurgically with a percutaneous catheter. *Biliary strictures* are usually anastomotic and may be related to local edema or ischemia. They are usually managed by stent placement, with or without balloon dilation.

Acute Cellular Rejection

The clinical presentation of *acute cellular rejection* (ACR) is variable. Patients may present with constitutional symptoms, such as fever associated with aminotransferase elevation, or with asymptomatic aminotransferase elevation. Abnormal aminotransferases within the first postoperative month should prompt a liver biopsy to determine the presence of ACR (13), which has a peak incidence on the 10th day following LT. ACR is treated by increasing the level of immunosuppression, initially with additional corticosteroid therapy, and may be managed in the outpatient setting. This approach is successful in >85% of cases. Patients with steroid-refractory ACR either have their maintenance immunosuppression changed or are treated with OKT3 (a murine monoclonal antibody to the CD3 receptor on T lymphocytes) or anti-thymocyte rabbit immunoglobulin. Both yield a 75% response rate. Treatment with such antilymphocyte antibody therapy requires hospitalization because of the potential adverse effects, including a cytokine release syndrome, aseptic

meningitis, capillary leak syndrome presenting as pulmonary edema, and gastrointestinal, renal, and dermatologic toxicities. The incidence of steroid-refractory rejection appears to have diminished with the implementation of tacrolimus-based immunosuppressive regimens. Newer immunosuppressive agents with less toxicity have recently been introduced. Mycophenolate mofetil is a reverse inhibitor of inosine monophosphate dehydrogenase and has gastrointestinal toxicity and bone marrow suppression as the main side effects. Sirolimus inhibits the response of lymphocytes to cytokine stimulation and inhibits antibody production by B cells. Because of its lack of nephrotoxicity, it may be used as an alternative to calcineurin inhibitors.

Cytomegalovirus and Other Viral Infections

Cytomegalovirus (and to a lesser extent *Herpes simplex virus*) may cause hepatitis within the first 6 weeks following LT (14). The clinical presentation includes fever and elevated serum aminotransferase levels. The routine use of prophylactic acyclovir or ganciclovir following LT has almost eliminated post-LT *Herpes simplex virus* hepatitis. Unfortunately, symptomatic CMV disease continues to occur relatively frequently after LT, especially with greater immunosuppression; this may result from reactivation or via primary acquisition from blood products or the hepatic allograft in a seronegative recipient. Seronegative LT recipients who receive seropositive organs are at greatest risk and should receive prophylaxis with ganciclovir. CMV hepatitis must be considered in patients with allograft dysfunction 21 days–3 months after LT (peak incidence, 30 days). Associated findings include fever and leukopenia. The diagnosis is confirmed by direct viral culture, the more rapid shell vial culture technique, or by the histologic documentation of cytopathic effects and microabscesses. Treatment is with intravenous ganciclovir or valganciclovir.

Jaundice Without Fever

Postoperative jaundice not attributable to a specific vascular, biliary, or hepatocellular process is termed *preservation injury*. The contributing causes are similar to those for primary nonfunction. Preservation injury is characterized by a rapid rise and decline of the serum aminotransferase levels followed by a progressive increase in the serum bilirubin. Although the general trend is one of improvement unless an additional insult occurs, preservation injury may take weeks to months to resolve and may be associated with later bile duct sequelae.

Recurrent Portal Hypertension

Portal vein thrombosis may occur in the first postoperative month and most commonly is manifested as recurrent gastrointestinal hemorrhage or ascites. Risk factors for portal vein thrombosis include preoperative portacaval shunt,

hypercoagulable states, and intraoperative interposition or graft use. Doppler ultrasound is diagnostic. If thrombosis is detected early, balloon dilation and stenting may prevent the need for reoperation with reconstruction or clot removal, although both are usually followed by the need for anticoagulation.

Beyond 30 Days After Orthotopic Liver Transplantation

Fever with Jaundice

The differential diagnosis of fever with jaundice after the first postoperative month includes ACR, CMV hepatitis, and biliary obstruction. ACR is less common during this window, and its occurrence usually reflects a reduction in immunosuppression because of either decreased absorption, drug-drug interactions, or poor compliance. CMV hepatitis may occur as late as three months following transplantation.

Biliary obstruction occurs in 12%–15% of patients after LT (11). Cholangitis suggests the presence of a biliary stricture with obstruction caused by sludge or stones. Ultrasonography may reveal biliary dilation but is not a reliable finding in this setting. Cholangiography confirms the diagnosis and identifies the site of obstruction, which can be relieved by dilatation and stenting in 70%–80% of cases. Diffuse bile duct stricturing occurs in four settings: late HAT, ABO incompatibility, prolonged cold ischemia, and recurrence of sclerosing cholangitis. The long-term outcome of diffuse biliary stricturing is uncertain, and these patients often require retransplantation.

Fever

The differential diagnosis includes opportunistic infections (including fungal infections), post-transplant lymphoproliferative disease, and, in recipients more than six months post-LT, community-acquired infection. *Post-transplant lymphoproliferative disease* (PTLD) develops in 2% of LT recipients and may present as fever of unknown origin. Associated symptoms and signs include lymphadenopathy, unexplained graft dysfunction, gastrointestinal bleeding, hepatitis, weight loss, and night sweats. Epstein-Barr virus infection has been clearly implicated in PTLD pathogenesis (15). Both polyclonal reactive lymphoid hyperplasia and monoclonal large-cell lymphomas have been described. Risk factors for the development of PTLD include a greater degree of immunosuppression (e.g., use of OKT3) and lack of previous exposure to Epstein-Barr virus. Primary sites of disease may include the lymph nodes and tonsillar regions, hepatic allograft, and gastrointestinal tract. The diagnosis is suggested by radiographic imaging studies and confirmed histologically. The cornerstone of management is a reduction of immunosuppression and high-dosage antiviral therapy with ganciclovir. Occasionally, chemotherapy may be of benefit.

Jaundice

Chronic ductopenic rejection affects up to 10% of LT recipients, but its incidence seems to be decreasing. It rarely occurs during the first two months after LT, and it is usually preceded by multiple bouts of ACR. The diagnosis is based upon histologic criteria, with a progressive loss of interlobular bile ducts in at least 50% of portal tracts and an obliterative arteriopathy (14). Ductopenic rejection commonly leads to irreversible graft failure and may necessitate retransplantation.

Disease Recurrence

With the improved 5-year survival rate following LT, recurrence of native disease has become an important issue in the long-term management of the LT recipient. Recurrence of hepatitis C (HCV) is the greatest challenge and is almost universal. The rate of recurrence is highly variable, and the average time to cirrhosis is 9–12 years. Treatment of recurrent viral infection is complicated and usually unsuccessful. Risk factors for hepatitis C recurrence include high HCV RNA pretransplant levels, episodes of acute rejection, increased donor age, and use of more potent immunosuppression (16). An accelerated variant, known as fibrosing cholestatic hepatitis, may result in cirrhosis within one year. Graft reinfection with hepatitis B has been greatly reduced through the use of hepatitis B immune globulin (HBIG), often in combination with lamivudine. Primary biliary cirrhosis, autoimmune hepatitis, and primary sclerosing cholangitis may also recur. The evaluation and management of these patients and the controversy surrounding the role of retransplantation for recurrent disease is beyond the scope of this discussion.

KEY POINTS

- Liver transplantation is the treatment of choice for patients with decompensated cirrhosis, early stage hepatocellular carcinoma, or fulminant hepatic failure.
- Patients with a Child-Turcotte-Pugh score of 7 or higher (Class B or above) or criteria that potentially meet MELD exception criteria (e.g., HCC) should be referred to a transplant hepatologist for liver transplantation evaluation.
- Assessment of the potential liver-transplant recipient should focus on the identification of factors that may preclude transplantation or increase surgical and postoperative risk.
- Hepatic allograft function in the immediate postoperative period may be monitored by glucose production, resolution of metabolic acidosis, and normalization of coagulation parameters and aminotransaminases.
- Evaluation of hepatic allograft dysfunction may include abdominal Doppler ultrasonography, liver biopsy, cholangiography, or angiography.

- Acute cellular rejection is one of the most common problems after LT and, after histologic confirmation, is treated by judiciously increasing the level of immunosuppression, adjusting the maintenance immunosuppressive regimen, and occasionally administering antilymphocyte antibody therapy.
- Suspicion of biliary leaks and strictures should prompt cholangiography as well as Doppler ultrasonography to assess for hepatic artery thrombosis. Management includes antibiotics and endoscopic therapy and drainage of associated fluid collections.
- The burden of recurrent hepatitis C with cirrhosis is increasing and presents unique challenges and dilemmas, particularly in the context of suboptimal treatment options and a limited donor organ pool.

Douglas A. Corley

INTRODUCTION

Acute pancreatitis (AP) is a common inpatient diagnosis, accounting for approximately 100,000 hospital admissions per year in the United States. The overall incidence varies among populations, but one study from Olmsted County, Minnesota, estimated 17 episodes per 100,000 people per year. Patients with AP have high levels of resource utilization, with median hospital stays of nine days for mild pancreatitis to 17 days for severe pancreatitis, and a frequent need for ICU-level care and interventional procedures. Patients with complicated pancreatitis may require parenteral nutrition and surgery, with average ICU stays of 4–14 days. Variations in management strategies between centers suggest that a unified, evidence-based approach to care may improve patient outcomes, decrease the length of hospital stays, and lower the utilization of health care resources.

This chapter presents an evidence-based approach to the management of AP. Information from risk-stratification and treatment trials is combined to present an overall pathway for the initial triage and management of patients with pancreatitis, combined with considerations for postdischarge management.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation and Differential Diagnosis

The diagnosis of AP typically requires a combination of physical symptoms and laboratory abnormalities and can be elusive in some patients. The evaluation of diagnostic tests is hampered by the lack of an adequate gold standard.

The classic symptom of AP is *upper abdominal pain, often radiating to the back* and sometimes accompanied by nausea or vomiting. The pain is typically steady, dull, and of gradual onset over several hours. Although frequently severe,

the abdominal pain can be mild or absent. Back pain or nausea and vomiting may be the only presenting symptoms. A small number of patients have no pain or vomiting and present with shock or coma. Pancreatitis can be asymptomatic, discovered incidentally on laboratory and radiologic tests obtained for other reasons.

Physical findings of patients with AP are not specific for this disorder. Patients typically have abdominal tenderness that is most pronounced in the epigastrium. Because of the retroperitoneal location of the pancreas, initial signs of peritonitis such as rebound tenderness, shake tenderness, and abdominal wall rigidity are less prominent than in patients with other causes of true peritonitis (Chapter 87). Peritoneal signs can develop with some of the late complications discussed subsequently. Patients with peritoneal signs on initial presentation should be evaluated carefully for a perforated viscus and other causes of peritonitis with the appropriate radiologic studies. Bowel sounds frequently are hypoactive because of an accompanying ileus (Chapter 88), and mild-to-moderate abdominal distension may be present. Purple or brown discolorations around the umbilicus (Cullen's sign) or on the flanks (Grey Turner's sign) are seen infrequently; these findings suggest fat necrosis and subcutaneous bleeding and may develop over the first few days in patients with necrotizing pancreatitis.

Evaluation of vital signs demonstrates nonspecific findings of inflammation and hypovolemia. Many patients have tachycardia, secondary to both pain and volume depletion. Patients may be orthostatic or frankly hypotensive secondary to volume depletion. Although the presence of fever requires evaluation for infectious causes (e.g., cholangitis), fever also can be secondary to underlying pancreatic inflammation in the absence of infection.

The differential diagnosis of AP is broad and includes peptic ulcer disease, perforated viscus, cholecystitis, cholangitis, mesenteric ischemia, abdominal aortic aneurysm, and intestinal obstruction; all these entities can be associated with abdominal pain and elevations of the serum amylase.

Plain radiographs of the abdomen usually differentiate pancreatitis from intestinal obstruction or free perforation of a viscus. Cholecystitis patients typically have pain that is more prominent in the right upper abdomen but can present almost identically to patients with AP. However, abdominal ultrasound in cholecystitis patients usually demonstrates the gallbladder wall thickening, gallstones, pericholecystic fluid, or “ultrasonographic Murphy’s sign” characteristic of this disorder (Chapter 84). Although cholecystitis can coexist with pancreatitis, in patients with cholecystitis but without AP, the elevation of amylase level is typically mild and unaccompanied by an elevation of lipase.

Table 86.1 lists the primary causes of pancreatitis. The most common etiologies of AP are chronic alcohol ingestion (40%–60%) and gallstone pancreatitis (30%–50%). An additional 10%–20% of patients have idiopathic pancreatitis; the majority of these patients appear to have microlithiasis (biliary crystals or “sludge”) or a motility abnormality of the ampulla, known as sphincter of Oddi dysfunction.

^b Major cause (>5% of cases).

^c Partial list of reported drugs, most are from case reports.

AP that develops during hospitalization for another condition has presenting symptoms, differential diagnosis, and causes similar to “outpatient pancreatitis”. Although not extensively studied, inpatient pancreatitis is less often related to alcohol and more commonly related to drugs, the perioperative state, ischemia from hypoperfusion or embolism, or microlithiasis. The evaluation and management of inpatient and outpatient pancreatitis are similar and thus are discussed together.

Role of Diagnostic Tests

Laboratory Tests

The effective use of many common laboratory tests in AP has not been studied, but laboratory evaluation should include those tests found useful for AP diagnosis, risk stratification, and evaluation of complications and causes.

Admission tests should include amylase and lipase levels for diagnosis; total bilirubin, alkaline phosphatase, alanine aminotransferase (ALT), and aspartate aminotransferase (AST) levels for evaluation of cholangitis and biliary obstruction; and calcium, albumin, complete blood cell count, lactate dehydrogenase, and an electrolyte panel including blood-urea nitrogen and creatinine measurements for evaluation of volume status and risk stratification. Direct measurement of arterial PO₂ and base deficit is an integral part of initial risk stratification. Until validated data on the utility of peripheral saturations are available, an arterial blood gas should be obtained initially in patients demonstrating a room-air oxygen saturation of less than 93%. For patients without a known cause of the pancreatitis, serum triglycerides should be obtained to evaluate for hypertriglyceridemia as a cause. Patients with fever should receive blood cultures to search for the bacteremia that commonly accompanies cholangitis.

The *serum amylase* is the most frequently used test for diagnosing AP; its advantages include simplicity, availability, and good performance characteristics, with an overall sensitivity of 80%–90% and a specificity of approximately 70%. The magnitude of amylase elevation correlates poorly with the severity of pancreatitis and its subsequent clinical course. *Fatal episodes of pancreatitis have been reported without elevations of the amylase level.* The serum amylase rises within 2–12 hours of symptom onset and typically remains elevated for 3–5 days; it returns to normal more rapidly than the serum lipase. Normal amylase levels with elevated lipase levels and a clinical picture consistent with pancreatitis have been reported with delayed presentations, with alcoholic pancreatitis, and with acute exacerbations of chronic pancreatitis. Finally, lipemic serum can falsely depress laboratory determination of both amylase and lipase. Falsely elevated levels of serum amylase can be seen with renal failure, intestinal obstruction or perforation, mesenteric ischemia, pancreatic ascites, salivary gland abnormalities, and other conditions. *Macroamylasemia*, an

uncommon condition consisting of poorly cleared aggregated amylase molecules, can cause a persistently elevated amylase level with a normal lipase level. These other sources of hyperamylasemia can usually be differentiated from pancreatitis by evaluating the serum lipase, by measuring the urinary levels of amylase (which are normal in renal failure or macroamylasemia despite high serum amylase levels), or by fractionating the amylase for the pancreatic subtype.

The *serum lipase* is about as sensitive as and is more specific (90%) than the serum amylase for diagnosing AP. It is not produced by the salivary glands; thus, false-positives are less frequent. *Combining the serum amylase and lipase is the most sensitive and specific strategy for diagnosing AP* (1). Elevation of either enzyme provides a sensitivity of approximately 95%, with a specificity of 90% provided by elevations of both enzymes. Urine tests, such as urinary trypsinogen-2, offer advantages in speed but not in accuracy of diagnosis compared with serum assays.

Laboratory evaluation facilitates the diagnosis of gallstone pancreatitis and cholangitis. A two-fold to three-fold elevation of any liver test (ALT, AST, alkaline phosphatase, or total bilirubin) is highly associated with gallstone pancreatitis (2). Overall, the most predictive tests are the ALT and AST. An ALT of more than 150 IU/L has a positive predictive value of 95% and a specificity of 96% but a sensitivity of only 48%; the AST performs similarly. Elevations of the alkaline phosphatase (>300 IU/L) and bilirubin (>2.9 mg/dL) have specificities greater than 90% but are very insensitive (<40%). These tests are thus relatively specific for gallstone pancreatitis if elevated; however, normal results do not exclude gallstones as the cause. Cholangitis is suggested by elevated liver tests accompanied by fever and leukocytosis.

Imaging Studies

Imaging tests in pancreatitis include plain radiographs, ultrasound, and computed tomography (CT). The appropriate use and cost effectiveness of these tests have not been well evaluated. Data support early use of some radiographic studies for diagnosis, triage, and guidance of therapy. Plain films of the abdomen are primarily helpful in diagnosing other causes of abdominal pain (see earlier in this chapter); a dilated "sentinel loop" of small bowel over the inflamed pancreas is a nonspecific finding of pancreatitis. A chest radiograph should be obtained in patients with impaired oxygen saturation to evaluate for evidence of acute respiratory distress syndrome (ARDS).

Abdominal ultrasound examination should be obtained within the first 24–48 hours in all patients with a first attack of pancreatitis and in any patient in whom there is no clear explanation for pancreatitis. Ultrasound effectively evaluates for the presence of cholelithiasis, cholecystitis, and common bile duct dilation in patients with potential gallstone pancreatitis. Ultrasound's shortcomings include its limited ability to evaluate pancreatic anatomy (due to interference from overlying bowel gas) and its poor sensitivity (<50%) for detecting common bile duct stones; the absence of ductal stones on ultrasound or CT does not exclude the presence of choledocholithiasis. Although it is often employed in patients with AP, validated risk-stratification protocols using ultrasonographic findings exist.

The *abdominal CT scan* provides clear visualization of the pancreas and its surrounding structures, and has implications for risk stratification (Table 86.2) (3). It also may facilitate diagnosis of AP in the small subset of patients with falsely normal amylase and lipase levels. Specific protocols ("pancreatic protocol") using rapid injection of intravenous contrast increase the accuracy of CT for detecting

TABLE 86.2
COMPUTED TOMOGRAPHY (CT) GRADING OF ACUTE PANCREATITIS

Category	CT findings	CT score	Necrosis present	Necrosis score

E	Findings of B/C plus two or more ill-defined fluid collections	4		
Total score ^a	Morbidity, %	Mortality, %		
0–3	8	3		
4–6	35	6		
7–10	92	17		

^a Total score is the sum of the CT score and the Necrosis score.

Adapted from Balthazar EJ, Robinson DL, Megibow AJ, Ranson JH. Acute pancreatitis: value of CT in establishing prognosis. *Radiology* 1990;174:331–336.

pancreatic necrosis. In one study, patients without pancreatic necrosis on any CT scans throughout their hospitalizations had no deaths and only a 6% complication rate; however, 22% of patients without necrosis on the initial CT scan subsequently developed complications. Therefore, a benign CT scan on admission does not preclude a complicated clinical course. In addition, the combination of early CT scans and clinical risk scores (see the following section) does not markedly improve the ability to predict which patients will require ICU admission beyond the clinical risk scores alone (4). *Currently, the routine use of early CT scans in all patients with AP is unnecessary.* If effective agents for altering the natural history of pancreatitis become available, early CT scans may be helpful to stratify patients for risk and guide appropriate therapy. In addition, patients with severe pancreatitis by clinical criteria may benefit from an early CT scan if the detection of extensive necrosis would prompt the initiation of prophylactic antibiotics. Magnetic resonance imaging may be useful in patients who cannot have CT scans performed (due to contrast allergy or renal insufficiency); its utility in evaluating for choledocholithiasis is improved in this patient population.

Prognostic Factors

Several risk factor scoring systems can predict the risk of severe pancreatitis with moderate accuracy. However, these systems typically do not reach their peak prognostic value until 48 hours after admission (5). The development of new disease-modifying agents that are effective if given early in the clinical course will increase the need for prompt prognostication. The most commonly used scoring systems are the Ranson criteria, the Glasgow criteria, and APACHE scores (5). Table 86.3 outlines the Ranson and Glasgow criteria. A modification of the Ranson criteria to improve its performance for gallstone pancreatitis has been proposed but has not been extensively evaluated. The presence of more than three Ranson criteria at any time within the first 48 hours has the highest sensitivity (86%), specificity (98%), and positive predictive value (86%) for a severe clinical course in patients with alcohol-induced pancreatitis. The peak APACHE-II score and Glasgow criteria are more accurate for gallstone pancreatitis. APACHE-II scores on admission do not perform as well as the other multiple-factor criteria and are more cumbersome to calculate.

As a single scale, *the Glasgow criteria have the best overall performance characteristics for correctly predicting the development of complicated pancreatitis* (defined as the presence of infection, organ failure, pancreatic necrosis, or pseudocyst or the development of a major complication such as myocardial infarction or pulmonary embolism). The scoring systems predict complicated pancreatitis more accurately than clinical acumen alone, particularly in patients with gallstone pancreatitis. Clinicians correctly predict a severe course in approximately 19% of patients with gallstone pancreatitis and in 55% of patients with alcohol-induced pancreatitis. This compares with correct predictions of ap-

TABLE 86.3

CLINICAL RISK-STRATIFICATION CRITERIA

Modified Glasgow Criteria ^a	
Room-air arterial PO ₂	<60 mm Hg
Serum albumin	<3.2 g/dL
Serum calcium	<8 mg/dL
White blood cell count	>15,000/μL
Aspartate or alanine aminotransferase	>200 IU/L
Lactate dehydrogenase	>600 U/L
Serum glucose ^b	>180 mg/dL
Blood urea nitrogen	>45 mg/dL
Ranson Criteria	
On admission	
Age	>55 y
White blood cell count	>16,000/μL
Serum glucose	>200 mg/dL
Lactate dehydrogenase	>350 IU/L
Aspartate aminotransferase	>250 IU/L
During the first 48 hrs	
Fall in hematocrit	of >10 points
Serum calcium	<8 mg/dL
Base deficit	>4 mEq/L
Increase in blood urea nitrogen	>5 mg/dL
Fluid sequestration	>6 L
Arterial PO ₂	<60 mm Hg

proximately 65% and 70%, respectively, for the presence of at least three factors from the Glasgow criteria (6). The presence of at least three Glasgow criteria corresponds to a mortality rate of 25%, compared with 4% in patients with fewer than three criteria (6). These scoring systems thus can guide initial triage decisions, but modifications in the level of care frequently are necessary as the patient's clinical course evolves. Numerous laboratory tests (such as urinary trypsinogen activation peptide and C-reactive protein) have been evaluated, but none markedly enhances early prognostication beyond standard risk scores.

Indications for Intensive Care Unit Admission

Indications for admission to the ICU include hypoxemia and persistent hypotension or oliguria despite aggressive initial volume resuscitation. In addition, the presence of three or more Ranson or Glasgow criteria within the first 48 hours, or a peak APACHE-II score of greater than 9 in the first 72 hours, are highly associated with complicated pancreatitis and death. Although validated guidelines for AP do

not exist, data suggest that patients with these features have a more severe clinical course and higher rates of ICU admission. In these patients, intensive or step-down care can facilitate vital-sign monitoring and access to equipment for rapid fluid resuscitation, intubation, and dialysis.

Initial Management

The principal goals of therapy in AP are controlling pain, treating reversible causes, preventing organ failure, and minimizing peripancreatic complications such as infection and complicated fluid collections. Figure 86.1 provides a suggested clinical pathway.

Supportive care with intravenous fluids, electrolyte replacement, and blood glucose monitoring with insulin (if needed) are standard clinical practices. Because pancreatic stimulation may aggravate pancreatitis symptoms, patients initially should not receive oral nutrition. Nasogastric suction may be employed for symptomatic relief in patients with vomiting or ileus; its routine use does not hasten recovery from AP.

Patients with inadequate volume resuscitation are at risk for hypovolemic shock, and experimental data support the role of adequate volume replacement as a primary initial intervention for AP. Volume replacement should be titrated to the patient's blood pressure, pulse rate, and urine output. Patients with persistent hypotension, tachycardia, and low urine outputs likely require vigorous ongoing fluid resuscitation; *patients with severe pancreatitis may require 8–12 liters of fluid over the first 24 hours*. The optimal fluid type for resuscitating AP patients is unknown, and the advantages and disadvantages of different types (e.g., crystalloids vs. colloids) are discussed in Chapter 25.

Pain control typically includes opiate analgesics. Although morphine has a theoretical advantage over meperidine in that it causes less spasm of the sphincter of Oddi, there is no evidence that this translates into a clinical advantage. Patient-controlled analgesia is associated with improved pain control and lower resource utilization.

Finally, reversible causes should be treated. Patients without a clear explanation for their pancreatitis should discontinue nonessential suspect medications and receive an evaluation for secondary causes such as gallstone pancreatitis (see the Diagnostic Tests section).

Despite extensive investigation, few therapies currently improve the outcome or symptoms of AP (Table 86.4). Although the trypsin inhibitor gabexate or somatostatin may decrease the incidence and severity of pancreatitis induced by endoscopic retrograde cholangiopancreatography (ERCP) (7), studies conflict, and neither agent is effective for treating AP. The platelet activation factor antagonist lexipafant decreased morbidity and mortality rates in initial trials, but subsequent investigations have not confirmed this observation (8). If proven to be effective, such agents may offer the potential for effective early pharmacologic intervention in AP.

Indications for Early Consultation

Management of pancreatitis varies markedly among institutions. Admission services include internal medicine, gastroenterology, and general surgery dependent upon institutional practices and expertise. No studies exist evaluating differences in outcome based on admitting service. For patients admitted to surgery or medicine services, early gastroenterology consultation for possible ERCP should be considered in patients with evidence of cholangitis, biliary pancreatitis, traumatic pancreatitis, evidence of pancreatic duct disruption, or severe, unremitting idiopathic pancreatitis. For patients admitted to medical services, early surgical consultation should be considered in patients with pancreatic necrosis, particularly if potential infection is indicated (i.e., fever, elevated white blood cell count). The management of complicated pancreatitis frequently requires a team approach with a medical intensivist, general surgeon, gastroenterologist, and interventional radiologist.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Laboratory Monitoring

The need for ongoing laboratory monitoring is dictated by the severity of the pancreatitis. Daily measurements of serum amylase or lipase have no demonstrated prognostic value. Follow-up measurements may be helpful in confirming normalization of the amylase; additional measurements on day 2 or 3 and on day 5 or 6 provide sufficient information in an uncomplicated patient. Persistent elevations are associated with ongoing pancreatitis, pancreatic ascites, and the development of pseudocysts. Because of the potential for large fluid and electrolyte shifts, initial daily monitoring of electrolytes is advisable. Additional monitoring for signs of organ failure includes determination of blood-urea nitrogen, creatinine, bicarbonate, and oxygen saturation levels. Calcium monitoring is an integral part of some risk-stratification criteria. AP may cause hyperglycemia; thus, monitoring of serum glucose, accompanied by appropriate insulin administration, is required.

Nutrition

The initial withholding of enteral nutrition in AP patients is standard practice. The delivery of fats and proteins to the duodenum results in stimulation of pancreatic secretion, which may be harmful in the acute setting. In the absence of clinical trial data, this practice is supported by observations that patients with early pancreatitis may have increases of pain with eating, and there is no known detriment caused by brief periods of minimal nutrition.

Patients with peripancreatic fluid collections, pancreatic infections, and other complications of pancreatitis

	Day 1: First 4 hours of stay	Day 1: Additional Tasks	Day 2	Day 3	Day 4	Day 5-10: Uncomplicated course	Complicated Pancreatitis
Tests	Amylase, lipase, Chem-7, CBC, calcium, albumin, LDH, triglycerides, ALT, AST, total bilirubin. Blood cultures if fever. ABG and CXR if room air saturation < 93%. Determine clinical risk stratification, other appropriate tests to establish diagnosis (e.g. abdominal film, CT)	Abdominal ultrasound for index presentation or unexplained pancreatitis Notify PMD. Consider CT for severe pancreatitis or if patient unstable	Chem-7, CBC, calcium, albumin; recheck ALT, AST, bili if initially abnormal, ABG if severe pancreatitis. Check blood cultures if obtained. Confirm official ultrasound interpretation	Amylase or lipase, Chem-7, CBC, calcium, albumin Check final culture results	Recheck unstable laboratory values (e.g., electrolytes)	Recheck unstable laboratory values (e.g., electrolytes)	If not improving after 4–5 days, consider abdominal CT, amylase or lipase, Chem-7, CBC, calcium, LFTs ?Specialty consult
Medications and Therapeutics	Intravenous fluid Opiate analgesics. IV antibiotics if possible cholangitis. Discontinue potentially offending medications. Glucose monitoring with insulin as needed	Intravenous fluid Opiate analgesics. TABLE 86.4
MEDICAL THERAPIES IN ACUTE PANCREATITIS

Effective therapies^a

- ERCP for patients with pancreatitis and cholangitis
- Analgesics for pain relief
- Antibiotics in patients with severe pancreatitis and risk factors for/clinical signs of cholangitis/pancreatic necrosis

Probably effective therapies^b

- Correction of electrolyte abnormalities
- Volume replacement
- Initially holding oral nutrition
- Debridement or drainage of infected necrosis
- Lexipafant administration within 48 h of initial symptoms
- Gabexate or somatostatin for prophylaxis of ERCP-induced pancreatitis
- Nasogastric suction for symptoms related to ileus

Probably ineffective therapies^c

- Pharmacologic inhibition of pancreatic secretion (e.g., octreotide)
- Trypsin inhibition after initiation of pancreatitis
- Peritoneal lavage
- Nasogastric suction

^a Demonstrated in randomized clinical trials without significant conflicting data.

^b Large clinical experience or generally supported by experimental studies.

^c No benefit in randomized trials.

ERCP, endoscopic retrograde cholangiopancreatography.

frequently require prolonged hospitalization; the optimal route of nutrition in these patients has changed in recent years. Traditionally, patients with complications received parenteral nutrition. Most late complications of AP, however, are secondary to peripancreatic damage and infection rather than from ongoing active pancreatitis. Recent small randomized trials of AP patients found that patients receiving enteral nutrition had fewer total complications, fewer infections, and lower overall hospital costs than patients receiving parenteral nutrition (9). These findings are consistent with trials of enteral versus parenteral nutrition for other gastrointestinal disorders (Chapter 15). Thus, *patients who lack contraindications to enteral feeding and who are unable to initiate oral nutrition after 5–7 days should receive enteral nutrition via nasoenteric tube rather than parenteral nutrition*. If pancreatitis recurs after starting enteral nutrition, patients are intolerant of enteral feeding, or other contraindications to enteral feeding exist, parenteral nutrition should be considered.

Antibiotics

Prophylactic antibiotic use in patients with severe pancreatitis is beneficial in reducing infectious complications but has not been clearly demonstrated to improve the overall survival rate. Septic complications are the most frequent late cause of death in AP. Thus, the use of prophylactic antibiotics in pancreatitis patients has been the subject of several randomized controlled trials. Early trials suggested no

benefit from prophylactic antibiotics. More recent trials using antibiotics with better pancreatic penetration (e.g., quinolones and imipenem) demonstrated significantly fewer infectious complications in treated patients than in placebo-treated control subjects (10), but concerns about the development of antibiotic resistance and fungal superinfections have tempered widespread use of prophylactic antibiotics in patients with AP.

The best current evidence supports prophylactic antibiotic use in patients with evidence of cholangitis or severe necrotizing pancreatitis. Patients with clinical evidence of severe pancreatitis should receive an early CT scan to look for pancreatic necrosis; patients without necrosis or fluid collections appear unlikely to benefit from prophylactic antibiotics. In other patients who develop clinical signs of infection, early antibiotic use should be considered. Patients may benefit from needle aspiration of necrotic tissue to guide antibiotic therapy (see the section on pancreatic necrosis). Further research (evaluating both mortality and nonlethal endpoints) will be needed to determine precisely which patients benefit from antibiotics.

Endoscopic Retrograde Cholangiopancreatography

ERCP with sphincterotomy improves outcomes in a subgroup of AP patients with gallstone pancreatitis. This technique uses endoscopic guidance to open the sphincter of Oddi using an electrocautery wire, with removal of common bile duct stones and “biliary sludge.” The primary benefit occurred in patients with severe pancreatitis and evidence of cholangitis or biliary obstruction (11,12). The only study demonstrating no morbidity-rate benefit excluded patients who were febrile or who had a total bilirubin level greater than 5 mg/dL. In studies of endoscopic sphincterotomy performed for any reason, complications (bleeding, perforation, pancreatitis, and death) occurred in approximately 10% of all patients and were usually managed conservatively. However, the overall complication rate appears lower in patients with AP, with a 2.3% rate noted in a recent trial. Because of the risk of complications and the apparent lack of efficacy in patients with mild pancreatitis, *endoscopic sphincterotomy should be reserved for patients with presumed gallstone pancreatitis and evidence of cholangitis, persistent biliary obstruction, or unremitting pancreatitis*. Patients without evidence of cholangitis and those with elevated liver tests that rapidly normalize typically do not require emergent sphincterotomy. Patients with severe idiopathic pancreatitis also may benefit given the substantial proportion of these patients having microlithiasis (see later in this chapter). Magnetic resonance cholangiopancreatography recently has been evaluated for diagnosing abnormalities of the pancreas and biliary tree. Although it is noninvasive, it is also expensive and does not offer a therapeutic potential. Its role in acutely diagnosing common bile-duct stones in this patient population is unclear.

Complications of Pancreatitis

Early Complications

Complications in the first 48 hours usually are related to hypovolemia, shock, intra-abdominal hemorrhage, ARDS, renal failure, and electrolyte abnormalities. Pancreatitis can result in massive volume shifts, with subsequent hypovolemic shock. ARDS and other severe pulmonary complications occur in approximately 15% of patients.

The management of early complications is primarily supportive. Patients require aggressive early hydration, as discussed for initial management. Serum electrolytes should be assayed at least daily for the first few days, with appropriate replacement. Hypocalcemia frequently develops; it is usually asymptomatic. Renal failure may require dialysis, and respiratory failure may require intubation. Patients with persistent hypotension after initial volume resuscitation, oliguria, or ARDS may benefit from hemodynamic monitoring to guide volume replacement.

Late Complications

Complications occurring after 5–7 days are primarily infectious. The principal one is *infected necrosis*, occurring in approximately 5% of patients. Although the majority of infections occur within the first two weeks, delayed presentations are not uncommon. In one series, almost 50% of infections occurred more than 2 weeks after presentation. Pancreatic infection is associated with a high mortality rate, accounting for up to half of all deaths in necrotizing pancreatitis. If pancreatic infection is suspected because of fever or an elevated white blood cell count, radiologically guided percutaneous aspiration should be performed. This method permits reasonable discrimination between infected and sterile necrosis and may allow isolation of a pathogen for culture and antibiotic sensitivities. Indications for CT scans in the setting of AP include failure to respond to conservative therapy after the first 5–7 days, persistent pain or elevations of serum amylase, fever beyond the first 5–7 days, or progressive abdominal distension. Under these conditions, the presence of necrosis, large peripancreatic fluid collections, or significant ascites suggestive of pancreatic duct disruption with resultant pancreatic ascites alters clinical management.

The management of pancreatic infection is primarily surgical. The traditional approach has been open debridement of the necrotic tissue. Because the devitalized tissue is typically neither liquefied nor vascularized, it would seem that nonsurgical drainage would be unlikely to successfully evacuate the infected tissue, and antibiotics would have limited penetrance. Nevertheless, percutaneous drainage, endoscopic drainage, and antibiotics alone all have been used successfully in selected patients with infected necrosis (there are no trials comparing these methods). For example,

a pancreatic abscess consisting largely of infected fluid rather than pancreatic tissue may be treated adequately with antibiotics and percutaneous drainage. It frequently is difficult, however, to distinguish between infected fluid and infected necrosis by CT. *The weight of the evidence suggests that patients with extensive areas of infected necrosis should be treated surgically.* Consultation with a general surgeon experienced in pancreatic surgery and an interventional radiologist trained in percutaneous drainage is advisable in patients with pancreatic infection to discriminate between available therapies. Studies indicate that the treatment of *limited sterile necrosis* with surgery, peritoneal lavage, or percutaneous evacuation is ineffective or even harmful.

Pancreatic Duct Disruption

A less common complication is pancreatic duct disruption. Pancreatic disruption can occur at any time. If localized, this disruption can lead to an expanding pseudocyst; if the leak is not contained, disrupted ducts may cause pancreatic ascites. Fluid in pancreatic ascites is high in amylase (approximately fivefold more than serum amylase), usually has a white blood cell count of more than 500 per cubic millimeter, and can lead to pancreatic hydrothorax. Treatments attempted for pancreatic duct disruption include octreotide to decrease pancreatic secretion, stenting of the pancreatic duct via ERCP to bypass the sphincter, percutaneous catheter drainage of pseudocysts, and surgical repair. No comparative trials exist, but these strategies appear equally efficacious (60%–90% in small series). The majority of duct disruptions resolve slowly with conservative therapy over 4–6 weeks. Initially, octreotide should be used as primary therapy or in conjunction with endoscopic or percutaneous drainage. Available data suggest a dose of at least 150 mg subcutaneously every eight hours. Critically ill inpatients may receive an intravenous infusion of 25–50 mg per hour. Patients who fail these therapies should be evaluated for surgical correction of the disrupted duct.

The majority of peripancreatic fluid collections resolve by six weeks after presentation; the remainder may develop into organized collections known as *pseudocysts* that are surrounded by adjacent organs and inflammatory material. Asymptomatic pseudocysts can be observed safely (13); infected, markedly symptomatic, or enlarging pseudocysts require drainage. Even large pseudocysts (>6 cm) can be followed, with interventions performed only for complications.

The optimal means of pseudocyst drainage is unknown and likely varies with the location of the fluid collection and whether it communicates with the pancreatic duct. Surgical techniques typically create a communication between the pseudocyst and adjacent bowel. Radiologic methods utilize continuous or intermittent drainage with percutaneous catheters. Endoscopic techniques either create a communication with adjacent stomach or duodenum or

place a stent across the ampulla through the pancreatic duct and into the pseudocyst. All these methods appear to have similar efficacy, and the optimal technique in a given patient should be decided with the appropriate consultants, considering the pseudocyst's anatomic location and local expertise.

DISCHARGE ISSUES

Patients with mild pancreatitis typically have an uncomplicated course characterized by a rapid improvement in symptoms over 3–5 days and are able to restart oral intake by days 3–6. The amylase rapidly returns to normal, and the average hospital stay is 8–10 days. In contrast, protracted pain, fever, abdominal distension, or pain upon refeeding suggest a complicated course. Criteria for discharge include the ability to take adequate oral nutrition without symptoms or signs of recurrent pancreatitis, and appropriate recognition and treatment of any complications. Patients with large asymptomatic pseudocysts, for example, do not require ongoing hospitalization; however, they do require close outpatient monitoring for the development of pain or fever. In addition, a follow-up CT scan or ultrasound should be obtained 1–3 weeks after discharge to confirm that the pseudocyst is not enlarging. Permanent pancreatic endocrine or exocrine insufficiency is uncommon in the absence of chronic pancreatitis. Patients requiring insulin during the hospitalization should be instructed in insulin administration and glucose monitoring; their insulin requirement frequently decreases or is eliminated as the pancreas recovers.

Important discharge issues include evaluation of the cause of pancreatitis and prevention of future episodes. Follow-up management should include cessation of alcohol use in patients with alcoholic pancreatitis, cholecystectomy in patients with gallstone pancreatitis, and further evaluation of patients with idiopathic pancreatitis.

Patients with gallstone pancreatitis should have a cholecystectomy as soon as the pancreatitis and its immediate complications resolve. More than 30% of patients with gallstone pancreatitis and uncorrected cholelithiasis have a recurrent episode, many within the next several months. Significant delays in surgery do not appear to improve surgical outcomes for patients with *mild-to-moderate pancreatitis*; thus, cholecystectomy should be performed prior to or soon after discharge from the index hospitalization in these patients. Patients with *severe pancreatitis* are at a higher risk of surgical complications; in this population, the risk of recurrent pancreatitis may be less than the risk of early surgery performed prior to the improvement of pancreatic necrosis and fluid collections. Selected patients with primarily biliary tract disease, particularly those at high risk for surgery, may require only an endoscopic biliary sphincterotomy.

Approximately one-third of patients with AP have “idiopathic pancreatitis,” without any potential causes found on

history or laboratory examination. The likelihood of recurrent episodes of pancreatitis in these patients is controversial, and the appropriate evaluation is unknown. However, numerous small series suggest that microlithiasis (“biliary sludge”) frequently is responsible (14). Microlithiasis is detected by aspirating bile percutaneously or during ERCP, or by ultrasonographic detection of sludge in an acute or convalescent patient. Nearly three out of four patients with idiopathic pancreatitis (without a prior cholecystectomy) will be found at ERCP to have either microlithiasis or common bile duct stones. Microlithiasis patients treated with cholecystectomy or biliary sphincterotomy have a lower recurrence rate of pancreatitis (10%) than patients treated conservatively (73%), in nonrandomized series. Patients with evidence of biliary sludge by ultrasonography or ERCP, therefore, should undergo cholecystectomy or biliary sphincterotomy.

An uncommon but potentially serious cause of idiopathic pancreatitis is a pancreatic or periampullary neoplasm. Although survival from most pancreatic neoplasms is poor, detection significantly alters management decisions. If not obtained during the attack of pancreatitis, patients with idiopathic pancreatitis should have an abdominal CT scan to rule out a pancreatic mass once the index episode of pancreatitis resolves.

If these investigations are unrevealing, the patient may be observed. Randomized studies suggest that anatomic or functional biliary obstruction is a frequent cause of idiopathic pancreatitis. Thus, if pancreatitis recurs, ERCP should be performed to evaluate the pancreatic anatomy. Based on its findings, sphincterotomy, aspiration of bile for crystal analysis, and/or biliary manometry should be considered.

COST CONSIDERATIONS AND RESOURCE USE

The vast majority of patients with AP require management and observation in the inpatient setting. The average hospital costs associated with complicated pancreatitis are estimated at more than 10 times those of mild pancreatitis. The serious complication rate is approximately 25%, with a total mortality rate of 2%–10%. The most important issue from the perspective of reducing the costs for AP patients is managing the use of the ICU and invasive procedures. The appropriate triage of patients to the ICU, identification of patients likely to have a complicated course, and initiation of appropriate individualized therapies are the principal determinants of hospital stay. The impact of a directed guideline on total cost is unknown. Avoiding daily blood tests once patients have stabilized, minimizing CT scans in patients with mild pancreatitis, and using enteral (rather than parenteral) nutrition in appropriate patients likely would reduce inpatient costs without adversely affecting patient outcomes.

KEY POINTS

- All patients with AP should be evaluated for possible admission.
- A combination of amylase and lipase levels is most sensitive and specific for diagnosis.
- Persistent hypotension or oliguria despite resuscitation, or the presence of several clinical risk-stratification criteria (Ranson or Glasgow score >3 or an APACHE-II score >9) identifies a subset of patients at greater need for ICU admission and at higher risk of subsequent complications.
- Patients with adverse prognostic indicators should be stabilized rapidly in an ICU and monitored for complications (e.g., renal failure, ARDS, and hypotension).
- Evaluation for the etiology of an index episode of pancreatitis includes a careful history for alcohol, medication, and toxin exposure; evaluation of serum aminotransferases and an abdominal ultrasound for gallstone pancreatitis; acute and convalescent evaluation for hyperlipidemia and hypercalcemia; and an abdominal CT to evaluate for a pancreatic neoplasm.
- ERCP with sphincterotomy improves outcomes in patients with gallstone pancreatitis and evidence of cholangitis or ongoing biliary obstruction.
- Use of prophylactic antibiotics in patients with severe pancreatitis may improve outcomes.
- For most patients requiring supplemental nutrition, enteral nutrition improves outcomes and decreases costs compared with parenteral nutrition.
- Identifiable causes of pancreatitis require in-hospital or posthospital interventions to decrease the risk of recurrent pancreatitis.
- Patients with more than one episode of unexplained pancreatitis should undergo ERCP for evaluation (and potential treatment) of biliary microlithiasis, functional disorders of the ampulla, and structural abnormalities of the pancreatic duct.

INTRODUCTION

This chapter discusses the evaluation of patients with acute abdominal pain. We have chosen three clinical conditions to highlight this process, but several principles apply to the evaluation of all patients with acute abdominal pain. The first of these principles is the importance of shifting the initial focus from making a diagnosis to caring for the acute needs of the patient. In addition to gathering information that elucidates a diagnosis, the physician should also initiate immediate resuscitative measures; sometimes these will reverse or alleviate the symptoms associated with the disease process. These initial resuscitation measures are based on an assessment of the standard “ABCs” of basic life support. In the setting of abdominal pain, the “C” in “ABC” should serve as a reminder to establish large-bore intravenous access for volume resuscitation and administration of medications. The risks incurred during resuscitation need to be weighed against the risks from inaction. For example, a patient with a history of congestive heart failure might develop

pulmonary edema from volume repletion but may also be at risk for myocardial infarction or renal complications as a result of inadequate fluid resuscitation.

Following the “ABCs,” the next three steps are employed variably but should be considered in each case.

“D, E, and F” represent nasogastric decompression, physical examination, and Foley catheterization. *Nasogastric decompression* is often necessary in a patient with nausea, vomiting, and abdominal pain. Decompressing the stomach reveals the nature of its contents and diminishes the risk of aspiration. *Foley catheterization* is integral to assessing the adequacy of resuscitation. A patient with an acute abdomen often requires large volumes of intravenous fluids before urine output begins. The fluid shifts that accompany diffuse peritonitis can approximate those seen with a 50% body surface area burn. In general, fluid resuscitation should be pursued vigorously until urine output is adequate or rales are auscultated on pulmonary examination. The initial *physical examination* is critical for establishing the pace and focus of the workup. A patient with mild vague abdominal tenderness can be evaluated with a

thorough history and repeat physical examinations, whereas a patient with signs of diffuse peritoneal inflammation requires immediate surgical consultation.

Once a patient is stabilized, a thorough history and physical examination are two of the most valuable pieces of information for accurately diagnosing the cause for abdominal pain. The history should elucidate the onset, nature, location, and duration of the pain as well as alleviating and aggravating factors. The onset may be discrete and memorable, as in the case of perforated viscus, but more often is insidious and difficult to define. Pain can be progressive (e.g., appendicitis), episodic (e.g., biliary colic), or sudden and severe (e.g., acute mesenteric ischemia). The origin, current location, and shift in pain help identify the location and status of the disease process.

Although not always feasible, physical examination should be performed early and often by the same examiner. A complete examination that assesses the heart, lungs, kidneys, and reproductive systems is essential to define potential nongastrointestinal sources of abdominal pain such as myocardial infarction, pneumonia, nephrolithiasis, or pelvic inflammatory disease. The abdominal examination should be directed to the point of maximum tenderness last. Tenderness upon light palpation is significant, especially if it persists while the patient is distracted. Pain elicited with the release of deep palpation ("rebound tenderness") does not necessarily differentiate among gastroenteritis, constipation, ileus, or more serious causes of abdominal pain. *The technique of eliciting rebound tenderness is crude and unnecessarily painful for a patient with peritoneal inflammation.* The same information can be obtained by detecting direct and referred percussion tenderness in the same manner as percussing the chest. This can be performed with only enough force to elicit a minimal response, and graded accordingly. Rectal and pelvic examinations are essential and further localize tenderness. By adhering to this initial approach, one can initiate rational diagnostic testing and therapy for the patient with abdominal pain regardless of the cause. The remainder of this chapter discusses three different causes of abdominal pain requiring surgical evaluation: acute appendicitis, diverticulitis, and ischemic bowel. Other causes of acute abdominal pain are covered elsewhere in this section of this book (e.g., cholecystitis, Chapter 84; pancreatitis, Chapter 86).

ACUTE APPENDICITIS

The appendix arises from the cecum and generally lies within the right lower quadrant of the abdomen. However, anatomic variation is common, and this can lead to an unusual presentation and delay in the diagnosis of acute appendicitis. Appendicitis may result from luminal obstruction secondary to fecaliths, lymphoid hyperplasia, parasites, or tumors. Venous engorgement, with resultant

impairment in arterial flow, leads to ischemia, then necrosis, first of the mucosa and subsequently of the muscular wall. Mucosal erosions or ischemia allows bacterial invasion and a subsequent local inflammatory response. The incidence of acute appendicitis is approximately 11 cases per year per 10,000 population. Appendectomy is the most common surgical procedure performed because of abdominal pain, resulting in approximately 300,000 yearly appendectomies in the United States (1).

Issues at the Time of Admission

Clinical Presentation

The clinical presentation of acute appendicitis is highly variable. Classically, the sequence of events begins with vague epigastric or periumbilical abdominal pain, followed by anorexia, nausea, and vomiting. This symptom complex is usually but not always associated with low-grade fever. Within 24 hours the pain migrates to the right lower quadrant, and there is discomfort on walking, coughing, or moving. Pain is usually constant and unremitting. Variation of this sequence is common, but the symptoms and signs are generally progressive. If perforation occurs, there may be temporary relief from pain until symptoms of peritonitis become evident.

The key to diagnosis is often the physical examination. Over 95% of patients have abdominal tenderness, often localized to one-finger palpation over McBurney's point. There may be mild muscular rigidity and localized peritoneal signs. Other signs include pain in the right lower quadrant with palpation of the left lower quadrant (Rovsing's sign). In less than 10% of patients, the psoas sign (pain in right hip with extension associated with retrocecal appendix) or obturator sign (pain with internal hip rotation associated with pelvic appendix) are also present. Rectal and pelvic examinations may help differentiate appendicitis from gynecologic problems.

Differential Diagnosis and Initial Evaluation

Acute appendicitis may mimic almost any acute abdominal illness. Conversely, most acute abdominal problems may resemble appendicitis. The differential diagnosis varies with the age and the gender of the patient (Table 87.1). The rate of incorrect (false-positive) diagnoses of appendicitis has been reported to be as high as 20% in males and 40% in females (2). *Perforated appendicitis* may have a different presentation, with higher fevers, longer duration of symptoms (2–5 days), and a history of pain that suddenly improves. A periappendiceal abscess or phlegmon may be palpable on physical examination.

If a patient presents with typical symptoms and signs, few diagnostic studies are needed. If the presentation is atypical, several studies may be helpful. The white blood cell count is greater than 10,000/ μ L, with neutrophilia in

70%–90% of cases. A normal white count does not rule out appendicitis, and in immunocompromised patients the count is often normal. Serial white blood cell counts usually demonstrate an elevation over the course of 4–8 hours. This finding has been shown to be associated with a 92% diagnostic sensitivity. Urinalysis may be abnormal with appendicitis, but marked elevations of the urinary cell counts suggest urinary tract disease (Chapter 68). Microscopic hematuria is more suggestive of nephrolithiasis, which can often mimic appendicitis. A pregnancy test in all women of childbearing age is mandatory.

Plain-film examinations are nonspecific but occasionally may show small-bowel obstruction, ileus, an appendicolith, or a gas-containing abscess. Rarely, perforated appendicitis may present with free intraperitoneal air. Chest radiograph may demonstrate right lower lobe pneumonia as an alternative diagnosis. *Graded compression ultrasonography* can be a useful tool in the diagnosis of appendicitis if a highly experienced ultrasonographer is available. An inflamed appendix is characterized by an outer diameter greater than 7 millimeters and noncompressibility. Appendicoliths, loss of normal appendiceal wall architecture, or periappendiceal fluid also may be seen. Although the reported sensitivity in selected series is 75%–95% and the specificity 85%–95%, this modality is limited by its dependence on the experience of the ultrasonographer. Nonvisualization of the appendix is common and does not exclude appendicitis. Even if nonvisualization occurs, ultrasonography may be helpful by identifying pelvic or biliary disease.

Computed tomography (CT) has been shown to be 94%–100% accurate in confirming or ruling out appen-

ditis (3). Like ultrasonography, CT is useful in diagnosing causes of abdominal pain other than appendicitis. CT has the advantage of less interobserver variability and increased sensitivity, but adequate oral contrast is essential. However, a focused appendiceal CT with rectal (but not oral) contrast has demonstrated sensitivity of 95% in the pediatric population (4). Findings on CT scan considered to be diagnostic of acute appendicitis include appendiceal distension, wall thickening, or peri-appendiceal inflammation. A series utilizing routine “appendiceal” CT suggested improved diagnostic accuracy, along with cost savings attributable to a decreased incidence of negative appendectomies and shorter average hospital stays (5). Confirmation of these findings and of their generalizability to the community setting needs to be documented prior to the adoption of appendiceal CT as the standard of care in evaluating patients with possible acute appendicitis. A recent report suggests that the widespread availability of CT examinations has not resulted in a reduction in the rate of negative appendectomy (6). If a periappendiceal abscess or phlegmon is suspected based on physical examination, CT should be performed to direct surgical or radiologic intervention.

Indications for Hospitalization and Intensive Care Unit Admission

Patients with a clear diagnosis of appendicitis require admission to the hospital and prompt surgical consultation for operative management. If the history and physical examination are equivocal and the etiology of abdominal pain is uncertain, then further evaluation is essential. This may be performed on either an inpatient or outpatient basis, depending on the patient’s presentation and modifying circumstances. Missed or delayed diagnosis of appendicitis can result in serious complications, whereas early diagnosis and treatment allows for a brief hospitalization and rapid recovery. Perforation is associated with a marked increase (from 8% to 40%) in the rate of postoperative complications and a prolonged hospital stay. Thus, the threshold for admission to the hospital and observation should be low for suspected appendicitis. This is especially true for pediatric, geriatric, and pregnant patients.

Appendicitis alone is generally not an indication for ICU admission. However, patients may require ICU care for other comorbid medical conditions, sepsis syndrome, or rare complications, such as *suppurative phlebitis* of the portal vein. Patients with this complication experience fever, chills, right upper quadrant abdominal pain and tenderness, malaise, mild jaundice, and anorexia. It is associated with late development of hepatic abscesses and has a 50% mortality rate. Acute appendicitis at the extremes of age has a higher incidence of delayed diagnosis and is associated with perforation in 50% of cases. These patients are more likely to be severely ill and require aggressive resuscitation in the ICU.

Initial Therapy

During the hospitalization, patients admitted for abdominal pain should have serial evaluations in the same manner as when they were evaluated in the office or emergency room. The symptoms and signs of acute appendicitis usually progress in the first 24 hours unless perforation has occurred. It is essential that the patient continue to be resuscitated, receive intravenous hydration, and have nothing by mouth during this time. Volume depletion and electrolyte abnormalities should be corrected. During this period, no antimicrobial agents should be given until a diagnosis is made.

If a patient does not prove to have acute appendicitis, the evaluation should be continued to determine the cause of pain. The patient should continue to receive nothing by mouth and receive intravenous hydration. Persistent or worsening unexplained tenderness is usually an indication for ultrasound or CT scan. Rising temperature, leukocytosis with migration of the pain to the right lower quadrant, and development of focal right lower quadrant tenderness are surgical indications. If an alternative diagnosis is made, the patient should be treated accordingly.

Once appendicitis is suspected or diagnosed, surgery is indicated. Patients should be resuscitated adequately prior to the administration of anesthesia and surgery. Any reversible coagulopathy should be corrected. An electrocardiogram and chest radiograph should be obtained in patients older than 40 years of age (Chapter 30). Preoperative antibiotic therapy should initially be directed against enteric Gram-negative rods and anaerobes (Chapter 64). Exploration and appendectomy generally are performed through a right lower quadrant muscle-splitting incision or laparoscopically. The advantage of the *open approach* is low cost and familiarity among surgeons and operating-room staff. *Laparoscopy* improves diagnostic accuracy (by sometimes discovering alternative causes in cases found to have a normal appendix, especially in female patients) and may be technically easier than the open approach in the obese patient. However, it has no proven advantage in recovery or hospitalization times. Because of the serious consequences of a delay in diagnosis, a 10%–30% “negative” appendectomy rate is the historic standard. If the appendix looks grossly normal, it is removed for microscopic analysis, and a careful exploration is performed to look for an alternative cause of pain.

Issues During the Course of Hospitalization

Figures 87.1 and 87.2 show critical pathways for uncomplicated and perforated appendicitis.

Following a routine appendectomy, antibiotics may be discontinued and the patient started on oral intake on the same or next postoperative day. If this is tolerated and the patient defervesces, discharge is appropriate. Persistent fevers often respond to pulmonary toilet, but a missed abscess or wound infection must also be considered.

Figure 87.1 Critical pathway for uncomplicated acute appendicitis. IV, intravenous; NPO, nothing by mouth; OOB, out of bed; POD, post-operative day.

If *perforation* is found, the appendix is removed, and, if contamination is minimal, the incision may be closed. Otherwise, the abdomen should be irrigated and the skin and subcutaneous tissue left open for healing by secondary intent or, in some cases, delayed primary closure on postoperative day 4. Antibiotics are continued postoperatively for 3–5 days. Oral intake is started when bowel function recovers, as evidenced by hunger or the passage of flatus.

Ideally, a *periappendiceal abscess* is diagnosed preoperatively; if so, it can be managed with antibiotics and percutaneous drainage by interventional radiologists. If an abscess is diagnosed at the time of appendectomy, it is evacuated, and drains are placed into the cavity. The appendix is removed if this can be done safely. If abscesses are drained without removal of the appendix, the colon must be evaluated to rule out other causes of perforation (such as diverticulitis or malignancy) prior to committing the patient to an interval appendectomy after 6–8 weeks. This may be done with colonoscopy or barium enema

prior to or shortly after discharge, once the acute inflammation has resolved. A periappendiceal abscess usually is accompanied by an ileus (Chapter 88). Once abdominal tenderness improves and bowel function returns, the patient may be started on oral intake. Patients usually defervesce after they are adequately drained, either percutaneously or surgically. Lack of improvement in serial physical examinations or fever curve suggests a persistent undrained collection, and a repeat imaging study such as CT or fluoroscopic sinography through the drain should be performed. Occasionally, definitive surgical drainage is required after an ineffective percutaneous attempt.

Discharge Issues

Following routine appendectomy without perforation, most patients are ready for discharge within 24 hours. Fevers and abdominal pain usually have resolved, and there is no rationale for continued oral antibiotic therapy.

Follow-up with the surgeon should be in 2–4 weeks. After appendectomy for perforated appendicitis, most patients are ready for discharge on postoperative day 3–5, depending on the degree of contamination, the fever curve, and the ability to tolerate oral intake. There is no need to continue antibiotics once the temperature and white blood cell (WBC) count are normal. Patients with wounds healing by secondary intent need to learn wound care and wet-to-dry dressing changes. A visit by a home care nurse followed by evaluation by the surgeon in 1–2 weeks ensures optimal wound management. Open wounds do not require antibiotic treatment.

Timing of discharge is variable following drainage of a periappendiceal abscess. It depends on the adequacy of drainage and is dictated by the clinical course, including the relief of pain, resolution of fever, and return of bowel function. The patient needs to learn to care for the drains, which can be removed by the surgeon when the output has tapered (which indicates obliteration of the abscess cavity). The presence of a drain alone is not an indication for

antibiotic therapy. Antibiotics are usually continued until the patient defervesces and has a normal white blood cell count. These patients also need visiting nursing care and early follow-up with the surgeon. If patients are debilitated, transfer to a skilled nursing facility may be required for ongoing wound care or rehabilitative therapy.

Patients should be encouraged to resume activities progressively as tolerated. Driving is safe when the patient is able to get in and out of the car and use the controls without discomfort. The diet should be advanced as tolerated. Patients should call their surgeons in case of fever, redness or drainage from the wound, or increase in pain.

DIVERTICULITIS

Diverticulitis is caused by a perforation of a diverticulum. In most cases, the perforation is microscopic, causing localized inflammation in the colonic wall or paracolic tissues. In more severe cases, an abscess may form, or the diverticulum may rupture freely into the peritoneal cavity, causing generalized peritonitis. The average age at presentation is in the early sixties; more than 90% of cases occur after 50 years of age. Fifty to 90% of cases in the United States occur in the left colon, particularly the sigmoid. However, among the Asian population, the incidence of right-sided disease is much higher (7). Fifty percent of patients have been symptomatic for less than one month before presentation; the duration of symptoms is inversely correlated with the severity of disease.

Issues at the Time of Admission

Clinical Presentation

Patients with acute diverticulitis can have a broad spectrum of symptoms but typically present with the gradual onset of left lower quadrant abdominal pain and low-grade fever. The pain tends to be constant and does not radiate. The localized inflammatory process may lead to irritation of the contiguous small bowel, colon, and bladder, which may subsequently cause anorexia, nausea, vomiting, diarrhea, constipation, dysuria, and urinary frequency or urgency. On physical examination, tenderness to palpation usually is present in the left lower quadrant or suprapubic region. A mass suggestive of a peridiverticular abscess or phlegmon also may be palpable. Rectal examination may reveal a boggy mass anteriorly if an abscess is present. Diffuse peritonitis is less common; when present, it usually represents frank perforation into the peritoneal cavity. Unlike diverticulosis (Chapter 78), acute diverticulitis usually is *not* associated with hemorrhage, although 30%–40% of cases have guaiac-positive stool. Pneumaturia or fecaluria suggests the presence of a colovesical fistula.

Differential Diagnosis and Initial Evaluation

A classic clinical presentation is often sufficient to establish the diagnosis without confirmatory testing. Laboratory studies are nonspecific and frequently unrevealing. Leukocytosis may be absent in up to one-half of cases. Urinalysis may be abnormal, with microscopic pyuria. An electrocardiogram should be considered in older patients with a history of coronary disease. In older individuals or immunocompromised patients, the presentation may be subtle, and immunocompromised patients are more likely to have complications of diverticulitis. The differential diagnosis is listed in Table 87.2.

When the diagnosis is unclear or complications of diverticulitis are suspected, further studies are necessary. Plain-film abdominal series, including an upright chest radiograph, should be obtained first to rule out free intraperitoneal air or a lower-lobe pneumonia. These studies may be normal or may demonstrate a distal large-bowel obstruction, localized ileus, or extracolonic air. *CT with intravenous and oral contrast is the study of choice.* Water-soluble rectal contrast may be used, but it carries the risk of perforation and should be carefully considered. CT scan is superior to barium enema in that it can directly demonstrate extraluminal complications of the disease such as abscess, phlegmon, free intraperitoneal air, or colovesical fistula and also can identify other causes of symptomatology.

If the results of the CT scan are equivocal or suggest an alternate diagnosis, contrast enema studies can be helpful in establishing the diagnosis and excluding cancer. *Barium should be avoided in the acute setting of diverticulitis* because of the risk of extravasation into the peritoneal cavity. Contrast studies can suggest the presence of an abscess in over 85% of cases but may underestimate the severity of extraluminal disease. Ultrasonography is up to 98% sensitive and 97%

specific in expert hands but is limited by higher false-negative rates in some series and greater interobserver variability.

Colonoscopy or sigmoidoscopy is generally contraindicated in the setting of acute diverticulitis. Limited examination with minimal or no air insufflation should be reserved for special situations in which the diagnosis of diverticulitis is uncertain and other diagnoses, such as ischemic bowel, obstructing carcinoma, or colitis, are being considered.

Indications for Hospitalization and Initial Intensive Care Unit Admission

Mild cases of acute diverticulitis in immunocompetent patients can be managed on an outpatient basis with clear liquids and oral antibiotics. Ideal patients for outpatient management are those who are able to tolerate a diet, have no systemic symptoms or diffuse peritoneal signs, and are reliable or have a reliable family. Immunocompromise, steroid therapy, and advanced age are contraindications to outpatient therapy. If outpatient therapy is elected, patients need to watch for systemic signs or progression of symptoms and should be instructed to return if these develop. Follow-up with the treating physician must occur within 48–72 hours after presentation to ensure resolution of symptoms. Patients who do not meet outpatient criteria or who fail outpatient management should be admitted to the hospital for total bowel rest, intravenous antibiotics, surgical consultation, and further evaluation as indicated. The decision for ICU admission should be based on the assessment of physiology and comorbidity as outlined at the start of this chapter. Patients with free perforation and peritonitis may need resuscitation in the ICU in preparation for urgent operative therapy.

Initial Therapy

Patients hospitalized for acute diverticulitis should be on complete bowel rest (NPO) and receive intravenous hydration and intravenous broad-spectrum antibiotics to provide coverage for Gram-negative organisms and anaerobes (Chapter 64). Figure 87.3 demonstrates an algorithm for the management of acute diverticulitis. Nasogastric decompression should be instituted for significant nausea, vomiting, or bowel obstruction. A Foley catheter may be placed for urinary retention. Appropriate analgesia should be administered. Enemas to treat constipation should be avoided. If the fever is greater than 38.5°C, a routine fever evaluation should be done (Chapter 62). As with any acute abdominal illness, patients must continue to be resuscitated during this time and have serial examinations performed to monitor the course of illness. Patients presenting with free perforation represent a surgical emergency and have a 6%–35% mortality rate. Aggressive resuscitation and cardiovascular support should be followed by prompt operative therapy. The same aggressive approach should be taken if a patient worsens on therapy.

Diverticulitis may be complicated by abscess, fistula, or bowel obstruction. These complications develop in about one-quarter of patients who present with symptomatic diverticulitis (7). Patients with recurrent diverticulitis have a 60% risk of a complicated course (8). In all types of diverticular complications, carcinoma must be ruled out as the cause. An *abscess* may resolve with conservative therapy if it is small and favorably located. It is preferable to drain a large abscess percutaneously prior to definitive therapy, because the presence of an abscess is a relative contraindication to primary anastomosis after colon resection. Seventy to 90% of abscesses can be percutaneously drained. *Fistulas* develop in only 2% of all patients with diverticulitis, but patients with fistulas represent 20% of all patients undergoing surgery for diverticulitis. Most commonly, fistulas occur between the colon and the bladder, but colovaginal, coloenteric, or colocutaneous fistulas also occur. A patient with a fistula should undergo an elective procedure to resect the affected bowel and close the fistula after the acute inflammation has resolved. *Bowel obstruction* from diverticular disease is an acute process, with perforation and bowel wall edema complicating a chronic response to previous inflammation. Obstruction is generally partial and usually is relieved as the edema from the acute inflammation resolves, leaving a fibrotic, strictured colon that can be resected electively. Patients with complete obstruction should undergo surgery expeditiously following acute resuscitation with hydration and nasogastric decompression (Chapter 88).

Indications for Early Consultation

Although most cases of diverticulitis are mild and resolve with medical management, prompt surgical consultation should be obtained for patients in whom significant systemic signs or peritonitis exist, and for those individuals presenting with a complication of diverticulitis such as abscess, fistula, obstruction, or free perforation. Consultation should be obtained at the onset of initial treatment in order to facilitate appropriate management.

Issues During the Course of Hospitalization

Most patients correctly diagnosed and treated for diverticulitis show significant improvement within the first 48 hours, denoted by decreased pain, less tenderness, and resolution of fever and leukocytosis. Bowel rest and antibiotics should be continued until the patient has improved subjectively and demonstrates return of bowel function. Nasogastric decompression is needed only in patients who present with nausea and vomiting; it can be discontinued as soon as the daily output decreases.

Worsening signs or symptoms or failure to improve during this period despite maximal medical therapy are indications for immediate reassessment. The diagnosis may be incorrect, or there may be unrecognized complications.

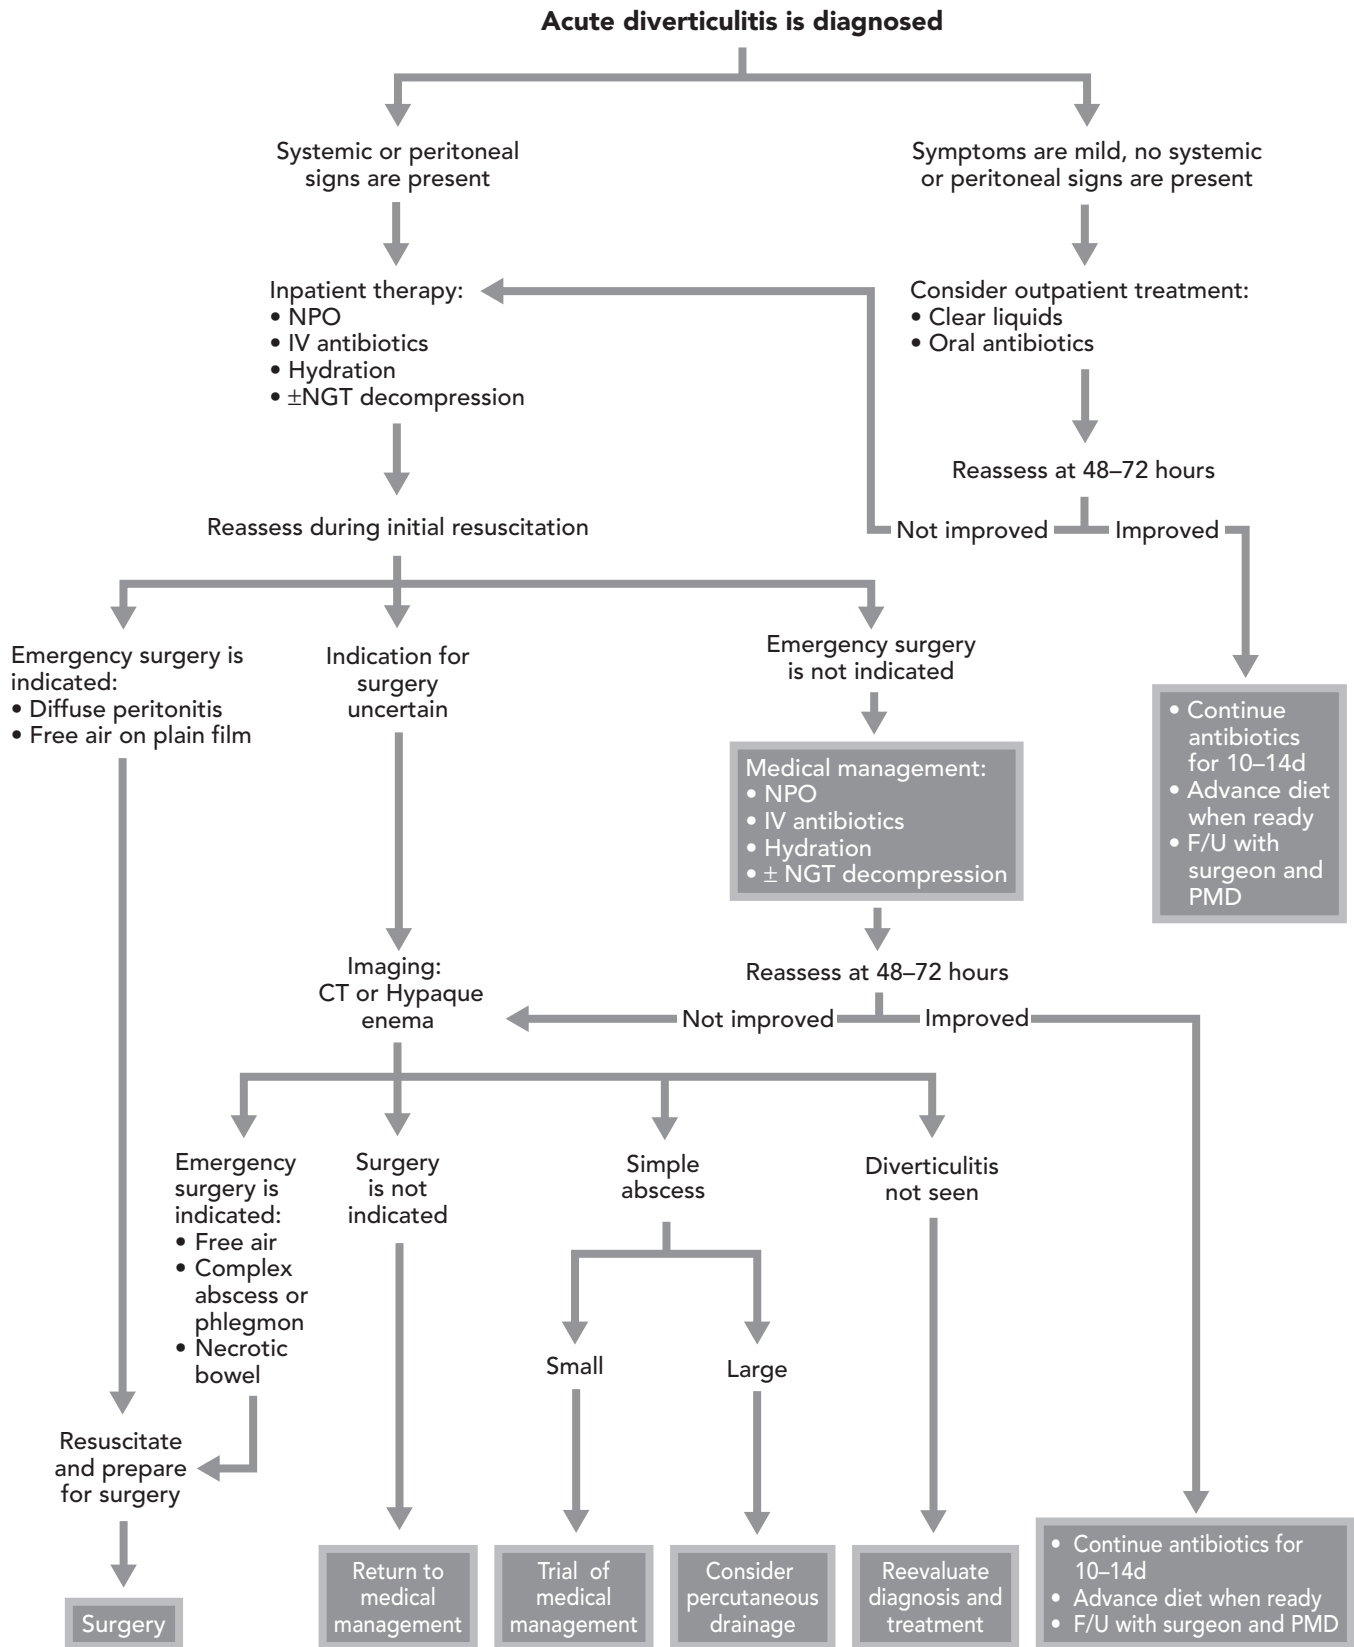

Figure 87.3 Algorithm for management of diverticulitis. *CT*, computerized tomography scan; *F/U*, follow-up; *IV*, intravenous; *NGT*, nasogastric tube; *NPO*, nothing by mouth; *PMD*, primary physician.

This occurs in 10%–25% of patients. In most cases, a CT scan should be obtained to seek an alternative diagnosis or to locate an abscess that might be drainable percutaneously. At this point, if no process amenable to medical management is identified, immediate surgical exploration is indicated. In preparation for surgery, an electrocardiogram and chest radiograph should be obtained in patients older than 40 years, and all comorbid conditions should be treated optimally (Chapter 30).

The exact nature of the surgical intervention depends on the severity of the disease and the nature of associated complications. Abscesses must be adequately drained. The diseased colonic segment should be resected if technically feasible. Under optimal circumstances, patients can undergo resection with primary colorectal anastomosis in a one-stage operation. A two-stage procedure is often required, with resection and colostomy formation followed later by re-anastomosis. There is now evidence suggesting that even in the presence of a pelvic abscess and focal peritonitis, a single-stage procedure can be performed with low risk of injury or death. This is preferable for most patients from both quality-of-life and cost standpoints. Rarely, patients who are critically ill may not be able to tolerate resection, in which case diversion and drainage may be the safest alternative.

Antibiotics should be continued after surgery for a duration determined by the patient's response to therapy. Five to seven days of intravenous antibiotics are usually sufficient. After the initial operation, an oral diet can be resumed when the patient feels hungry. This usually occurs on postoperative day 2 or 3, although it may take longer if significant contamination was present or ileus has developed.

If the patient has persistent high fevers, unimproving tenderness and pain, or persistent or worsening leukocytosis after surgical intervention, a recurrent abscess may be present. Alternatively, infection with resistant organisms is a possibility, and the antibiotic regimen should be reconsidered. Such a patient should be kept on bowel rest, and total parenteral nutrition should be considered. For patients with a primary anastomosis, anastomotic leak must also be ruled out. If present, it should be treated appropriately. If drain output has declined precipitously, the drain may be occluded, and a sinogram with catheter exchange may be helpful. Repeat imaging with CT may be helpful in directing further therapy.

Discharge Issues

Most patients with diverticulitis respond to medical therapy and are ready for discharge 5–7 days after initiation of therapy. By this time, the patient should have resolution of fever and marked improvement of abdominal pain, tenderness, and leukocytosis. Although it is not necessary that the patient tolerate a regular diet prior to discharge, he or she must be able to maintain oral hydration without an increase in abdominal pain. Oral antibiotics should be continued.

Usually a 10–14 day combined total course of therapy is adequate. Follow-up with the treating physician or surgeon should occur 2–4 weeks after discharge. Successful nonsurgical treatment of diverticulitis should always be followed by examination of the colon by colonoscopy or by flexible sigmoidoscopy with barium enema once the acute inflammation has resolved, to rule out carcinoma.

Approximately 10%–30% of patients who respond to medical therapy later go on to have another episode of diverticulitis. Age younger than 50 years and polycystic renal disease are risk factors for recurrent disease. Elective resection may be indicated. Patients with complications such as fistulas or strictures also ultimately require surgical intervention.

Following surgical intervention, the criteria for discharge are similar to those following other abdominal operations. Surgical follow-up should occur within 1–2 weeks for those with drains or open wounds and within 2–4 weeks for those with simple surgical resection without drains. Patients should be instructed to resume their diets gradually, as tolerated. Dietary changes should be directed at decreasing intraluminal pressure, which is thought to be partly responsible for diverticula formation. High fiber intake with generous fluid intake should be advised, as this appears to reduce complications in patients with diverticula.

ACUTE BOWEL ISCHEMIA AND ISCHEMIC COLITIS

Acute mesenteric ischemia results from insufficiency of the blood supply to the bowel resulting from embolic or thrombotic arterial occlusion, venous occlusion, or nonocclusive hypoperfusion. Although uncommon, acute mesenteric ischemia has a high mortality rate, with many series reporting rates over 60% (9). This is because diagnosis is difficult and patients often present late and have multiple comorbidities. Ischemic colitis usually follows a more benign clinical course. Untreated, however, it too can progress to transmural necrosis and systemic sepsis, with a high mortality rate. The watershed areas of the right and left colon are at particularly high risk. An important subset of patients develops colon ischemia following major operations such as abdominal aortic aneurysm repair or cardiac surgery involving cardiopulmonary bypass. Chronic mesenteric ischemia is not discussed here because it involves different pathophysiologic and therapeutic considerations.

Issues at the Time of Admission

Clinical Presentation

Acute intestinal ischemia, typically secondary to an embolus, is heralded by the sudden onset of poorly localized, severe, crampy abdominal pain, classically out of proportion

to physical examination findings. Acute ischemia usually occurs in patients with cardiovascular comorbidities. Risk factors include arrhythmias, structural cardiac disease, hypotension, atherosclerosis, and hypercoagulable states. Nausea, vomiting, diarrhea, or hematochezia may be present and suggest evolving intestinal infarction. An abdominal bruit is present in 10%–25% of cases. With ischemia resulting from arterial thrombosis, venous occlusion, or ischemic colitis, the progression of symptoms is more insidious and starts with vague gastrointestinal symptoms of pain, bloating, changes in bowel habits, or nausea. Initially, peritoneal irritation may not be present, but the signs and symptoms progress as bowel infarction and necrosis begin. Later in the disease course, abdominal distention, guarding, rebound tenderness, or altered mental status with signs of systemic sepsis, renal failure, and cardiovascular compromise may occur. Not infrequently, the patient in whom acute bowel ischemia is being considered is already in critical condition, obtunded or intubated in the ICU. In this particular setting, the pathophysiology usually is related to nonocclusive ischemia or vasospasm.

Differential Diagnosis and Initial Evaluation

Diagnosis of ischemic bowel is often very difficult because the initial physical findings may be unremarkable. Thus, the differential diagnosis is vast. However, the absence of abnormal physical findings in the setting of severe, sudden abdominal pain is an important clue to the diagnosis of acute mesenteric occlusion. Diagnosis is often based on early suspicion and clinical intuition because no specific noninvasive diagnostic study can reliably diagnose or exclude mesenteric ischemia. Most abnormal findings occur late and are nonspecific. These include leukocytosis with a left shift; hemoconcentration; elevations in serum phosphate and amylase; and elevated lactate level with resultant metabolic acidosis.

Plain radiographs may be completely normal or show nonspecific findings. In more advanced cases of acute mesenteric ischemia, bowel-wall thickening, pneumatosis intestinalis, portal venous air, or free air may be seen. These late findings usually represent full-thickness necrosis and portend a poor prognosis. CT of the abdomen and pelvis with oral, rectal, and intravenous contrast may show bowel wall thickening, intramural or portal venous air, or thrombus within the mesenteric arteries or veins. Although less sensitive for arterial occlusions, CT is the diagnostic study of choice for mesenteric venous thrombosis, with reported sensitivities as high as 90%. Duplex ultrasound scanning also can be helpful in the diagnosis of either arterial or venous occlusion but is often technically difficult because of overlying bowel gas.

The definitive diagnostic study for arterial pathology is mesenteric angiography. It can differentiate occlusive from nonocclusive sources of ischemia and can direct intervention. Furthermore, it offers the opportunity for non-

surgical interventions such as selective vasodilator or thrombolytic infusion. Emboli usually are seen impacted 3–10 cm from the origin of the superior mesenteric artery and distal to the origin of the middle colic branch. A meniscus sign often is seen at the point of occlusion. In contrast, superior mesenteric artery thrombosis usually occurs at the origin and may manifest as nonvisualization of the artery. Alternatively, nonocclusive mesenteric ischemia is seen as vasospasm, with multiple areas of narrowing of the mesenteric arteries without occlusion. In the setting of venous thrombosis, arteriography may demonstrate subtle signs such as delayed visualization of the venous phase, prolonged opacification of the bowel wall, or nonvisualization of the ischemic segments. Flexible colonoscopy can evaluate the mucosal viability of the colon and terminal ileum and is the procedure of choice to evaluate early ischemic colitis.

Indications for Hospitalization and Initial ICU Admission

All patients in whom acute mesenteric ischemia is suspected should be admitted to the hospital for observation and further evaluation. Many patients with mesenteric ischemia need initial ICU admission for resuscitation because of hemodynamic instability caused by hypovolemia or systemic sepsis. Mesenteric ischemia is also more likely to occur in patients with significant cardiovascular comorbidities, which themselves may need ICU management. The underlying cause of mesenteric ischemia must be evaluated and treated concurrently.

Initial Therapy

The goal of initial intervention is resuscitation, regardless of the cause of the ischemia. The loss of intravascular volume to surrounding tissues is typically massive, and volume should be aggressively replaced with crystalloid and colloid (Chapter 25). Acidosis caused by tissue hypoperfusion may not be fully corrected with volume alone, and the administration of sodium bicarbonate may be necessary (Chapter 105). Broad-spectrum intravenous antibiotics to cover aerobic and anaerobic intestinal flora should be given immediately (Chapter 64). Systemic sepsis arising from ischemic bowel may be especially difficult to manage and is recalcitrant to therapy unless the source of sepsis is removed.

If the history and clinical presentation strongly suggest acute visceral embolization, immediate laparotomy with embolectomy and resection of infarcted bowel should be performed after preoperative resuscitation. For patients with superior mesenteric artery (SMA) thrombosis, nonocclusive ischemia, or unclear diagnosis, mesenteric angiography with selective cannulation should be performed urgently to establish the diagnosis and plan further therapy. If an embolus or thrombosis is confirmed, the patient

should be prepared immediately for embolectomy or thrombectomy as above. In selected cases, intra-arterial thrombolytics and vasodilators may be successful. Nonocclusive ischemia is the entity more commonly seen in ICU patients. The highest priority is reversal of any precipitating causes. Vasoconstricting agents should be discontinued if possible, and systemic vasodilators should be used in conjunction with positive inotropes to maintain splanchnic perfusion pressure. If the diagnosis is established angiographically, a catheter should be left in place and intra-arterial papaverine delivered continuously. Surgery is indicated only if there is evidence of bowel necrosis. Premature operative intervention in this setting may prove detrimental.

Patients with mesenteric venous occlusion should be anticoagulated with heparin, and a hypercoagulability evaluation should be undertaken (Chapter 98). Initial surgical intervention is reserved for evidence of bowel necrosis or perforation.

Flexible sigmoidoscopy or colonoscopy should be performed early for ischemic colitis. If ischemia is mild and there are no signs of peritonitis or sepsis, these patients sometimes can be managed with oral antibiotics and a clear liquid diet, but the cause of ischemia should be pursued and corrected if possible. If ischemic colitis progresses to full-thickness necrosis, operative intervention must be undertaken.

Indications for Early Consultation

The management of acute mesenteric ischemia requires a multidisciplinary approach involving surgeons and interventional radiologists. Early surgical consultation should be obtained whenever mesenteric ischemia is suspected. The interventional radiology team is also needed for urgent angiography unless immediate exploration is indicated.

Issues During the Course of Hospitalization

Approximately 25%–50% of cases of acute mesenteric ischemia are caused by *arterial embolus*, usually originating in the left atrium as a consequence of atrial fibrillation. The immediate definitive treatment is embolectomy with enterectomy if necessary. *Arterial thrombosis* accounts for another 25%–50% of acute ischemia. Thrombectomy alone is usually insufficient therapy, as the diseased vessel is likely to reocclude. Surgical treatment consists of revascularization with enterectomy as needed.

Operative therapy is usually performed through a midline incision so that the entire abdomen can be evaluated. Heparin is given to avoid additional thrombus formation. The primary goal is to restore blood flow to the intestine. Once the SMA is identified at the root of the mesentery, an embolectomy or thrombectomy can be performed. If thrombosis has occurred in a diseased artery, mesenteric bypass or endarterectomy may be necessary to establish ad-

equate blood flow (10). After revascularization, the bowel viability must be assessed and areas of necrosis resected. There are often areas of the bowel in which viability is questionable. For these cases, a second-look laparotomy can be performed in 24–48 hours to re-assess viability.

Nonocclusive mesenteric ischemia occurs as a result of a low cardiac output state, and management can be challenging. In most cases, treatment of the underlying conditions with resuscitation and discontinuation of vasopressors results in resolution. However, if no improvement is seen in 24 hours, angiography should be performed and a continuous papaverine infusion (30–60 mg/h for 12–24 hours) into the mesenteric vessels initiated. Significant clinical deterioration often reflects bowel infarction and signals the need for laparotomy. If the patient remains stable or improves, the angiogram should be repeated.

Mesenteric venous thrombosis that has not progressed to bowel necrosis should be treated by immediate anticoagulation with heparin. Thrombectomy usually is contraindicated, as most patients have diffuse thrombosis. All patients with local or diffuse peritonitis should undergo immediate laparotomy with resection of clearly infarcted bowel. Peritonitis may become apparent after the patient has been fully anticoagulated. In this case, heparin should be continued throughout the perioperative period. Simultaneously, the underlying disorder that caused the thrombosis should be addressed. More than 80% of all cases of mesenteric venous thrombosis are secondary to hypercoagulable states; hematology consultation should be obtained (Chapter 98).

The primary therapy for *ischemic colitis* is supportive. In the hospital setting, intravenous hydration and antibiotics should be administered. Cautious colonoscopy may be performed early to document the extent and severity of the disease and may be repeated at 24- to 72-hour intervals to evaluate the progression or regression of disease. Necrosis or gangrene seen on colonoscopy or clinical evidence of peritonitis should prompt surgical intervention. Patients treated conservatively should show improvement within the first several days and resolution of symptoms by two weeks.

With all forms of bowel ischemia, the hospital course depends on multiple factors, including underlying systemic disorders and the severity of the ischemic disease. Generally, patients should have complete bowel rest and be started on oral intake slowly after they have demonstrated a trend toward improvement, as evidenced by stability in hemodynamic status, resolution of sepsis, and return of bowel activity.

Regardless of the precise nature of ischemia, the development of peritonitis or evidence of bowel necrosis should prompt surgical intervention. At the time of exploration, all infarcted bowel is resected. However, it is often difficult to reliably ascertain the viability of the bowel by visual inspection alone. A second-look laparotomy at 24–48 hours may be necessary. Bowel viability determines whether intraoperative management involves the creation of an enterostomy

or a primary anastomosis. All patients need continued close monitoring for evidence of ongoing bowel infarction.

Discharge Issues

Patients are ready for discharge if they have become physiologically stable with the resolution of sepsis, improvement of pain, and return of bowel function. The timing of discharge is variable. Among the highest priorities at the time of discharge is the optimal treatment of underlying systemic diseases to minimize the likelihood of recurrent bowel ischemia. Early follow-up should be scheduled to ensure optimization of medical therapy and to monitor for recurrent disease. As is the case after any operation for an intra-abdominal source of sepsis, the patient may have enterostomies, drains, open wounds, parenteral nutrition, or antibiotics to manage at home. A visiting nurse is often helpful, and follow-up with the surgeon should occur within 1–2 weeks. Diet and activities should be resumed as tolerated. Driving can be resumed when the patient is off opiates and feels comfortable. There is no indication for routine antibiotics at discharge.

COST CONSIDERATIONS AND RESOURCE USE

Approximately 250,000 appendectomies are performed in the United States each year, at a total cost of about \$1.5 billion. About 20% of the appendectomies performed find no pathology attributable to the appendix. This has led to efforts to improve the diagnostic accuracy of appendicitis with modalities such as ultrasound and limited abdominal CT scan. If accurate preoperative diagnosis could be achieved routinely without the need for extensive and expensive diagnostic studies, the cost of the “negative” appendectomy could be avoided.

Recent advances in surgical and interventional radiologic techniques have reduced the morbidity and cost resulting from treating complicated diverticulitis. Percutaneous drainage of a large peridiverticular abscess allows the surgeon to treat the disease definitively with a single operation in which the colon is resected and a primary anastomosis is created. This previously required two or three operations and a temporary colostomy. The resultant savings in the cost of multiple operations, hospitalizations, and patient morbidity are significant.

Despite advances in the treatment of mesenteric ischemia, there have been only small gains in patient survival. This reflects the difficulty of diagnosis and treatment. As the population ages, the incidence of mesenteric ischemia has increased, with a resultant increase in the cost of treating these patients. Early diagnosis and intervention, and increased focus on prevention, offer the only chance to decrease the mortality rate and cost.

KEY POINTS

General

- Although the causes of intra-abdominal emergencies are legion, unifying themes should guide the care of these acutely ill patients. Most importantly, attention should be directed to rapid and aggressive resuscitation of the patient before searching for the diagnosis.
- Physical examination performed early and often by the same examiner is the safest, most cost-effective tool in the evaluation of abdominal pain.
- Early surgical consultation and a multidisciplinary approach are important to ensure rapid intervention should the necessity for surgery arise or the patient's condition rapidly deteriorate.

Acute Appendicitis

- The classic presentation of acute appendicitis is vague periumbilical pain that shifts to become localized right lower quadrant pain, associated with anorexia.

Acute Diverticulitis

- Complete bowel rest, intravenous hydration, broad-spectrum antibiotic therapy, and serial physical examinations are the key elements of the management of diverticulitis.
- CT with intravenous and oral contrast is the study of choice in the evaluation of acute diverticulitis.
- Successful nonsurgical treatment of diverticulitis should be followed by examination of the colon to rule out carcinoma.

Ischemic Bowel

- Early recognition and intervention is the key to successful treatment of acute mesenteric ischemia.
- A paucity of abnormal physical findings in the setting of severe, sudden abdominal pain is an important clue to the diagnosis of acute mesenteric occlusion.

Ileus and Obstruction of the Gastrointestinal Tract

Daniel T. Dempsey Sean P. Harbison

INTRODUCTION

Bowel obstruction is defined as any mechanical or functional process that interferes with normal transportation of intestinal contents through the alimentary tube. Complete bowel obstruction implies total luminal compromise; partial obstruction implies otherwise. The cause of bowel obstruction usually is categorized as extrinsic, intrinsic, or luminal (Table 88.1). *Ileus* is defined as any functional or reflex abnormality of gut peristalsis that interferes with the passage of luminal contents. Ileus may be focal or generalized and is thought to be caused by dysfunction of the enteric nervous system or smooth muscle. Causes of ileus may be categorized as reflex, metabolic, drug induced, systemic, or other (Table 88.2). Bowel obstruction and ileus are important clinical entities because they are common and may result in death if not properly managed.

The care of the patient with ileus or bowel obstruction is guided by the following principles:

1. Patients with complete small-bowel obstruction require an urgent operation.
2. Patients with complete colon obstruction (except some with sigmoid volvulus) require an urgent operation.
3. Ileus is often an indication of a serious underlying medical or surgical problem.
4. Proximal decompression and fluid resuscitation are critically important in the management of patients with ileus and bowel obstruction.

This chapter emphasizes the importance of these simple principles. Gastric-outlet obstruction and gastroparesis are not discussed.

BOWEL OBSTRUCTION OR ILEUS AS A PRESENTING COMPLAINT

Issues at the Time of Admission

Clinical Presentation

Patients presenting with intestinal obstruction or ileus usually complain of abdominal discomfort or pain, nausea with or without vomiting, anorexia, decreased output of stool and flatus, and abdominal distension (1). The constellation of signs and symptoms depends on the degree and level of obstruction. *Proximal* small bowel obstruction typically produces crampy abdominal pain, frequent bilious vomiting, and variable amounts of abdominal distension. *Distal* small bowel obstruction causes impressive abdominal distension, less frequent (but often feculent) vomiting, and intermittent crampy abdominal pain. *Colon* obstruction may cause severe distension and little vomiting, especially if the ileocecal valve is competent. *Ileus* presents with distension and anorexia. Because ileus often is indicative of an intra-abdominal process (e.g., pancreatitis) or a systemic illness (e.g., pneumonia), accompanying symptoms can be myriad (2).

Differential Diagnosis and Initial Evaluation

A good physical examination is essential (see Table 88.3). The vital signs and the general appearance of the patient are important. Fever may indicate a strangulation obstruction or an abscess associated with obstruction or ileus (e.g., appendiceal abscess with distal small-bowel obstruction).

TABLE 88.2
CAUSES OF ILEUS

Reflex	Drug-induced
Spinal cord injury	Opiates

Kidney or liver failure	<i>Clostridium difficile</i>)
	Pseudo-obstruction

TABLE 88.3
IMPORTANT PHYSICAL FINDINGS IN PATIENTS WITH BOWEL OBSTRUCTION

Sign or symptom	Possible causes
Hypotension/tachycardia	Intravascular volume depletion Sepsis (bowel gangrene or perforation)
Tachypnea, rhonchi	Pneumonia
Cachexia, lymphadenopathy	Advanced malignancy
Jaundice	Periampullary malignancy Gallstone ileus
Irregular heart rate/heart murmur	Embolism with ischemic bowel
Bruit (abdominal/carotid/femoral)	Thrombosis with ischemic bowel
Abdominal scars	Adhesive small bowel obstruction
Peritoneal signs	Strangulation, obstruction Acute abdomen causing bowel obstruction (e.g., appendiceal abscess)
Hernia (groin, abdominal)	Incarceration or strangulation
Guaiaac-positive stool	Carcinoma Ischemia

Cachexia may suggest that the obstruction is caused by carcinoma (primary bowel or metastatic) or that the patient has intestinal ischemia presenting as ileus or obstruction. Tachycardia and hypotension may indicate septic shock from an abdominal catastrophe or urosepsis with reflex ileus. It is notoriously difficult for even the most experienced clinician to discern the presence of threatened or strangulated bowel in the patient with a small-bowel obstruction (2,3). Thus, if a complete obstruction is suspected (the situation in which most bowel strangulation occurs), an urgent operation is necessary.

More commonly, in the patient with bowel obstruction, tachycardia and hypotension reflect a fluid deficit. *The patient with bowel obstruction or ileus often has a profound deficit in extracellular fluid volume.* Thus, fluid resuscitation is an important part of initial clinical management (Figure 88.1; Chapter 87). Blood should be sent for determination of electrolyte, blood-urea nitrogen, glucose, calcium, and amylase levels and complete blood count (CBC) with differential count.

In every patient presenting with abdominal pain and distension, nausea or vomiting, and alteration in bowel function, *early surgical consultation is mandatory* (4). The following questions must be addressed:

- Does the patient have a small- or large-bowel obstruction?
- If so, is it a complete obstruction?

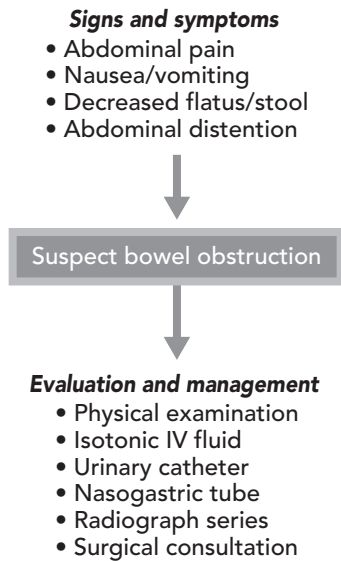

Figure 88.1 Initial approach to bowel obstruction and ileus. IV, intravenous.

- If the patient has a partial obstruction, is early operation necessary?
- What is the likely cause of the obstruction?
- If the patient has ileus, why?

Upright chest and abdominal and supine abdominal radiographs constitute the standard “obstruction series;” they should be obtained in every patient with suspected bowel obstruction or ileus (Figure 88.2). Computed tomography (CT) or magnetic resonance imaging is not necessary routinely but may yield important information in selected patients (5,6). If the radiographs show distended small and large intestine, the diagnosis is either ileus or colonic obstruction, and a sigmoidoscopy or contrast enema is indicated. If there is small-bowel distension without colonic distension, the diagnosis is probably small-bowel obstruction. The presence or absence of air in the colon in this setting is an unreliable determinant of complete small-bowel obstruction. If the patient denies passage of stool or flatus, by definition the patient has a *complete* bowel obstruction. This is a surgical emergency because intestinal necrosis or perforation occurs frequently in this setting. Clinical judgment is notoriously poor in predicting bowel compromise in patients with bowel obstruction (3). If a lucid patient admits to passage of stool or flatus, the patient has a *partial* small-bowel obstruction. The patient with obvious partial small-bowel obstruction does not necessarily require operation if there is no tenderness, leukocytosis, fever, tachycardia, or physical signs of peritoneal irritation (after fluid resuscitation) (7). In patients with bowel obstruction in whom nonoperative therapy is contemplated, enteroclysis with water soluble contrast is a useful way to confirm a partial obstruction. At times, it may also be therapeutic (8).

The common causes of small-bowel obstruction in the adult are (in descending order of frequency) adhesions, hernia, and cancer (Table 88.1). Abscess (commonly appendiceal or diverticular) or ischemia are important but less common causes of small-bowel obstruction. The common causes of large-bowel obstruction in the adult are cancer, diverticulitis, and volvulus. Causes of ileus are myriad and include a variety of intra-abdominal and systemic conditions (Table 88.2).

All patients with a diagnosis of small- or large-bowel obstruction should have a nasogastric tube inserted for decompression. Distension of bowel loops with fluid and gas is important in the pathophysiology of bowel obstruction, and decompression via tube is an effective way to decrease the distension. Long intestinal nasoenteric tubes are rarely necessary and may increase the risk of aspiration. Nasogastric decompression also makes general anesthesia safer in patients requiring an operation because it lowers the risk of aspiration on induction.

An unusual but noteworthy disorder is *chronic intestinal pseudo-obstruction* (9). Patients with it (not to be confused with hospitalized patients who develop colonic pseudo-obstruction or Ogilvie’s syndrome) are thought to have a diffuse motor disorder of the GI tract. The presentation may be very similar to that of mechanical bowel obstruction. In fact, many of these patients have had previous abdominal operations, and they can develop mechanical obstruction from adhesions and hernias, with an attendant risk of bowel strangulation or perforation. Management of this difficult subset of patients is best done in a referral center by surgeons and gastroenterologists experienced with this disease.

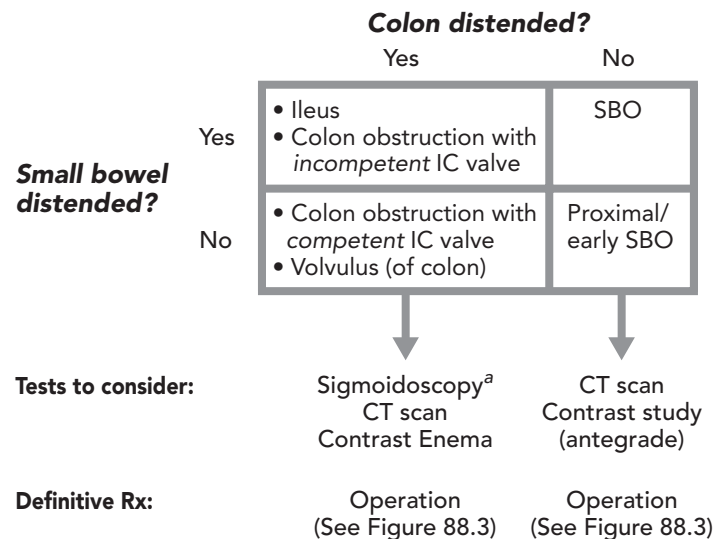

Figure 88.2 Differential diagnosis and treatment of small- and large-bowel distension. ^aMay be therapeutic in sigmoid volvulus. IC, ileocecal; SBO, small-bowel obstruction.

Indications for Hospitalization and ICU Admission

All patients with the diagnosis of acute small- or large-bowel obstruction require hospitalization. Patients with complete obstruction require an urgent operation, usually within 6–12 hours. Patients with partial small-bowel obstruction may be treated nonoperatively, provided that they have no fever, tachycardia, leukocytosis, or pain or tenderness. Occasionally, patients with bowel obstruction and terminal disease who are not deemed candidates for an operation may be treated palliatively at home or in the hospital (Chapter 19) (10). Most patients with ileus severe enough to have caused a visit to an emergency department or whose symptoms have lasted more than 24 hours require hospitalization to treat the associated illness, dehydration, and underlying cause.

Patients with bowel obstruction should be admitted to the ICU if they have hemodynamic instability after the initial resuscitation or if invasive hemodynamic monitoring is required for safe fluid resuscitation. This usually includes patients with compromised cardiovascular, pulmonary, or renal status (Chapter 25). Patients with possible aspiration pneumonia, a frequent complication of bowel obstruction, also should be admitted to the ICU (Chapter 66). Patients with ileus may require admission to the ICU, depending on the severity of the primary disease causing the ileus.

Indications for Operation

Patients with complete small- or large-bowel obstruction require an *urgent operation* (Figure 88.3). This is because intestinal strangulation or perforation in this setting is a very real possibility (3). Patients with partial small-bowel obstruction who have unremitting abdominal pain, tenderness, fever, or leukocytosis also require surgery. Otherwise, the patient with partial obstruction may be treated with nasogastric tube suction and intravenous fluids with the hope that the partial obstruction resolves (7). If there is no sign of clinical or radiologic improvement in 48 hours, surgery should be considered. Patients with acute sigmoid volvulus can often be decompressed with a sigmoidoscope; an urgent operation is not required unless pain and peritoneal signs are present (11). Recurrence is common, and elective surgery should be considered. Treatment of partial colon obstruction depends upon the cause. If the patient has a partially obstructing colorectal carcinoma, early elective surgery should be performed. If the patient has acute diverticulitis, several days of antibiotic treatment usually result in improvement in gastrointestinal function. Patients with a colonic stricture from any cause who present with signs and symptoms of partial obstruction usually require elective surgery.

Patients with ileus may require an operation to treat the primary disease that has given rise to the ileus (e.g., pancreatic debridement in necrotizing pancreatitis, appendec-

tomy for perforated appendicitis, or patch closure for perforated duodenal ulcer). Patients with primary colonic ileus (also called colonic pseudo-obstruction, or Ogilvie's syndrome) usually can be treated with colonoscopic decompression (12). If this is not possible, operative decompression may be necessary.

Obstructing Colon Carcinoma

Primary carcinoma of the colon may present with bowel obstruction. Colon cancers may involve the small bowel by direct extension and rarely also may cause symptoms of small-bowel obstruction. Metastatic colon carcinoma is a much more common cause of small-bowel obstruction (see later in this chapter). If the colon obstruction is deemed to be complete on clinical or radiologic grounds, an urgent operation is indicated (Figure 88.3). A diverting loop colostomy is the procedure of choice in debilitated or high-risk patients. Otherwise, the obstructing tumor may be removed at the initial operation. Because preoperative bowel preparation is impossible, primary colon anastomosis usually is contraindicated, and a double-barrel colostomy, or "Hartmann procedure" (proximal colostomy, distal closed defunctionalized segment), is performed. This is reversed with a second procedure at a later date (at least two months later) after the remaining colectomy is studied to rule out a synchronous lesion. If the primary tumor is resected with a proximal colectomy, a primary ileocolonic anastomosis is acceptable. Recently, some groups have practiced intraoperative colonic lavage and primary colonic anastomosis in patients with obstructing colon carcinoma, with acceptable results. If the primary colon tumor is not completely obstructing, it may be possible to cleanse the colon with a mechanical bowel preparation and perform a one-stage procedure (i.e., resection of tumor with primary anastomosis). Preoperative or intraoperative endoscopy is advisable to rule out other synchronous lesions when this technique is used (11).

Colon carcinoma frequently metastasizes to small intestine, omentum, mesentery, and peritoneum. Thus, in Western society, metastatic colon cancer is a fairly common cause of small-bowel obstruction. A more common cause of small-bowel obstruction in the patient who has undergone colon resection is adhesions. Thus, the primary differential diagnosis in the patient presenting with small-bowel obstruction months or years following a colon resection for carcinoma is adhesions vs. metastatic carcinoma. There is no completely accurate way of determining the cause preoperatively. Adhesions usually are treated with lysis; obstructing metastases are treated by resection, bypass, or enterostomy.

Initial Therapy

Early treatment of patients with bowel obstruction or ileus consists of nasogastric tube decompression and appropri-

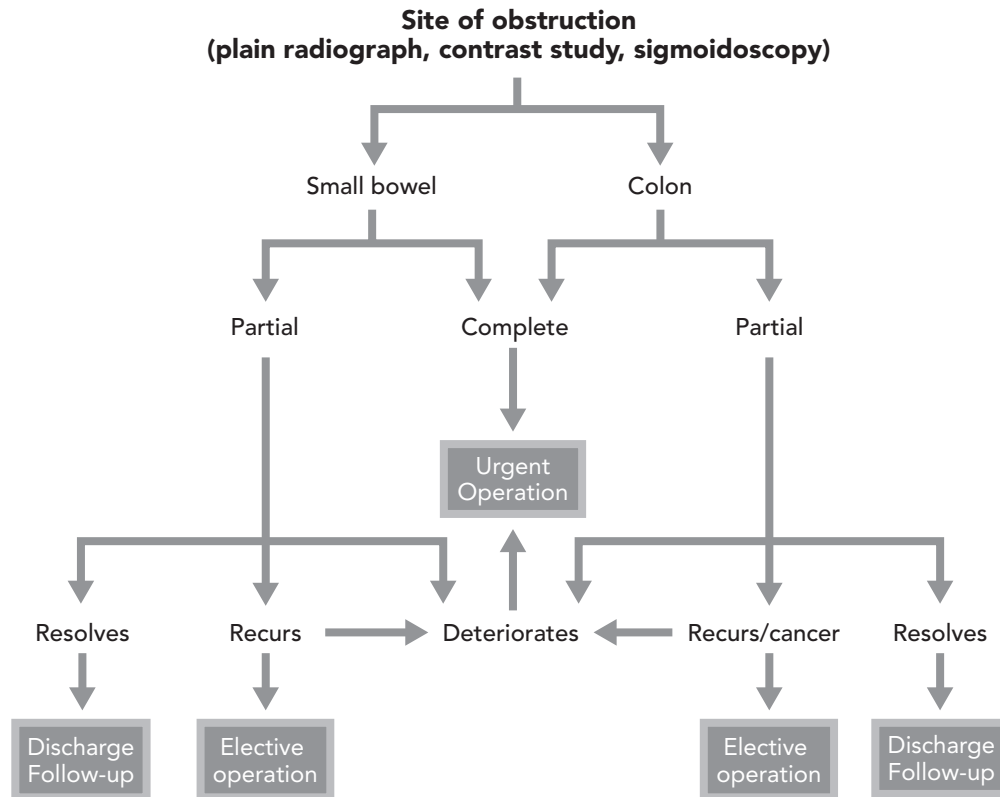

Figure 88.3 Management of bowel obstruction.

ate intravenous fluid resuscitation. Those with complete obstruction or peritonitis require early surgery. Patients with partial obstruction and those with ileus may be observed with frequent examinations and daily plain-film abdominal series if there is no sign of abdominal catastrophe. Patients with a colonic ileus may be helped with a rectal tube, but colonoscopic decompression is more effective.

Patients operated upon for bowel obstruction are given perioperative antibiotics. This may be extended to a therapeutic course if ischemic bowel is resected, if an abscess or peritonitis is encountered, or if spillage of gastrointestinal contents occurs. The use of antibiotics in patients with partial obstruction or ileus is controversial. Antibiotics should be given if the disease process that has contributed to the development of the ileus requires antibiotics (e.g., pneumonia); otherwise, there is no clear indication. Fever, tenderness, and leukocytosis should be regarded as indications for operation rather than as indications for antibiotics in most patients.

Indications for Early Consultation

A surgeon must see all patients with intestinal obstruction, preferably within 2 hours of presentation (4). Surgical consultation is also prudent in most patients with ileus. Gastroenterology consultation is usually unnecessary in patients with bowel obstruction or ileus but might be helpful

for colonoscopic decompression in patients with ileus and massive colonic distension (cecum greater than 10–12 cm in diameter).

Issues During the Course of Hospitalization

Fluid resuscitation and nasogastric tube decompression are important in all patients presenting with bowel obstruction or ileus. One of the most important issues after admission is to determine whether the patient has a complete bowel obstruction. Patients with partial obstruction who are not operated upon should be followed closely because they may develop complete obstruction or signs of bowel compromise during hospitalization. Most patients with partial small-bowel obstruction resolve with appropriate conservative management, but radiologic investigation or operation should be considered if no improvement occurs within 48 hours. Whether or not they undergo operations, hospitalized patients with bowel obstruction or ileus require close monitoring. The abdomen and chest must be examined by a physician at least twice daily, and vital signs, fluid balance, and nasogastric tube function assessed. Bowel strangulation or perforation and aspiration pneumonia are complications that can be prevented by aggressive gut decompression and early operation (3,13). Serum electrolytes and blood counts should be monitored daily until the nasogastric tube is

removed and bowel function returns. Serial abdominal radiographs are important in patients who are treated nonoperatively or in postoperative patients who fail to improve clinically. Wound infection, fluid overload, pneumonia, and pulmonary embolism are not uncommon postoperative complications in patients operated on for bowel obstruction (14).

A variety of important issues must be considered if the patient with bowel obstruction or ileus fails to improve. These generally can be grouped as occurring in patients who have just been operated on for obstruction versus those inpatients with presumed partial obstruction or ileus who are being treated nonoperatively. In the patient who has been operated on for bowel obstruction, it is important to know the operative findings and what was done at the operation. What was the cause of the obstruction? Was the bowel completely viable? Was the bowel entered? (That is, was a bowel resection necessary? Was the bowel injured and repaired during a difficult dissection?) Generally, patients operated on for bowel obstruction have return of bowel function within 5 days of the operation. Patients with chronic obstruction or those with slow progressive development of bowel obstruction may require much more time postoperatively for bowel function to resume. If the patient is not progressing as expected, one should consider peritonitis, abscess, intestinal ischemia, persistent or recurrent obstruction, electrolyte disorders (e.g., hypokalemia), and "postoperative ileus" (15).

In the patient with partial obstruction or ileus who fails to improve, the main issue is whether the patient in fact has a complete obstruction or compromised bowel. Thus, patients with evidence of systemic toxicity or peritonitis should be operated on. Partial obstruction may progress to complete obstruction, and rarely, partial obstruction may be associated with bowel strangulation or perforation. Patients with ileus also may develop ischemic perforation of massively distended bowel, frequently the cecum.

Two difficult situations must be approached individually in consultation with a general surgeon. The first is the patient who requires multiple admissions for partial small-bowel obstruction that resolves with medical management (7). Most of these patients are best managed with an elective operation, although there may be relative contraindications to an operation (e.g., medical comorbidities or intra-abdominal scarring). The second problematic situation is the patient with bowel obstruction and advanced abdominal malignancy, in whom optimal palliation might or might not involve surgery (10).

Discharge Issues

The length of hospitalization varies depending on the primary disease. Patients requiring surgery are hospitalized for approximately 5–7 days. Patients who have resolution of partial obstruction without the need for surgery are often

ready for discharge in three days. Patients with ileus generally have improvement in their gut motor function as the primary disease process resolves.

The patient with bowel obstruction or ileus may be discharged from the hospital when bowel function has returned and an oral diet is tolerated. Generally, distension and nausea have resolved at this point and the patient is passing flatus and has had a bowel movement. The patient should be tolerating a full liquid or regular diet. With earlier discharges in the modern era, postoperative complications that previously were recognized in the hospital may present after discharge (13). The patient should be instructed to contact the physician for fever, abdominal pain, nausea, or vomiting.

ILEUS OR OBSTRUCTION DEVELOPING IN THE HOSPITAL

Patients developing bowel obstruction or ileus in the hospital usually fall into two categories: those recovering from abdominal surgery, and those with other problems, usually medical. These patients are less likely to require an urgent operation, but the same principles discussed previously generally apply (15). Although most of these patients can be managed conservatively, the clinician must be vigilant for the possibility of bowel strangulation or perforation. These patients all should be managed in consultation with a general surgeon.

Issues During the Course of Hospitalization

The Patient Recovering from an Abdominal Operation

The patient recovering from an abdominal operation may develop progressive abdominal distension, hypoperistalsis, and obstipation (15). A functioning nasogastric tube should be placed (if not already present) and intravenous fluids given to maintain euolemia. The patient should be examined and an obstruction series ordered. The differential diagnosis includes an abdominal catastrophe (leaking anastomosis with peritonitis, ischemic bowel, perforation), localized abscess, anastomotic obstruction, adhesions, internal or wound herniation, and postoperative ileus. The patient who has an abdominal disaster generally has systemic signs of toxicity as well as peritoneal signs. The plain films may show free intra-abdominal air (not pathognomonic, because this may persist for several days after laparotomy), and a CT scan may show pneumatosis intestinalis, pneumoperitoneum, a generous amount of free intraperitoneal fluid, or a fluid collection with air bubbles. Patients with these findings require an immediate operation. Broad-spectrum antibiotics are administered, and a functioning nasogastric tube must be in place to avoid pulmonary aspiration during the induction of general anesthesia.

A localized abdominal or pelvic abscess may be associated with mechanical obstruction or ileus postoperatively. There may be focal tenderness, fever, and leukocytosis. Rectal examination may reveal a tender bulge in the cul-de-sac, and the diagnosis can be confirmed with CT scan and needle aspiration. Percutaneous drainage usually is successful if a safe course to the collection can be charted without passing through distended bowel loops. Otherwise, operative drainage may be necessary. Transrectal drainage of pelvic abscesses remains a useful technique.

The patient who has had a bowel resection may develop mechanical or functional obstruction at the anastomotic site during the postoperative period. Common causes are edema, leaks, adhesions, and other technical problems. In the absence of signs of sepsis, these patients are usually managed expectantly, with nasogastric decompression and intravenous fluids. Serial radiographs are useful in monitoring the degree of distension and the progression of gas distally. If a small anastomotic leak is suspected, intravenous antibiotics are appropriate. These patients rarely develop ischemia or perforation unless they have a colorectal anastomosis and a competent ileocecal valve. In this case, massive colonic distension proximal to the anastomosis may result in a cecal perforation or a disruption of the anastomosis. Cecostomy or decompressing loop colostomy should be considered if cecal diameter exceeds 10–12 centimeters.

Postoperative adhesions form within days of an operation, and these may cause mechanical obstruction at any time. Postoperative mechanical small-bowel obstruction secondary to adhesions may be difficult to distinguish from postoperative ileus. This fact, coupled with the observation that bowel strangulation or perforation is unusual in this setting, make expectant nonoperative therapy the treatment of choice (15). Surgery is indicated for peritoneal signs or if the patient fails to improve by 10–14 days.

Internal herniation or volvulus should always be considered as a cause of bowel obstruction in a patient who has undergone a bowel resection. The bowel may herniate through the mesenteric defect of the resected bowel, and strangulation may occur. Rarely, during the course of intestinal resection the remaining bowel (usually small bowel) is inadvertently rotated on its axis, causing a *volvulus*, which results in ischemia. The patient presents with pain and acidosis within 24–48 hours of the index operation and requires an immediate operation. Massive bowel loss is the usual outcome. *Internal herniation* presents as a mechanical obstruction and should be suspected if localized distended bowel loops are seen on radiograph or CT scan. The loops may be located eccentrically within the abdomen. If this diagnosis is suspected, an urgent operation is also indicated.

Postoperative ileus is probably the most common cause of abdominal distension, nausea and vomiting, and obstipation seen in the patient recovering from an abdominal or pelvic operation. The pathophysiology is poorly understood, but the result is a disruption in normal peristalsis. In

patients recovering from laparotomy, effective peristalsis returns first to the small intestine, then to the stomach, and finally to the colon. In some patients, pain, medications (e.g., opiates), electrolyte disturbances, and other disease states may result in a prolonged delay in the return of bowel function. Progressive distension usually can be prevented by maintaining a functioning nasogastric tube. Rectal tube and colonoscopic decompression may be useful in patients with massive colonic dilatation, but should be used very cautiously, if at all, in patients who have just undergone colon resection. Early ambulation, decreasing the opiate dose, and correcting electrolyte disturbances helps in some patients. Enemas and suppositories may be useful in patients who do not have a left-sided colon anastomosis. Oral stimulants (bisacodyl, magnesium compounds) and promotility agents (cholinergic agonists, cisapride) may have a role in some patients but should be used cautiously and in consultation with the surgeon.

Opiate analgesia is thought to play an important role in ileus after abdominal surgery. Systemic opiates affect pain and splanchnic receptors equally, contributing to disrupted peristalsis. An investigational agent, ADL 8-2698 (Adalor) selectively reverses opioid inhibition of gastrointestinal motility without blocking systemic analgesia. The effectiveness of this agent is currently being determined.

Cisapride is a promotility agent that works through a cholinergic mechanism and commonly is used to treat gastroparesis, gastroesophageal reflux, and idiopathic constipation (16). It has been tried with more modest success in postoperative ileus, colonic inertia, and intestinal pseudo-obstruction. The usual adult dose is 10 mg orally 4 times daily. It is generally contraindicated in mechanical small-bowel obstruction because increased motor activity from the drug may lead to increased intraluminal intestinal pressure.

Intestinal distension and altered motility are important pathophysiologic components of both mechanical small-bowel obstruction and ileus. *Octreotide*, a long-acting somatostatin analog, has been tried in these diseases. Research in both animals and humans shows that this drug decreases luminal fluid accumulation in small-bowel obstruction and increases effective peristalsis in ileus. Patients with routine mechanical small-bowel obstruction or postoperative ileus should not be considered candidates for treatment with this agent because its effectiveness has not been shown in these settings. However, patients with terminal cancer and malignant bowel obstruction, or those with unusual causes of ileus (e.g., scleroderma, idiopathic pseudo-obstruction, small-bowel transplant), may get significant improvement in symptoms with octreotide in divided subcutaneous doses of 300–600 mg daily (17).

The Patient Hospitalized with Other Diagnoses

A hospitalized patient who develops abdominal distension while being treated for some seemingly unrelated problem

may have an ileus or an intra-abdominal catastrophe. Such a patient should be evaluated and managed as outlined previously. The most important initial consideration is whether the patient has abdominal pain or tenderness. If so, the patient should be seen expeditiously by a surgeon. Unlike the patient discussed previously who comes to the hospital with abdominal pain and distension and has mechanical bowel obstruction, the patient who develops abdominal distension while being treated in the hospital for another problem is more likely to have an acute surgical condition of the abdomen or an ileus rather than simple mechanical obstruction. Other medical problems that have led to hospitalization may distract the managing team and delay recognition of a new problem, and they also make an operation more risky. These facts, together with the greater acuity of illness in modern hospitalized patients and the greater percentage of immunosuppressed patients, help explain the high mortality rate in patients requiring an urgent abdominal operation in this setting. Thus, the surgeon should be involved as early as possible.

If the patient is able to cooperate, a diagnosis usually can be reached by taking a history, performing an examination, reviewing the chart and recent laboratory data, and evaluating a plain radiograph series. Ileus may be suspected according to the algorithm in Figure 88.2. Ileus may be associated with other serious intra-abdominal pathology requiring an urgent operation. As a general rule, a CT scan can rule out such pathology, with the exception of ischemic bowel (Chapter 87). The diagnosis of intestinal ischemia should be pursued vigorously unless the lucid patient denies significant abdominal pain.

Colonic pseudo-obstruction (Ogilvie's syndrome) is not uncommon in the hospitalized, bedbound, elderly patient. It presents with abdominal distension, and radiographs show a distended air-filled colon with or without small-bowel distension. Although some patients respond to rectal tube insertion and frequent repositioning, colonoscopic decompression is the treatment of choice (12). If this is unsuccessful or if there is abdominal tenderness, laparotomy and operative decompression must be considered. Laparoscopic exploration (to rule out actual or impending perforation) and cecostomy are less invasive options.

Toxic megacolon is another important diagnostic consideration in the hospitalized patient. This occurs in the setting of inflammatory bowel disease or antibiotic-associated colitis (Chapters 81 and 77, respectively). Patients appear ill, with fever and tachycardia. There is abdominal distension, hypoperistalsis, and tenderness, frequently along the course of the colon. Plain radiographs show an air-filled, often featureless colon. CT scan shows a thick-walled colon. Clinical deterioration, increasing toxicity, worsening abdominal examination, and radiologic signs of impending or actual perforation all are indications for surgery. Abdominal colectomy and ileostomy is the procedure of choice, even though the colon may not appear compromised at the time of the operation.

Discharge Issues

The patient who has developed ileus or bowel obstruction while in the hospital for another problem may be discharged when gastrointestinal function has returned and the initial problems are under control. The patient should be tolerating at least a full liquid diet. If oral medications are required, there must be a means of assuring that the patient is taking and tolerating the medication. Follow-up and monitoring of nutritional status are important in many of these patients (13).

COST CONSIDERATIONS AND RESOURCE USE

Early surgery, avoidance of unnecessary tests, and judicious use of antibiotics all are part of good clinical care in the patient with bowel obstruction. Adequate and expeditious fluid resuscitation and nasogastric decompression are clinically important and help save resources.

The use of laparoscopy in the patient with bowel obstruction is controversial, and much of the controversy revolves around the safety and cost (14). The technique is safe in experienced hands and probably leads to some cost savings for patients in whom laparotomy is avoided (a small minority of patients with bowel obstruction or ileus). These patients can be discharged earlier and may return to work sooner (18). However, the technique may increase costs in the operating room. Minimizing these costs by the selective use of this technology by experienced surgeons might lead to an overall reduction in the cost of caring for small-bowel obstruction in selected patients (19).

KEY POINTS

- Patients presenting to the hospital with bowel obstruction or ileus should be seen promptly by a general surgeon. All patients with bowel obstruction or ileus require hospitalization.
- Careful fluid resuscitation and nasogastric decompression are important in all patients with bowel obstruction or a significant ileus. Selective use of specialized procedures such as CT scan, flexible colonoscopy, contrast radiography, and arteriography may be useful in some patients.
- The patient with complete obstruction requires an urgent operation. The patient with partial obstruction may require an urgent operation based on clinical or radiologic findings; those managed nonoperatively are best admitted to a surgical service for close monitoring.
- Patients with ileus often have a surgical problem causing the ileus (e.g., diverticulitis, appendicitis, perforated ulcer, ischemic bowel). Those patients without an obvious surgical problem still warrant careful monitoring, lest dangerous distension with ischemia and perforation supervene.

- Patients who develop bowel obstruction or ileus while in the hospital, including those recovering from an abdominal or pelvic operation, may have an acute surgical condition of the abdomen.
- Ischemia always must be considered as a possible cause of ileus or obstruction, and early arteriography should be performed in the appropriate circumstance.

Hematology-Oncology

X

Signs, Symptoms, and Laboratory Abnormalities in Hematology–Oncology

Hope S. Rugo

TOPICS COVERED IN CHAPTER

- Splenomegaly 885
- Lymphadenopathy 887
- Anemia 889
- Neutropenia 893
- Leukocytosis 894
- Pancytopenia 895

INTRODUCTION

Nonspecific symptoms such as fatigue resulting from anemia, or signs such as splenomegaly or lymphadenopathy, are often the first clinical manifestations of serious underlying disease. Early recognition and evaluation are critical to patient management. Appropriate and timely therapy can maintain quality of life and function and in some cases prolong survival.

Abnormalities in the complete blood count are among the most common presenting laboratory findings on admission to the hospital. In addition, hospitalization commonly causes additional hematologic disorders, resulting from either the illness that led to admission or the treatments rendered during the inpatient stay. Careful review of

blood counts and the peripheral blood smear can result in earlier diagnosis and treatment of both hematologic and nonhematologic illnesses. Disorders of platelets and coagulation are discussed in Chapter 98, and polycythemia is covered in Chapter 95.

SIGNS AND LABORATORY ABNORMALITIES

Splenomegaly

Presenting at the Time of Admission

Examination of the left upper quadrant for splenomegaly may be difficult in an obese or uncooperative patient. Palpation with the patient in the left decubitus position or with the knees raised during deep inspiration may help circumvent these difficulties. Occasionally, dilated loops of bowel mimic an enlarged spleen. Confirmation of suspected splenomegaly is best obtained by ultrasound examination.

The differential diagnosis of splenomegaly is listed in Table 89.1. Patients may present with left upper quadrant fullness, anorexia, or early satiety resulting from a markedly

TABLE 89.1
DIFFERENTIAL DIAGNOSIS OF SPLENOMEGALY

Disease category	Examples	Specific blood-smear findings
Malignancy Myeloproliferative/dysplastic	Chronic myelogenous leukemia Myelofibrosis with agnogenic myeloid metaplasia Myelodysplastic syndromes Chronic myelomonocytic leukemia Acute myelogenous leukemia	Left shift and basophilia Nucleated red blood cells, tear drop-shaped red blood cells Dysplastic neutrophils Dysplastic monocytes Blasts with granules
Lymphoproliferative	Chronic lymphocytic leukemia Non-Hodgkin's lymphoma Hodgkin's disease Acute lymphocytic leukemia Hairy cell leukemia	Lymphocytes and smudge cells Blasts with prominent nucleoli Spiculated lymphocytes
Infection	Schistosomiasis Leishmaniasis Disseminated mycobacteria Bacterial endocarditis Acute viral hepatitis Malaria	 Dohle bodies, vacuoles Red cell inclusions on thick smear
Hemolytic anemia Hereditary	Hereditary spherocytosis Sickle cell disease with splenic sequestration crisis Thalassemia (severe) Autoimmune hemolytic anemia, with (Evans' syndrome) or without ITP	Spherocytes Sickled red cells Microcytes, fragments Spherocytes
Acquired	Autoimmune neutropenia with rheumatoid arthritis (Felty's syndrome)	
Infiltrative disorders	Lipid storage disorders (Gaucher's disease) Amyloid	
Portal vein obstruction (sequestration)	Cirrhosis Portal vein thrombosis	Target cells Target cells

ITP, immune-mediated thrombocytopenic purpura.

enlarged spleen. The size and character of the enlarged spleen, as well as the presence of tenderness or left-sided pleuritic pain, help in the differential diagnosis. A massively enlarged and firm spleen is almost always caused by an underlying infiltrative malignancy such as a lymphoproliferative or myeloproliferative disorder (1). Marked enlargement of the spleen also may be seen in chronic infections such as malaria and from infiltrative processes such as Gaucher's disease. Splenic or pleuritic pain may be caused by splenic infarct; this pain is usually acute and lasts 2–3 days. Splenic infarcts generally are caused by emboli, acceleration of myeloproliferative or myelodysplastic diseases, or splenic abscesses.

Evaluation of splenomegaly should include a focused physical examination to look for the presence of lymphadenopathy or hepatomegaly. The evaluation of lymphadenopathy is discussed subsequently. The presence of both splenomegaly and significant lymphadenopathy is likely to

result from a lymphoproliferative disease or a chronic infection. If hepatomegaly is found, evaluation should focus on disorders involving the liver (Chapter 77). The finding of lymphadenopathy or hepatomegaly should prompt a computed tomography scan to look for additional abdominal pathology. Positron emission tomography (PET) scanning may be a useful way to distinguish benign from malignant lymphadenopathy. The physical examination also may reveal spider angiomas and other stigmata of liver disease, or ecchymoses and petechiae, suggesting coexistent marrow pathology or cellular sequestration.

A complete blood count and examination of the peripheral blood smear are essential. If the white cells are elevated and the blood smear shows a lymphocytosis, *chronic lymphocytic leukemia* is possible. The diagnosis is established by flow-cytometric analysis of the peripheral blood. Alternatively, if the white-cell count is elevated but the blood smear shows a "left shift," nucleated red blood cells and ba-

sophilia, a *myeloproliferative disease* such as chronic myelogenous leukemia is likely (2) (Chapter 95). The presence of blast cells on the peripheral smear suggests *acute leukemia* (Chapter 93). The diagnosis is made by bone-marrow evaluation with cytogenetics.

Malignant disease with splenomegaly often is accompanied by anemia. However, if anemia is the predominant abnormality and the blood smear shows abnormal red-cell morphology such as spherocytes (Table 89.2), then a hemolytic anemia is the likely cause of splenomegaly. The evaluation of hemolytic anemia is covered subsequently. Hemolytic anemia or immune thrombocytopenia may complicate the marked splenomegaly found in lymphoproliferative diseases such as chronic lymphocytic leukemia. A patient with a chronic hemolytic anemia such as sickle-cell disease may develop splenic sequestration crisis and present with splenomegaly, fever, and severe anemia (Chapter 97). This is because of marrow suppression from acute infection with parvovirus B19; it is usually self-limited.

Patients with *chronic infections* (e.g., malaria, tuberculosis, or endocarditis) may have splenomegaly associated with recurrent fevers. Diagnosis is made by examination of the blood smear for parasites, blood cultures, chest radiograph, and placement of a purified protein derivative (PPD) skin test. A biopsy of an enlarged lymph node or bone-marrow culture may be necessary to make the diagnosis of disseminated mycobacterial infection. Liver chemistry tests should be obtained to rule out acute viral hepatitis or portal vein obstruction caused by cirrhosis or thrombosis. Ultrasound with evaluation of blood flow can help evaluate the presence of *portal vein thrombosis*. Patients with portal vein thrombosis should undergo further testing for hypercoagulable states or myeloproliferative disease such as polycythemia vera (Chapters 95 and 98). Infiltrative disease and lipid-storage disorders usually are evaluated by bone-marrow aspiration and biopsy, as well as fat pad biopsy for amyloid.

Management of splenomegaly is entirely dependent on the underlying cause. Regardless of the cause, a massively enlarged spleen traps white blood cells, red blood cells, and platelets, leading to variable cytopenias. Patients with splenomegaly may not respond to transfusions of red blood cells and platelets; the latter can complicate plans for procedures. If a procedure is planned for a patient with splenomegaly and thrombocytopenia, it is important to check the response to transfused platelets immediately after the transfusion to ensure that the resulting count is adequate. Occasionally, patients with splenomegaly require splenectomy. This is usually beneficial in autoimmune hemolytic anemia and is curative in hereditary spherocytosis. In addition, patients with significant cytopenias from sequestration caused by chronic myeloproliferative or lymphoproliferative diseases that are unresponsive to chemotherapy may benefit from splenectomy. In general, splenectomy is not advisable for patients with significant

obstruction to portal vein blood flow. Splenic irradiation is a rarely used technique to manage massive splenomegaly associated with malignancy in a patient who is not a surgical candidate. Pain resulting from splenic infarcts is generally transient and responds to pain medications.

Presenting During Hospitalization

Mild or moderate splenomegaly may develop during hospitalization. The differential diagnosis is much narrower than for splenomegaly observed at presentation. Patients with chronic hemolytic anemia are at risk for *splenic sequestration crisis* resulting from infection with parvovirus B19 (see above). An already enlarged spleen resulting from myeloproliferative or lymphoproliferative disease may increase in size after multiple transfusions, because of sequestration of blood products.

Hospitalized patients often are given medications that can cause hemolytic anemia (see the section on “Anemia” later in this chapter). The development of a hyperproductive anemia with splenomegaly in a hospitalized patient should provoke an investigation into possible drug-induced hemolysis. Patients with acute presentations of autoimmune diseases may develop splenomegaly while hospitalized for evaluation of fever. The diagnosis may be elusive and is often one of exclusion. As with splenomegaly presenting on admission to the hospital, management is entirely dependent on the etiology of splenomegaly.

Lymphadenopathy

Presenting at the Time of Admission

The most common cause of lymphadenopathy on admission to the hospital is a contiguous infected area. However, both isolated nodal enlargement and generalized lymphadenopathy are associated with lymphoma, leukemia, HIV disease, other chronic infections, and autoimmune disease (3). The differential diagnosis of lymphadenopathy depends on the age of the patient, the time course, associated symptoms, the presence of localized or generalized adenopathy, consistency of the nodes, and the areas of involvement (Table 89.3). As with other symptoms and signs, an older patient is less likely to have a benign cause of adenopathy. Reactive lymph-node hyperplasia is most common in children. Acute, painful adenopathy is more likely associated with infection than are slowly progressive, nontender nodes. Associated symptoms such as weight loss, fevers, and night sweats may be seen with lymphoproliferative disease, chronic infections, and autoimmune disease.

Malignancy more often presents as a single nontender enlarged node rather than the generalized mild adenopathy seen in response to infection or autoimmune disease. A hard, fixed node usually represents involvement with

TABLE 89.2
APPROACH TO ANEMIA

Reticulocyte count	MCV	Blood smear	Diagnosis	Workup
Low	Low	Hypochromia, target cells, basophilic stippling, pencil cells, thrombocytosis	Iron deficiency	Iron, iron binding capacity, ferritin (and consider serum transferrin receptor)
		Target cells, basophilic stippling	Thalassemia trait	Hemoglobin electrophoresis
		Mixed population of red blood cells	Sideroblastic anemia or myelodysplasia	Bone marrow aspirate with iron stain to look for ringed sideroblasts
Low–normal	Low	Unremarkable Basophilic stippling	Anemia of chronic disease Lead poisoning	Occupational history, free erythrocyte protoporphyrin, lead levels
Low	Normal	Tear drops and red cell fragments in myelophthitic process (leukoerythroblastic), rouleaux in myeloma	<i>Primary marrow failure:</i> aplastic anemia, pure red cell aplasia, myelophthitic (infiltrative) process, myelodysplasia, leukemias, myeloma, early iron deficiency	Iron studies, bone marrow aspiration and biopsy with iron stain and cytogenetics
		Burr cells in renal disease, pencil cells in HIV	<i>Secondary marrow failure:</i> hypo- and hyperthyroidism, anemia of chronic disease, anemia of renal failure, HIV infection	Thyroid function tests, creatinine, HIV serology, erythropoietin level
Low ^a	High	Normal Macro-ovalocytes, hypersegmented neutrophils	Splenomegaly with sequestration <i>Megaloblastic anemia:</i> vitamin B ₁₂ or folate deficiency, myelodysplastic syndrome, drug-induced	B ₁₂ and folate level, LDH, Schilling test, bone marrow aspirate and biopsy with cytogenetics if normal levels found
		Acanthocytes, spur cells and target cells in liver disease, reticulocytes	<i>Nonmegaloblastic anemia:</i> liver disease, hypothyroidism, reticulocytosis	Liver function tests, thyroid function tests
High	Normal–high	Normal	Acute blood loss	
		Spherocytes (warm) or red-cell agglutination (cold)	<i>Acquired hemolytic anemia:</i> autoimmune or drug-induced hemolytic anemia (warm or cold)	Direct Coombs test (DAT), cold agglutinins, LDH, direct bilirubin
		Schistocytes	<i>Mechanical hemolysis:</i> valve or microangiopathic hemolytic anemia (TTP/HUS)	LDH, creatinine, coagulation tests to rule out DIC
		Red blood cell inclusions (malaria, babesiosis) Dysplastic neutrophils	<i>Infection:</i> <i>Clostridium</i> , malaria, babesiosis, <i>Bartonella</i> , sepsis Paroxysmal nocturnal hemoglobinuria	Blood cultures, examination of thick smear Urine hemosiderin, flow cytometry for CD 55/59
High	Low	Abnormal size and shape of red blood cells (hemoglobinopathy), bite cells (G6PD), spherocytes (HS)	<i>Hereditary hemolytic anemia:</i> hemoglobinopathies (e.g., sickle-cell disease), enzyme defects (e.g., G6PD deficiency) membrane defects (HS), unstable hemoglobins	Hemoglobin electrophoresis, G6PD level in nonacute setting, Heinz body prep, osmotic fragility testing
		Target cells, basophilic stippling, fragments	α - or β -thalassemia	Hemoglobin electrophoresis, family history

^a Except when macrocytosis is due to hemolytic anemia and reticulocytosis.

DAT, direct antiglobulin test; DIC, disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; HIV, human immunodeficiency virus; HS, hereditary spherocytosis; HUS, hemolytic uremic syndrome; LDH, lactate dehydrogenase; TTP, thrombotic thrombocytopenic purpura.

TABLE 89.3
DIFFERENTIAL DIAGNOSIS OF
LYMPHADENOPATHY

Infection	Autoimmune
Epstein-Barr virus	Systemic lupus
Cytomegalovirus	erythematosus
HIV	Rheumatoid arthritis
Toxoplasmosis	Sarcoid
Tuberculosis	Pseudolymphoma
Histoplasmosis	Malignancy
Coccidioidomycosis	Hematologic (lymphoid and
Brucellosis	myeloid)
Bacterial endocarditis	Other
Viral hepatitis	Drug reaction
Secondary syphilis	Dilantin
Cat scratch disease	Hydralazine
Bacterial skin infections	Allopurinol

metastatic carcinoma or sarcoma. In contrast, rubbery, mobile, and matted nodes often are found in lymphoproliferative diseases. Soft, mobile nodes are more common in reactive adenopathy; the nodes associated with mycobacterial infection may be fluctuant. Firm or hard supraclavicular adenopathy often indicates underlying intrathoracic or intraabdominal carcinoma, although a single enlarged, rubbery supraclavicular node in a young adult is one of the most common presentations of Hodgkin's disease. Unilateral enlarged axillary nodes may indicate advanced breast cancer. An isolated hard periumbilical node (Sister Mary Joseph node) is associated with metastatic adenocarcinoma, usually of gastric origin. Intraabdominal lymphadenopathy may be palpated as an abdominal mass and be confused with colon or ovarian cancer. In contrast, occipital adenopathy rarely is associated with malignancy. Epitrochlear nodes may be seen with infection (e.g., cat scratch disease, cellulitis), sarcoidosis, or with lymphoproliferative disease.

Evaluation of lymphadenopathy should include a careful physical examination with digital rectal and bimanual examinations. A chest radiograph and appropriate scans also should be obtained. Computed tomography, magnetic resonance imaging, gallium, and positron emission tomography scans also may be indicated, depending on the circumstances. *Fine-needle aspiration* (FNA) of the enlarged node should be performed and the aspirate sent for microbiologic studies, cytology, and flow-cytometric analysis if indicated. If adenopathy is caused by carcinoma or sarcoma, fine-needle aspiration may allow diagnosis without invasive surgery to remove a biopsy sample from the primary tumor. *In general, a biopsy should be performed if the fine-needle aspiration is nondiagnostic or suggests lymphoma.* The tissue sections obtained with a biopsy allows the subtype of lymphoma to be determined, which significantly influences treatment recommendations and prognosis. If possible, it is prudent to avoid biopsy of an inguinal node, because of the

common occurrence of reactive hyperplasia that may confuse the diagnosis. If mediastinal and abdominal adenopathy are the only sites of disease, mediastinoscopy or laparoscopy with biopsy may be required.

Generalized lymphadenopathy is often a presenting sign of HIV disease (Chapter 74). Other infections should be evaluated with serologic tests, cultures, and node biopsy if necessary. Endocrinopathies such as thyrotoxicosis and adrenal insufficiency may be associated with mild lymphadenopathy.

Treatment of lymphadenopathy depends on the underlying diagnosis.

Presenting During Hospitalization

Lymphadenopathy presenting during hospitalization may be caused by a drug reaction or evolving autoimmune disease. A newly enlarged lymph node may indicate progression of an underlying malignancy. The most common cause of new lymphadenopathy during hospitalization is infection. This usually results from bacterial contamination of a peripheral or central line site. In addition, patients with untreated chronic infection may develop adenopathy if they are receiving corticosteroids.

Anemia

Anemia can be classified by the size of the red cell (mean corpuscular volume [MCV]) or by the response of the bone marrow (hyperproductive versus hypoproductive) to a decreased red cell mass. An MCV less than 70 fL is consistent with iron deficiency or thalassemia; an MCV over 125 fL is almost always diagnostic of megaloblastic anemia. The reticulocyte count helps differentiate a hypoproductive anemia from a hyperproductive anemia. The reticulocyte count may be expressed as a percentage of the red blood cell count, but this does not correct for the degree of anemia. A more useful number is the absolute reticulocyte count, which is calculated as follows: Absolute reticulocyte count = % reticulocytes \times red blood cell count/ μL^3 .

A result greater than 100,000 per cubic millimeter indicates increased production of red cells. Reticulocytes are larger than mature red blood cells; a significant reticulocytosis increases the MCV. Review of the peripheral blood smear is a critical diagnostic procedure in the evaluation of anemia. The differential diagnosis of anemia based on the MCV, reticulocyte count, and review of the peripheral smear is shown in Table 89.2 (4).

Presenting at the Time of Admission

Anemia is the most common laboratory abnormality in the newly admitted patient. It may be the first sign of a serious systemic illness or may indicate reaction to medications, infection, or a primary bone-marrow process. A

Careful evaluation should include a detailed history with attention to diet, prescription and nonprescription medications, alternative therapies, occupation (e.g., lead exposure), menstrual history, recent travel (e.g., malaria, tuberculosis), hospitalizations or surgeries, prior history of anemia, and family history (of anemia, autoimmune disease, or infections). The duration of symptoms such as fatigue and shortness of breath, and the presence of pica or neurologic symptoms also can help narrow the differential diagnosis. Many patients with *hereditary hemolytic anemias* have a history of cholecystitis, with resulting cholecystectomy, caused by bilirubin gallstones. Physical examination should include a thorough examination of the skin (ecchymoses, spider angiomas, jaundice), oropharynx (glossitis and angular cheilosis in nutritional deficiencies, petechiae, gum swelling, telangiectasias), nails (spoon nails in iron deficiency), lymph nodes, and abdomen (hepatomegaly or splenomegaly), and a neurologic examination with attention to position and vibration sense (vitamin B₁₂ deficiency).

The most common cause of anemia worldwide is *iron deficiency* (5). This microcytic, hypochromic, hypoproliferative anemia may initially present as mild normocytic anemia. The most common causes of iron deficiency include blood loss from the gastrointestinal tract, menstruation, blood donation, and increased requirements with inadequate dietary iron (e.g., pregnancy and lactation). The cause of blood loss from the gastrointestinal tract always should be thoroughly investigated for serious pathology, although prolonged use of aspirin or other nonsteroidal antiinflammatory drugs may cause enough blood loss to result in iron deficiency. Blood loss also may be caused by significant hematuria or chronic intravascular hemolysis (e.g., mechanical heart valve or paroxysmal nocturnal hemoglobinuria).

It is important to evaluate microcytic anemia with appropriate iron studies before instituting therapy (6). Tests should include a serum iron level, transferrin level, percentage saturation, and ferritin level. A low ferritin level (<30 µg/L is a sensitive cut-off) may be the only way to detect early iron deficiency. As the depletion in iron stores progresses, the transferrin level rises as the iron level and saturation fall. Characteristic changes in red blood cell morphology may be found on the peripheral blood smear. As iron deficiency progresses, red blood cell abnormalities become more pronounced. If iron studies are normal, the most likely diagnosis is *thalassemia* or *anemia of chronic disease* (AOCD). With thalassemia, the MCV is usually very low for the degree of anemia, and the red blood cell morphology is abnormal (Table 89.2). One useful formula for differentiating pure thalassemia from iron deficiency is the *Mentzer index*: MCV/red blood cell count is usually less than 20 in thalassemia and more than 20 in iron deficiency. The hemoglobin electrophoresis can be diagnostic for severe α- and β-thalassemia but is normal in α-thalassemia minor. The most important reasons for diag-

nosizing thalassemia are to avoid inappropriate iron supplementation (resulting in iron overload) and to facilitate genetic counseling.

AOCD may be microcytic or, more commonly, normocytic and is seen with malignancy, autoimmune disease, chronic infections, or other debilitating illnesses (7). It may be particularly difficult to differentiate the anemia of chronic disease from the anemia of iron deficiency. The *serum transferrin receptor* (sTfR) may help delineate these two disorders. Nutritional iron deficiency is associated with an increased level of sTfR; this level is not affected by AOCD. The sTfR results are affected by a number of other hematologic disorders (including erythropoiesis, thalassemia, hemolytic anemia, and megaloblastic anemia), limiting the specificity of this test for general hematologic evaluation. Elevation of this value appears to be relatively sensitive and specific for the diagnosis of iron deficiency (6), but lack of standardization for the assay limits its widespread use. A less expensive test that can be used as a quick screen for iron deficiency even in the absence of anemia is the erythrocyte zinc protoporphyrin/hemoglobin ratio; this ratio also is affected by other hematologic disorders.

Table 89.4 shows the key differences and similarities in laboratory studies. AOCD is associated with an inappropriately low erythropoietin level for the degree of anemia. The erythropoietin level is extremely low if anemia is caused by renal insufficiency. Other causes of a normocytic, hypoproliferative anemia, such as hypothyroidism or a primary bone-marrow infiltrative process, should be considered. If other cell counts are abnormal, aplastic anemia, myelodysplasia, leukemia, myelofibrosis, and other infiltrative processes also should be considered. Splenic sequestration can lead to a hypoproliferative anemia. The degree of anemia should correlate with the degree of splenomegaly (i.e., if the spleen is barely palpable, it is not the cause of significant anemia).

TABLE 89.4
DIFFERENTIATING IRON DEFICIENCY FROM ANEMIA OF CHRONIC DISEASE

Parameter	Anemia of chronic disease	Iron deficiency
Iron	Low	Low
Transferrin (TIBC)	Normal–low	High
Saturation	Low	Low
Ferritin	Normal–high	Low
Serum transferrin receptor	Normal	High
Erythropoietin	Low	High

TIBC, Total iron binding capacity.

The evaluation of a *hypoproliferative, normocytic anemia* should include appropriate iron studies (Table 89.4) and review of the peripheral smear. A careful physical examination should be performed to look for signs of underlying malignancy that might cause AOCD or infiltrate the marrow. A chest radiograph is indicated. Additional laboratory studies (as indicated) and an erythropoietin level may help determine the cause of anemia. If a diagnosis is not readily apparent, a bone-marrow aspirate and biopsy are indicated.

Hypoproliferative, macrocytic anemia is seen most commonly with folate or B₁₂ deficiency or myelodysplastic syndromes. In addition, chronic drug therapy (e.g., cyclosporine, azathioprine, and hydroxyurea) can cause a megaloblastic anemia. B₁₂ deficiency may be seen in patients with decreased absorption of dietary B₁₂ resulting from decreased production of intrinsic factor (pernicious anemia, gastrectomy), abnormalities of the ileum (surgical resection, inflammatory bowel disease) or gastric mucosa (infection with *Helicobacter pylori*), or bacterial overgrowth (blind loop syndrome). Dietary B₁₂ deficiency is very rare and is seen only in strict vegetarians who avoid all dairy products. Pernicious anemia is a hereditary autoimmune disease; signs of B₁₂ deficiency are not usually evident before 35 years of age. Because of high body stores, deficiency of B₁₂ resulting from malabsorption may not be evident for many years after gastric or ileal resection. Patients with a history of bowel surgery should be screened for deficiency before clinical symptoms develop. Folate deficiency is most often caused by inadequate dietary intake and may be exacerbated at times of increased requirements such as during pregnancy or in patients with hemolytic anemia. Deficient dietary intake of folate is seen in alcoholics, in elderly patients who do not eat fresh fruits and vegetables, and during starvation. Occasionally, medications, including phenytoin, trimethoprim–sulfamethoxazole, and sulfasalazine, may interfere with absorption of folate from the gastrointestinal tract. Patients with tropical sprue also may malabsorb folate. Nonmegaloblastic hypoproliferative macrocytic anemia can be seen associated with liver disease and hypothyroidism.

The diagnostic approach to *macrocytic anemia* should begin with a careful history, a serum B₁₂ level, a red-cell folate level, and review of the peripheral smear. Even if the red blood cells are normocytic, the presence of hypersegmented neutrophils (defined as more than one five-lobed or at least one six-lobed or more neutrophil) should instigate a workup for B₁₂ or folate deficiency (8). A normocytic anemia might be seen, caused by thalassemia or iron deficiency, in addition to deficiencies of B₁₂ or folate. A B₁₂ level less than 100 pg/mL is diagnostic of overt deficiency; the lactate dehydrogenase (LDH) is also elevated. Further evaluation of B₁₂ deficiency has included the Schilling test, which is performed after replacement of B₁₂. Several additional blood tests can now be used to confirm the diagnosis, and assess etiology. Methylmalonic acid is elevated

when cobalamin levels are low, and falls with replacement therapy. Antibodies to intrinsic factor are a highly specific but insensitive method of diagnosing pernicious anemia; only 50% of patients with pernicious anemia have elevated antibodies. A low red blood cell folate level (<150 mg/mL) is consistent with folate deficiency. Serum homocysteine levels will also be elevated. It is still important to rule out concurrent B₁₂ deficiency, because the hematologic effects may be masked by folate replacement, leaving the resultant neurologic damage untreated.

Hyperproductive, normocytic anemias are caused by acute blood loss or hemolysis. The most common form of acquired immune hemolytic anemia is caused by warm (IgG) antibodies that adhere to the red blood cell surface, with subsequent destruction of the red cell by the spleen (extravascular hemolysis). Antibody production may be idiopathic, or associated with systemic autoimmune disease, lymphoproliferative disease, or medications (9). High-dosage penicillin, cephalosporins, and hydralazine are common offending agents. About 10% of patients with acquired immune hemolytic anemia have coexistent immune thrombocytopenia (Evans' syndrome). *Intravascular hemolysis* is seen with cold agglutinin disease, paroxysmal nocturnal hemoglobinuria (a myelodysplastic syndrome), and, rarely, toxins (e.g., snake venom, arsine). *Cold agglutinin disease* is caused by IgM antibodies that adhere to the red cell surface at temperatures lower than 37°C (e.g., in the peripheral circulation or in cold weather). The red cells are then susceptible to complement-induced lysis and sequestration. Cold agglutinin disease may be idiopathic in older patients or may be associated with lymphoproliferative or autoimmune diseases. Waldenström's macroglobulinemia is a B-cell malignancy in which a monoclonal IgM paraprotein is produced. Cold agglutinins also may be found following *Mycoplasma pneumoniae* infection or infectious mononucleosis. The hemolytic anemia associated with infections is usually mild.

Infection of the red blood cell with malarial or other parasites or direct action of a toxin (e.g., *Clostridium* spp.), as well as sepsis with or without disseminated intravascular coagulation (DIC), can cause acute hemolysis. Methemoglobinemia caused by medications or toxins causes hemolysis because of oxidation and subsequent precipitation of hemoglobin. *Microangiopathic hemolytic anemias* are a heterogeneous group of disorders associated with thrombocytopenia, elevated LDH, schistocytes on the peripheral blood smear, and variable neurologic and renal dysfunction (Chapter 98). The differential diagnosis includes thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, malignant hypertension, microangiopathic hemolytic anemias associated with pregnancy, DIC, vasculitis, and hemolysis caused by a mechanical valve. A markedly elevated LDH in the absence of coagulopathy is consistent with microangiopathic hemolytic anemia. Urgent therapy with large-volume plasma exchange is indicated to avoid serious and life-threatening complications.

Inherited hemolytic anemia usually is caused by hemoglobinopathies (e.g., thalassemia, sickle cell disease) but also may result from defects in the red cell membrane (e.g., hereditary spherocytosis, elliptocytosis), reduced capability of the red cell to adapt to oxidative stress (G6PD deficiency), and abnormalities in the glycolytic pathway (pyruvate kinase deficiency). *Hereditary spherocytosis* is an autosomal dominant disease with variably severe extravascular hemolytic anemia that is not uncommonly diagnosed in adults. Patients usually have a lifelong history of anemia and may have splenomegaly on physical examination. *G6PD deficiency* is an X-linked recessive disorder seen in 10%–15% of African-American men (10). Women rarely are affected. G6PD is an enzyme that is critical to the production of reduced glutathione, which protects hemoglobin from oxidation. In the common form of this disease, older red cells lack adequate levels of G6PD and are therefore unusually sensitive to oxidative stress from drugs (see Table 89.5 for a list of common drugs causing oxidative hemolysis) or infection. Patients may present with jaundice and dark urine. Hemolysis is self-limited, even if the offending agent is continued. After the older G6PD-deficient red cells have been destroyed, the younger cells with adequate levels of the enzyme are able to resist the oxidative stress.

The evaluation of *hyperproductive anemias* begins with a direct antiglobulin test (DAT) and review of the peripheral smear. The indirect bilirubin and LDH are elevated with active hemolysis. If the DAT is positive for IgG with or without complement, acquired immune hemolytic anemia or drug-induced hemolysis is likely; the smear shows spherocytes. If the DAT is positive for complement and the smear shows clumping of red cells, cold agglutinins should be checked, as IgM is not identified by the DAT. If the DAT is negative and the smear shows spherocytes, hereditary spherocytosis should be suspected. An osmotic fragility test can establish this diagnosis. Intravascular hemolysis is associated with hemoglobinemia and filtration of hemoglobin through the glomerulus. The hemoglobin is absorbed by tubular cells and may be detected as hemosiderin in the urine.

TABLE 89.5
COMMON DRUGS THAT CAN CAUSE
OXIDATIVE HEMOLYSIS

Medications	Other
Sulfonamide drugs	Amyl nitrite
Sulfones	Moth balls (naphthalene)
Pyridium	Hydrogen peroxide
Nitrofurantoin	Fava beans
Quinidine	
Primaquine	
Phenylhydrazine	

Blood cultures and review of the thick smear should be performed if infection is suspected. A hemoglobin electrophoresis may be useful to diagnose underlying hemoglobinopathies. G6PD levels should not be measured immediately during or after an acute hemolytic episode, because the younger red blood cells that have survived the hemolysis and reticulocytes may have a normal level of the enzyme. Instead, levels should be measured about 3 months after the hemolytic event. Hemolytic anemia can be present without elevation of the reticulocyte count in the setting of coexistent nutritional deficiency, or if there is suppression of erythropoiesis by an infiltrative process or anemia of chronic disease.

Presenting During Hospitalization

Anemia presenting during hospitalization commonly is caused by frequent drawing of blood or gastrointestinal blood loss. AOCD may be exacerbated in ill, hospitalized patients. Drugs given during hospitalization (e.g., immunosuppressive or chemotherapeutic agents, high-dose antibiotics) may further suppress reticulocytosis. Hemolysis may be caused by therapy with drugs such as high-dosage penicillin or sulfonamides (with G6PD deficiency) or worsening of an autoimmune disease. Severe hypophosphatemia (resulting from use of medications or nutritional deficiency) is associated with hemolysis. Sepsis with DIC or microangiopathic hemolytic anemia also may develop during hospitalization. Mechanical hemolysis may be seen after cardiopulmonary bypass. The approach to diagnosing and managing anemia acquired during hospitalization is similar to anemia presenting on admission; a detailed review of events and medications given during the hospitalization is required for complete evaluation.

Treatment of Selected Causes

Treatment of iron deficiency with oral iron (325 mg three times daily) is usually adequate; gastrointestinal intolerance is reduced with coated formulations and absorption may be increased with concomitant vitamin C ingestion. The hemoglobin should begin to rise within 1 week of beginning therapy. Hemoglobin levels usually return to normal within 2 months after beginning replacement, but iron should be continued for 3–6 months to replete iron stores. Occasionally patients may not tolerate or cannot adequately absorb oral iron; these patients may require treatment with parenteral iron. The usual dose is 1.5 to 2.0 g. The infusion takes 4–6 hours and rarely can be complicated by severe hypersensitivity reactions. A test dose should be given, and the infusion must be carefully monitored, with medications for treating anaphylaxis available (Chapter 120).

AOCD is often mild and relatively asymptomatic; severe and symptomatic anemia may be treated with red cell transfusions or erythropoietin. Erythropoietin is given by

subcutaneous injection three times a week; a larger dose (40,000 units) once a week is equally effective and much more convenient for the patient. A longer acting erythropoietin (darbopoietin) is now available and may be given every two (200 micrograms) or three (300 micrograms) weeks by subcutaneous injection. B₁₂ deficiency has traditionally been treated with intramuscular B₁₂ injections (100 mg) given daily for 1 week, weekly for 1 month, then monthly for life. An emerging and easier alternative is initial treatment with injections to treat acute symptoms, then chronic replacement with oral B₁₂ at a dose of 1000 micrograms per day (11). There are insufficient data to treat severe neurologic symptoms with oral B₁₂. Initial replacement may be complicated by hypokalemia. B₁₂ deficiency associated with *Helicobacter pylori* infection may improve with effective therapy for the infectious process. Folate deficiency is treated with 1 mg/d of oral folic acid. Patients with increased requirements for folate (as described previously) should receive regular supplementation with daily folic acid. Replacement of B₁₂ and folate should result in reticulocytosis within 1 week and recovery of the hemoglobin to normal levels within 2 months. If reticulocytosis is not seen, either an alternative or coexistent diagnosis should be suspected and ruled out. In the absence of known iron deficiency, this would require a bone-marrow aspiration and biopsy. Transfusion generally is not indicated and can result in high-output congestive heart failure due to the increase in plasma volume associated with a chronic reduction in red cells. Neurologic effects of B₁₂ deficiency improve slowly and may not completely resolve. Megaloblastic anemia associated with medications is usually mild (although the MCV may be dramatically elevated), and does not require specific therapy.

All patients with hemolysis should receive folate supplementation. Acquired immune hemolytic anemia is treated with prednisone, 1–2 mg/kg. In cases in which a rapid response is required for symptomatic severe anemia, intravenous immunoglobulin (2 mg/kg) or plasmapheresis to remove circulating antibodies can be effective. Transfusions should be given cautiously because of difficulty with cross-matching. Steroids are gradually tapered over 3 months, usually with recurrence or persistence of hemolysis. If the anemia is well compensated, no additional therapy is required. Most patients require splenectomy at some time for persistent and poorly compensated hemolysis. Immunosuppressive or cytotoxic therapy is used for continued anemia. If hemolysis is caused by medications, the offending agents should be discontinued if possible. Hemolysis resulting from lymphoproliferative disease is managed by treating the underlying malignancy; occasionally splenectomy is also required. Idiopathic cold agglutinin disease is treated by avoidance of cold temperatures and immunosuppressive and often cytotoxic therapy. Acute hemolysis may be treated with plasma exchange.

Hereditary hemolytic anemia caused by hereditary spherocytosis is treated with splenectomy. Although spherocytes remain, hemolysis ceases, as does the risk of parvovirus B19 aplastic crisis. Patients with G6PD deficiency do not generally require therapy in the acute setting other than folate supplementation, but should be counseled carefully regarding the risks of hemolysis from oxidative stress caused by infection, ketoacidosis, or the medications listed in Table 89.5.

cytes remain, hemolysis ceases, as does the risk of parvovirus B19 aplastic crisis. Patients with G6PD deficiency do not generally require therapy in the acute setting other than folate supplementation, but should be counseled carefully regarding the risks of hemolysis from oxidative stress caused by infection, ketoacidosis, or the medications listed in Table 89.5.

Neutropenia

Presenting at the Time of Admission

Neutropenia is defined as an absolute neutrophil count less than 1,500 per microliter. However, certain population groups (e.g., African-Americans) and certain families may normally have neutrophil counts between 1,200 and 1,500 per microliter. The risk of infection is related both to the degree of neutropenia (higher if the absolute neutrophil count is less than 500 per microliter and very high if the count is less than 100 per microliter) and the functional properties of the neutrophils. Neutropenia with concomitant steroid use or associated with myelodysplastic syndromes results in a significantly higher risk of infection. In contrast, “benign” familial neutropenia is associated with a very low risk of infection.

The differential diagnosis of neutropenia can be divided into *decreased production, peripheral destruction, splenic sequestration, or a combination* of these causes. Causes of neutropenia include infections, medications, autoimmunity, and congenital or cyclic neutropenia. Any agent capable of causing aplastic anemia and pancytopenia also is capable of causing isolated neutropenia. Viral infections may cause neutropenia both by decreasing marrow production and by causing peripheral destruction. Infections that have been associated with neutropenia include varicella, measles, rubella, hepatitis A, B, or C, cytomegalovirus, influenza, and the Epstein-Barr virus. HIV infection causes neutropenia by peripheral destruction with production of autoantibodies; bone-marrow suppression and sequestration also may contribute. Significant neutropenia can occur in the setting of bacterial sepsis, resulting from a combination of suppression of marrow production and destruction of peripheral cells. Chronic infection can cause modest neutropenia.

Drug-induced neutropenia is one of the most common causes of “benign” neutropenia (12). Chemotherapeutic drugs (Chapter 90) cause direct marrow suppression; other agents cause immune neutropenia both from peripheral destruction and from destruction of marrow precursors by antibodies. Most drugs suppress the marrow in a dose-dependent manner. Common medications causing neutropenia include phenytoin, procainamide, antibiotics (sulfonamides, semisynthetic penicillins, and cephalosporins), antithyroid agents (methimazole and others), hypoglycemic agents (tolbutamide, chlorpropamide), phenothiazines (chlorpromazine), and

antiretrovirals. Prolonged use of drugs such as azathioprine to prevent organ rejection following transplantation or to treat autoimmune disease can be associated with severe neutropenia.

Autoimmune neutropenia (12) usually is associated with underlying autoimmune disease but also may be idiopathic or caused by drugs or infections. Immune neutropenia can be associated with immune hemolytic anemia or immune thrombocytopenia. The severity of neutropenia is variable, but the risk of infection may be extremely high in severely neutropenic patients on chronic immunosuppression for autoimmune disease. Systemic lupus erythematosus (Chapter 112) is the autoimmune disease most frequently associated with neutropenia.

Patients with neutropenia may present with mouth ulcers, fever, and systemic infection. For a complete discussion of infectious complications, see Chapter 63. Physical examination may reveal signs of autoimmune disease such as rheumatoid arthritis or splenomegaly. The evaluation of neutropenia should begin with a review of the peripheral smear. The presence of morphologic abnormalities in the red cells or remaining white cells suggests a primary marrow process. A thorough medication history, including over-the-counter preparations, should be obtained. Laboratory studies should include viral serology for hepatitis and HIV. A positive antinuclear antibody (ANA) may be useful in establishing the diagnosis of immune neutropenia and also may be found in HIV-associated neutropenia; however, the test is neither sensitive nor specific. If a diagnosis such as viral infection or drug-mediated neutropenia is not readily apparent or the neutropenia is severe or fails to resolve, bone-marrow aspiration and biopsy should be done. In most cases, the aspirate shows maturation arrest with normal or increased cellularity.

Neutropenia resulting from medications should resolve within 1–2 weeks of stopping the offending agent. If neutropenia is mild and associated with a medication that is not easily replaced, careful monitoring while continuing the drug is possible. Treatment of neutropenia associated with infection includes antibiotics and support of significant neutropenia with myeloid growth factors (Chapters 63 and 90). Patients with asymptomatic, modest neutropenia and without sites of tissue breakdown can be managed as outpatients. Antibacterial mouthwashes decrease the risk of infection.

Severe neutropenia, or neutropenia with recurrent or serious infections associated with autoimmune disease, usually is treated with steroids and other cytotoxic therapy if necessary. Treatment with intravenous gamma globulin may improve the neutrophil count, but the effect is transient. Myeloid growth factors are usually effective, and prolonged use in severe neutropenia may allow reduction in immunosuppression. Splenectomy is controversial and should be reserved for patients with repeated bacterial infections or refractory neutropenia. Although the neutrophil count often responds, the effect may be transient and there

may be a subsequent increased risk of infection. Neutropenia associated with absent white cell progenitors is treated with antithymocyte globulin and cyclosporine.

Presenting During Hospitalization

Neutropenia presenting during hospitalization is likely caused by medications or severe infection. Any possible offending agent should be stopped and the possibility of infection should be investigated. Patients should be followed until the neutropenia resolves. Persistent neutropenia requires a more extensive evaluation, as outlined previously.

Leukocytosis

Presenting at the Time of Admission

An elevation in the white cell count may be caused by increased total neutrophils, lymphocytes, monocytes, or rarely eosinophils. Immature myeloid or lymphoid cells can cause leukocytosis in the setting of acute leukemia. By far the most common cause of leukocytosis is *neutrophilia* (13). Leukocytosis with neutrophilia is a common presenting abnormal laboratory value on admission to the hospital. The major differential is between primary and secondary causes (e.g., leukemoid reaction) (Table 89.6). A markedly elevated white blood cell count ($>70,000/\mu\text{L}$) is rarely associated with benign disease. Splenomegaly may be a sign of leukocytosis due to a defined systemic disorder such as a myeloproliferative disease. Chronic leukocytosis

TABLE 89.6
DIFFERENTIAL DIAGNOSIS OF LEUKOCYTOSIS WITH NEUTROPHILIA

Primary neutrophilia	Paraneoplastic:
Myeloproliferative disease	Nonhematopoietic malignancy
Chronic myelogenous leukemia	Drug-induced
Myelofibrosis	Steroids
Polycythemia vera	Lithium
Essential thrombocythemia	β -agonists
Benign neutrophilia	Myeloid growth factors
Down syndrome	Chronic marrow stimulation
Familial or idiopathic	Hemolytic anemia
Secondary (reactive)	Immune thrombocytopenia
neutrophilia	Recovery from marrow suppression
Infection	Asplenia or hyposplenism
Acute	
Chronic	
Stress	
Exercise, catecholamines	
Postictal state	
Chronic inflammation	
Tissue damage	

rarely can occur in patients who are otherwise well.

Lymphocytosis may be reactive in the setting of pertussis, viral infection, or a lymphoproliferative disorder such as chronic lymphocytic leukemia, hairy-cell leukemia, or leukemic phase of lymphoma. Viral infections usually are evident from fever, sore throat, and other symptoms. A diagnosis of chronic lymphocytic leukemia requires a sustained peripheral lymphocytosis of more than 5,000 per microliter. Lymphadenopathy and splenomegaly are common physical findings. Monocytosis may be reactive in the setting of chronic infections (e.g., tuberculosis, endocarditis), autoimmune disease, carcinomas or lymphomas, or postsplenectomy. Recovery from marrow injury or chronic neutropenia also may be associated with monocytosis. Malignant monocytosis is seen in chronic myelomonocytic leukemia and myelodysplastic syndromes.

The most common causes of *eosinophilia* are atopic disorders and helminthic infections. Other causes are autoimmune disorders, drug reactions, and paraneoplastic causes (most commonly, Hodgkin's disease). Eosinophilia caused by drugs is rarely symptomatic and usually resolves with withdrawal of the offending agent, although tissue damage can occur (e.g., hypersensitivity pneumonitis). One notable exception is the chronic *eosinophilia–myalgia syndrome* seen following the ingestion of contaminated tryptophan. Primary eosinophilic disorders include idiopathic hypereosinophilic syndrome, Churg–Strauss syndrome with vasculitis (Chapter 111), and diseases associated with infiltration of specific organs such as eosinophilic pneumonitis (Chapter 57).

Evaluation of leukocytosis should begin with a careful review of the peripheral blood smear. Leukemoid reactions and myeloproliferative disease (2) may be indistinguishable on the blood smear and are characterized by a “left” shift in the neutrophils with increased bands, as well as metamyelocytes, myelocytes, promyelocytes, and rare blasts. In the setting of infection or stress, neutrophils may show toxic granulations, cytoplasmic vacuoles, and Döhle's bodies. Hypogranular and increased basophils, and occasionally eosinophils, are found in myeloproliferative disease and may be the first clue to the diagnosis. The leukocyte alkaline phosphatase score may be useful in distinguishing a leukemoid reaction from chronic myelogenous leukemia. This score is high in secondary leukocytosis and low in chronic myelogenous leukemia. In contrast, blast cells and neutrophils on the peripheral smear (“leukemic hiatus”) are characteristic of acute leukemia. Variably sized mature lymphocytes with “smudge” cells (crushed lymphocytes) are suggestive of chronic lymphocytic leukemia. Lymphocytes with an atypical appearance and hairy-like projections may be seen in some but not all cases of hairy-cell leukemia. The monocytes and neutrophils in chronic myelomonocytic leukemia are dysplastic; rare blasts also may be seen. If a myeloproliferative disease or leukemia is suspected, a bone-marrow aspirate and biopsy with cytogenetics, special stains, and flow cy-

tometry should be obtained. In an older or ill patient, or one in whom the bone marrow is inaspirable, peripheral blood may be sent for chromosome and DNA analysis, special stains, and flow cytometry.

A patient with eosinophilia should be asked about travel history, animal exposure, and personal or family history of atopy, eczema, or asthma, as well as for a detailed medication history. Serial stool samples should be examined for ova and parasites. The detection of *Strongyloides stercoralis* may be difficult and can require serologic testing. Review of the peripheral blood smear may show dysplastic features suggestive of a primary hematologic disorder.

The goal in secondary leukocytosis is to treat the underlying disorder. There are no untoward effects of benign leukocytosis; no specific therapy is required. However, leukocytosis that does not resolve following treatment of infection or resolution of stress should be investigated thoroughly, as it may represent early chronic myelogenous leukemia. Unlike the leukocytosis with acute leukemia, marked elevations of the white blood count caused by differentiated cells in chronic myelogenous leukemia are not usually dangerous. The treatment of leukocytosis resulting from myeloproliferative disease and leukemias is covered in Chapters 93 and 95.

Presenting During Hospitalization

Leukocytosis of any sort occurring during hospitalization is usually caused by infection or a reaction to medications. Leukocytosis may be the first sign of infection, especially in an immunocompromised patient. For further discussion, see Chapters 62 and 63.

Pancytopenia

Presenting at the Time of Admission

Pancytopenia is defined as a reduction in all three blood cell lines. The differential diagnosis is broad and includes toxin or immune suppression of marrow precursors, infiltration of the marrow, and splenic sequestration. *Aplastic anemia* is characterized by a hypocellular bone marrow with normal cytogenetics. The most common cause is thought to be autoimmune suppression of hematopoiesis by a T-cell-mediated mechanism. Aplastic anemia also may be caused by direct stem-cell injury from drugs, including phenytoin, sulfonamides, carbamazepine, tolbutamide, gold salts, and chloramphenicol, and from toxins including benzene, toluene, and some insecticides. Pancytopenia with an aplastic marrow has been seen following pregnancy and infection with hepatitis B or C. Treatment with chemotherapy or radiation therapy (especially to the pelvis) may result in aplasia. Autoimmune pancytopenia may be seen with systemic lupus; the marrow is cellular often without appreciable abnormalities. Nutritional deficiency in B₁₂ or folate can result in marked pancytopenia.

Infiltration of the marrow may present as pancytopenia. Primary bone-marrow disorders include hairy-cell leukemia, myelodysplasia, myelofibrosis, and acute leukemia. Disseminated infections resulting from tuberculosis, brucellosis, leishmaniasis, and HIV can result in pancytopenia. Modest pancytopenia, caused by sequestration, is a frequent finding in patients with significant splenomegaly.

The symptoms of patients with pancytopenia usually result from the decrease in cell counts, with stomatitis and fever related to neutropenia, fatigue and dyspnea from anemia, and bleeding from thrombocytopenia. Fever also may be a sign of malignancy or infection. The evaluation of pancytopenia almost always includes bone-marrow aspiration and biopsy after a drug and toxin history, careful physical examination, and review of the peripheral smear.

Treatment of aplastic anemia depends on the underlying cause. Aplastic anemia caused by medications may resolve with cessation of the offending agent. "Idiopathic," or autoimmune, aplastic anemia may respond to immunosuppressive therapy with antithymocyte globulin and cyclosporine. Allogeneic bone-marrow transplantation (Chapter 96) is the only curative treatment for severe aplastic anemia or aplasia resulting from direct stem-cell injury by toxins. Androgen therapy has been used for refractory aplastic anemia in patients who are not candidates for bone-marrow transplantation with some response. Pancytopenia caused by deficiency of B₁₂ or folate responds rapidly to replacement with recovery of counts within 7–14 days.

Presenting During Hospitalization

Like neutropenia, pancytopenia presenting during hospitalization is almost always caused by drug toxicity or infection. Treatment includes cessation of the offending drug, and transfusion and antibiotics as needed.

KEY POINTS

- Careful evaluation of the peripheral blood smear is essential for the evaluation of abnormal blood counts.
- Splenomegaly and lymphadenopathy are usually signs of underlying systemic illness and always require evaluation.
- Medications are a common cause of blood-count abnormalities in hospitalized patients.
- Nutritional deficiencies should be carefully screened for, particularly in elderly patients.

- Anemia may be classified by the size of the red blood cell, the reticulocyte count, and review of the peripheral blood smear.
- Leukocytosis is usually due to neutrophilia; the differential diagnosis is primarily between a reactive process and myeloproliferative disease.

Principles of Chemotherapy

90

Robert J. Ignoffo

INTRODUCTION

History of Chemotherapy

Dr. Paul Erlich coined the term *chemotherapy* in the early 1900s as a result of his work in developing new antibiotics for use against parasitic organisms. However, it was not until 1945 when the alkylating agents were discovered and used successfully in the treatment of lymphomas and Hodgkin's disease. During the same era, Huggins and Hodges determined that androgens promoted the growth of prostate cancer cells and subsequently tested the concept of androgen deprivation, showing that castration and estrogens were effective in the treatment of prostate cancer. Today the term chemotherapy is used for both cytotoxic and hormonal therapy.

After the initial success of cytotoxic chemotherapy, other alkylating agents were developed, including cyclophosphamide, which was claimed to have a selective effect on tumor cells. Although toxicities were observed on normal cells, cyclophosphamide therapy became a mainstay in the treatment of many malignancies. Soon thereafter, antimetabolites (i.e., methotrexate and fluorouracil) were discovered to have anticancer activity. Preclinical studies demonstrated that combinations of multiple agents could produce synergistic activity when given in the appropriate schedule. In the late 1970s it was shown that chemotherapy was effective in early stages of responsive cancers, probably because of increased tumor sensitivity in the setting of small tumor size or fewer numbers of cancer cells. In the 1980s, the advent of platinum therapy heralded advances in the treatment of

genitourinary and gynecologic tumors. This was followed in the 1990s by the maturing of important studies of adjuvant chemotherapy showing an improved survival for breast and colorectal cancer, and the emergence of the effective new drugs to prevent chemotherapy toxicities. These supportive care drugs included mesna to prevent ifosfamide uropathy, hematopoietic growth factors (G-CSF, GM-CSF, erythropoietin, and oprelvekin) to minimize myelosuppression, 5-HT₃ antagonists (ondansetron, granisetron, and dolasetron) to prevent acute chemotherapy-induced nausea and vomiting, dexrazoxane to prevent anthracycline-induced cardiomyopathy, and amifostine to prevent cisplatin-induced nephrotoxicity and neurotoxicity. These supportive therapies could possibly enhance patient compliance and allow for improved dose intensity of chemotherapy. The burgeoning biotechnology revolution holds the promise of more selective therapies, some of which are already finding their way into clinical practice (1).

Current Strategies in the Use of Chemotherapy and Biologic Therapy

Chemotherapy may be used in a variety of ways to treat cancer: as induction chemotherapy for advanced disease; as adjuvant chemotherapy after initial surgical debulking of localized cancer; as neoadjuvant chemotherapy for large cancers given prior to primary surgery; and as site-directed chemotherapy via installation into sanctuaries (intrathecal or peritoneal) or regional perfusion of tumors (e.g. intra-arterial).

Induction chemotherapy is most often used in the treatment of hematologic malignancies such as acute leukemias or lymphoma, with the goal of producing a complete or partial remission. High-dose chemotherapy is usually given in the hospital setting and often requires bone marrow rescue either with bone marrow or peripheral stem cells (Chapter 96). Patients undergoing high-dose chemotherapy often develop severe bone marrow suppression. The resulting grade 4 neutropenia usually requires empiric antibiotic therapy with broad-spectrum agents.

Other strategies include adjuvant and neoadjuvant chemotherapy. The rationale of *adjuvant chemotherapy* is to eliminate small numbers of remaining cancer cells that may be present systemically after primary surgery or radiation therapy. Adjuvant chemotherapy uses drugs that are very active in an advanced stage of the same cancer. *Neoadjuvant chemotherapy* is systemic chemotherapy that is used for localized cancers that may not be surgically resectable initially. This therapy may completely eradicate the localized tumor or result in shrinkage of the tumor such that it becomes surgically resectable. This strategy also has the advantage of providing information on the tumor's sensitivity to postsurgical chemotherapy. *Regional therapies* are used to improve the therapeutic advantage of a cytotoxic drug by increasing intratumor drug concentration while minimizing systemic exposure of the drug. Examples of regional chemotherapy are intra-arterial perfusion, intraperitoneal (belly-bath) instillation, and intrathecal injection.

CLINICAL OUTCOMES IN EVALUATING THE RESPONSE FROM CHEMOTHERAPY

In its early years of development, chemotherapy was not expected to cure patients but rather to shrink tumors and provide palliation. Responses to chemotherapy were of short duration, and relapse was common and heralded the development of drug resistance. With the discovery of new drugs and combinations, however, a higher rate of tumor response and even cure became an increasing reality. Unfortunately, these advances affected a relatively small percentage of the total population of cancer patients, with about 90% of the cures being observed in only 10% of the known cancers.

Goals of Therapy

The goals of therapy are often determined on a case-by-case basis and should involve both the physician and patient. The most desirable response, of course, is cure. *Cure* comes when a therapy leads to total eradication of the cancer and allows the patient to live a normal life span. Similarly, *complete remission* is total eradication of measurable cancer or normalization of a tumor marker; it must

be obtained before cure can be achieved. The best way to monitor the quality of a complete remission is by assessing the duration of the disease-free survival. For acute leukemia, complete remission involves normalization of a patient's bone marrow and at least a 2-year disease-free survival.

Partial remission is the next most desirable outcome. It is defined as a decrease of measurable cancer by at least 50% of its original volume. Partial remissions are meaningful to patients if they result in either a prolonged survival or palliation of symptoms. Furthermore, partial responses may also be useful in determining the effectiveness of a new drug or new drug regimen. Outcomes such as median duration of remission and median overall survival are used for comparing the efficacy of new therapies. Improved quality of life and palliation of symptoms are considered as important, if not more so, as partial remission, especially in patients with advanced incurable cancer. The achievement of stable disease can be beneficial to a patient who has rapidly progressive cancer with worsening symptoms. Progressive disease is defined as the development of any new cancer lesion or an increase of cancer volume by 25% or more, and it may or may not be associated with worsening symptoms.

Some patients without measurable tumors may have a tumor marker that can be used as an indicator of response or recurrence of systemic cancer. Examples include testicular cancer or gestational trophoblastic tumor, both of which can be monitored with a serum test for the β -subunit of human chorionic gonadotropin (β -HCG). Similarly, the tumor marker CA-125 can be used to assess the response of ovarian cancer to treatment. As with a partial remission, a 50% decrease in a tumor marker usually corresponds to tumor response, while an increase indicates tumor progression.

In the setting of minimal residual disease, as in patients who have had initial debulking surgery, complete response is not a relevant clinical outcome because the primary tumor has been totally removed. Other response indicators must be used, such as freedom from recurrence or relapse-free survival. These indicators report the amount of time elapsed for the regrowth of tumor cells to a clinically detectable level of cancer.

Table 90.1 lists the response rate for several cancers over time. The improved cure rate for cancers such as acute leukemia, Hodgkin's disease, testicular carcinoma, and choriocarcinoma is primarily caused by the use of combination chemotherapy. Recent advances have also been observed with multimodal therapy, using surgery, radiation therapy, hormonal therapy, and adjuvant chemotherapy, for breast and colorectal cancer. Improvements in response and long-term survival have also been realized for previously highly resistant solid tumors such as malignant melanoma and ovarian carcinoma. Table 90.2 lists several of these cancers and regimens associated with improved response.

TABLE 90.1
CURABLE OR HIGHLY RESPONSIVE CANCERS
AND COMMONLY USED CHEMOTHERAPY

Cancer	Chemotherapy regimen
Acute myelogenous leukemia	Daunorubicin + cytarabine; Idarubicin + cytarabine
Acute lymphoblastic leukemia	Vincristine + prednisone + thioguanine
Hodgkin's disease (stage III or IV)	Adriamycin + bleomycin + vinblastine + dacarbazine; Mechlorethamine + vincristine + procarbazine + prednisone
Non-Hodgkin's lymphoma (high-grade)	Cyclophosphamide + hydroxydaunorubicin (doxorubicin) + vincristine + prednisone
Neuroblastoma	Cyclophosphamide + doxorubicin + vincristine
Testicular carcinoma (nonseminoma)	Bleomycin + etoposide + cisplatin

PRINCIPLES OF SUCCESSFUL CHEMOTHERAPY

Several principles of chemotherapy have been associated with a positive outcome in cancer patients. These principles include the following:

1. *Use combinations of chemotherapeutic drugs.* With a few exceptions, combinations of drugs with synergistic activity produce higher response rates and more cures than monotherapy. Combinations with different mechanisms of action usually offer the best chance for optimal response and also delay the onset of drug resistance.
2. *Use combinations of chemotherapy drugs with nonoverlapping toxicities.* Most chemotherapeutic drugs affect rapidly dividing normal cell populations such as bone marrow, hair follicles, gonadal tissue, and mucosa. Thus, myelosuppression, sterility, alopecia, and mucositis are common side effects. The agents also produce a wide variety of other organ system toxicities. Thus, combination regimens are often developed that allow the maximally tolerated doses of each drug in the regimen.
3. *Use an optimal dose intensity or dose density of chemotherapy.* The effectiveness of a drug combination often depends on both the dose and the dose schedule prescribed. For example, the effectiveness of the combination of cyclophosphamide, methotrexate, and fluorouracil in breast cancer is optimal when the dose intensity is at least 75% of the ideal dosage. Recently,

the use of combination fluorouracil, epirubicin, and cyclophosphamide given in a dose-dense fashion (e.g. every 2 weeks) was shown to decrease the recurrence rate in patients with high-risk breast cancer.

4. *Use supportive care drugs and therapies to prevent or minimize grade III or IV chemotherapy-induced toxicity.* Supportive care drugs and therapies, including hematopoietic growth factors, antiemetics, cytoprotectants (mesna, dexrazoxane, amifostine, and mannitol), pre- and postchemotherapy hydration, and antidotes (leucovorin), can be used prophylactically for chemotherapy regimens that commonly cause significant toxicity. Such therapies improve a patient's quality of life and enhance patients' abilities to tolerate chemotherapy.
5. *Use strategies to overcome drug resistance.* Some tumor cells contain cell-membrane proteins that act as gatekeepers, denying entry of toxic substances into the cell as well as pumping substances through the cell membrane to the outside. This pump is referred to as P-glycoprotein or P-gp. It is found in several body sites, including the blood-brain barrier, the intestinal mucosa, the liver, and the kidney. P-gp is one of the mechanisms of tumor resistance and can be induced by some drugs. Another pump is the multidrug resistance gene (MDR-1), which is present in many normal tissues and also serves as a protective mechanism against toxic substances. Attempts to overcome tumor resistance has been the subject of recent intense research. One strategy has been the use of very high doses of chemotherapy with bone marrow rescue. This approach results in high concentrations of cytotoxic drugs and is often used in cases of tumor relapse. Unfortunately, the toxicities of high-dose therapy are substantial. More selective methods have been investigated recently and include developing drugs that block either the P-gp protein or MDR-1.

TABLE 90.2
CANCERS DEMONSTRATING IMPROVED
RESPONSE TO CHEMOTHERAPY

Cancer	Chemotherapy
Colorectal cancer	Leucovorin + fluorouracil + irinotecan; Leucovorin + fluorouracil + oxaliplatin
Melanoma	Cisplatin + vinblastine + dacarbazine (or temozolamide) + α -interferon + interleukin 2
Soft-tissue sarcoma	High-dose ifosfamide
Ovarian cancer (stage III/IV)	Paclitaxel + cisplatin; Paclitaxel + carboplatin
Non-small cell lung cancer	Cisplatin or carboplatin + paclitaxel

PHARMACOLOGY OF ANTINEOPLASTICS AND BIOLOGIC DRUGS

Pharmacokinetics and Pharmacodynamics

Pharmacokinetic and pharmacodynamic studies are being increasingly utilized in oncology to characterize the absorption, distribution, metabolism, and excretion of chemotherapy drugs. Pharmacokinetic data provide clinicians with the means to design more effective administration schedules and dosage regimens. The most important pharmacokinetic parameters are the amount of free drug available for effect, the active metabolites, the routes of elimination, and the half-life. Metabolism is probably the most complex aspect of pharmacokinetics. Cytochrome P450 enzymes in the liver, especially the CYP3A4 isoenzymes, are involved in the metabolism of several cytotoxic drugs. Clinicians should be aware that many cancer patients take alternative medications (such as St John's Wort) that may alter the metabolism of chemotherapy drugs, particularly the taxanes. Drug interactions, along with the large variations in hepatic enzyme activity, are probably responsible for widely variable toxicities of and responses to chemotherapy. A complete description of these interactions is beyond the scope of this chapter.

The amount of free drug is inversely related to the degree of protein binding. Unfortunately, for most chemotherapeutic drugs, the degree of protein binding varies widely among patients. Thus, dosing the drug on the basis of body weight or body surface area may not correlate closely to drug clearance. Nevertheless, relative dosing using weight or body surface area remains the most common method of dosing chemotherapy.

Some chemotherapeutic drugs must be activated by hepatic enzymes. For example, cyclophosphamide is activated by hepatic CYP3A4 to two active metabolites. Patients may vary in their ability to activate the drug, which can result in fluctuating levels of active metabolites and variable responses to the treatment. Improving hepatic metabolism of cyclophosphamide can be accomplished with inducing drugs such as cimetidine or phenobarbital. In some cases, the ratio of metabolites in the body may explain a particular toxicity. For example, a high level of the metabolite of irinotecan (SN-38) is associated with a high incidence of severe diarrhea. Some patients with enhanced metabolism are at greater risk for severe diarrhea. Pharmacokinetic assessment may identify such patients.

The major routes of elimination for some chemotherapeutic drugs are the kidney and liver. Diminished liver or kidney function may lead to decreased drug clearance. The dose of chemotherapy should be reduced to account for the decreased clearance to minimize excessive organ-system toxicity. Patients with decreased drug clearance will have a prolonged drug half-life. Drugs that are affected by altered renal or hepatic clearance are listed in Table 90.3.

Side Effects of Chemotherapy

Table 90.4 lists side effects associated with chemotherapy drugs that are commonly used in the hospital setting.

CARE OF THE HOSPITALIZED PATIENT

Indications for Admission of the Oncology Patient

With the advent of better supportive care therapies and skilled oncology nurses, most chemotherapy is currently administered in the outpatient setting. However, many cancer patients are still admitted to the hospital for high-dose chemotherapy or complicated chemotherapy regimens. Other reasons for admission include the treatment of complications caused by chemotherapy, oncologic emergencies (Chapter 92), or pain control (Chapter 18).

Prescribing of Cancer Chemotherapy

Erroneous chemotherapy orders may have disastrous consequences. In one review, the most frequently observed errors were caused by poor handwriting or prescribing practices that lead to misinterpretation of the chemotherapy order by nurses and pharmacists (2). Computerized order sets and/or preprinted standardized chemotherapy order forms are recommended both for regimens that are used commonly in practice as well as for clinical studies (see also Chapter 21). The advantage of preprinted, standardized chemotherapy order forms are that they prompt the prescriber to enter the information necessary for all health care personnel to double check the order for accuracy. At the very least, to ensure that orders are written with utmost clarity, clinicians should follow order-writing guidelines that have been established by a collaborative practice committee at their institution or adopt guidelines of other institutions or organizations. The guidelines used at UCSF Medical Center are shown in Table 90.5. The use of computer software programs that compare the chemotherapy dose to existing protocols for the institution may further improve the chemotherapy ordering process. These software programs are in the early stages of development (Chapter 10).

Administration of Cancer Chemotherapy

Several classes of chemotherapy may be administered in the hospital setting. Some of the more commonly prescribed drugs include cytarabine, daunorubicin, cyclophosphamide, ifosfamide plus mesna uroprotection, high-dose methotrexate with leucovorin rescue, carboplatin, and cisplatin. Other agents include busulfan, etoposide, fluorouracil, paclitaxel, thiotepa, idarubicin, and doxorubicin. Continuous infusions are also monitored in the hospital setting, especially vesicant drugs such as daunorubicin,

TABLE 90.3
CONDITIONS ALTERING THE CLEARANCE OF SELECTED
CHEMOTHERAPEUTIC DRUGS

Drug	Condition	Percentage of full dose
Bleomycin	Renal impairment: CrCl > 35 ml/min	100
	CrCl 10–50 ml/min	50
	CrCl < 10 ml/min	40
Carboplatin	Renal impairment	Dose (mg) = AUC × (CrCl + 25) ^a
Carmustine	Renal impairment CrCl: <10 ml/min	25–50
Cisplatin	Renal impairment CrCl: <50 ml/min	0
Cyclophosphamide	Renal impairment CrCl: <10 ml/min	50
Cytarabine	Renal impairment CrCl: 10–50 ml/min	50
	CrCl <10 ml/min	25
Daunorubicin	Hepatic dysfunction	
	Bili 1.2–3.0 mg/dL	75
	Bili >3.0 mg/dL	50
Doxorubicin	Hepatic dysfunction	
	Bili 1.2–3.0 mg/dL	50
	Bili >3.0 mg/dL	25
Epirubicin	Hepatic dysfunction	
	Bili 1.2–3.0 mg/dL	50
	Bili >3.0 mg/dL	25
Etoposide	Hepatic dysfunction	
	Bili 1.2–3.0 mg/dL	50
	Bili >3.0 mg/dL	0
Fluorouracil	Hepatic dysfunction	
	Bili 1.2–3.0 mg/dL	100
	Bili >3.0 mg/dL	50
Idarubicin	Hepatic dysfunction	
	Bili 2.5–5.0 mg/dL	50
	Bili >5.0 mg/dL	0
Ifosfamide	Renal impairment: CrCl 10–50 ml/min	75
	CrCl <10 ml/min	50
Lomustine	Renal impairment: CrCl 10 ml/min	25–50
Methotrexate	Renal impairment: CrCl 10–50 ml/min	25–50
	CrCl <10 ml/min	0

	Bili >3.0 mg/dL	25
Vinorelbine	Hepatic dysfunction	
	Bili 1.2–3.0 mg/dL	50
	Bili >3.0 mg/dL	25

^a This is the “Calvert formula.”

AUC, area under the curve, in mg/mL × minutes; *bili*, total bilirubin; *CrCl*, creatinine clearance.

doxorubicin, vincristine, and vinblastine. When administered as a long infusion, these drugs should be given via a central venous access line to minimize the risk of local skin reactions. In addition to intravenous, other routes of administration include intraperitoneal (IP), intrapleural (IPI), intrathecal (IT), and intravesicle (bladder). These

routes require special knowledge and clinician expertise for proper administration. Drugs given by the intraperitoneal route include cisplatin, carboplatin, etoposide, fluorouracil, and bleomycin. Drugs given by the intrathecal route include cytarabine, methotrexate, and thiotepa. BCG and mitomycin are frequently given by bladder instillation.

TABLE 90.4
SIDE EFFECTS OF CHEMOTHERAPY DRUGS COMMONLY USED IN THE HOSPITAL SETTING

Drug	Adverse effects
Asparaginase	Hypersensitivity, anaphylaxis, hepatic aminotransferase and alkaline phosphatase elevation, increased serum bilirubin, decreased clotting factor synthesis leading to elevated prothrombin time and bleeding, rare disseminated intravascular coagulation, CNS (lethargy and somnolence), pancreatitis
Bleomycin	Anaphylaxis, rash, pulmonary fibrosis (doses > 200 Units/m ²)
Busulfan	Myelosuppression, nausea, vomiting, hyperpigmentation, seizures after high doses (4 mg/kg/day), alopecia
Carboplatin (Paraplatin)	Myelosuppression, acute nausea and vomiting, peripheral neuropathy
Carmustine	Myelosuppression, acute nausea and vomiting, delayed pulmonary toxicity, encephalopathy and seizures, vasculitis along the vein used for drug injection
Cisplatin (Platinol)	Myelosuppression, acute emesis, delayed emesis (days 2–5), peripheral neuropathy, acute renal failure, chronic renal failure, hypomagnesemia, hypokalemia, fatigue and weakness, high-frequency hearing loss, hypersensitivity reactions, alopecia
Cyclophosphamide	Myelosuppression, acute emesis, delayed emesis, cystitis, SIADH within 48 hours, cardiomyopathy after high-dose therapy, alopecia
Cytarabine (Ara-C)	Myelosuppression, mucositis, stomatitis, CNS (lethargy, confusion, ataxia, seizures), conjunctivitis after high-dose therapy, nausea and vomiting
Dacarbazine (DTIC)	Myelosuppression, acute emesis, acute nausea, flulike syndrome (fever and chills), hypotension after rapid infusion, hepatic aminotransferase elevations, hypersensitivity reactions
Daunorubicin HCl (Cerubidine)	Myelosuppression, acute emesis, delayed emesis, fever, alopecia, cardiomyopathy (dose related), acute arrhythmias, mucositis, diarrhea, hyperpigmentation of nails, nail ridging, hepatic aminotransferase elevation, orange urinary coloration, local skin necrosis upon extravasation
Doxorubicin HCl (Adriamycin)	Myelosuppression, acute emesis, delayed emesis, fever, alopecia, cardiomyopathy (dose related), acute arrhythmias, mucositis, diarrhea, hyperpigmentation of nails, nail ridging, hepatic aminotransferase elevation, orange urinary coloration, local skin necrosis upon extravasation
Etoposide (VP-16)	Myelosuppression, acute emesis, hypotension during IV administration, alopecia, hypersensitivity reactions, CNS (lethargy, sedation) after high doses, metabolic acidosis after high doses
Fluorouracil	Myelosuppression, mucositis, stomatitis, diarrhea, ataxia, venous hyperpigmentation, dacrocystitis (tear duct inflammation and blockage), alopecia, nail changes
Idarubicin	Myelosuppression, acute emesis, delayed emesis, fever, alopecia, cardiomyopathy (dose related), acute arrhythmias, mucositis, diarrhea, hyperpigmentation of nails, nail ridging, hepatic aminotransferase elevation, orange urinary coloration, local skin necrosis upon extravasation
Ifosfamide/Mesna (IFEX/MESNEX)	Myelosuppression, acute emesis, delayed emesis, cystitis, SIADH within 48 hours, cardiomyopathy after high-dose therapy, alopecia, CNS (lethargy, confusion, ataxia, seizures), hepatic aminotransferases and alkaline phosphatase, rare nephrotoxicity
Interferon alfa (Intron, Roferon)	Myelosuppression, weakness, fever, chills, malaise, myalgia, anorexia, somnolence, depression, tremor, seizures
Melphalan	Myelosuppression, acute emesis, hypotension, alopecia, pulmonary fibrosis, hypersensitivity
Methotrexate	Myelosuppression, mucositis, stomatitis, hepatic aminotransferase elevation, moderate acute emesis after high doses, acute renal failure after very high doses in patients with inadequate prehydration and urinary alkalinization, rare acute pneumonitis
Mitoxantrone (Novantrone)	Myelosuppression, cardiomyopathy, CHF, mild nausea and vomiting, blue-green urinary discoloration, alopecia
Octreotide (Sandostatin)	Mild nausea, abdominal pain, local skin reactions at injection site
Paclitaxel (Taxol)	Myelosuppression, mild acute emesis, peripheral neuropathy, hypersensitivity reactions, rare bradycardia and hypotension, alopecia, local skin reactions upon extravasation but not necrosis
Streptozocin	Myelosuppression, renal dysfunction, acute emesis, hyperglycemia, hepatic aminotransferase elevation, venous irritation during IV administration

CHF, congestive heart failure; CNS, central nervous system; SIADH, syndrome of inappropriate antidiuretic hormone.

TABLE 90.5
CHEMOTHERAPY ORDER-WRITING GUIDELINES AT UCSF MEDICAL CENTER

1. All orders should contain the patient's name, height, weight, and BSA in order for nurse or pharmacist to double check the calculation.
2. No abbreviations or brand names should be allowed. (i.e., do not use "MTX" for "methotrexate" or "U" for "units").
3. The total daily dose should be written as " X mg/kg or $\text{mg}/\text{m}^2 = Y$ mg on day 1" for single-day regimens. Indicate the duration of infusion if an IV infusion, i.e., 1 hour, 4 hours, etc. Multiday regimens should be written as " X mg/kg or $\text{mg}/\text{m}^2 = Y$ mg daily for Z days."
4. Do not write a zero after a whole number (e.g., 2.0 mg). Leave off the decimal and zero (e.g., 2 mg). Decimal points are easily obliterated by the lines on order sheets and can lead to serious errors in dosage.
5. Continuous infusions of vesicant drugs should be given only via a central line.
6. A co-signature by an attending physician is required for all transplant protocol orders. A co-signature by the oncologist will be required within 24 hours if orders are faxed. Faxed orders **must** be written on an acceptable institutional order form.
7. For intravenous agents, write the method of drug administration as either "IV push" or "IV infusion."
8. The solution and volume may be specified for IV infusions of chemotherapy. If not specified, the solution and volume will be determined by the pharmacist or clinic nurse based on the appropriate guideline.
9. Whenever possible, order practical doses of chemotherapy. The pharmacist may confer with you regarding the acceptability of rounding certain drug doses to their most practical dose as long as it does not vary by more than 5% from the original dose. The exceptions are vincristine, in which exact dosing is required, and vinblastine, mitoxantrone, and idarubicin, which should be rounded to the nearest **mg**.
10. Leave a space between the number and its unit value, e.g., 100 mg, not 100mg.
11. Changes in chemotherapy must be written by the fellow or attending (verbal orders to nurses or house staff are not acceptable).
12. Orders should not contain Latin abbreviations. Specifically, do not use qd, bid, or qid. Use the term *daily* instead of *qd*, *q12h* instead of *bid*, etc.
13. Order anti-emetics, hydration, and other supportive care on the same chemotherapy order form.

BSA; body surface area.

Each of these drugs is absorbed systemically and may produce systemic side effects, especially myelosuppression.

It is desirable that patients receive their chemotherapy within a few hours of being admitted to the hospital. In order to enhance efficiency, clinicians should try to obtain all the preliminary data (e.g., labs, radiographs) the day before the patient is admitted. Hydration and premedications should be given promptly on the patient's arrival and soon followed by the first dose of chemotherapy. Patients receiving chemotherapy do not necessarily require daily laboratory tests. Exceptions are drugs specified on protocol or certain antineoplastics (cisplatin, ifosfamide, methotrexate, cytarabine, and aldesleukin), which can produce rapid changes in electrolytes or renal function or require prolonged postchemotherapy assessment.

High-Dose Chemotherapy

Recent advances in the role of supportive care and bone marrow rescue have allowed for dose intensification of chemotherapy for both hematologic and solid tumors. High-dose therapy is often given in the hospital setting because of the high incidence of acute side effects and major organ system toxicity. However, for some drugs, the initial doses may be administered in the outpatient setting with hospital admission 3–5 days later when severe bone marrow suppression is expected. Hematopoietic growth factors can be used to decrease the intensity and onset of life-threatening bone marrow suppression. Measures to prevent life-threatening bacterial infection include the use of prophylactic antibiotics during the period of severe neutropenia (Chapter 63). Thrombocytopenia and anemia are also

common and are treated with transfusions, erythropoietin, or oprelvekin. Severe mucositis and diarrhea are common after high-dose chemotherapy. They typically peak at the same time as the hematologic toxicity, and last for 3–5 days after recovery of the neutrophils. During this time period, patients may require parenteral nutrition. Use of the recently-approved agent palifermin (recombinant human keratinocyte growth factor) may decrease the severity and duration of severe oral mucositis (3). High-dose therapy may cause major organ system complications, including cardiomyopathy, pulmonary toxicity, vasculitis, and hepatic veno-occlusive disease.

Prevention of Chemotherapy-Induced Complications

Chemotherapy-Induced Nausea and Vomiting

Until recently, nausea and vomiting were the most feared side effects of chemotherapy. With the advent of 5-HT₃ antagonists, 60%–90% of patients have complete protection from acute chemotherapy-induced emesis. The emetogenic potential of individual chemotherapy drugs tends to be severe in hospitalized patients because combinations that include cisplatin or high-dose chemotherapy are often given. Chemotherapy orders of highly emetogenic drugs (Table 90.6) should be accompanied by an antiemetic order for a 5-HT₃ antagonist with or without dexamethasone (Table 90.7). This regimen should control acute emesis in about 60%–80% of patients, but not delayed nausea or emesis, which occurs in about 40%–60% of patients given cisplatin or high-dose chemotherapy. A

TABLE 90.6
EMETOGENIC POTENTIAL OF COMMONLY USED CHEMOTHERAPEUTIC AGENTS

Level IV–V (Moderately high to high 60–100%)	Level III (Moderate 30–60%)	Level II (Mod–low 10–30%)	Level I (Low <10%)
Busulfan (4 mg/kg/day)	Amifostine (≥ 740 mg/m ²)	Asparaginase	Bleomycin
Carmustine	Azacitidine	Cytarabine	Busulfan
Cisplatin (≥ 50 mg/m ² /day)	Carboplatin	(<250 mg/m ² /day)	Chlorambucil
Cyclophosphamide (≥ 750 mg/m ² /day)	Cisplatin	Daunorubicin (Liposomal)	Cladribine (2-CdA)
Cytarabine (≥ 500 mg/m ² /day)	(≤ 50 mg/m ² /day)	Docetaxel	Cyclophosphamide (oral)
Dacarbazine	Cyclophosphamide	Etoposide	Cytarabine (<20 mg IV or <50 mg IT)
Dactinomycin	(<750 mg/m ² /day)	(<200 mg/m ² /day)	Doxorubicin (Liposomal)
Etoposide, high dose (≥ 400 mg/m ² /day)	Cytarabine	Gemcitabine	Flouxuridine IA
Ifosfamide ($\geq 2,500$ mg/m ² /day)	(250–500 mg/m ² /day)	Irinotecan	Fludarabine
Lomustine	Daunorubicin	Methotrexate	Hydroxyurea
Mechlorethamine	Doxorubicin	(≤ 250 mg/m ²)	Melphalan (oral)
Melphalan (≥ 100 mg/m ² /day)	Etoposide	Mitomycin	Mercaptopurine
Methotrexate, high-dose (>1,000 mg/m ² /day)	(≤ 200 –400 mg/m ² /day)	Paclitaxel	Methotrexate
Paclitaxel (>250 mg/m ² /day)	Estramustine phosphate	(<175 mg/m ² /day)	(<50 mg/m ² /day)
Pentostatin	Flouxuridine IV	Thiotepa (≤ 12 mg/m ² /day)	Pegasparaginase
Plicamycin	Flourouracil (>1000 mg)	Topotecan	Tamoxifen
Streptozocin	Idarubicin		Thioguanine
Thiotepa (>100 mg/m ² /day)	Ifosfamide		Tretinoin
	(<2,500 mg/m ² /day)		Vinblastine
	Melphalan		Vinorelbine
	(50–100 mg/m ² /day)		
	Methotrexate		
	(250–1000 mg/m ² /day)		
	Mitomycin		
	Mitoxantrone		
	(≤ 15 mg/m ² /day)		
	Paclitaxel		
	(175–250 mg/m ² /day)		
	Procarbazine		
	Teniposide		

IA, intra-arterial; IT, intrathecal; IV, intravenous.

regimen of oral dexamethasone and ondansetron, both given 8 mg twice daily orally, often helps prevent delayed chemotherapy induced emesis (4). Although dexamethasone is effective in preventing emesis in patients with solid tumors treated with chemotherapy, some hematologists are concerned that this corticosteroid increases the risk of fungal infection in induction regimens for acute leukemia. While few studies implicate short courses of dexamethasone in causing fungal infection, further study is needed to establish its role in the setting of high-dose chemotherapy for acute leukemias.

Chemotherapy-Induced Neutropenia

One of the most common complications that may result in hospitalization of the chemotherapy patient is febrile neutropenia. The usual pattern of myelosuppression is the occurrence of neutrophil nadir between day 7 and 14

after chemotherapy. Severe neutropenia, defined as a neutrophil count of 500/ μ L or less with associated fever and shaking chills, should lead to a presumptive diagnosis of Gram-negative bacteremia. Mortality (about 3%) is associated with prolonged neutropenia (greater than seven days), especially below a neutrophil count of 100/ μ L and other high-risk features (e.g., expected long duration of neutropenia).

The hospital management of chemotherapy-induced febrile neutropenia involves appropriate cultures, followed by immediate prophylactic broad-spectrum antibiotic therapy to prevent progression to septic shock and death (also see Chapter 63) (5). Filgrastim and sargramostim have also been studied in the treatment of severe febrile neutropenia. Although several studies have demonstrated that these agents shorten the duration of severe neutropenia, mortality has not been affected. This is probably because of rapid neutrophil recovery (3–5 days) from the effects of

TABLE 90.7**AGENTS FOR THE PREVENTION OF CHEMOTHERAPY-INDUCED EMESIS****Level IV–V or Combinations including level III**

Granisetron 2 mg PO or 1 mg PO (on each day of chemotherapy) prior to chemotherapy. If patients cannot tolerate oral granisetron, may use intravenous granisetron (10 mcg/kg IV q24h).

OR

Granisetron 10 mcg/kg (round up to the nearest 50 mcg) IV over 5–15 minutes q24 hours (on each day of chemotherapy) or as IV push over 30 seconds.

OR

Ondansetron 8 mg IV q8h or Ondansetron 8 to 16 mg IV over 15 minutes \times 1 (on each day of chemotherapy).

OR

Dolasetron 100 mg IV or PO prior to chemotherapy.

All of the above may continue up to 24 hours after the last dose of chemotherapy.

PLUS

Dexamethasone 10–20 mg IV over 15–30 minutes prior to chemotherapy or 10 mg PO/IV bid on days of chemotherapy for 1–5 days (if not contraindicated).

Combinations of Level II or III

Ondansetron 16–24 mg PO qd (on each day of chemotherapy).

OR

Granisetron 1 mg PO q12 hours (on each day of chemotherapy).

OR

Ondansetron 8 mg IV over 15–30 minutes \times 1 (for each day of chemotherapy).

All of the above may continue up to 24 hours after the last dose of chemotherapy.

PLUS

Dexamethasone 10–20 mg IV over 15–30 minutes prior to chemotherapy or 10 mg PO/IV bid on days of chemotherapy for 1–5 days (if not contraindicated).

For levels see Table 90.6.

Oral agents should be administered at least 60 minutes prior to chemotherapy. Intravenous agents should be administered at least 30 minutes prior to chemotherapy. Ondansetron and Granisetron should be discontinued 12–24 hours after the completion of the last dose of chemotherapy.
IV, intravenous; PO, orally.

chemotherapy. Thus, the use of broad-spectrum antibiotics without concurrent hematopoietic growth factor is adequate to manage most uncomplicated patients. However, patients with shaking chills and ill appearance are at greater risk for life-threatening sepsis and may benefit from filgrastim or sargramostim to shorten the course of neutropenia. Some experts recommend using hematopoietic growth factors in the treatment of febrile neutropenia in the presence of constitutional symptoms and evidence for clinical infection (e.g. pneumonitis, cellulitis).

Patients who have developed life-threatening febrile neutropenia after chemotherapy should be treated prophylactically with a hematopoietic growth factor (filgrastim, pegfilgrastim, or sargramostim) to prevent future episodes of severe neutropenia. When using filgrastim in an adult, dose the drug by weight, and give full vial sizes. For those under 70 kilograms, use one 300 microgram vial. Pegfilgrastim, a longer-acting neutrophil stimulator, should be reserved for outpatient prevention of neutropenia (6). Its role in the acute management of chemotherapy-induced neutropenia is not well defined.

Other Oncologic Emergencies

Hypercalcemia, spinal cord compression, and superior vena cava syndrome are reviewed in Chapter 92. Tumor lysis syndrome is covered in Chapter 94. Pain management and palliative care are discussed in Chapters 18 and 19, respectively.

DISCHARGE ISSUES AND FOLLOW-UP CARE

Management of Infections as an Outpatient

Patients considered low-risk may be converted from intravenous to oral antibiotic therapy after initial response to antibiotics. A variety of antibiotics are available and should be chosen based upon site of infection, therapeutic response, and the typical antibiotic sensitivities for the particular institution (Chapter 63).

Delayed Emesis

Patients who have received cisplatin, cyclophosphamide, or high-dose chemotherapy may develop delayed nausea and vomiting 3–5 days after discharge. Patients should be discharged with antiemetics to manage delayed emesis. The most cost-effective therapy is a combination of ondansetron (or prochlorperazine or metoclopramide) plus dexamethasone (Table 90.7). The neurokinin-1 receptor antagonist aprepitant may be used for patients with severe delayed emesis (7). It must be given on day 1–3, in conjunction with a 5-HT₃ antagonist and dexamethasone. The dose of dexamethasone should be decreased to a maximum of 12 mg.

Prevention of Hemorrhagic Cystitis

The cytotoxic drugs cyclophosphamide or ifosfamide can cause severe bladder and ureteral toxicity. Complete protection for cyclophosphamide toxicity is virtually assured by using hydration (eight 6-ounce glasses of water or liquid) over the 24 hours following chemotherapy. Ifosfamide requires a uroprotectant drug, mesna, plus hydration for 24 hours post-therapy. Mesna is given by the intravenous route during hospitalization but may be converted to oral mesna every 4 hours for 3 doses at discharge. It is critical that patients are compliant with this regimen.

Methotrexate Monitoring

Methotrexate is an important antimetabolite drug that requires the antidote leucovorin for rescue of methotrexate doses greater than 500 milligrams. Patients must be instructed to take their oral leucovorin exactly as prescribed. In addition, they must return to the clinic for follow-up serum samples of methotrexate to determine the duration of leucovorin rescue (usually 3 days).

KEY POINTS

- Although cancer patients are being treated more often in the ambulatory setting, many patients still are admitted to the hospital for a variety of reasons, including administration of high-dose chemotherapy and management of complications related to chemotherapy.
- More cancer patients are responding to chemotherapy than in the past because of newer strategies such as dose-intense chemotherapy, high-dose chemotherapy with bone marrow rescue, and improved supportive care.
- High-dose therapies usually necessitate admission to the hospital for close monitoring. However, newer

supportive care therapies, especially antibiotics and antiemetics, allow the clinician to initially treat patients in the ambulatory setting.

- Hospitals should streamline the processing of chemotherapy orders. All information (laboratory data, premedications) relevant to the protocol should be obtained prior to hospitalization.
- The hospital physician should be familiar with the management of chemotherapy-induced complications, especially febrile neutropenia and emesis.
- Discharge issues that should be considered are prevention of delayed emesis, prevention of cyclophosphamide-induced cystitis, and monitoring of methotrexate serum levels.

Principles of Transfusion Medicine

91

Susan A. Galel Edgar G. Engleman

INTRODUCTION

Various blood components—either fresh or commercially processed—are available for clinical use. The appropriate use of blood components depends on an understanding of their characteristics, therapeutic value, and risks.

FRESH BLOOD COMPONENTS

Blood Collection

Fresh blood components are obtained from healthy volunteer donors. These donors are extensively screened for potential exposure to infectious diseases. The standard blood donation consists of approximately 500-milliliter “units” of whole blood collected in a citrate anticoagulant. This volume represents approximately 10% of a donor’s blood. Each unit of whole blood can then be separated by centrifugation into its components: red cells, plasma, and platelets. One hundred milliliters of a nutrient additive solution is usually added to each red cell product to prolong its shelf life. Each blood component derived from one donation of whole blood is referred to as a “unit” of that component and constitutes approximately 10% replacement therapy for an adult patient (1).

Apheresis

Apheresis is an alternative approach to blood collection, in which a donor’s blood is drawn into an automated processor that centrifuges the blood into its components and selectively harvests the desired component(s). The remainder of the donor’s blood is returned to the donor. By means of

continuous flow and centrifugation, multiple unit-equivalents of a particular blood component can be harvested. This technology is a primary source of platelets and plasma. The product of an apheresis platelet collection is equivalent to approximately six whole blood-derived platelet units. Apheresis technology can also be used to collect two units of red cells from larger donors, returning plasma and saline to the donors to preserve their intravascular volume. Granulocyte concentrates can also be collected by apheresis. To obtain therapeutic doses of granulocytes, however, donors must be premedicated with steroids and/or granulocyte colony stimulating factor (G-CSF) to increase their predonation white blood cell count.

Table 91.1 summarizes the therapeutic value of the most commonly prepared components of fresh blood.

MODIFICATIONS OF COMPONENTS OF FRESH BLOOD

Leukocyte Reduction

During centrifugation and separation of whole blood into components, white blood cells are partitioned into both the red cell and platelet products. These white blood cells, up to 10^9 per product, may cause febrile transfusion reactions and can stimulate human leukocyte antigen (HLA) immunization in transfusion recipients. White cells can be removed from blood components by passing the components through special synthetic fiber filters, which reduces levels of white cells from approximately 10^9 per product to 10^5 per product. Some platelet apheresis technologies select blood components so specifically that the products are essentially leukocyte-reduced at collection. The U.S. Food and Drug Administration (FDA) defines leukocyte-reduced

TABLE 91.1
FRESH BLOOD COMPONENTS AND THEIR USE

Component	Approximate unit volume	Therapeutic indication	Therapeutic impact/unit ^a	Approximate dose ^b	Approximate preparation and/or compatibility testing time
Whole blood ^c	500 mL	Acute hypovolemia with anemia	↑ Hgb ~ 1 g/dL ↑ Blood vol ~ 10%	Determined by estimated volume deficit	Type and cross-match (60 min)
Red blood cells	325 mL ^d	Anemia	↑ Hgb ~ 1 g/dL ↑ Blood vol ~ 5%	Determined by degree of anemia	Type and cross-match (60 min)
Fresh frozen plasma	200 mL	Replacement of multiple coagulation factors Warfarin reversal Factor V deficiency Thrombocytopenia	↑ Coagulation factors ~ 8% ↑ Blood vol ~ 4%	4 units (10–15 mL/kg)	Thawing (30 min)
Platelet concentrate			↑ Platelet count by		
a) single unit	a) 50 mL		a) 2–7,000/μL	a) 6 units	a) ± Pooling (15–30 min)
b) pheresis unit	b) 250 mL		b) 15–40,000/μL	b) 1 pheresis unit	b) None
Cryoprecipitate	15 mL	Hypofibrinogenemia Topical fibrin adhesive	↑ Fibrinogen ~ 5 mg/dL (also includes factors VIII, XIII, von Willebrand factor)	10–15 units (1 U/5 kg)	Thawing (30 min) ± pooling (15–30 min)

^a Anticipated response expressed either as a directly measurable increment or as a percentage of normal blood volume replacement in an adult.

^b Common empiric adult doses.

^c Transfusion services do not routinely store whole blood.

^d Volume includes 100 mL nutrient additive solution.

products as those that contain fewer than 5×10^6 white blood cells per product. Most red cell and platelet pheresis products produced today are leukocyte-reduced.

Frozen Red Blood Cells

Red blood cells can be preserved for up to 10 years by freezing. After thawing, the shelf life is limited to 24 hours unless freezing and thawing were carried out using new closed-processing systems. Frozen storage is most applicable to cells of rare phenotype and is typically a service of large regional blood suppliers. Most hospitals do not maintain their own frozen storage facilities.

Washed Blood Products

“Washing” refers to the removal of plasma from cellular products (red blood cells, platelets) by resuspending the product in saline solution. This practice is primarily indicated for patients with known sensitivity to plasma proteins, such as patients with immunoglobulin A (IgA) deficiency (who may be extremely sensitive to IgA). Washing has no role in leukocyte reduction.

Irradiated Blood Products

Cellular products, including leukocyte-reduced products, contain lymphocytes potentially capable of mediating graft-versus-host disease in susceptible patients. Gamma-irradiated ($\geq 2,500$ rads) blood products are recommended for such patients (see Adverse Effects of Transfusion).

Pathogen-Inactivated Products

Several processes to inactivate residual pathogens in fresh blood products have been the subject of clinical trials. Chemicals that can bind to nucleic acid are added to the blood component; in some cases, exposure to light is required to achieve covalent binding. This binding renders pathogens unable to replicate. Product shelf life or in vivo recovery may be mildly diminished by the treatment. Substantial incremental costs, reduced therapeutic effectiveness of the product, and potential toxicities raise questions regarding the appropriate application of these technologies. These processes may serve as a reasonable approach for reducing the risk of transmission of nucleic acid-containing pathogens for which there are currently no donor screening tests.

COMMERCIAL BLOOD PRODUCTS

Red Cell Substitutes

Effective red cell substitutes must bind oxygen at pulmonary oxygen pressures, release oxygen at tissue oxygen pressures, and have adequate intravascular retention and limited toxicity. Currently, no red cell substitutes are licensed for clinical use in the United States. For many years, trials of red cell substitutes were foiled by toxicity and difficulty in demonstrating efficacy. Several red cell substitutes have been evaluated in recent clinical trials. Some are perfluorocarbon emulsions, which actually dissolve oxygen and have linear oxygen-carrying characteristics. The vast majority of oxygen carriers in trials, however, are hemoglobin-based products, in which the hemoglobin molecules are cross-linked to reproduce the classic S-shaped cooperative oxygen-binding curve. Some of the products use recombinant hemoglobin and may ultimately be acceptable to Jehovah's Witnesses, but others are made from outdated human red cells or bovine red cells. Although hemoglobin solutions most accurately mimic natural red cell oxygen-carrying characteristics, concerns have been raised that the binding of hemoglobin to nitric oxide and the resultant vasoconstriction may limit the ability of these products to deliver oxygen to tissues. All these products have very limited intravascular retention, and it is doubtful that their safety profile will be better than that of fresh red cell products. The most appealing features of these products would be immediate availability and universal applicability. Therefore, the products are most likely to be useful in settings of acute trauma or surgery.

Commercial Plasma Protein Products

Relatively purified preparations of selected plasma proteins can be isolated from pooled human plasma by means of industrial techniques. Thousands of units of plasma are pooled, and the pool is subjected to various precipitation or affinity purification steps that separate different plasma proteins. The earliest products produced in this way had a high probability of carrying infectious agents because of the large numbers of donors represented in each pool. Thus, in the 1970s and 1980s, many patients with hemophilia became infected with hepatitis viruses and HIV through clotting factor products derived from pooled plasma.

Today, the U.S. FDA requires that most products derived from pooled plasma be further processed with heat, ultrafiltration, or chemicals (e.g., with organic solvents and detergents that inactivate lipid-coated viruses) to reduce viral infectivity. These processes essentially eliminate the risk for transmission of HIV, hepatitis B virus, and hepatitis C virus. However, some other infectious agents—in particular viruses that do not have lipid coats such as hepatitis A virus and the B19 parvovirus—may

survive the usual inactivation processes, and transmission of these agents by some pooled plasma products has been documented. Given the fact that thousands of donors are represented in each plasma pool and not all infectious agents are inactivated, the theoretical risk of transmitting some infectious agents remains higher with pooled products than with fresh products from single donors. For example, concerns have been raised regarding the potential for transmitting prions (the causative agents of spongiform encephalopathies) via pooled plasma products, although there is no evidence that such transmissions have occurred. Because of persistent concerns regarding infectivity of pooled plasma products, several human plasma proteins have been produced by recombinant DNA techniques, including clotting factors VIII, IX, and VIIa. However, these products may be expensive.

Table 91.2 illustrates the variety of plasma protein products currently available.

ROLE OF TRANSFUSION IN THE CARE OF THE HOSPITALIZED PATIENT

Indications for Use of Blood Components

Intravascular Volume Replacement

The need for volume replacement must be distinguished from the need for specific blood components. Normal blood volume is approximately 70 mL per kilogram, or 3,500 mL for an average-size female adult and 5,000 mL for an average-size male adult. Acute volume losses of 500–750 mL (10%–15%) can be tolerated in otherwise healthy persons without replacement because of sympathetically mediated vasoconstriction and increased cardiac output. Larger losses result in hypotension when cardiac output is compromised by inadequate preload. Volume replacement is typically initiated with crystalloid or colloid solutions. Blood components should be used for volume replacement only if the specific components themselves are needed. In general, red cells are the first blood component for which replacement is considered.

Replacement of Red Cells

The role of red blood cells is to carry and deliver oxygen to the tissues. Oxygen delivery is a function of blood flow and the oxygen (O_2) content of blood, as follows:

$$O_2 \text{ Delivery} = \text{Cardiac Output} \times \text{Arterial } O_2 \text{ Content}$$

where O_2 content is defined by the hemoglobin level and the oxygen saturation (expressed as a percentage) of hemoglobin. As the hemoglobin content of the blood declines, oxygen delivery is maintained through an increase in cardiac output. As noted above, this increase in cardiac output is dependent on adequate intravascular volume.

TABLE 91.2
EXAMPLES OF COMMERCIAL PLASMA PROTEIN PRODUCTS

Products	Source	Therapeutic use
Plasma substitutes		
Albumin	Human ^a	Raise oncotic pressure
Immunoglobulins		
Immune serum globulin	Human	Mitigate exposure to viruses
Intravenous IgG	Human	Immunodeficiency, therapy of immune disorders
Rh immune globulin	Immune human	Mitigate exposure to RhD antigen; treatment of ITP
Coagulation factors		
Factor VIII	Human	Factor VIII deficiency, von Willebrand's disease
	Recombinant ^b	Factor VIII deficiency
	Porcine	Treatment of factor VIII inhibitors
Factor IX complex		
Factor IX (purified)	Human	Factor IX deficiency
	Recombinant	Factor IX deficiency
Partially purified	Human	Factor IX deficiency
		Deficiency of Vitamin K-dependent factors
Activated	Human	Treatment of factor VIII inhibitors
Fibrinogen	Human	Topical fibrin adhesives
Antithrombin III	Human	AT III deficiency
Factor VIIa	Recombinant	Treatment of factor VIII or factor IX inhibitors
		Uncontrolled bleeding ^c

^a All human source products are derived from pools of plasma from thousands of donors. These donors may have been paid.

^b Recombinant products may be stabilized in human source albumin.

^c Not yet an approved indication, but anecdotally reported to be effective at times.

AT III, antithrombin III; FFP, fresh frozen plasma; ITP, idiopathic thrombocytopenic purpura; RhD, Rhesus D antigen.

When normal intravascular volume is maintained and the heart and lungs are healthy, increases in cardiac output alone have been shown to compensate for acute losses of up to three-fourths of red cells, or a reduction in hemoglobin levels to 3 g/dL. In the face of myocardial, pulmonary, or peripheral vascular disease, oxygen delivery to specific tissues becomes inadequate at hemoglobin levels well above 3 g/dL.

Several organizations have published guidelines for red cell replacement therapy (2–4). All these panels agree that reduced hemoglobin levels to 6–7 g/dL are well tolerated in otherwise healthy persons. Oxygen delivery to the myocardium becomes inadequate at hemoglobin levels between 3 and 6 g/dL. All the published practice guidelines suggest that transfusion should be given to patients with hemoglobin levels below 6 g/dL. At hemoglobin levels above 6 g/dL, the need for transfusion should be assessed on a case-by-case basis. Clinical signs, such as tachycardia or lightheadedness, may suggest the need for transfusion. In patients undergoing invasive monitoring, the finding of low levels of mixed venous oxygen (<25 mm Hg) or high levels of oxygen extraction (>50%) is objective evidence of inadequate oxygen delivery (2,3,5). However, even these measurements may not adequately assess oxygen delivery to key critical tissues, such as the myocardium. Concern has been raised that certain populations, particularly elderly patients and those with coronary artery, pulmonary, or pe-

ripheral vascular disease, may be at increased risk for adverse events with hemoglobin levels between 6 and 10 g/dL. There is some evidence that critically ill patients with ischemic heart disease may benefit from a hemoglobin of 10 or above (6, 7). However, the appropriate transfusion trigger for critically ill patients in general is not clear, as two large studies found an association of transfusion with *increased* mortality in some critically ill patients (8, 9). Thus, a more restrictive transfusion regimen (e.g., to maintain hemoglobin between 7 and 9) may be more appropriate for critically ill patients without ischemic heart disease. More studies are needed to define the risks and benefits of red cell transfusion in the critical care setting. *In summary, evidence suggests that replacement of red cells is unnecessary at hemoglobin levels above 10 g/dL and usually indicated at hemoglobin levels below 6 g/dL.* Between these levels, the need for replacement should be considered on a case-by-case basis. Red cells are usually replaced in the form of packed red blood cells. Although whole blood may be the product of choice in hypovolemic anemia, in practice it is not usually available.

Replacement of Platelets and Plasma

Table 91.2 lists available agents for the treatment of bleeding diatheses. Guidelines for the transfusion of platelets and clotting factors are discussed in detail in Chapter 98.

Granulocyte Transfusion

Granulocyte transfusion may be considered for patients with neutropenia and life-threatening infections that are not responding to antimicrobials. The therapeutic effectiveness of this treatment is controversial. Acquisition of these products is complicated by the need to prescreen donors for infectious diseases (because products must be infused immediately after collection) and the need to premedicate donors to increase their predonation white blood cell counts. Physicians considering this intervention should consult their transfusion service medical director.

Empiric Therapy of Acute Bleeding

In patients who have experienced an acute hemorrhage, the initial hemoglobin determination may not accurately reflect the degree of red cell deficiency. Empiric therapy can be based on estimated volumes lost. The general strategy is similar to that described above: the first goal should be intravascular volume replacement with crystalloid, colloid, or both. If blood loss continues after replacement of 1,500 to 2,000 mL of fluid (i.e., 30%–40% of blood volume), red cell replacement should be considered. The need for platelet and plasma transfusion should be guided by the results of laboratory testing if it is rapidly available. However, replacement of these components is generally not needed until one or two entire blood volumes have been replaced.

PRINCIPLES OF RED BLOOD CELL COMPATIBILITY

Compatibility testing is necessary for red blood cell and plasma transfusion to prevent hemolytic transfusion reactions. The most important component of compatibility testing is the determination of the ABO blood type.

ABO System

The ABO antigens are carbohydrate chains on large membrane-bound glycosphingolipid molecules, expressed on

almost all tissues of the body. The A and B antigens are produced by genetically encoded glycosyltransferases that modify the terminal sugar of the precursor O substance. These A and B antigens are similar to carbohydrates found on common bacteria, and during the first year of life all people begin to produce antibodies that cross-react with the carbohydrate A and B antigens other than those expressed by their own cells. Thus, group O persons, who express neither the A nor B antigens, produce antibodies against both A and B; group A persons produce only anti-B, and group B persons produce anti-A. These antibodies are typically of the immunoglobulin M (IgM) class and are complement fixing. If red blood cells are infused bearing the A or B antigen that the recipient lacks, these naturally occurring IgM antibodies will cause a rapid, intravascular lysis of the transfused cells, activating complement and releasing hemoglobin into the bloodstream. This *acute hemolytic transfusion reaction* can result in disseminated intravascular coagulation, shock, renal failure, and death.

Thus, if red blood cells are to be transfused safely, it is essential to type patients for their A and B antigens and provide red cells compatible with their pre-existing anti-A or anti-B IgM antibodies. Group O cells, which express neither A nor B antigens, can be safely infused into patients of any ABO type. Plasma components must also be selected for ABO compatibility; these contain the anti-A or anti-B antibodies of the plasma donor, and infusion of plasma containing anti-A or anti-B would cause hemolysis of the red cells of a recipient expressing those antigens. Table 91.3 illustrates the selection of red cell and plasma products according to donor and recipient ABO type. ABO compatibility is the most essential aspect of blood transfusion, and infusion of ABO-incompatible blood is the most common cause of fatal transfusion reactions. Most of these events are a consequence of *human error*, as when a typing specimen is obtained from the wrong patient or a unit of blood is infused into the wrong patient (Chapter 20). Therefore, we cannot overemphasize the importance of verifying the identity of the patient at the time the specimen is drawn for typing and at the time the blood is administered.

TABLE 91.3
ABO COMPATIBILITY

Patient's blood type	Antigens on RBC	Antibodies in plasma	Compatible donors	
			RBC	Plasma
A	A	Anti-B	A or O	A or AB
B	B	Anti-A	B or O	B or AB
O	None	Anti-A, anti-B	O	O, A, B, or AB
AB	A and B	None	AB, A, B, or O	AB

RBC, red blood cell.

Rhesus and Other Non-ABO Red Cell Antigens

Whereas antibodies to the A and B carbohydrate antigens are produced spontaneously, antibodies to other red cell antigens, such as Rhesus (RhD) antigen, are produced only after specific exposure to foreign red cells, either through transfusion or pregnancy. Among the non-ABO red cell antigens, RhD is the most immunogenic. About 15% of people lack the RhD antigen and are said to be “Rh-negative.” If these people are challenged with red cells bearing the RhD antigen (“Rh-positive blood”), there is a high likelihood that they will produce anti-RhD antibody. The other non-ABO red cell antigens are much less immunogenic, with antibodies produced in fewer than 5% of transfusion recipients. Antibodies to non-ABO antigens, including anti-RhD antibodies, are typically of the immunoglobulin G (IgG) class and do not fix complement. If red cells bearing the target antigen are transfused into a person who has produced one of these IgG antibodies, the antibodies bind to the transfused cells, and the survival of the antibody-coated cells is likely to be shortened because of accelerated destruction in the spleen. Non-ABO antibodies only rarely cause intravascular hemolysis. In women of childbearing age, these IgG antibodies may be of additional concern because they can cross the placenta and destroy fetal cells bearing the target antigen.

Compatibility Testing

The three components of routine compatibility testing are type, screen, and cross-match. ABO and Rh typing is performed by incubating patient red cells with anti-A, anti-B, or anti-RhD reagents, centrifuging specimens, and looking for agglutination. Because of the importance of ABO typing in transfusion, ABO type is confirmed by verifying the presence of the expected anti-A or anti-B antibodies in the patient’s plasma by incubating patient plasma with reagent cells of known ABO type. ABO/Rh typing takes approximately 10 minutes to perform.

Antibody screening is performed to detect IgG non-ABO anti-red cell antibodies. The plasma of the transfusion recipient is incubated with a panel of group O cells selected for their expression of the clinically significant non-ABO antigens to which patients may become sensitized. The binding of patient IgG to the target cells is detected by adding an anti-IgG reagent. Anti-Rh and other non-ABO antibodies are detected by this process, which takes approximately 30–45 minutes.

In patients with negative results on antibody screens, ABO/Rh-compatible cells (Table 91.3) are provided for transfusion. The only “cross-match” performed is a final check on ABO compatibility between donor and recipient. The check can be performed either electronically (by computer verification of donor and recipient ABO types) or serologically, with an “immediate spin” (IS) cross-match.

IS cross-matching is performed by incubating the patient’s plasma with donor red cells, centrifuging, and looking for agglutination. A positive IS cross-match would indicate the presence of IgM antibodies (i.e., anti-ABO) against donor cells. The completion of type, screen, and IS cross-match takes approximately one hour.

If the result of the antibody screen is positive, further testing is required to identify the specific non-ABO antigen(s) to which the patient’s IgG antibody is directed. Donor red cells that lack the target antigen(s) must then be located. Finally, compatibility between the patient’s antibodies and donor cells is verified with an “IgG serologic cross-match,” performed by incubating patient plasma with donor cells, adding an anti-IgG reagent to detect binding, and looking for agglutination. Only antigen-negative, “IgG cross-match–compatible” cells should be transfused. Antibody identification and selection of IgG cross-match–compatible cells can take 2 hours or longer.

Selection of Red Cells for Transfusion in Emergencies

Except in emergencies, transfusion should be withheld until the antibody screen is performed and compatibility is verified. *In emergencies, selection of red cells on the basis of ABO compatibility alone (Table 91.3) is sufficient for avoidance of most acute intravascular hemolytic reactions.* When feasible, RhD-negative (Rh-negative) patients are also provided with Rh-negative cellular components because of the high likelihood that these patients will produce anti-Rh antibodies after transfusion. Avoidance of Rh immunization is of particular importance in women of childbearing age. A positive antibody screen often results in a delay in providing cells for transfusion because of the additional testing required. Clinicians are urged to communicate with the transfusion service physician regarding the clinical urgency of transfusion and to discuss the relative risks and benefits of transfusion before the completion of laboratory testing.

ADVERSE EFFECTS OF TRANSFUSION

Acute Complications

Hemolytic Reactions

Acute intravascular hemolysis occurs in approximately 1 in 30,000 transfusions. This is most frequently a consequence of infusion of ABO-incompatible blood and is the most common cause of fatal transfusion reaction. Symptoms may include fever, chills, chest or back pain, and hypotension. Laboratory tests reveal hemoglobinemia, hemoglobinuria, and possibly coagulopathy. Treatment is supportive, with particular attention to hydration and diuresis to prevent renal failure. Diagnosis is based on the presence in the recipient’s plasma of free hemoglobin in

addition to antibodies that bind to the red cells from the donor unit. The result of a post-transfusion direct antiglobulin test, a test for antibody bound to red cells circulating in the recipient, may be negative if the incompatible cells were immediately lysed.

Extravascular hemolysis is caused by non-ABO red cell antibodies, including most Rh antibodies. Extravascular hemolysis may be seen if a non-ABO antibody is not detected on the pre-transfusion antibody screen. More commonly, it is caused by IgG non-ABO antibodies produced following transfusion (*delayed transfusion reaction*). Although fever may be seen, often there are no symptoms at all. Destruction of the transfused cells is usually gradual. Splenic enlargement may occur if several units of transfused cells are destroyed. Laboratory testing demonstrates serologic incompatibility of recipient plasma with the donor red cells, a falling hematocrit, and hyperbilirubinemia; results of direct antiglobulin testing are positive.

Allergic Reactions

Allergic reactions occur in up to 1% of transfusions and typically reflect the recipient's reaction to plasma in the transfused product. Symptoms usually are limited to urticarial rash. Reactions may recur with subsequent transfusions, but the severity does not usually increase with time. Symptoms can often be reduced by pretreatment of the recipient with antihistamines. Rarely, systemic anaphylactic reactions can occur, often in patients with no prior history of reaction (Chapter 120). The majority of anaphylactic reactions have no identifiable cause, although some are caused by anti-IgA antibodies in patients with IgA deficiency. Transfusion of plasma should be avoided in patients with a history of anaphylactic transfusion reactions, and for these patients, red cell and platelet products should be thoroughly washed with saline solution to remove plasma before infusion.

Febrile Reactions

Fever occurring during or immediately after infusion may indicate an acute hemolytic reaction, but more often it reflects a nonhemolytic reaction mediated by white blood cells and their metabolic products. Febrile nonhemolytic reactions are associated with up to 1% of red cell transfusions and with a much higher proportion of platelet transfusions. Symptoms may include fever, chills, flushing, nausea and vomiting, hypertension, and, rarely, shortness of breath. Febrile nonhemolytic reactions are frequently caused by the binding of antibodies in the transfusion recipient to white blood cells in the transfused product. These reactions can be minimized by the use of leukocyte-reduced blood products. Febrile nonhemolytic reactions to platelet products may also be caused by cytokines produced *in vitro* by white blood cells in the platelet products. Leukocyte reduction of platelet products before storage or

removal of product supernatant immediately before infusion may reduce the number of febrile nonhemolytic reactions associated with these products. Rarely, anti-white cell antibodies of donor origin, present in the plasma of a transfused product, can cause febrile nonhemolytic reactions or cytokine-mediated pulmonary edema (*transfusion-related acute lung injury*) in a transfusion recipient.

Bacterial Contamination

Fever at the time of, or shortly after, transfusion may indicate bacterial contamination of the blood product. The presence of asymptomatic bacteremia in a blood donor or of donor skin flora at the phlebotomy site can result in the contamination of blood products. Low-level contamination with bacteria, most commonly nonvirulent skin flora, is found in approximately 1 in 5,000 blood products. Rarely, contaminating organisms multiply to a significant extent during storage of the blood product, especially platelet products, which are stored at room temperature rather than in the refrigerator. Fever resulting from bacterial contamination is reported to occur with infusion of 1 in 10,000 platelet concentrates and 1 in 30,000 red cell units. Rarely, infusion of bacterially contaminated red cells or platelets can cause sepsis, endotoxin-mediated shock, or even death. The small numbers of bacteria that may be present in blood products on the day of collection cannot be detected by currently available technology. Recently implemented processes that detect bacteria in platelet products after 24 hours of storage can interdict at least some contaminated products.

Complications Related to Large or Rapid Transfusions

The infusion of multiple units of blood or plasma can result in volume overload and pulmonary edema. The rapid infusion of large volumes of blood can also cause acute metabolic complications, including transient hypocalcemia (a consequence of the binding of free calcium by the citrate anticoagulant), hyperkalemia (resulting from the presence of free potassium in the supernatant of stored red cells), and hypothermia (related to infusion of large volumes of refrigerated blood). These metabolic complications are not generally encountered except in the setting of trauma or surgery.

Other Immunologic Complications of Transfusion

Approximately 30% of multiply transfused patients become immunized to HLA antigens expressed on white cells and platelets. Anti-HLA antibodies may cause refractoriness to platelet transfusion and febrile nonhemolytic transfusion reactions. HLA allo-immunization can be prevented or delayed by the prophylactic use of leukocyte-reduced blood

products. Other immunologic effects may include transfusion-related immunosuppression. Several authors have suggested an association between transfusion and an increased risk of cancer recurrence, postoperative infection, or activation of endogenous viruses such as HIV and cytomegalovirus. However, these effects have not been conclusively demonstrated. Rarely, white blood cells from the transfused product can engraft in the recipient and cause graft-versus-host disease.

Viral Infections Transmitted by Transfusion

HIV and Hepatitis

The risk for transmitting hepatitis or HIV viruses by transfusion is now extremely low. Blood donors are screened with explicit questioning to identify previous exposure to these viruses or a history of activities that increase their risk for exposure to blood-borne or sexually transmitted disease. Risk activities that blood banks must inquire about are defined by the U.S. Public Health Service and the FDA and are revised periodically based on epidemiologic investigation. Blood may be drawn only from persons who pass questioning. Questioning alone eliminates approximately 90% of virally infected potential donors. All blood that is collected then undergoes a panel of serologic tests mandated by the FDA. Table 91.4 shows a list of the tests currently performed on donated blood. Only blood that passes both questioning and testing can be used for transfusion.

The combined effectiveness of donor questioning and testing is so high that the risk for transmitting hepatitis virus or HIV by transfusion is too small to be measured accurately by prospective studies. Estimated risk has been calculated by using epidemiologic models (10, 11). The majority of disease transmissions are thought to be caused

TABLE 91.4
DONOR SCREENING TESTS FOR INFECTIOUS DISEASE (UNITED STATES)

Agent	Donors tested for
HIV	Antibody to HIV-1 and HIV-2 ^a HIV-1 nucleic acid ^b
Hepatitis B	Antibody to hepatitis B core antigen ^a Hepatitis B surface antigen
Hepatitis C	Antibody to hepatitis C ^c HCV nucleic acid ^b
HTLV	Antibody to HTLV-I and HTLV-II ^c
Syphilis	RPR or anti-treponemal antibody

^a Test detects both IgM and IgG antibodies.

^b Test may be performed on pooled specimens from 16–24 donors.

^c Test detects only IgG antibodies.

HTLV, human T-cell lymphotropic virus; RPR, rapid plasma reagin.

TABLE 91.5
RATES OF VIRAL TRANSMISSION BY TRANSFUSION OF SCREENED BLOOD

	Estimated risk of transmission (per unit transfused)
Human immunodeficiency virus	1/1,779,000
Hepatitis C virus	1/1,613,000
Hepatitis B virus	1/171,000
Human T-cell lymphotropic virus	1/428,000

Estimates are based on Dodd et al. (10), adjusted as recommended by Glynn et al. (11) to reflect a mix of 80% repeat donors and 20% first-time donors with a two-fold increased incidence of new infections in first-time donors.

when blood from donors recently exposed to infectious agents but whose test results have not yet become positive (so-called window-period donations) is transfused. Recent introduction of donor screening tests that detect HCV and HIV nucleic acid has shortened the estimated window period for these agents to 10–11 days. These highly sensitive donor screening tests, combined with the low incidence of infections in the blood donor population, are responsible for the extremely low estimated risks of transfusion-transmitted viral infection today (Table 91.5).

Cytomegalovirus

This common virus can cause severe morbidity in premature or unborn infants and in patients who are immunodeficient, immunosuppressed, or have had their spleens removed. Patients previously unexposed to this virus (CMV-seronegative) should be protected from transfusion transmission of the virus by the use of blood obtained from CMV antibody-negative blood donors. Extensive leukocyte reduction also appears effective in reducing the CMV infectivity of blood components.

Other Agents

Any agent found in the blood of an apparently healthy blood donor can be transmitted by transfusion. Parasites have only rarely been reported to be transmitted by transfusion in the United States, where there is currently no blood donor testing for parasitic infection. Up to three cases of transfusion-transmitted malaria occur in the United States each year. Recent studies show that approximately 1 in 10,000 U.S. blood donors is infected with *Trypanosoma cruzi*, the parasite that causes Chagas disease, but transfusion transmission of this infection appears to be rare. Transfusion transmission of the intraerythrocytic

parasite *Babesia* may be much more common. Investigational testing for West Nile virus (WNV) RNA was implemented in 2003 following documented transmission of this agent during the 2002 epidemic. Concern about transmission of other infectious agents, such as new retroviruses or prions, has also been raised. The AIDS epidemic generated a heightened awareness of the importance of maintaining surveillance for new emerging pathogens and of continually assessing the need for additional donor testing or blood product processing. Additional nucleic acid-based donor screening tests and/or processes that inactivate residual pathogens in blood products are likely to be used in the future.

Transfusion Options

Autologous Blood

Autologous blood is blood collected from patients and retained for their own use. In general, this is the safest transfusion option because it eliminates the potential for transmission of viral infection and for most transfusion reactions. The benefits of autologous transfusion are limited by the extremely low risk for transmission of viral disease associated with allogeneic blood transfusions and by the high likelihood that many patients will die of their underlying disease before a transfusion-transmitted virus will become clinically manifest. The cost of autologous collection strategies must be weighed against the limited benefits. Analyses suggest that autologous transfusion is most cost effective in the youngest patients (12). In some patients, the risks of autologous collection and transfusion may outweigh the potential benefits; examples include patients who are too ill to tolerate the donation process safely or patients with bacterial infections whose products may be contaminated.

Designated (Directed) Donations

Some patients request that their friends or relatives donate blood products specifically for their use. These so-called designated or directed donors must pass all the same questions and tests that volunteer community donors do. The rates of infectious disease markers in directed donations are not lower than those in donations from volunteer community donors. On the contrary, there is a concern that directed donations are potentially *less* safe because such donors might be more reluctant to admit to risky behaviors that could result in the deferral of their donation. Patients who ask friends and relatives to donate may actually compromise their own safety if they put undue pressure on these people to donate. Blood components from designated donations are usually released for general transfusion if not needed by the intended recipient. All directed donations from blood relatives of the recipient must un-

dergo gamma irradiation to prevent transfusion-related graft-versus-host disease.

COST CONSIDERATIONS IN TRANSFUSION MEDICINE

Since the mid-1980s, public fears of transfusion-transmitted HIV have fueled an increase in government regulation of the blood industry, the application of many additional donor screening tests, and the commercial production of recombinant and virally inactivated plasma protein products. This has dramatically increased the safety of blood but also has raised the cost of blood products. Today, the acquisition cost of leukocyte-reduced red blood cells is \$200–\$300 per unit. Irradiation adds further costs to each product. Commercial products can cost thousands of dollars per dose. Blood products constitute a significant proportion of the total operating costs of hospitals. Therefore, cost containment considerations, as well as risk-versus-benefit concerns, often enter into discussions of transfusion guidelines. The general guideline of “using only what is necessary” is, of course, applicable. In addition, however, the cost effectiveness of expensive options such as autologous, designated, recombinant, or pathogen-inactivated products should be evaluated rationally.

CONCLUSIONS

Although blood transfusions continue to save many lives, the field of transfusion medicine has changed dramatically in recent years. Concern in the 1980s about transfusion-related infection led to stricter guidelines regarding indications for transfusion, such that transfusions are now recommended only when absolutely necessary. Similar safety concerns catalyzed the addition of a number of mandatory blood screening procedures, including assays for the presence of selected infectious agents, so that the incidence of life-threatening transfusion-related infections is now extremely low. New methods for preparing blood products, including genetic engineering and viral inactivation technologies, have led to the availability of numerous alternative forms of blood products with improved potency and safety, but almost all these products are substantially more expensive than standard blood components. Therefore, when considering transfusion alternatives, physicians must carefully weigh both benefits and costs.

KEY POINTS

- The need for volume replacement should be distinguished from the need for blood components.
- In cases of acute bleeding, red cells are the first blood component to be considered for replacement.

- Red cell transfusion is usually indicated in patients with hemoglobin levels below 6 g/dL and is usually not indicated in patients with hemoglobin levels above 10 g/dL. In patients with hemoglobin levels between 6 and 10 g/dL, the need for transfusion of red cells should be assessed on a case-by-case basis.
- The risk for transmission of known viral agents by fresh blood components is now extremely low.
- Recombinant plasma proteins may be safer than pooled plasma products but may also be extremely expensive.
- The cost effectiveness of transfusion options such as autologous donation is limited by the extremely low risk for transmission of viral disease by allogeneic blood components.

Oncologic Emergencies

92

Judith A. Luce

INTRODUCTION

Cancer is a common disease and a common cause of hospitalization for adults. Health care expenses for patients having cancer are usually concentrated in the last few months of life, when quality of life is declining and the utility of hospital-based interventions may also be declining. Therefore, it is important that physicians evaluating cancer patients with acute, potentially life-threatening complications carefully consider the context in which these complications present. What is the patient's short and long-term prognosis? What are the patient's wishes for the final days of life? What alternatives remain for systemic and local treatment of the patient's problems? Is it medically appropriate to treat the problem or not? The optimum approach to these complex questions usually involves consultation with a multidisciplinary management team.

In most adult patients who present with oncologic emergencies, cancer has already been diagnosed. Initial presentations with the entities discussed in this chapter are relatively uncommon, however, the cancers most likely to cause these emergencies will be emphasized in order to guide the physician who needs to make a tissue diagnosis prior to initiating specific cancer-directed therapy. There is little cost-effectiveness and outcomes research regarding the treatment of oncologic emergencies. Therefore, implementing many of the recommendations made in this chapter depends on the status of individual patients. Ambulatory, well-supported patients with access to transportation and home care may receive treatment for many of these conditions with minimal or no hospitalization. Others require hospitalization to enforce bed rest or to ensure compliance with more complex therapies or observation of evolving problems such as neurologic symptoms. Clinical judgment is of paramount importance.

This chapter covers cancer-related neurologic conditions, pericardial effusion, superior vena cava syndrome, and hypercalcemia. Infections in the immunocompromised host

are covered in Chapter 63, and the tumor lysis syndrome is reviewed in Chapter 94. When found early, these conditions are often not truly emergencies, and the evaluation and treatment can be carried out over several days. Even when discovered very late, they may not be emergencies. For example, neurologic injury may have progressed to the point at which no intervention can restore function. The patients for whom time is of the greatest importance are those whose symptoms are severe but of very brief duration. Rapid reversal within hours may result in an outcome that restores function, and delays may be critical.

NEUROLOGIC EMERGENCIES

Issues at the Time of Admission

Clinical Presentation

There are three cancer-related neurologic conditions that may be regarded as emergencies: metastases to the brain, spinal cord compression, and meningeal carcinomatosis. Cerebral metastases are common, occurring in up to half of all patients with cancer at the time of autopsy; the highest rates occur in hematogenously disseminated cancers. Breast cancer and lung cancer are the most common causes of central nervous system (CNS) metastases, but the diagnosis should also be considered in advanced melanoma, renal cell carcinoma, rectal cancer, and gastric cancer. As many as one-fourth of patients with advanced cancer develop symptomatic CNS disease.

Cerebral metastases may present with focal CNS deficits, with global changes in mentation or behavior, or with seizures. Headache, nausea, and dizziness are nonspecific symptoms; difficulties with memory and other subtle signs of CNS dysfunction may occur. Seizures are most common in patients having multiple metastases, particularly to the frontal lobe, and are rare in patients with lesions in the posterior fossa.

Meningeal carcinomatosis may similarly present non-specifically with nausea, headache, mentation difficulties, or with seizures. A classic presentation is the presence of asymmetric radiculopathy (lower motor neuron deficit) of the cranial nerves and peripheral nerves. This presentation may be quite rapid in onset and variable in severity. Meningeal carcinomatosis occurs most often in breast and lung cancer and in cancers with involvement of the vertebral bodies and retroperitoneum. Non-Hodgkin's lymphoma and leukemia may also involve the meninges, especially in advanced or relapsing disease. Meningeal carcinomatosis occurs in fewer than 5% of cancer patients.

Meningeal involvement must be distinguished from *spinal cord compression*, which may also present with radiculopathy that is asymmetric; however, spinal cord compression does not involve cranial nerves and may also be accompanied by a sensory deficit. The most florid manifestation of spinal cord compression is myelopathy, which consists of sensory and motor loss below a specific spinal level, accompanied by bowel and bladder dysfunction. Back pain is an almost universal feature of spinal cord compression, but is rare in meningeal carcinomatosis. Most spinal cord compression occurs in the thoracic spine (70%), but *cauda equina syndrome* may result when the compression occurs in the lumbar spine. The most common causes of spinal cord compression are breast cancer, prostate cancer, lung cancer, and lymphoma. Spinal cord compression may occur in as many as 8% of patients with prostate cancer, and slightly fewer with lung or breast cancer. Spinal cord compression develops in approximately 20% of patients with spread of cancer to the vertebral bodies.

Differential Diagnosis and Evaluation

Newly onset back pain in a patient having known metastatic cancer should trigger an evaluation for spinal cord compression. Evaluation of new back pain in patients with known vertebral metastases results in a diagnosis of cord compression in about 30% of patients with normal neurologic findings. If the neurologic examination is normal and the pain is not severe, investigation can take place on an outpatient basis, and should begin with a bone scan and spinal radiography. The positive predictive value of abnormal bone scan is at least 40%, and the positive predictive value of abnormal spine x-rays much higher.

The presence of *any* neurologic finding should prompt performance of an MRI of the entire spine. All regions should be imaged to rule out multiple synchronous metastases, which may occur in as many as half of patients with spinal cord compression. Benign fracture, disc disease, abscess, and hematoma may be in the differential diagnosis, and are usually readily distinguishable from cancer by an MRI. MRI imaging is also a critical prelude to radiation therapy treatment planning. Thus, this test must be performed even when the physical examination, bone scan, and plain radiographic findings are diagnostic.

Because of the overlap between the presentation of CNS metastases and meningeal carcinomatosis, patients with both presentations are usually first evaluated with an MRI, which is the evaluation of choice for patients for whom the suspicion is high for either condition. Computed tomography (CT) is insensitive for the detection of meningeal changes, and an MRI can detect CNS metastases smaller than those seen on CT, thus potentially altering the treatment plan.

The definitive diagnosis of meningeal carcinomatosis involves large-volume lumbar puncture and CSF cytology. Obtaining up to three large volume specimens (at least 5 mL) will provide a diagnosis in the vast majority of patients. Abnormalities such as low glucose and high protein levels may be seen but are not diagnostic; cell counts are not helpful unless other causes of meningitis are in the differential diagnosis.

Some patients who present with neurologic emergencies may require staging of the cancer in order to make therapy decisions. This is particularly true if this is the first sign of metastatic disease or the first diagnosis of cancer. Other patients may require formal evaluation of spinal stability by a neurosurgeon or orthopedic surgeon, or formal consideration of surgical intervention (Table 92.1).

Indications for Hospitalization

Clear indications for hospitalization are listed in Table 92.2. Patients with minimal neurologic injury who are capable of self-care and whose symptoms are not rapidly evolving may be evaluated and treated as outpatients, as long as the evaluation will take place rapidly and therapy is initiated within a few days. However, most patients are admitted because evaluation is usually faster in the inpa-

TABLE 92.1
WHEN TO CALL THE NEUROSURGEON IN NEUROLOGIC EMERGENCIES

No tissue diagnosis available: needs biopsy
Possible resection of <i>solitary</i> CNS metastasis
Slow paced cancer
Primary site controlled or readily controllable
Low likelihood of significant neurologic injury due to resection
No other contraindications to craniotomy
CNS metastases, treatable cancer, evidence of imminent herniation
Cord compression, treatable cancer, rapid onset of severe neurologic injury (within hours)
Cord compression, unstable spine with potential for good functional outcome
Progression during radiation therapy and otherwise good prognosis
Previous radiation therapy, local recurrence with otherwise good prognosis
Need for insertion of Ommaya reservoir for intrathecal therapy of meningeal disease

TABLE 92.2
INDICATIONS FOR HOSPITALIZATION
FOR NEUROLOGIC EMERGENCIES

Rapidly evolving neurologic changes, including seizures
 Severe neurologic injury of recent onset
 Inability to perform self-care at home
 Unstable spine

tient setting and the necessary consultations may be obtained rapidly. Intensive care unit admission is necessary for neurological monitoring if the neurologic status is evolving and the patient has not expressed wishes to the contrary.

Initial Therapy

The mainstay of therapy for patients with neurologic emergencies is bedrest and careful nursing observation. Patients who are not ambulatory will require precautions for thrombosis, urinary retention, decubitus ulcers, and contractures. Patients who are ambulatory but who have had rapid progression of symptoms may require frequent monitoring of neurologic vital signs. Patients who have known or suspected spinal cord compression must remain at bedrest until spinal stability has been established, symptoms are not worsening, and pain has been appropriately managed. All patients require evaluation by physical and occupational therapy for treatment of functional problems.

Steroids have been shown to be effective initial therapy for CNS metastases, which are often accompanied by considerable surrounding edema. The usual drug is dexamethasone at a dose of 4 mg either orally or intravenously every six hours. The utility of a loading dose or higher doses has not been proven by clinical trials, but higher doses may be necessary in patients on diphenylhydantoin because of the associated accelerated metabolism of dexamethasone.

One clinical trial found no additional efficacy for total dexamethasone doses above 4 mg daily (1). Dexamethasone can produce rapid neurologic improvement in up to half of patients; this is generally regarded as a favorable sign for potential neurologic recovery. The use of mannitol or other drugs aimed at reducing intracranial pressure has not been demonstrated to be beneficial. Management of patients without steroids is possible if there is little or no cerebral edema, but the preponderance of evidence suggests that steroid-treated patients have better neurologic outcomes.

Dexamethasone may be of benefit to patients with spinal cord compression, although this has not been proven (2). Dexamethasone is of no benefit to patients with meningeal carcinomatosis. Prolonged dexamethasone therapy should be accompanied by chemoprophylaxis for *Pneumocystis jirovecii* (formerly *P. carinii*) pneumonia to prevent this opportunistic infection. All patients who present with seizures or who undergo resection of their CNS tumors should receive anti-seizure therapy, but prophylaxis for seizures is controversial, especially in low-risk patients.

Radiation therapy is the mainstay of treatment of patients with spinal cord compression and cerebral metastases. Spinal cord radiation is usually performed as multiple fractional doses to a wide area surrounding the site of compression. CNS radiation therapy may be administered as whole brain radiation in fractionated doses or as localized treatment of metastases (called stereotactic radiosurgery [or "gamma knife"]), either alone or combined with whole brain radiation. Patients who are eligible for the stereotactic approach are those with potential for longer survival (Table 92.3), and with less than 5–6 metastases, none larger than 3 cm in diameter. The indications for either approach have not yet been standardized, and controversy remains about whether the functional outcomes are better with one or the other (3, 4).

Some cases of spinal cord compression may be successfully treated with *systemic therapy*. Previously untreated small cell lung carcinoma and non-Hodgkin's lymphoma have been shown to respond well to chemotherapy as

TABLE 92.3
PROGNOSTIC INDICATORS AND SURVIVAL IN PATIENTS WITH
CEREBRAL METASTASES TREATED WITH RADIATION THERAPY (6)

Class	Performance status ^a	Age	Primary tumor controlled?	Other mets?	Median survival, months
1	≥70%	<65	Yes	No	7–10 months
2	≥70%	>65	Or not controlled	No or yes	4–6 months
3a	≤70%	<65	Yes	No	6–8 months
3b	≤70%	>65	Or not controlled	No or yes	1.5–3 months

^aPerformance status: >70% is out of bed, ambulatory, capable of self-care without assistance, though not working.
 Mets, metastases.

initial treatment. As adjuncts to radiation therapy, hormone therapies may be used for breast and prostate cancer patients. Prostate cancer patients without prior hormone therapy benefit from treatment. However, only orchiectomy or high-dose ketoconazole (800–1200 mg orally per day) produce sufficiently rapid responses to help patients with acute cord compression. Primary CNS lymphoma is treated first with chemotherapy (the regimens usually include high-dose methotrexate) prior to considering irradiation. Oral chemotherapy with temozolomide may benefit certain patients with symptomatic CNS or meningeal metastases who have failed previous radiation therapy (5).

Meningeal carcinomatosis is treated with radiation therapy to the site of greatest involvement—the whole brain if cranial neuropathies are present, or on the spinal cord if peripheral radiculopathy is the presenting problem. Total cranial and spinal irradiation is not usually performed because of marrow suppression. In addition to radiation therapy, *intrathecal chemotherapy* is administered, usually through a ventricular Ommaya reservoir. Placement of this device by neurosurgeons through a burr hole in the skull is a low-risk procedure that is well tolerated by most patients. Chemotherapy is placed in the reservoir two or three times weekly until cytology of the CSF shows either no response or clearance of malignant cells. The complications of an Ommaya reservoir include infection and meningeal irritation. Although chemotherapy may also be administered through repeated lumbar punctures, this is less well tolerated and less likely to ensure even distribution of the cytotoxic drugs.

Indications for Early Consultation

Oncology consultation is essential to making the critical early decisions about whether and how to treat patients with neurologic emergencies. Many patients who are at risk for oncologic emergencies are already under the care of an oncologist, and the oncologist will order and administer chemotherapy for appropriate patients with neurologic emergencies. Radiation therapy consultation is appropriate for nearly all patients with neurologic emergencies, because even if surgical resection is undertaken, it will usually be followed by consolidation radiation therapy unless the patient has already received radiotherapy. The indications for neurosurgical intervention are listed in Table 92.1. Physical and occupational therapy consultations are also needed in most patients with neurologic signs and symptoms.

Issues During the Course of Hospitalization

Neurologic signs or symptoms may progress while patients are undergoing treatment. When the spinal cord is compressed, the most widely accepted surgical therapy is posterior decompression by laminectomy. This is usually well tolerated and successful if the underlying neurologic injury

is mild or very recent. Neurosurgical intervention to decompress the brain in patients with threatened herniation or to relieve symptoms of hydrocephalus in patients with meningeal disease is controversial and much less likely to result in good quality of life. Hemorrhage into vascular CNS tumors may also occur during treatment, and is usually not treatable. During the early phases of treatment, the patient's neurologic status should be monitored. In the event of deterioration, patients should be promptly re-imaged.

The treatment of spine instability is another complex issue that may arise during hospitalization. If bony destruction by tumor has progressed to render ambulation unsafe, a procedure to stabilize the spine must be considered. Generally, one of two approaches is employed: definitive attempts to provide long-term stability with bone grafts and other mechanical devices, or less invasive surgeries using methacrylate and external appliances to attempt short term stabilization. Some procedures combine these strategies, and the precise procedure should be determined by the expertise of the consulting surgeon and the precise nature of the lesion. However, all of these surgeries are more complex than laminectomy for decompression. Stabilization requires an anterior approach; for the thoracic spine it requires thoracotomy. Whether these procedures are appropriate or will be tolerated by the patient is a decision that must be made by a multidisciplinary team in consultation with patients and their families.

Complications of steroid therapy and of bedrest, and loss of neurologic function and performance status, frequently arise during treatment of neurologic emergencies. Most of these should be treated the same as in a patient without cancer. One major exception might be the use of aggressive supportive measures such as feeding tubes, which requires discussion with patients and their families regarding the overall aims of end-of-life support (Chapter 19). Radiation therapy to the thoracic spine and cervical spine is usually accompanied by transient esophagitis; radiation therapy to the lumbar spine may be accompanied by nausea, diarrhea, and abdominal pain.

Discharge Issues

Patients with spinal stability and stable neurologic signs and symptoms may be discharged home to complete their radiation therapy as outpatients. Physical therapy, occupational therapy, and home nursing support may be offered to patients for whom the potential for rehabilitation is good. Hospice referral should be considered in appropriate patients. Ambulation status at the time of admission is the single most important predictor of post-discharge neurologic status. Those who are ambulatory at the time of diagnosis tend to remain that way, and those who are not have a varied, but markedly less favorable, outcome.

Survival following neurologic emergencies is generally short. Patients with previously untreated (but highly treatable) cancers have the best survival rates and neurologic

outcomes. For spinal cord compression, these patients are those with newly diagnosed small cell lung cancer, breast cancer, and prostate cancer, as well as those with Hodgkin's or non-Hodgkin's lymphomas. Neurologic outcomes are good with chemotherapy alone in patients with small cell lung cancer and lymphomas, although radiation therapy may also be given. Pain relief should be achievable, even for less treatable cancers. Patients may have recurrence at a previously treated site if their cancer recurs. This occurs in about half of the patients with metastatic prostate cancer, at an average of approximately 2 years. Survival is shorter in patients with paraplegia and incontinence, and longer for ambulatory patients and patients with only a single site of vertebral metastasis.

Survival data for CNS metastases treated with radiation therapy, with or without surgery, have been reported in several large patient series (Table 92.3) (6). Patients with solitary (without systemic disease) cerebral metastases who have undergone resection and irradiation have a median survival of more than a year. Patients for whom surgery is not possible have an average survival of 6 months, and relatively high rates of recurrence of neurologic symptoms. The outcomes are very dependent on the age of the patient and the severity of neurologic symptoms. Less radiation-responsive tumors have the poorest survival, and there is little evidence that radiation therapy enhances survival in patients with such tumors.

Meningeal carcinomatosis has the worst prognosis of all: only a few months for patients with treatable malignancies, and a few weeks for patients with tumors that generally do not respond well to intrathecal chemotherapy. Patients with leukemia or lymphoma have the best outcomes, followed by patients with small cell lung cancer and breast cancer. Others have very poor short-term prognoses.

PERICARDIAL EFFUSION AND TAMPONADE

Issues at the Time of Admission

Clinical Presentation

The presentation of pericardial tamponade in cancer patients is quite varied (the entity of tamponade is described more fully in Chapter 46; this section focuses on malignant pericardial disease). The classic findings of Kussmaul's sign, narrow pulse pressure, pulsus paradoxus and ECG findings of low voltage may be present. However, tamponade in cancer patients may also present as left- or right-sided heart failure, or with more subtle findings including fatigue, dyspnea, failure to thrive, and hiccups. Chest pressure, anxiety, and dyspnea may lead to a suspicion of coronary ischemia. Patients may even complain of upper gastrointestinal symptoms. Suspicion may be raised only by an enlarging cardiac silhouette on a chest x-ray.

These protean manifestations are part of the reason that pericardial disease in cancer patients is diagnosed more often post-mortem than in life.

Differential Diagnosis

Patients who have received mediastinal radiation therapy have a significant risk of benign pericardial inflammation, especially if 4,000 or more cGy have been delivered to a considerable area of the heart. Pericarditis may be acute, appearing during or immediately after the treatment; or chronic, with a delay of a few months to many years. Viral and bacterial causes of pericarditis should be considered, especially in immunosuppressed patients. The possibility of constrictive pericarditis due to fungal or mycobacterial organisms should be entertained in the appropriate risk groups.

The initial step in the diagnosis of pericardial effusion and tamponade is echocardiography. This may demonstrate thickened pericardium and pericardial fluid. Signs of tamponade physiology, including paradoxical septal motion, right atrial collapse, and low stroke volumes, should be sought. Pericardiocentesis should be performed at the time of initial echocardiography, especially if the patient is hemodynamically compromised (see Chapter 46). CT or MRI scanning of the thorax may assist in the diagnosis but should not be done in preference to echocardiography (7).

The definitive diagnosis rests in part on the clinical circumstances and in part on the pericardial fluid cytology. Patients with bulky thoracic tumors or extensive mediastinal involvement who have not had previous irradiation and who lack evidence of infection are highly likely to have malignant pericardial effusion, even if the first fluid cytology is not diagnostic. The fluid in malignant pericardial disease is often bloody. Because cytology is relatively insensitive, if the first sample is negative and there is reason to question the diagnosis, repeat pericardiocentesis should be performed.

Indications for Early Consultation

Cardiology consultation should be part of the initial evaluation of patients with confirmed or suspected pericardial tamponade, while hemodynamically compromised patients require CCU admission. Thoracic surgery consultation may be necessary if patients have failed initial therapy or have evidence of pericardial constriction (see the section on "Treatment" below).

Issues During the Course of Hospitalization

Treatment

There are many choices for treatment of pericardial tamponade, as shown in Table 92.4. Needle drainage and catheter drainage are the most common initial steps, and are

TABLE 92.4
SURGICAL TECHNIQUES FOR
TREATMENT OF MALIGNANT
PERICARDIAL EFFUSION

Catheter drainage
One-time; removed the same day
Simple catheter drainage until “dry”
Catheter drainage with sclerosis
Catheter drainage with repeated sclerosis
Percutaneous balloon catheter pericardiectomy
Subxiphoid pericardiectomy
Thoracotomy with
Pericardial “window”
Pericardiectomy

generally successful in restoring hemodynamic function. For the majority of patients, a single drainage procedure is sufficient to resolve the problem, and it does not recur (8). Some clinicians routinely use a sclerosing agent, usually doxycycline, at the end of the initial drainage. However, sclerosis is quite painful and may not be necessary. Sclerosis with chemotherapy or radiopharmaceuticals is a great deal more expensive and has not been shown to be superior to no sclerosis or doxycycline. Pericardial catheters are usually not left in longer than about 72 hours because of the risk of infection. Drainage with or without sclerosis is the least costly approach to malignant pericardial effusion (8).

If more than 20–25 mL of fluid continue to drain from a pericardial catheter daily, or if the fluid reaccumulates rapidly, a more definitive drainage procedure should be considered. The most common of these is subxiphoid pericardiectomy, a surgical procedure in which the pericardium is opened inferiorly and drained into the peritoneal cavity through the membranous portion of the diaphragm. This procedure is minimally invasive; it is usually performed using a percutaneous balloon catheter, although a minimally invasive surgical technique is also available.

Thoracotomy and surgical “window” placement or pericardial stripping may be offered to selected patients who are not only able to tolerate a much more invasive procedure but who are also reasonably likely to have enough quality of life remaining to benefit from such surgery. Patients with constrictive pericarditis may be candidates for such a procedure. The rare patient who fails subxiphoid drainage may also benefit.

After the initial drainage procedure, local or systemic therapy may be used to resolve pericardial effusion and tamponade. Cancers for which effective therapy exists are usually treated in this manner. Radiation therapy may be used to a limited extent in previously untreated patients. Most healthy hearts will tolerate 1,800–2,500 cGy, and this dose may allow some patients with responsive diseases to remain asymptomatic. Other supportive measures are similar to those for patients having benign pericardial tamponade.

Discharge Issues

Patients who are hemodynamically stable and have undergone the final therapeutic maneuver may be discharged home. Those who are well enough to be sent home should be followed by visiting nurses until it is clear that pericardial fluid is not rapidly reaccumulating and hemodynamic compromise reoccurring. Nursing facility or hospice placement may be an option for patients who have no further intervention planned.

The prognosis of patients with pericardial effusion and tamponade depends on their underlying disease. Patients with treatable cancers such as lymphoma usually enjoy a relatively long survival. The exception is HIV-infected patients with primary effusion lymphomas who present with tamponade. Most solid tumors are bulky and at a terminal stage when tamponade occurs; survival times are very short, usually less than 6 months.

Appropriate follow-up of patients who have had an episode of tamponade is difficult. Since many of these patients are very close to the end of their lives, further testing for recurrence may not be appropriate. On the other hand, vigorous, active patients may wish to have echocardiographic follow-up in order to avoid emergency hospitalization. These decisions must be made individually, since there are few data to provide guidelines.

SUPERIOR VENA CAVA SYNDROME

Issues at the Time of Admission

Clinical Presentation

Superior vena cava syndrome (SVCS) is the oncologic emergency most likely to be the first symptom of cancer. As many as half of the patients with SVCS do not have a pre-existing cancer diagnosis. SVCS is a clinical diagnosis. Patients complain of dyspnea, and present with facial and upper extremity swelling. Occasionally, patients may complain of cough, chest tightness, or other symptoms caused by the tumor in the thorax. Physical findings typically consist of venous distention across the upper chest and neck, facial edema and plethora. Arm edema is present in approximately 15% of patients. Patients may have other physical findings caused by the mass within the thorax, including signs of airway obstruction, pleural effusion, or volume loss.

Differential Diagnosis

SVCS is usually due to cancer in the modern era, but non-malignant causes are still found in about 15% of patients. Thrombosis around central lines is a common event that may cause SVCS. Histoplasmosis and other chronic inflammatory diseases cause the remainder of the benign cases.

Most cases of malignant SVCS are caused by lung cancer, usually small cell lung cancer. It has been estimated that SVCS occurs in more than 20% of patients with small cell lung cancer. Non-Hodgkin's lymphomas account for 7%–10% of cases of SVCS, and breast cancer for another 10%. Rare causes include germ cell tumors of the mediastinum, thymoma, and Hodgkin's disease.

Chest x-rays are abnormal in 85% of cases of SVCS. Superior mediastinal widening is seen in the majority of cases, and right hilar mass or pleural effusions are common findings. Anterior mediastinal mass should be a clue to thymoma, lymphoma, or germ cell tumor. Cardiomegaly is occasionally seen.

CT of the thorax is the most important diagnostic tool. In addition to demonstrating the anatomy of SVCS, it accurately guides both biopsy and radiation therapy. MRI is not clearly superior to CT for this purpose and is much less widely used.

Because SVCS is often the first sign of cancer, priority should be given to making a tissue diagnosis. Sputum cytology and fine needle aspiration are the most commonly used and highest yield techniques. The yield of sputum cytology in suspected lung cancer might be as high as 50%. Lymph nodes in the supraclavicular and axillary areas should be sought; fine needle aspiration biopsy of these is useful when they are present. If pleural effusion is present, thoracentesis may produce a histologic diagnosis. Bronchoscopy can be safely performed if the patient is suspected of having lung cancer, and has a high yield in SVCS (about 50%).

If these less invasive procedures are not helpful diagnostically, it may be necessary to obtain tissue from within the thorax. The safest technique is CT-guided fine needle aspiration biopsy. Either mediastinoscopy or limited anterior thoracotomy can be safe and highly effective ways to establish a diagnosis. Neither procedure is associated with a significant increase in serious complications in patients with SVCS, although rare patients do require additional surgical intervention.

Although as many as half of all patients with SVCS have some thrombus in association with the obstruction to blood flow, the identification of thrombus is of no clinical or therapeutic significance (see the section on "Issues During the Course of Hospitalization" below). Venography may be performed as part of the evaluation to identify candidates for vascular stenting.

Initial Therapy

Routine care of patients with SVCS includes bed rest with elevation of the head of the bed, oxygen therapy as indicated, and other comfort measures for relief of pain and cough. Steroids and diuretics have been used for symptom management, although no clear data support their benefit.

Anticoagulation is controversial. The routine use of heparin or warfarin anticoagulation has not been shown to hasten the relief of symptoms, and thrombolysis is risky

and without proven benefits. Life threatening pulmonary embolization is highly unusual in patients with SVCS, and anticoagulation may delay efficient diagnosis and treatment. In contrast, when SVCS in cancer patients is caused by thrombosed central lines, this entity is quite effectively treated with local thrombolysis followed by heparin and warfarin. Removal of the catheter is necessary only if the clot fails to lyse. The use of angioplasty has been reported, although the expertise and experience necessary to safely perform this procedure is not widely available.

Vascular stenting as initial therapy for SVCS is also controversial. Insertion of a stent produces rapid relief of symptoms for 95% of patients with SVCS due to lung cancer (9). Long-term complications of stent placement, including rates of thrombosis or reocclusion rates, have not been well established. Whether cancer patients with superior vena cava stents should all receive anticoagulation remains an unanswered question. Most experts recommend that stents be the initial therapy when patients have recurred after radiation treatment of SVCS, when patients have SVCS due to cancers that are not likely to respond to radiation and chemotherapy, or when radiation therapy might be uniquely burdensome. There are no cost comparison studies and no long-term follow-up studies of stent placement.

SVCS caused by small cell lung cancer and by lymphoma is treated with chemotherapy, and clinical resolution occurs just as rapidly as with radiation therapy. Radiation therapy is the primary treatment for all other malignant causes, although chemotherapy is increasingly used concurrently for diseases such as non-small cell lung cancer. Radiation and/or chemotherapy of SVCS in non-small cell lung cancer results in relief of symptoms for more than 60% of patients. *The initiation of either chemotherapy or radiation therapy should be prompt, but SVCS is not so urgent as to mandate treatment immediately* (i.e., especially prior to making an accurate tissue diagnosis).

Issues During the Course of Hospitalization

The signs and symptoms of patients with SVCS begin to resolve in 5–7 days after the start of treatment. Resolution of symptoms is not necessarily accompanied by radiographic change; thus, there is no indication to follow the chest x-ray frequently. Complications of radiation therapy include esophagitis, bone marrow suppression, fatigue, and mild immunosuppression. These side effects are treated expectantly. Patients who have large lung cancers are at risk of developing bronchial obstruction or pneumonia during treatment. Clinically apparent pulmonary embolism as a complication of SVCS is rare, but should be treated conventionally if it occurs (Chapter 53). Most patients with SVCS should receive prophylaxis for deep venous thrombosis while they are at bedrest.

Patients may fail to respond to treatment because of formation of thrombus, refractoriness of the primary tumor,

or hemorrhage or edema around the primary tumor that further occlude the vena cava. The assumption that treatment is failing should not be made until at least two weeks of radiation therapy has been delivered, since responses to radiation may still occur. The evaluation of patients with poor responses should include repeat chest CT and possibly venography.

Patients whose SVCS recurs after an initial response, and patients who have failed to respond to radiation, are candidates for vascular stent or surgical intervention. Several types of vascular stents have been developed. Stenting is clearly less invasive than surgical options (such as thoracotomy with vascular excision and grafting or SVC bypass), although individual anatomy may not always permit stent placement. Complications of stents and grafts include infection, stent migration, mediastinitis, graft failure, perforation, and thrombosis. Patients must be carefully selected, and the extent of institutional expertise considered.

Discharge Issues

Patients who are physiologically stable while being treated for SVCS may be discharged home. Outpatient radiation therapy and chemotherapy may be augmented by home nursing visits if necessary. The response to treatment is followed clinically. Repeated imaging of the tumor is planned as needed to evaluate further therapy. Analgesia for esophagitis should be offered prophylactically; the patient's oral intake and hydration may require monitoring once esophagitis occurs.

The prognosis of SVCS depends on the cause. Small cell lung cancer and lymphoma are highly responsive to initial therapy, potentially curable, and often accompanied by durable remissions. Non-small cell lung cancer is much less responsive, and relapse is common. Seventeen percent of small cell lung cancer patients and 19% of non-small cell lung cancer patients experienced recurrence of SVCS after treatment (9). SVCS caused by other cancers responds variably, depending on whether effective treatment is available. Thymoma has a variable natural history, and survival may be long even when treatment is relatively ineffective. Extragonadal germ cell tumors are treatment-responsive, but have a much worse prognosis than testicular germ cell tumors.

HYPERCALCEMIA

Issues at the Time of Hospitalization

Etiology

Hypercalcemia is the most common life-threatening metabolic emergency in cancer patients. Its incidence is highest in patients with breast cancer and multiple myeloma, 40% of whom may have hypercalcemia during the course of their illness. Hypercalcemia is less common in

non-small cell lung cancer, squamous carcinomas of other sites, and renal cell carcinoma, and is rare in prostate cancer, pancreatic cancer, and other gastrointestinal cancers.

The most common cause of cancer-related hypercalcemia is *tumor production of parathormone-related protein (PTH-rp)*, a peptide that shares the N-terminal 8–13 residues with human parathormone, is abundant in many normal tissues, and has unknown physiologic function. Patients with measurable levels of PTH-rp may also display phosphaturia, hypophosphatemia, and other parathormone-related abnormalities. Other pathways that cause increased bone resorption and release of calcium may be important to the pathogenesis of hypercalcemia in malignancy. Tumors may produce mediators such as calcitriol (in Hodgkin's disease), prostaglandins, cytokines such as TGF- β , interleukin-6, and tumor necrosis factor, all of which may result in the hypercalcemia of malignancy.

Clinical Presentation

Patients with hypercalcemia have a wide range of presenting signs and symptoms, related to the severity of hypercalcemia. At low levels of hypercalcemia, patients may exhibit only fatigue, anorexia, constipation, mild nausea, and polyuria. Symptoms may be more progressive and severe if the hypercalcemia is more sudden in onset. As levels of calcium increase, CNS symptoms dominate, including lethargy, muscle weakness, confusion, psychosis or delirium, and coma. Volume depletion is a prominent feature of hypercalcemia, because of the combination of anorexia, isosthenuria, and nephrogenic diabetes insipidus. Hypotension and ECG changes are generally seen late in the illness.

Differential Diagnosis and Evaluation

Most patients hospitalized with symptomatic hypercalcemia have a known cancer diagnosis. The evaluation of patients who present with hypercalcemia and do not have a cancer diagnosis begins with a careful history and physical examination. Such often present with readily observable physical findings and symptoms to suggest the presence of cancer. Laboratory data should include complete blood count, differential and platelet counts, measures of renal function, a chest radiograph, urinalysis, and serum protein electrophoresis if other laboratory data are normal. Additional imaging studies should be chosen based on symptoms, signs, and laboratory abnormalities. Serum PTH and PTH-rp levels may be measured, but are rarely necessary to prove the source of malignant hypercalcemia.

Indications for Hospitalization

Patients with mild hypercalcemia may be treated as outpatients, provided that they are able to increase their intake of salt and water adequately and the diagnosis is clear. Most

patients with moderate-to-severe hypercalcemia require hospitalization for adequate volume repletion and rapid correction of the problem. Any patient with significant elevation in serum creatinine or inability to hydrate themselves adequately must be admitted, regardless of the serum calcium level.

The most common acute problems in patients with altered mental status and hypercalcemia are complications of stupor, including aspiration pneumonitis and falls. These must be anticipated when deciding whether to admit. The processes that may trigger hypercalcemia in an otherwise stable outpatient include intercurrent illnesses, immobilization, use of diuretics (especially thiazides), and administration of hormonal therapy to breast cancer patients. The presence of any of these comorbidities should also be a factor in the decision to admit a patient.

Initial Therapy

Volume repletion with normal saline is the single most important therapy for hypercalcemia. Patients are usually moderately to severely volume depleted, and, because natriuresis increases calcium excretion, normal saline is the fluid of choice. *The early use of furosemide is contraindicated*, as it may actually reduce the amount of calcium that is excreted and worsen volume depletion. Close monitoring of patients with heart disease and renal insufficiency is necessary, at times in an ICU setting, but initial therapy must include vigorous volume resuscitation despite the risk for fluid overload.

Pharmacotherapy directed at reducing serum calcium levels is outlined in Table 92.5. *Calcitonin* is the drug of choice for very rapid reduction in calcium levels, because all other agents require about 48 hours to take effect.

Calcitonin use cannot be sustained due to the rapid development of tachyphylaxis. The *aminobisphosphonates zoledronate and pamidronate* are the most commonly used drugs for hypercalcemia because of their potency, long duration of action, and safety in the presence of mild renal failure. All of the drugs used for hypercalcemia have comparable costs. Plicamycin is the only drug that may be used in patients with severe renal failure. Steroids are potent inhibitors of calcitriol and should be employed for the treatment of hypercalcemia in patients with Hodgkin's disease. Steroids may have an anti-tumor effect in other hematologic malignancies and are useful when combined with other pharmacotherapy for hypercalcemia.

Patients hospitalized for hypercalcemia should receive close monitoring of their neurologic status, renal function, and urine output. Low calcium diets may be ordered, although patient acceptance is poor. However, milk and other very high calcium foods should be eliminated. Because bedrest increases mobilization of calcium from the skeleton, it is discouraged unless the patient's mental status is too depressed to safely allow sitting or ambulation.

Indications for Early Consultation

Severe hypercalcemia (greater than 15 mg/dL) is a potential indication for hemodialysis. Patients who have coma, severe renal failure, electrocardiographic changes, or who cannot receive aggressive hydration should be considered for dialysis. Patients who have hypercalcemia along with other standard indications for acute dialysis due to renal failure should be treated with hemodialysis. The effect of dialysis on calcium is transitory, and all such patients must also be treated aggressively with drugs to lower their calcium levels.

TABLE 92.5
DRUGS FOR TREATMENT OF HYPERCALCEMIA

Drug	Dose	Precautions/Comments
Zoledronate	4–8 mg IV over 15 min	Agent of choice due to greatest potency, most rapid action, longest duration, ease of use Use up to a creatinine of 4.5
Pamidronate	60 or 90 mg IV over 2–4 hours	Flu symptoms, myalgias, bone pain Use up to a creatinine of about 3.0 Takes 48–72 hours
Calcitonin	4–8 units/kg sq every 6–12 hours	Myalgias, arthralgias most common side effects Tachyphylaxis at 48–72 hrs
Etidronate	7.5 mg/kg IV over 2–4 hrs qd for 3–5 days	Mild nausea, rare hypersensitivity Less potent than pamidronate; rarely used Oral may be used for maintenance
Plicamycin (mithramycin)	25 mcg/kg IV × 1 (repeat in 5–7 d)	Thrombocytopenia in some patients. Vesicant; requires careful administration.

Consultation for cancer diagnosis and management is likely to be needed during hospitalization. Effective long-term control of hypercalcemia is best achieved by effective treatment of the underlying cancer.

Issues During the Course of Hospitalization

Failure to respond to initial treatment of hypercalcemia is a common and potentially serious problem. The patient's volume status should be carefully reassessed to be sure that repletion has been adequate. Failure to correct volume depletion and produce natriuresis is the most common cause of unresponsiveness to treatment. Poor renal function can also decrease calcium excretion, and this is an indication for hemodialysis. Patients with clear evidence of volume overload should be treated with furosemide. The addition of calcitonin to an aminobisphosphonate-treated patient may improve early responses. In one large series, failure to respond to drug therapy was associated with a 100% in-hospital mortality (10).

Volume overload, hypokalemia and hypomagnesemia, and complications of stupor and coma are additional problems in patients treated for hypercalcemia. Careful monitoring of intake and output and electrolytes is important, and assessment of volume status is crucial during the first few days of treatment.

Treatment of the underlying malignancy may complicate the hospital course. Chemotherapy and hormone therapy may have an impact on the disease process. Studies of outcome in patients with hypercalcemia and cancer show conclusively that the only patients who enjoy long survival are those whose cancer is successfully treated (10).

Discharge Issues

Patients are ready for discharge when they are capable of being supported at home. Home nursing and home hospice are frequently needed. Further treatment of hypercalcemia may not be undertaken in hospice patients, and outpatient prescriptions should be directed at palliating other symptoms (Chapter 19).

Maintenance of normocalcemia is a goal for highly functional patients at discharge, and may be accomplished in a variety of ways. Patients who have chemotherapy-responsive disease may not need further treatment of their calcium, or may only need a single additional dose of a potent drug such as an aminobisphosphonate. Patients with mild hypercalcemia may be maintained with less potent agents such as steroids or non-steroidal anti-inflammatory agents, which may have a moderating effect on the hypercalcemia of squamous carcinomas. Intermittent outpatient dosing of aminobisphosphonates has been advocated for maintenance of normocalcemia, and has been shown to be cost-effective as maintenance therapy for patients with extensive osseous disease, especially those with multiple myeloma and breast cancer. Oral etidronate therapy has

also been proposed for maintenance, although there are no long-term studies of outcome.

Unfortunately, hypercalcemia of malignancy is often an end-stage event. The average survival of patients hospitalized for hypercalcemia is 30 days. The addition of systemic anti-cancer therapy only lengthens this survival to 135 days (10). About half of the patients discharged from the hospital have relief of their hypercalcemic symptoms.

KEY POINTS

- Magnetic resonance imaging is the method of choice for the evaluation of neurologic emergencies in patients with cancer.
- The urgency of therapy for neurologic complications of cancer is dependent on the duration and severity of the neurologic deficit.
- Treatment of neurologic emergencies may involve surgery, radiation therapy, and chemotherapy.
- Malignant pericardial effusion is treated most often with catheter drainage or subxiphoid pericardiectomy.
- Superior vena cava syndrome is recognizable clinically and most often occurs in the setting of lung cancer.
- Keys to successful treatment of hypercalcemia include use of aggressive hydration with saline solution and potent drugs such as aminobisphosphonates.

INTRODUCTION

The term *leukemia* encompasses a number of diseases characterized by the clonal proliferation of hematopoietic stem cells, which results in the accumulation of abnormal (leukemic) cells in the bone marrow and a decreased production of normal blood cells. The four most common types of leukemia are acute myelogenous leukemia, acute lymphoblastic leukemia, chronic myelogenous leukemia, and chronic lymphocytic leukemia. In general, patients with chronic leukemia are treated on an outpatient basis. The chronic leukemias, which are readily distinguished from the acute leukemias by the clinical presentation and blood smear findings (Table 93.1), are not extensively discussed in this chapter.

EPIDEMIOLOGY AND ETIOLOGY

Acute myelogenous leukemia (AML) is characterized by the proliferation of primitive hematopoietic cells of myeloid lineage, and acute lymphoblastic leukemia (ALL) by the proliferation of primitive lymphoid hematopoietic cells. The overall incidence of acute myeloid leukemia is 3.6 per 100,000 in the population, with a much greater incidence in older people. Acute lymphocytic leukemia has an overall incidence of 1.5 per 100,000 in the population, with a much higher incidence in young children than adults (1). Unfortunately, the majority of adults in whom acute leukemia is diagnosed ultimately die of the disease.

The etiology of acute leukemia is unknown and is undoubtedly complex, including genetic and environmental factors. Exposure to high levels of ionizing radiation is a well-established risk factor. Increased rates of leukemia have been observed in survivors of the atomic bombs and in workers in the radium industry. Previous chemotherapy with alkylating agents for other malignant diseases also increases the risk for acute leukemia, as does industrial over-

exposure to benzene, carbon tetrachloride, and carbon disulfide. The role of pesticide exposure is controversial, but a higher-than-expected incidence of acute leukemia has been observed in farmers and agricultural workers. A small increased risk is also probably associated with smoking. Several genetic syndromes, including Down syndrome, Bloom syndrome, Fanconi's anemia, and ataxia-telangiectasia, are associated with an increased risk for the development of acute leukemia. The risk associated with a family history of leukemia is uncertain, and although there is an increased risk for childhood leukemia in twins (especially during infancy), no increased risk has been documented in adult twins. Most patients, however, have no history of exposure to any known risk factor (2).

CLASSIFICATION

AML and ALL are each divided into multiple subtypes based on morphology, histochemistry, immunophenotyping by flow cytometry, and cytogenetics. However, cytogenetic description is replacing the French-American-British Cooperative Group (FAB) system of classification of Acute Leukemia (Table 93.2). Retrospective studies have found that a normal white blood cell count, younger age, and normal hemoglobin at presentation are favorable prognostic factors. Cytogenetic analyses have furthered these observations by allowing more in-depth risk assessment based on survival statistics. Individuals with t(15;17) have "FAB M3" or promyelocytic leukemia and do very well. Unfortunately, overall only 20% of patients with other types of AML survive long term. Leukemia patients with (t[8;21] or inv[16]) are felt to have a high chance for cure with standard therapy (55% 5-year survival with continuous remission). Those with normal cytogenetics or t(9;11) are at intermediate risk (24% 5-year survival in remission), and those with complex genetic changes or other single abnormalities are felt to be at a very high risk for

TABLE 93.1**SUMMARY OF CHARACTERISTICS OF THE TWO MOST COMMON CHRONIC LEUKEMIAS**

Diagnosis	Clinical characteristics	Common laboratory abnormalities	Cellular characteristics	Median survival
CML	Median onset in fourth decade; fatigue, splenomegaly	Increased WBC, low LAP score, PB blasts (<30%), splenomegaly, hemolytic anemia, thrombocytopenia	Philadelphia chromosome-positive	~3–5 y
CLL	Median onset in seventh decade; adenopathy, splenomegaly, hepatomegaly	Lymphocytosis and smudge cells, >30% lymphocytes in BM, anemia, thrombocytopenia	CD5-positive B cells	10 y in early stage, 3 y in advanced stage

BM, bone marrow; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; LAP, leukocyte alkaline phosphatase; PB, peripheral blood; Philadelphia chromosome, [t(9;22)]; WBC, white blood cells.

relapse (5% survival in remission at five years) (3). For patients with ALL arising *de novo*, the overall long-term survival is approximately 20%. Important unfavorable prognostic factors in ALL include older age at onset, mature B-cell ALL, and a high white cell count at presentation. However, here too, cytogenetic analyses have further defined outcomes based on the abnormalities found in these patients. Adults with t(9;22) have less of a chance to attain a remission and poorer long-term survival than those with normal cytogenetics or other changes. A slow response time (longer time to attain remission) is the worst prognostic factor (4).

GENERAL PRINCIPLES OF MANAGEMENT

The goals of therapy of acute leukemia are to *eliminate the neoplastic clone and restore normal hematopoiesis*. Therapy is generally divided into two phases: the *induction phase*, designed to achieve a complete remission; and *post-remission therapy*, to prevent relapse and achieve cure. Complete remission is defined as fewer than 5% blasts in the bone marrow and restoration of normal hematopoiesis with an absolute neutrophil count of at least 1,500/ μ L and a platelet count of 100,000/ μ L. The achievement of complete remission is the only clinically significant response to therapy and is a necessary first step toward cure. Post-remission therapy (consolidation) attempts to eradicate minimal residual disease. Patients with ALL are also treated with more prolonged courses of lower-dose maintenance chemotherapy. This chapter focuses on the issues involved in the administration of induction therapy to a patient with a newly diagnosed disease. The successful completion of induction therapy depends on the ability to support patients through the many attendant complications associated with a 2- to 5-week period of pancytopenia.

ACUTE MYELOGENOUS LEUKEMIA

Issues at the Time of Admission

Adult acute myeloid (or nonlymphoid) leukemias typically present after a few weeks of general decline in overall well being as a consequence of either the leukemia itself or associated neutropenia, anemia, and thrombocytopenia. Fatigue, malaise, bruising, and occasionally anorexia with weight loss are reported. Presenting signs typically reflect anemia (e.g., pallor of the skin), thrombocytopenia (e.g., petechiae or ecchymoses), or both. Adenopathy or fever may also be present. Hepatosplenomegaly and lymphadenopathy are more common with ALL. Neurologic symptoms are uncommon. A delay in diagnosis is common, but when symptoms persist and intensify or the above signs are noted, a blood cell count and qualitative review of the smear often reveal abnormalities that prompt further analysis.

By the time patients present to the hospital for evaluation and therapy, most will have some degree of anemia and many are also severely thrombocytopenic. The white blood cell count is variable, with approximately 20% of patients presenting with counts below 5,000/ μ L and fewer than 20% with counts above 100,000/ μ L. Leukemic blasts are nearly always found in the peripheral blood. The prothrombin and partial thromboplastin times may be prolonged, especially in some forms of AML. Chemistries are usually normal, although the uric acid may be elevated in patients with high white blood cell counts.

Because of the variable nature of the presenting blood cell counts, the differential diagnosis may remain broad (Table 93.3). Review of the blood film and bone marrow biopsy specimen from a patient with leukemia will show a hypercellular marrow, lack of heterogeneity, and lack of maturation with a significant increase in blast forms (>30%), in addition to a suppression of normal precursors.

TABLE 93.2
FAB COOPERATIVE GROUP CLASSIFICATION OF ACUTE LEUKEMIA

FAB subtype	Description	Morphology	Histochemistry	Immunophenotype	Cytogenetics
AML-M0	Undifferentiated	>30% agranular blasts	Negative	CD13, 33, 34 HLA-DR	
AML-M1	Myeloblastic without Differentiation	>90% blasts with rare granules and Auer rods	Sudan black Myeloperoxidase	CD13, 14, 15, 33, 34 HLA-DR	Occasional inv(3)
AML-M2	Myeloblastic with Differentiation	30%–90% blasts with granules and many Auer rods	Sudan black Myeloperoxidase Chloroacetate esterase	CD13, 15, 33, 34 HLA-DR	t(8;21)
AML-M3	Promyelocytic	>30% blasts with hypergranular promyelocytes	Myeloperoxidase (intensely positive)	CD13, 15, 33	t(15;17)
AML-M4	Myelomonocytic	>30% blasts with 20%–80% of monocytic lineage plus monocytosis in blood	α -naphthyl butyrate esterase	CD13, 14, 15, 33, 34 HLA-DR	inv(16) in eosinophilic variant
AML-M5	Monocytic	Large, often bizarre cells, >80% monocytic lineage	α -naphthyl butyrate esterase	CD13, 14, 33, 34 HLA-DR	abnormal 11q23
AML-M6	Erythroid	>50% of cells of erythroid lineage, often dysplastic; > 30% of nonerythroid cells are blasts	Periodic acid Schiff	CD13, 33, 41, 71 HLA-DR Glycophorin A	del(5) del(7)
AML-M7	Megakaryocytic	> 30% blasts of megakaryocytic origin	Platelet peroxidase by electron microscopy	CD41, 61	inv(3) t(3;3) trisomy 21
ALL-L1	Childhood form	Small cells with minimal cytoplasm, no granules, and rare nucleoli	TdT	B cell: CD10, 19, 20, 22, 34; HLA-DR; cytoplasmic immunoglobulin T cell: CD2, 5, 7, 10, 34	t(9;22) t(4;11) t(1;9)
ALL-L2	Adult form	Larger cells with moderate amount of cytoplasm and prominent nucleoli	TdT	B cell: CD10, 19, 20, 22, 34; HLA-DR; cytoplasmic immunoglobulin T cell: CD2, 5, 7, 10, 34	t(9;22) t(4;11) t(1;9)
ALL-L3	Burkitt's type	Large, round cells with basophilic cytoplasm and vacuoles		CD10, 19, 20, 21, 22 Surface immunoglobulin	t(8;14) t(2;8) t(8;22)

ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; CD, clusters of differentiation; del, deletion; FAB, French-American-British; HLA, human leukocyte antigen; inv, inversion; M0–M7 and L1–L3 denote leukemia subtype; t, translocation; TdT, terminal deoxytransferase.

In contrast, the bone marrow specimens of patients with *aplastic anemia*, including those with an accompanying viral infection, are very hypocellular. Cultures and tests based on the polymerase chain reaction can rule out such viral infections. *Myelodysplasia*, a preleukemic condition, also is characterized by a hypocellular marrow with ringed sideroblasts and mildly increased blast counts, but not above the 30% required for a diagnosis of acute leukemia. The history is

very important in elucidating any potential *environmental or medication exposures* that might cause conditions that mimic leukemia. Typically, slightly more variability and maturation are found in the marrow and blood of these patients than in patients with leukemia. Sarcoidosis and tuberculosis are associated with the appearance of granulomas on biopsy specimens of the marrow. In patients presenting with high white blood cell counts, the differential diagnosis

TABLE 93.3
DIFFERENTIAL DIAGNOSIS OTHER THAN ACUTE LEUKEMIA BASED ON BLOOD CELL COUNTS

Pancytopenia (abnormally low counts of platelets, white cells, and red cells)
Aplastic anemia
Paroxysmal nocturnal hemoglobinuria
Parvovirus B19 infection (typically limited to or affecting red cells most severely)
Chronic infections (tuberculosis, cytomegalovirus, Epstein-Barr virus)
Medications (trimethoprim-sulfamethoxazole, chlorambucil or other chemotherapeutic agents)
Autoimmune illnesses (sarcoidosis)
Myelodysplasia
Leukocytosis (abnormally elevated white cell count)
Stress (extreme environments)
Smoking
Exercise
Pregnancy
Severe nausea or vomiting
Chronic infections (parasites, fungus)
Medications (prednisone, digitalis, heparin)
Hemolysis/hemorrhage
Post-splenectomy
Metabolic conditions (gout, hyperthyroidism, ketoacidosis)
Plasmacytosis
Chronic myeloid leukemia
Lymphocytosis (abnormally elevated lymphocyte count)
Viral infection
Chronic lymphocytic leukemia
Hairy cell leukemia
Transformed lymphoma

is still broad (Table 93.3). However, a review of the history coupled with the peripheral blood film and marrow findings usually reveals the correct diagnosis.

The process of evaluation is outlined in Figure 93.1. An early hematologic consultation should be obtained for all patients in whom a diagnosis of acute leukemia is being considered. A Wright's-stained blood film revealing an increase in blast forms is essential for a diagnosis of acute leukemia. In addition, analysis of the peripheral blood or marrow cells by flow cytometry is required to support the diagnosis by proving monoclonality. Cytogenetic analysis is also important because it provides information related to prognosis and therapeutic decisions. Therefore, on admission, all patients should have a blood film prepared in addition to undergoing bone marrow aspiration and biopsy. Adequate samples can be obtained in the majority of patients with minimal discomfort from the posterior iliac crests. Sternal aspirates should be obtained only from patients in whom sampling from the posterior iliac crests is not possible because of their clinical condition or body habitus. The bone marrow should be evaluated with routine Wright's staining plus special lineage-specific stains.

In addition, flow cytometry of the aspirate (or of the peripheral blood if the number of circulating blasts is significant) and standard cytogenetics should be requested. Other initial laboratory studies should include a chemistry panel including values for electrolytes, renal function, serum liver chemistries, lactate dehydrogenase, calcium, phosphorus, and uric acid; coagulation studies; type and screen; and urinalysis. Blood and urine cultures should be obtained for all febrile patients. Lumbar puncture is usually not carried out as part of the initial workup. Rather, it is delayed until peripheral blood blasts have cleared to avoid confusing central nervous system involvement with a "bloody" tap. A chest radiograph should also be obtained for all patients. Peripheral blood for HLA typing (A/B/DR) should be taken from all patients at the time of diagnosis in anticipation of the need for HLA-matched platelets and the need to identify a potential bone marrow donor. This initial evaluation yields a combination of morphologic and cytogenetic data that allow one to predict the course of an individual patient's illness and determine appropriate therapy.

Initial Therapy

All patients with a new diagnosis of acute leukemia require hospitalization. Initial management should concentrate on stabilization of the patient and preparation for chemotherapy with placement of central venous access. If severe anemia (hematocrit <25 g/dL) or thrombocytopenia (platelets <10,000/ μ L) or symptoms referable to the cytopenias are present, then the patient should have a transfusion. Filtered blood products (to prevent transmission of cytomegalovirus and reduce the risk for allo-immunization and nonhemolytic, febrile transfusion reactions) and irradiated blood products (to prevent transfusion-associated graft-versus-host disease) should be used (Chapter 91).

If the patient is neutropenic (absolute neutrophil count <1,000/ μ L) and febrile, a standard infectious evaluation with blood cultures, urinalysis and culture, and chest radiography, should be undertaken and broad-spectrum antibiotics immediately begun (Chapters 63 and 64). A careful physical examination (ruling out oral and rectal abscesses) should also be included. All patients become neutropenic following chemotherapy. The risk for infection is influenced by the depth and duration of neutropenia and by other factors, such as the presence of mucositis and indwelling catheters. Although the definition of fever varies across studies, we favor the initiation of empiric antibiotic coverage in a patient with a temperature above 38.5°C or three or more temperatures above 38.0°C in a 24-hour period. Signs and symptoms of infection without fever should also prompt administration of antibiotics in neutropenic patients. The early use of antibiotics has reduced infection-related mortality to 5%–10%, with most deaths from infection occurring in patients with prolonged neutropenia. In the past, the primary goal of therapy was the treatment of Gram-negative bacterial infections. However, *Gram-positive organisms are also emerging as major causes of infection*

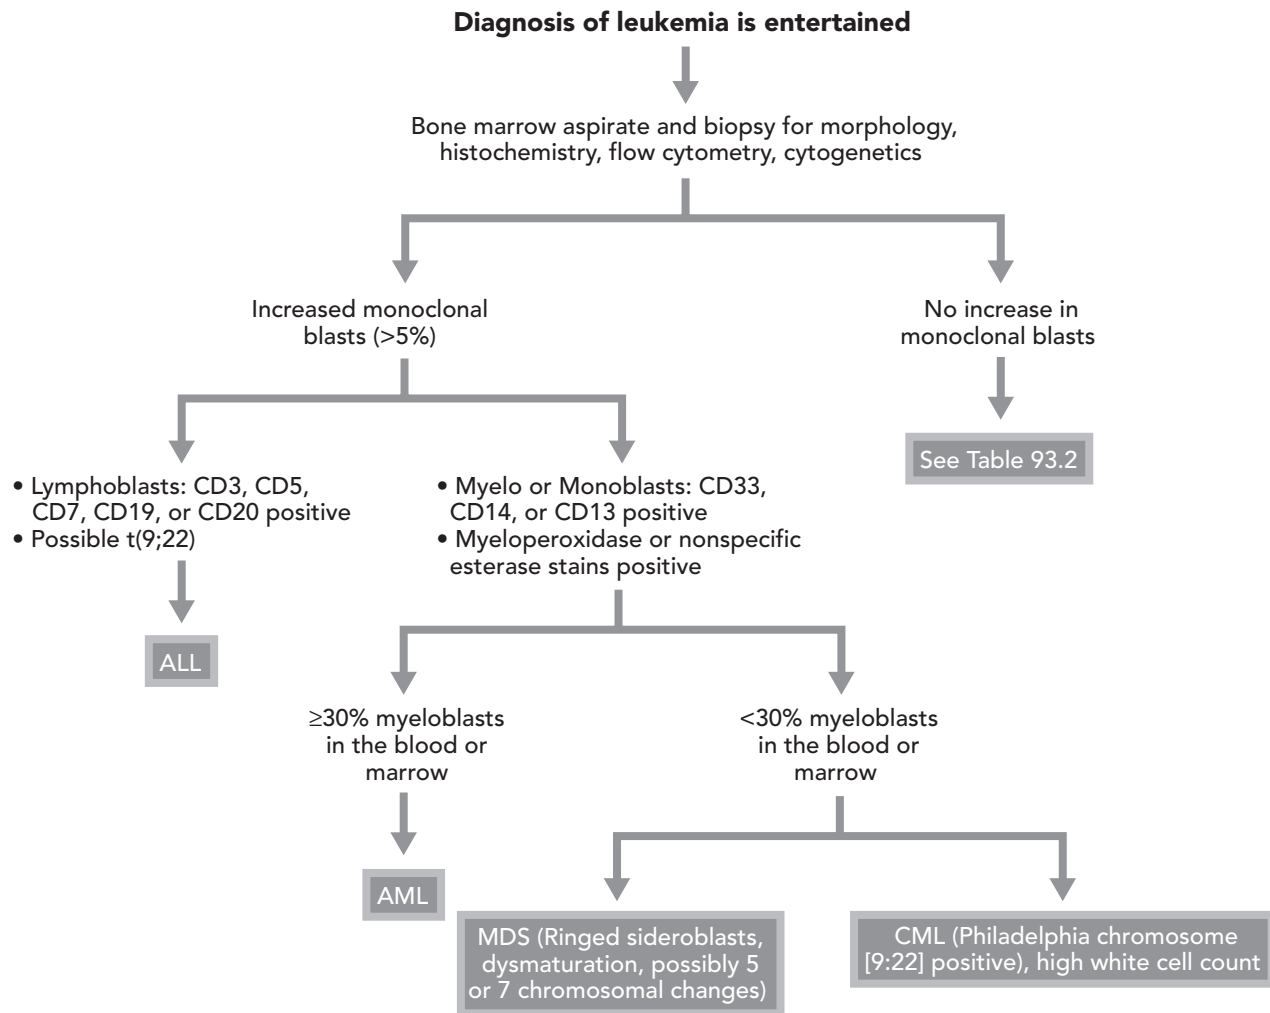

Figure 93.1 Algorithm for evaluation of a patient suspected of having acute leukemia. The initial steps require a bone marrow examination to prove whether or not there is an increase in monoclonal blast cells. If so, the subsequent steps entail defining the specific type of abnormal blasts to allow for proper classification of the illness. ALL, acute lymphoblastic leukemia; AML, acute myelogenous leukemia; CML, chronic myelocogenous leukemia; MDS, myelodysplastic syndrome; t, translocation.

in neutropenic patients. Many reasonable options are available for single- or double-agent coverage, such as the third-generation cephalosporins, monobactams, or a broad-spectrum penicillin in combination with an aminoglycoside or a quinolone antibiotic (Chapter 63).

If the presenting white blood cell count is very high ($>100,000/\mu\text{L}$), the patient may be in danger of *tumor lysis* (Chapter 94). Aggressive hydration (at least 200 mL of fluid per hour) and 300 mg of allopurinol per day may be used to minimize this risk. Laboratory values should be followed every 6–8 hours until the white cell counts are nearly entering the neutropenic stage, which typically takes 4–5 days after induction therapy is initiated. Leukostasis may also develop in patients with blast counts above $100,000/\mu\text{L}$, and with signs of end-organ compromise, such as changes in mental status or angina. Emergent leukapheresis should be considered, along with 500–1,000 mg of hydroxyurea every 6 hours until definitive chemotherapy can be initiated.

Subtypes of leukemia present certain special considerations. All leukemia patients, but particularly those with *promyelocytic leukemia*, are prone to *disseminated intravascular coagulation*, and coagulation parameters should be evaluated on admission and followed daily during induction therapy (Chapter 98). If laboratory abnormalities consistent with disseminated intravascular coagulation are present but the patient has no manifestation of bleeding or clotting, then it is appropriate to follow the patient closely with laboratory monitoring every 6–8 hours during therapy. If the patient has evidence of clotting or bleeding from disseminated intravascular coagulation, therapy may be very difficult, and the outcome is often poor.

Monocytic leukemia is often an invasive disease (into skin, joints, and visceral organs). Not uncommonly, patients present with a persistent cough and chest radiographic findings of diffuse bilateral infiltrates, which often leads to a delay in initiation of chemotherapy while antibiotics are administered for pneumonia. Patients in this

situation should be carefully evaluated, cultures taken, and antibiotics started, but chemotherapy for the leukemia should not be delayed beyond 1–2 days, as the pulmonary infiltrates often clear with chemotherapy. Bronchoscopy for cultures, cytology, and even biopsy to rule out infection may be needed early in the evaluation so as not to delay appropriate therapy. Monocytic leukemia can also present with renal failure resulting from infiltration of the kidney, which can be seen on ultrasonography. The physical examination must attempt to identify reservoir sites of disease. Granulocytic sarcomas or chloromas (nodules of leukemia cells) may develop in multiple sites, including the skin, liver, lungs, bowel, and bone.

Various chemotherapy regimens are used for induction chemotherapy (Chapter 90). Typically, a nucleoside analog such as cytarabine (continuous infusion of 100–200 mg/m² daily for seven days) is combined with an anthracycline such as idarubicin (12 mg/m² daily for days one through three). Addition of a topoisomerase inhibitor such as etoposide is advocated by some to improve remission rates. A bone marrow examination is usually repeated 2 weeks after the start of chemotherapy, and, if residual blasts are identified, a second round of induction is immediately begun. This is typically slightly less intense than the first cycle (e.g., five days of cytarabine and two days of an anthracycline). It is important to note that those with t(15;17) FAB M3 cytogenetics require a different initial therapy. In these patients, all-trans retinoic acid is delivered first to induce maturation of the leukemic blasts, with most patients achieving a remission within a 6-week period. This is followed with standard induction and consolidation chemotherapy to optimize the long-term outlook for the patients. One to three cycles of consolidation therapy are given. Patients are typically much more stable at the initiation of consolidation than during induction. High dose therapy with autologous or allogeneic hematopoietic stem cell support is advocated by some investigators, but this has not been proven to improve long-term survival when used as initial consolidation therapy.

Chronic myelogenous leukemia is typically managed on an outpatient basis until it progresses to a blast crisis, which is often indistinguishable from acute leukemia, presenting with extremely high white blood cell counts (often >200,000/μL). The prognosis for patients with chronic myelogenous leukemia in blast crisis is extremely poor, but an attempt should be made to induce younger patients into a second chronic phase and then proceed to allogeneic bone marrow transplantation (Chapter 96) if an appropriate donor can be identified.

Issues During the Course of Hospitalization

Febrile neutropenia should be treated aggressively. Daily physical examinations should rule out oral or perirectal abscesses, in addition to more common causes. Digital rectal examinations should not be performed on neutropenic patients. Prophylactic antibiotic therapy with a quinolone

started during induction or consolidation may decrease the numbers of episodes of fever and readmissions during consolidation. However, when a patient becomes febrile, these antibiotics are not sufficient, and broader coverage must be initiated. The treatment of the febrile neutropenic patient is discussed in detail in Chapter 63.

Transfusion support to maintain the platelet count above 10,000/μL and the hematocrit above 25 g/dL with filtered, irradiated blood products remains appropriate. If patients are febrile or actively bleeding, the platelet transfusion threshold is often increased to 20,000/μL (5). Transfusions of packed red blood cells are indicated to keep hemoglobin levels above 7–8 g/dL to maintain adequate oxygen-carrying capacity. Growth factor support may be effective in patients over 55 years of age and may hasten the recovery of granulocytes when it is started at some point after the completion of induction therapy (usually initiated between days 11 and 14).

Severe mucositis may require opiates for pain control. Attention must be paid during the daily oral examination to ensure that superinfection with *Candida* or herpes virus is not also involved. Empiric therapy with acyclovir, fluconazole, or both is often used. Colitis with severe abdominal cramping, bloating, and radiographic findings of distended loops of bowel are consistent with neutropenic colitis (typhlitis) as a side effect of chemotherapy, neutropenia, or secondary causes. *Clostridium difficile* infection must be excluded, and supportive care, often including nasogastric drainage, is required.

The side effects of chemotherapy are numerous and should be monitored by the hematologist, but a few bear mentioning. Cytarabine, a standard agent used in many regimens, at higher doses may cause cerebellar dysfunction that requires immediate discontinuation of the drug. All patients receiving doses of more than 1 g/m² should undergo a neurologic exam looking for cerebellar findings before each dose of the drug is administered. In addition, at doses above 1 g/m², steroid eye drops must be used to prevent severe conjunctivitis. Cyclophosphamide, which is sometimes used in consolidation therapy, can cause hemorrhagic cystitis (Chapter 90). The commonly used anthracycline agents cause cardiomyopathy at high cumulative doses. The use of all-trans retinoic acid has been a great advance in the therapy of promyelocytic leukemia, but the “retinoid syndrome” is seen in up to 40% of patients. This is a constellation of findings including high fevers with respiratory distress, pulmonary infiltrates and pleural effusions, weight gain, and leukocytosis. Early recognition and initiation of steroid therapy (10 mg of dexamethasone every 12 hours) usually allows for successful management.

Recovery and Discharge Issues

The bone marrow examination is repeated at recovery of white cells (absolute neutrophil count above 1,000/μL and platelet count above 100,000/μL, usually 3–4 weeks after

the initiation of chemotherapy) to document whether remission has been attained. At discharge, important issues are nutrition (Chapter 15), which should include high-carbohydrate and caloric supplements if needed, and daily exercise to promote recovery from the long hospital stay and prepare for future chemotherapy. Oral electrolyte supplements such as potassium and magnesium may be required for a few weeks after chemotherapy. Antifungal and antiviral therapy can be discontinued at the same time as broad-spectrum antibiotics unless invasive fungal disease has been documented. The initial duration of hospitalization for induction is typically 4 weeks, with patients remaining hospitalized for the initial delivery of chemotherapy and the management of fevers (during the neutropenic phase) and chemotherapy side effects. These challenging phases are generally followed by the simultaneous recovery of blood cell counts and improvement in performance status. On recovery, patients can be discharged if they maintain adequate oral intake, ambulate with minimal assistance, and have any infections well controlled. The discharge decision must be made carefully after such intensive chemotherapy; premature discharge before the ability to perform activities of daily living has returned commonly leads to readmissions, prolonged requirements for recovery, delays of consolidation therapy, and increased total costs.

Depending on the clinical condition and remission status of the patient, consolidation therapy usually begins 2–3 weeks after recovery from induction. Consolidation often requires a 1-week hospitalization to deliver the chemotherapy in a supervised setting, and then discharge with close outpatient follow-up through the 3- to 4-week recovery period. When consolidation is complete, the approach to follow-up depends on the risk for relapse and the patient's clinical status. Typically, patients should be observed closely at 3-month intervals for approximately two years, with bone marrow examinations performed at the first sign of possible relapse.

ACUTE LYMPHOBLASTIC LEUKEMIA

Issues at the Time of Admission

The evaluation and stabilization of the patient with ALL are similar to those for patients with AML; however, the initial evaluation of ALL must take into account reservoirs of disease, including the testes and central nervous system. At presentation, a careful genital examination must be performed. A lumbar puncture for cell counts, chemistry, and cytology should be performed in all patients with ALL after peripheral blood blasts have cleared.

The treatment of ALL involves multiple-agent chemotherapy with prophylactic treatment of potential reservoirs, followed by prolonged administration of maintenance chemotherapy at regular intervals. Many regimens

continue therapy for up to two years, although some newer regimens, directed at L3 ALL or Burkitt's disease, provide a dose-dense approach with more intense alkylator support and shorter total duration of therapy (6, 7). The potential complications of therapy are the same as for AML. The agent L-asparaginase, which is utilized in the treatment of ALL, has the potential to cause severe pancreatitis. Serum amylase and lipase levels should be followed. This agent also inhibits the synthesis of proteins, including vitamin K-dependent coagulation factors and antithrombin III and proteins C and S, with the potential to cause both coagulopathies and thrombosis. Coagulation parameters and fibrinogen levels should be followed and fresh frozen plasma administered before L-asparaginase when the fibrinogen level falls below 100 mg/dL. Patients should also be monitored for hypersensitivity reactions during repeated doses of L-asparaginase. Unlike patients with AML, those with ALL receive prophylactic intrathecal chemotherapy, typically in the form of 8–10 doses of methotrexate weekly, depending on the regimen used. If the patient has active central nervous system disease, additional intrathecal chemotherapy is given and craniospinal radiation is commonly administered.

Issues During the Course of Hospitalization

See the preceding discussion of AML.

Recovery and Discharge Issues

The same issues that apply to ensuring a safe discharge for patients with AML also apply to those with ALL. Consolidation and maintenance therapy can generally be performed in an outpatient setting with close follow-up.

COST CONSIDERATIONS AND RESOURCE USE

The treatment of acute leukemia is expensive. Patients require prolonged hospitalizations, often with intensive care, and significant quantities of blood products and broad-spectrum antibiotics and other antimicrobial agents are administered. The average costs of induction therapy for patients with newly diagnosed AML range from \$50,000 to more than \$100,000. Opportunities to conserve resources, especially blood products, and contain costs have been identified and shown not to have a negative impact on outcome. Lowering the platelet transfusion threshold from 20,000/ μ L to 10,000/ μ L results in a decreased number of transfusions and lower costs without increased complications of bleeding (5). The use of filtered, leukocyte-depleted, ABO-compatible platelet products is associated with a decrease in allo-immunization and fewer platelet transfusions, which in turn results in a

decrease in cost of approximately \$14,000 per patient with acute leukemia (8).

The role of *hematopoietic growth factor support* in the management of acute leukemia remains controversial. In general, growth factor use results in fewer days of neutropenia and antibiotic use, but it does not necessarily reduce the number of days of hospitalization or improve overall survival. At the same time, growth factor use has not been associated with an increased relapse rate. Prospective trials assessing the cost effectiveness of growth factor use have yielded conflicting results. Some studies note significantly shorter durations of hospitalization and antibiotic use, while others do not (9–11) (Chapters 9 and 90). The routine use of growth factors in patients undergoing chemotherapy for acute leukemia cannot be strongly recommended, although the use is increasing, especially in patients over age 55.

Early discharge from the hospital may be an option for some patients. Those who have recovered from neutropenia and have a good performance status, but are still transfusion-dependent, can be supported with red blood cell and platelet transfusions on an outpatient basis. Prolonged therapy with antimicrobial agents can also be administered in the outpatient setting if patients are otherwise clinically stable.

KEY POINTS

- Acute leukemia remains a difficult problem for the patient and the hospital physician; patients often have protracted inpatient courses that require significant intensive care unit stays.
- Approximately 75% of treated patients attain a remission and are discharged home for further therapy.
- Pitfalls in the management of a patient with newly diagnosed acute leukemia include failure to recognize how quickly a patient can decompensate and delay in referral to a hematologist.
- A thorough initial evaluation and aggressive management of the consequences of both leukemia and its treatment (including coagulopathies, fevers, infections, and chemotherapy toxicity) will optimize a patient's chances for attaining a remission and potential cure of the disease.

INTRODUCTION

The non-Hodgkin's lymphomas and Hodgkin's disease comprise a heterogeneous group of lymphoid neoplasms with differing presenting features, natural histories, and responses to treatment. They also are among the most treatable and curable of all malignancies. The treatment goals guide the approach to specific problems.

Non-Hodgkin's lymphoma (NHL) is the sixth most common cause of cancer in the United States, with 54,000 new cases and as many as 24,000 deaths estimated in 2002. Whereas the overall incidence of cancer increased about 1% annually, the incidence of NHL rose 3%–4% annually, rising more than 50% between 1973 and 1990 (1). Some of this increase represented AIDS-related lymphomas in young men. However, significant increases have been observed in women and in all age groups except the very young. The incidence of NHL in the United States increases with advancing age, with 8.5 cases per 100,000 for people under age 65 and 68.8 per 100,000 for the group over 65. There is a slight male preponderance. Whites are affected more than African Americans and other minorities. The incidence of NHL is significantly higher in industrialized countries than in the developing world.

Hodgkin's disease is far less common than NHL, with an annual incidence in the United States of 7,000 cases and 1,500 deaths. Unlike NHL, the incidence of Hodgkin's disease has remained relatively stable. Hodgkin's disease has a bimodal distribution in developed countries, with most cases occurring in persons between the ages of 15 and 34, and a second, smaller peak in incidence observed in people over age 50. Like NHL, Hodgkin's disease is more common in whites than in blacks and more common in men than in women. Other epidemiologic features of Hodgkin's disease include increased risk with higher educational levels of patients or their mothers, fewer siblings, single-family homes, familial association, and history of mononucleosis. There is a small increase in the incidence of Hodgkin's disease among HIV-infected patients.

Risk Factors

Current evidence suggests that factors or conditions precipitating immunosuppression or chronic antigenic stimulation provide a milieu for the development of NHL. Congenital immunodeficiency states all confer a greatly increased risk for the development of lymphoma. In people with acquired immunodeficiency (e.g., after transplantation of a solid organ or HIV infection), the risk increases as much as 50- to 100-fold in comparison with a baseline population. NHL ultimately develops in as many as 5% of cardiac transplant patients (Chapter 40).

Several infectious agents have been implicated as causal in specific types of lymphomas. *Helicobacter pylori* infection is clearly involved in the development of mucosa-associated lymphoid tissue (MALT) lymphomas in the stomach. Eradication of the bacteria with antibiotics (Table 80.3) leads to regression of the lymphoma in cases limited to the mucosal surface. There are similar associations between Epstein-Barr virus (EBV) and African Burkitt lymphoma, and between HTLV-I (human T-cell lymphotropic virus type I) and cutaneous T-cell lymphoma, in which viral infection and integration into the malignant cells have been demonstrated. Both EBV infection and a history of infectious mononucleosis in young adults have been associated with many of the T-cell lymphomas.

TYPICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The typical presentation of lymphoma is painless lymphadenopathy. However, the differential diagnosis of an enlarged lymph node or nodes is extensive (Chapter 89). The most common causes of lymphadenopathy in one series were lymphoma, tuberculosis, toxoplasmosis, infectious mononucleosis, and Hodgkin's disease (2). Rarely, a rapidly enlarging lymph node containing lymphoma may

be painful and associated with signs of inflammation. The adenopathy of lymphoma is often characterized by rounded nodules or groups of nodules clustered together, sometimes with adjacent groups of enlarged nodal sites. The neck, axillae, inguinal region, and mediastinum are the most common sites of enlarged nodes in lymphomas and Hodgkin's disease. Epitrochlear or femoral adenopathy strongly suggest NHL.

Constitutional (also known as "B") symptoms, although common in lymphomas and Hodgkin's disease, are often not helpful in distinguishing these neoplasms from infectious entities. Pruritus or pain at involved nodal sites after ingestion of alcohol more strongly suggests Hodgkin's disease. Other, less common presenting features of lymphomas and Hodgkin's disease include cytopenias, which result from bone marrow involvement or immune destruction, and extranodal lesions, which can involve the skin, gastrointestinal tract, Waldeyer's ring, testes, and other sites. Neurologic symptoms caused by enlarging masses can be seen in primary central nervous system (CNS) lymphomas, and peripheral neuropathy can be part of a paraneoplastic syndrome.

Nodal size has some predictive value, as most lymphadenopathy less than 1 cm² in size, especially when unaccompanied by systemic symptoms, is benign. Patients with persistent adenopathy (lasting longer than 2–3 weeks), enlarging adenopathy, constitutional symptoms, abnormal blood cell counts or serum chemistries, or underlying immune deficiency should be evaluated further with biopsy of abnormal tissue.

Diagnosis

The diagnosis of NHL requires examination of an adequate sample of representative tissue. Tissue can be obtained by fine-needle aspiration, core needle biopsy, or excisional lymph node biopsy. Although fine-needle aspiration may be adequate for cell type, it does not allow the examination of lymph node architecture to classify many lymphomas. In addition, the paucity of tissue makes a diagnosis of Hodgkin's disease difficult and does not allow for further immunophenotyping. In general, the greater amount of lymph tissue obtained with multiple core biopsies or lymph node excision is preferred. If infection is in the differential diagnosis, tissue should be processed for routine histology and microbiologic examination. Specimens that demonstrate NHL are studied by immunophenotyping to determine B or T cell lineage and for classification. In selected cases, classical cytogenetics or Fluorescence *in situ* Hybridization (FISH) may allow more precise diagnosis. Storage of frozen material for genotyping to determine monoclonality is encouraged in difficult cases. It may become more routine in the future as a means to measure gene expression quantitatively.

Classification

The classification of NHL has undergone several revisions over the last four decades. Two of the more important and commonly used classifications are described here. The older classification, known as the *Working Formulation*, was based on microscopic appearance and survival characteristics. The Working Formulation separated the lymphomas into low-, intermediate-, and high-grade categories. Simplistically, survival among untreated patients was considered to be measured in years for low-grade disease, months for intermediate-grade disease, and weeks for high-grade disease. Although it did not account for the subtle differences within each category, the Working Formulation provided a useful clinical framework to guide the approach to a complicated array of disorders.

The World Health Organization (WHO) classification (3) has now replaced the Working Formulation. The WHO classification is based on cell of origin, primarily B-cells or T-cells, and characterizes NHL entities as individual diseases. In addition to morphologic features, immunophenotypic and genetic markers and clinical characteristics are integrated into the current NHL classification (Table 94.1).

Staging

While classification systems have been frequently updated and modified, staging for lymphomas has remained static. The *Ann Arbor staging system*, initially proposed for Hodgkin's disease, is also used for NHL (4) (Table 94.2). It stages lymphomas according to the number of nodal sites involved, their relation to the diaphragm, and the extent of extranodal disease. The presence of "B" symptoms is indicated by adding a letter "B" to the Roman numeral stage. An "A" denotes the absence of "B" symptoms.

Although the Ann Arbor staging system provides important prognostic information for Hodgkin's disease, it remains inadequate for NHL, which does not follow the same orderly progression of contiguous disease sites. Systemic involvement is more common, which makes distinctions about the relationship of disease to the diaphragm less important. To provide better prognostic information for NHL, independent prognostic factors have been defined. Factors that are independently predictive of overall survival include age less than 60 (vs. 60 and older), stage I or II (vs. stage III or IV), number of extranodal sites of disease, performance status, and serum lactate dehydrogenase level (5). On the basis of these variables, patients can be divided into four risk groups ranging from low-risk (zero or one adverse prognostic factor) to high-risk (4–5 adverse prognostic factors). Overall, the 5-year survival is 78% in low-risk patients, but only 26% in the most unfavorable group. Staging evaluation should be guided by a hematologist/oncologist and

include abdominal and chest computed tomography, bone marrow biopsy, and the routine laboratory determinations mentioned above. Fluorine-18 deoxyglucose positron emission tomography (FDG-PET) scanning is increasingly becoming an important imaging modality, especially when following up with patients in whom the initial presentation was bulky (6). Multiple studies have

TABLE 94.2
ANN ARBOR STAGING SYSTEM

Stage	Characteristics
I	Involvement of a single lymphatic region (I), or localized involvement of a single extralymphatic organ or site (IE).
II	Involvement of two or more lymphatic regions on the same side of the diaphragm (II), or localized involvement of a single extralymphatic organ or site and one or more lymphatic regions on the same side of the diaphragm (IIE).
III	Involvement of lymphatic regions on both sides of the diaphragm (III), which may also be accompanied either by localized involvement of an extralymphatic organ or site (IIIE), or by involvement of the spleen (IIIS), or by both (IIIE+S).
IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymphatic involvement.

The absence or presence of unexplained fever, night sweats, and/or weight loss of more than 10% of the usual body weight in the six months before diagnosis is denoted by the suffix letters A (absence) or B (presence).

demonstrated better predictive accuracy with FDG-PET than with computed tomography in restaging of NHL patients after therapy.

SPECIFIC CATEGORIES OF LYMPHOMAS

Given the wide diversity of entities, clinical behaviors, and treatments, it is helpful to understand some basic concepts about the different types of lymphomas.

Diffuse Small Cell Lymphomas

Diffuse small cell lymphomas are a group of B-cell lymphomas that include the entities of small lymphocytic lymphoma, lymphoplasmacytoid lymphoma, marginal zone lymphoma, and mantle cell lymphoma. With the exception of mantle cell lymphoma, which can have a more aggressive course, the diffuse small cell lymphomas are categorized as indolent. Diffuse small cell lymphomas make up 10%–20% of all NHLs. Men are affected more than women, and the average age at diagnosis is 50 years. Diffuse small cell lymphomas typically present in advanced stages, with diffuse adenopathy and bone marrow involvement. Splenomegaly and other extranodal sites of involvement are common. Anemia and thrombocytopenia can result from splenic or marrow involvement, or both. Mantle cell lymphoma tends to follow a shorter, more aggressive course than that of the other diffuse small cell lymphomas, with median survival times of 3–5 years.

Although the other entities in this group are not thought to be curable, survival is measured in years; many patients are alive more than 10 years after diagnosis. Marginal zone lymphomas frequently involve extranodal sites alone at presentation, particularly in the gastrointestinal tract, and this subset is referred to as mucosa-associated lymphoid tissue (MALT) lymphoma.

Treatment may be reserved for symptomatic disease in selected patients, because early intervention has not been demonstrated to alter survival. Symptoms can take the form of discomfort from compression of extranodal structures by adenopathy and clinically significant anemia or thrombocytopenia. Most patients respond to therapy, with significant or complete regression of measurable disease during initial treatment. Unfortunately, relapses are characteristic. Remissions typically last 2–4 years. If symptoms are confined to one area of disease, such as a single mass or lymph node group, radiation can be used to control local problems when chemotherapy is contraindicated. Diffuse small cell lymphoma undergoes transformation to a higher grade lymphoma in up to 10% of patients.

Follicular Lymphomas

This group of mostly indolent lymphomas includes follicular center lymphoma of small cleaved cell type (grade I), follicular mixed small and large cell type (grade II), and follicular large cell type (grade III). Follicular lymphomas comprise 35%–40% of all NHLs. They affect men and women equally, and the mean age at diagnosis is 55 years. As with other indolent lymphomas, disease is usually advanced at presentation. Typical features include widespread adenopathy, often with bone marrow or splenic involvement. The follicular lymphomas have an indolent course in most patients, with median survival time varying from 6–10 years from diagnosis. Some patients have a more aggressive disease, whereas others live more than 20 years following diagnosis. Intermittent relapses are the rule. Because of this natural history, a watchful waiting strategy has been employed, with treatment delayed until symptoms caused by bulky adenopathy, organ compromise, or constitutional symptoms develop. The disease course is highly variable, but most patients require treatment within four years of diagnosis. Controversy exists regarding whether some patients with stage I or II disease are cured with local radiation therapy.

Historically, treatment has included alkylating agents such as cyclophosphamide or chlorambucil, alone or in combination with other chemotherapeutic drugs and steroids (Chapter 90). The pan-B-cell monoclonal antibody (rituximab) is approved for the re-treatment of follicular lymphomas based on a 50% response rate (7). Newer data indicate that rituximab alone is effective in previously untreated patients and prolongs time to treatment failure in combination with chemotherapy. In addition, monoclonal antibodies conjugated to radioisotopes have been

approved for the treatment of recurrent follicular lymphoma (8, 9). Like other indolent lymphomas, most follicular lymphomas respond to treatment but repeatedly relapse. Histologic transformation to higher grade lymphoma is more common than in the diffuse low-grade lymphomas (up to 60% of patients). When diagnosed, this must be treated with intensive chemotherapy. Although transformation is often an ominous prognostic sign, transformed lymphoma is sometimes curable, and patients who respond completely to therapy may have a life expectancy similar to that of patients with the underlying low-grade lymphoma.

Diffuse Aggressive Lymphomas

The diffuse aggressive lymphomas include diffuse large B-cell lymphoma, which accounts for about one-third of all NHLs, and the rare peripheral T-cell lymphomas. Diffuse large B-cell lymphomas are characterized by aggressive growth leading to clinical consequences in weeks to months and the potential to be cured with current therapies. Diffuse aggressive lymphomas present with early-stage or localized disease in more than 30% of patients. Extranodal sites of disease are common, as in primary lymphomas of the CNS, testis, and stomach. Approximately 20% of patients present with classic “B” symptoms. Given the aggressive nature of these lymphomas, treatment should begin as soon as staging studies are complete. The new standard of treatment is combination chemotherapy plus rituximab, based upon superior efficacy in multiple clinical trials (10). Treatment is generally given for about six months; radiation therapy delivered after a shortened course of chemotherapy may be used for patients with favorable localized disease presentations. The peripheral T-cell lymphomas are a heterogeneous group of lymphoproliferative diseases with unique clinical and pathologic features. As a group, they are characterized by relatively poor response to or early relapse after treatment and brief survival times. An exception are the anaplastic large T-cell lymphomas that occur in younger patients; these are frequently cured with combination chemotherapy.

Other Important Non-Hodgkin’s Lymphomas

Lymphoblastic lymphoma is a rare, aggressive T-cell lymphoma. It commonly presents with a rapidly enlarging mediastinal mass. Superior vena cava syndrome (Chapter 92), pleural or pericardial effusion, and bone marrow involvement with circulating lymphoma cells may be seen at presentation. Burkitt lymphoma is a high-grade B-cell lymphoma presenting with rapidly enlarging masses in the head and neck or abdominal regions, frequently with bone marrow and central nervous system involvement. Lymphoblastic lymphomas and Burkitt lymphomas have high proliferative rates and are exquisitely sensitive to chemotherapy induction with regimens used for acute

leukemia. This combination of high tumor burden and high growth fraction make tumor lysis syndrome a frequent complication of therapy. Hospitalization during initial therapy is often required (see later in this chapter).

HIV-associated lymphomas usually occur as late manifestations of HIV disease, often after previous AIDS-defining illnesses. They are typically B-cell lymphomas of intermediate or high grade that present in extralymphatic sites, particularly the CNS, gastrointestinal tract, bone marrow, and liver. Constitutional symptoms are present in 80% of patients at diagnosis. The CD4 cell count at diagnosis is prognostically significant. The advent of highly active antiretroviral therapy has resulted in better therapeutic tolerance for therapy and improved overall outcomes (11).

Hodgkin's Disease

Hodgkin's disease is classified in the broad category of lymphoid malignancies but remains separate from the NHLs given its unique pathologic and clinical patterns. The *Reed-Sternberg cell*, the malignant cell in Hodgkin's disease, derives from a B-cell lineage. Hodgkin's disease is divided into classical (nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte depletion) and lymphocyte predominant subtypes. Hodgkin's disease most commonly presents as asymptomatic lymph node enlargement, often in the neck, supraclavicular fossa, or axilla. Another common presentation is an anterior mediastinal mass incidentally discovered on chest radiograph. Lone abdominal or inguinal disease is uncommon. Other presenting features characteristic of Hodgkin's disease include pruritus and cyclic fevers.

The initial evaluation of the patient with Hodgkin's disease is similar to that for NHL. Most patients present with stage II or III disease. "B" symptoms are more common in patients with advanced disease. Although uniformly fatal if untreated, Hodgkin's disease is among the most curable of all malignancies, with approximately 75%–85% of patients surviving more than 10 years after diagnosis. More than 90% of patients with early stage disease are cured with primary or secondary treatment. Patients with localized disease are currently managed with brief chemotherapy and limited radiotherapy. Patients with widespread disease receive chemotherapy as the basis of treatment. The contribution of radiation therapy is debatable after a full course of chemotherapy in advanced disease. Recurrent disease is treated with high-dose chemotherapy and autologous stem cell transplantation, often with good results (Chapter 96). Given the long-term survival of the majority of patients with Hodgkin's disease, late complications of treatment are common and have become a major cause of morbidity and mortality. These complications include coronary artery disease, cardiomyopathy, cardiac valvular lesions, secondary cancers (associated with radiation therapy), and secondary acute leukemia (associated with chemotherapy containing alkylating agents). NHL is seen as a complication of either

radiation therapy or chemotherapy. Other common long-term complications include hypothyroidism and infertility.

COMPLICATIONS REQUIRING HOSPITALIZATION

The diagnosis, staging, and treatment of lymphomas currently are performed entirely on an outpatient basis. With the exception of particularly dose-intensive treatments or chemotherapy regimens requiring continuous infusions over several days, hospital admissions rarely are planned as part of the management strategy. Therefore, the inpatient physician most often plays a role in the management of complications that arise from the disease or its treatment.

Tumor Lysis Syndrome

The tumor lysis syndrome is a series of metabolic derangements (hyperuricemia, hyperphosphatemia, hypocalcemia, and hyperkalemia) that can result in acute renal failure or death. The syndrome develops when induction therapy for sensitive malignancies leads to the sudden release of intracellular ions, nucleic acids, and proteins that overwhelm the kidneys' ability to excrete them. Although most clinical consequences occur after treatment, high cellular turnover in rapidly dividing tumors often leads to a degree of renal insufficiency before the initiation of therapy. Tumor lysis syndrome is most commonly observed with high-grade NHLs.

Hyperuricemia and *hyperuricosuria* are usually the earliest manifestations of the tumor lysis syndrome. The increased uric acid load leads to the deposition of uric acid crystals in the collecting ducts and distal tubules. Once the crystals are delivered to the distal tubules, the relatively acid environment renders the uric acid even less soluble. Further deposition takes place and impairs urine excretion. This results in a decreased glomerular filtration rate and, without treatment, acute renal failure. Any condition that predisposes to a decreased glomerular filtration rate or decreased urine flow can predispose to acute renal failure.

Hyperphosphatemia develops later than hyperuricemia, often 48 hours into treatment, peaking on the second and third days of therapy. As the serum phosphate rises, it can form complexes with serum calcium and precipitate, resulting in hypocalcemia. In the most severe circumstances, this can lead to cramping, tetany, and cardiac arrhythmias. Less common but potentially more life-threatening is hyperkalemia, which can develop with the release of intracellular potassium from the disrupted tumor cells. When this is superimposed on renal insufficiency, dramatic increases in potassium levels can occur. If not corrected, hyperkalemia can lead to cardiac arrhythmias and sudden death (Chapter 104).

Initial Therapy

The best management of tumor lysis syndrome is to prevent it through early recognition of patients at risk and prompt institution of prophylactic measures. Patients at highest risk for development of the syndrome include those who have tumors with high proliferative rates, high serum levels of lactate dehydrogenase, and elevated serum levels of uric acid before treatment. Patients at highest risk

for the development of clinical consequences include those with underlying renal insufficiency and volume depletion.

Figure 94.1 shows a critical pathway for the management of tumor lysis syndrome. Whenever possible, patients at high risk for the development of tumor lysis syndrome should be admitted to the hospital 24–48 hours before the institution of therapy. Unfortunately, given the aggressive nature of these tumors, delaying treatment is often difficult. All supplemental potassium should be avoided, with a goal

of attaining a low-to-normal serum level before therapy. As soon as possible, an *intravenous infusion of saline solution* should be started. In patients with underlying cardiac or renal dysfunction, this is accomplished most safely in an ICU setting. Aggressive hydration (up to 4 L/d) should be instituted before therapy and continued during and for several days after the treatment. Sometimes, as many as 5 or 6 L of saline solution may be necessary. *Allopurinol* has long been the mainstay in preventing tumor lysis syndrome. It should be given as long before the start of therapy as possible in patients at high risk for tumor lysis. The goal of treatment is to normalize or greatly reduce the serum uric acid level to minimize uric acid deposition in the kidney. Allopurinol can cause a syndrome of rash, hepatitis, eosinophilia, and worsening renal function in patients with underlying renal insufficiency. Lower doses should be used in these patients, and the drug should be discontinued at the first sign of rash. The role of alkalinization of the urine remains controversial. Recombinant urate oxidase (rasburicase) is a new IV, once-a-day agent that produces a sharp and consistent decrease in uric acid levels in patients undergoing cytoreductive therapy. In a randomized study of patients at high risk of tumor lysis, rasburicase led to more rapid control and lower levels of plasma uric acid than allopurinol (12).

Even when mild hypocalcemia develops, calcium replacement should be avoided unless serious clinical consequences such as tetany or cardiac arrhythmias occur. Aluminum hydroxide should be used to minimize hyperphosphatemia. Hyperkalemia should be watched for closely and treated aggressively with standard treatments (Chapter 104).

Indications for Consultation

Despite aggressive preventive measures and management of electrolyte disturbances, oliguria and acute renal failure or very severe electrolyte disturbances develop in some patients. A nephrologist should be consulted in cases of oliguria, inability to hydrate adequately because of third spacing, or an electrolyte disturbance that does not readily respond to the measures described above. Hemodialysis is often required short-term and can be life-saving, as the renal impairments are most often reversible (Chapter 100).

Discharge Issues

Tumor lysis is an uncommon and life-threatening situation. The patient should be discharged only after the cycle of chemotherapy is completed and any electrolyte imbalances have been corrected. Good urine output should be maintained through this period. Stabilization of lactate dehydrogenase and uric acid beyond 48–72 hours suggests that further tumor lysis is not going to occur. The patient should not have uncontrolled nausea or vomiting, which might impair the ability to consume fluids by mouth. Allopurinol or rasburicase should be continued.

Hypercalcemia

Although hypercalcemia is common in many malignancies, it is unusual in NHL and Hodgkin's disease. HTLV-I-associated T-cell lymphoma is an exception. NHL patients with hypercalcemia usually have high tumor burdens and advanced disease. Their debilitation leads to inactivity and dehydration, which exacerbate the hypercalcemia. Acute hypercalcemia should be treated urgently, as described in Chapter 92. Corticosteroids can be quite effective in the treatment of hypercalcemia secondary to lymphoma.

Infections

Fever and neutropenia are the most common serious treatment-related complications. Because cure is the goal of treatment for many aggressive lymphomas, the therapeutic regimens are dose-intensive and often leave patients severely neutropenic and at high risk for infection and its sequelae. The general approach to fever and neutropenia is the same as in other immunocompromised hosts (Chapter 63). However, it is worth noting several points specific to lymphoma.

Issues at the Time of Admission

In addition to being neutropenic as a consequence of cytotoxic therapy, many lymphoma patients are otherwise immunodeficient from their disease process. Patients often have deficiencies in cell-mediated immunity that place them at increased risk for opportunistic, nonbacterial infections (Chapter 63). A particularly high incidence of these infections has been noted in NHL patients receiving purine analog agents such as 2-CDA and fludarabine. Prophylaxis against infection with *Pneumocystis jirovecii* (formerly *P. carinii*) and herpes viruses should be considered in this population. Additional sources of immune compromise include immunoglobulin deficiency (in patients with small lymphocytic lymphoma), impairment of phagocytic function, and previous splenectomy (secondary to staging or treatment). Despite the widespread use of rituximab, which depletes B-cells for many months, infectious complications of this therapy have rarely been reported.

Although the modern approach to fever in the immunocompromised host often includes outpatient treatment and oral antibiotics, lymphoma patients undergoing chemotherapy rarely fit into the low-risk group that can be safely managed on an outpatient basis. This is particularly true in the special cases listed above. Admission to the hospital for intravenous administration of broad-spectrum antibiotics and close observation is usually warranted.

Discharge Issues

Despite the frequent use of dose-intense therapy, the routine use of hematopoietic growth factors has not been shown to decrease mortality in lymphoma patients (with

the exception of patients receiving high-dose therapy during bone marrow transplantation). However, the prophylactic use of growth factors can decrease the incidence of neutropenic fever and chemotherapy-induced anemia, and it often allows patients to stay on a therapeutic regimen without persistent delays in treatment because of low blood counts. Thus, growth factors are recommended for patients who have been hospitalized for fever and neutropenia during previous cycles of therapy, or for patients in whom potentially curative treatment is delayed because of neutropenia. Newer liposomal formulations of growth factors (pegfilgrastim and darbepoetin) have been approved (13, 14). These preparations allow for dosing intervals of 2–3 weeks, with an efficacy equivalent to the shorter acting preparations.

Syndromes of Organ Involvement or Compression

Non-Hodgkin's lymphoma can involve and compromise any organ system. Nodal disease can cause external compression of normal structures by extension, or disease can develop *de novo* in extranodal sites. This can occur at any time in the course of the disease and often presents challenging diagnostic and management problems.

Issues on Admission

Several general principles apply to lymphoma patients with growing masses and organ compromise. In patients without a diagnosis, a good sample of representative tissue must be obtained for diagnosis. Once a diagnosis is established, the goals of treatment can be defined. If the patient has a curable disease, local problems usually are best treated with systemic chemotherapy as part of the overall treatment plan. However, if the disease is incurable, local problems can be palliated with systemic chemotherapy or local radiation.

Patients with a known diagnosis and relapsed or progressive disease present complex issues. Many patients with a first relapse of aggressive NHL or Hodgkin's disease remain curable with measures such as high-dose chemotherapy and stem cell transplantation. In these patients, systemic treatment of local disease is usually indicated. In patients with indolent NHL, progressive disease should prompt consideration of *histologic transformation*. This requires repeated biopsy at times of changing disease manifestations, such as a rapid increase in size or development of new "B" symptoms. If histologic transformation is present, a more aggressive approach is warranted. Patients with multiple relapses and multiple prior treatments often lack the bone marrow reserve to tolerate intensive chemotherapy. In these instances, local radiotherapy can often palliate focal symptoms. Therefore, the approach to local acute problems must take into account the most ef-

fective immediate therapy as well as the patient's treatment history and prognosis.

Issues During Hospitalization—Specific Anatomic Sites

Chest

The mediastinum is one of the more common sites of NHL. Growing thoracic disease can extend to and compromise the adjacent great vessels, heart, lung, and thoracic duct. *Superior vena cava syndrome* (SVCS) is the clinical picture of dyspnea, cough, and edema of the face and upper extremities arising from obstruction of the superior vena cava. NHL is the second leading malignant cause of superior vena cava syndrome (after lung cancer). In NHL, superior vena cava syndrome is often a presenting feature of disease; it may also occur after a recurrence or histologic transformation of low-grade disease to a more aggressive type. The evaluation and management of SVCS is described in Chapter 92.

In patients without a diagnosis, a pathologic diagnosis should be obtained whenever possible before therapy is begun. In patients with previously diagnosed indolent lymphomas, biopsy of a new, rapidly growing mass should be performed to evaluate a histologic transformation. In NHL, careful physical examination often reveals an accessible peripheral node for biopsy, so that the need to obtain tissue from a mass obstructing the superior vena cava is avoided.

In contrast to lung cancer (where radiation therapy is generally preferred), chemotherapy is typically the initial treatment of choice and can provide equally prompt resolution of SVCS. However, both medical and radiation oncologists should be consulted urgently at the time of diagnosis of SVCS.

Other problems arising in the chest include pleural and pericardial effusions. They can develop in any type of NHL and can present at any time during the course of the disease. They may develop rapidly, presenting with acute dyspnea, or have a more insidious onset. *Pleural effusions* can develop either from obstruction of the thoracic duct by mediastinal adenopathy or by direct involvement of the pleura. Thoracentesis should be performed for diagnosis and symptomatic relief (Chapter 60). At times, lymphoma is not diagnosed by cytologic examination of the fluid; immunophenotyping may increase the diagnostic yield in such instances. The best treatment for this complication remains treating the underlying lymphoma. Effusions often respond to chemotherapy, which makes pleurodesis unnecessary. In slowly resolving effusions, several therapeutic thoracentesis procedures are required before systemic therapy takes effect. Pleurodesis should be reserved for palliation of patients with refractory effusions, unresponsive disease, or an inability to tolerate systemic treatment.

Less common but more immediately life-threatening are *pericardial effusions*. These most often result from direct extension of the disease to the pericardium from adjacent lymph nodes. Small effusions are easily demonstrated by computed tomography of the thorax. Patients with cough, orthopnea, dyspnea, or distended neck veins should undergo echocardiography to evaluate for cardiac tamponade (Chapter 46). Urgent drainage is necessary for symptomatic effusions. Chemotherapy is the preferred and most definitive treatment. In rare cases, an indwelling pericardial drain or window is required to prevent reaccumulation of fluid (Chapter 92).

Pulmonary nodules are occasionally seen with NHL or Hodgkin's disease. They are most common in patients with mediastinal disease. Biopsy is indicated in patients without mediastinal or widespread adenopathy or with lung nodules as the sole site of recurrence. Infections and primary lung carcinomas can develop in heavily treated patients and can mimic lymphoma (Chapter 61).

Abdomen

The gastrointestinal tract, primarily the stomach and small bowel, is involved in 16% of patients with NHL, most commonly Burkitt and diffuse large B-cell lymphomas. Large masses can cause obstruction. Lymphoma can occasionally erode through bowel walls. As lymphoma quickly regresses with treatment, the result can be *gastrointestinal bleeding* or a *perforated viscus*. Perforation can occur in 5%–15% of these patients, with mortality as high as 50% in patients in whom an acute abdomen develops. Surgery should be limited to patients with active bleeding or perforation. Patients at risk for perforation should be educated about the signs and symptoms of abdominal pain, bleeding, and fever. If perforation is suspected, the patient should be admitted to the hospital and abdominal radiography or computed tomography performed to evaluate for free air (Chapter 87). Urgent surgical consultation should be obtained. Early intervention with broad-spectrum antibiotics and, if necessary, surgical resection, are the best ways to minimize mortality from this infrequent complication. Gastrointestinal bleeding and perforation are most common shortly after the initial course of chemotherapy. However, these complications can still develop more than a month into treatment.

Extensive retroperitoneal and pelvic disease from NHL can lead to *ureteral obstruction*, resulting in hydronephrosis and renal insufficiency (Chapter 103). Often, nonspecific symptoms of back pain or intermittent abdominal cramping are present for weeks to months before the lymphoma is detected. In patients with known disease, a high degree of suspicion must be maintained. Abdominal ultrasonography or computed tomography can quickly rule out ureteral obstruction and hydronephrosis. Ureteral obstruction is best managed by systemic treatment in patients with newly diagnosed aggressive lymphomas. In patients with

extensive low-grade lymphoma, systemic chemotherapy also is often the best course. In patients with indolent disease who present with a local obstruction, or in patients who may not tolerate further chemotherapy, local radiation can alleviate the obstruction. If renal function is compromised or the patient is very symptomatic, stenting can often palliate the obstruction while definitive treatment is provided. Stenting does expose the patient to a risk for perforation and infection but is necessary at times to preserve renal function.

Hyperbilirubinemia can result from hepatic infiltration with lymphoma or extrinsic constriction of the biliary system by periportal lymphadenopathy (Chapters 77 and 84). As in other circumstances, this often responds promptly to systemic chemotherapy. As a result, biliary drainage or stenting is rarely indicated, except in patients with cholangitis or refractory disease. When patients with hyperbilirubinemia are treated, modification of the doses of drugs excreted in bile, such as adriamycin and vincristine, should be considered (Table 90.3).

Splenomegaly is frequently observed at presentation in patients with Hodgkin's disease or NHL, particularly diffuse small cell lymphomas. It may be discovered on physical examination or present symptomatically with pain or thrombocytopenia. In rare cases of "splenic lymphoma," the spleen is the primary or sole site of disease. Good responses have been observed with splenectomy, but cytotoxic chemotherapy can achieve equally good results and leave a functional spleen. In general, splenectomy should be reserved for patients with pancytopenia or thrombocytopenia that does not respond to systemic treatment of the lymphoma, or for palliation of symptoms such as pain in patients with refractory disease.

Nervous System

The CNS can be involved at initial presentation of advanced-stage disease, at relapse, or by primary CNS lymphoma. CNS disease is more common in high-grade lymphomas and diffuse histologies and is rare in follicular subtypes. Hodgkin's disease very rarely spreads to the CNS. Other risk factors for CNS disease include bone marrow involvement and epidural, testicular, and paranasal sinus disease. Potential CNS involvement in high-risk patients should be evaluated with cytologic analysis of cerebrospinal fluid.

Parenchymal brain involvement presents with symptoms of increased intracranial pressure or with focal neurologic deficits. *Leptomeningeal disease* often presents with cranial nerve palsies, mental status decline, or both. NHL of the brain is diagnosed by radiologic imaging. Magnetic resonance imaging can show greater detail, but computed tomography often suffices. Lymphoma appears as contrast-enhancing lesions on either study. Stereotactic biopsy is necessary to differentiate lymphoma from infection. Rapid disappearance of CNS mass lesions after initiation of

corticosteroids has been described with these lymphomas. Leptomeningeal disease can be more difficult to diagnose; cerebrospinal fluid cytology can be positive in as few as 20% of patients. Immunophenotyping of cerebrospinal fluid can increase the yield.

Spinal cord compression is rare in NHL. It most often occurs by direct extension from extradural masses. Cord compression can develop with any histologic subtype and should be evaluated as an oncologic emergency, as described in Chapter 92. As in other instances of organ compromise from lymphoma, chemotherapy often achieves as rapid a response as radiation therapy while simultaneously treating systemic disease.

COST CONSIDERATIONS

Most of the presentation, diagnosis, and management of lymphomas takes place entirely on an outpatient basis. Preventing hospitalization is the main way to control costs in managing this disease. Most hospitalizations are for complications of the disease or its treatment. Few cost analyses have been performed in the management of lymphoma complications. However, the routine use of hematopoietic growth factors is expensive and has not been shown to improve outcome except in the specific circumstances listed above.

KEY POINTS

- Non-Hodgkin's lymphoma and Hodgkin's disease are among the most treatable and curable of all malignancies. The treatment goals guide the approach to specific problems.
- Most diagnosis and treatment can be performed on an outpatient basis.
- Tumor lysis syndrome is a constellation of life-threatening metabolic disturbances that occur during the treatment of aggressive lymphomas and other malignancies. The best management is identification of patients at risk and institution of preventative measures, such as vigorous hydration and allopurinol.
- Acute renal failure in the setting of the tumor lysis syndrome is almost always reversible, even if a short course of hemodialysis is required.
- Infections in lymphoma patients undergoing treatment can be complicated by other immune deficiencies. Particular therapeutic urgency is required for splenectomized patients.
- Unlike other malignancies, non-Hodgkin's lymphoma or Hodgkin's disease causing obstruction or compression of normal structures can best be treated by chemotherapy.

- Gastrointestinal bleeding and perforation are uncommon but potentially fatal complications in the treatment of lymphoma of the gastrointestinal tract. Early surgical evaluation should be sought.

Chronic

Myeloproliferative

Disorders

95

Ayalew Tefferi

INTRODUCTION

Hematologic malignancies are organized into lymphoid or myeloid disorders, depending on whether the clonal (neoplastic) process involves cells of the myeloid lineage (granulocytes, monocytes, erythrocytes, platelets) or lymphoid lineage (lymphocytes, plasma cells). Within each lineage, disease is classified as acute or chronic, depending on the percentage of blasts in the bone marrow; more than 20% defines acute leukemia. Accordingly, the chronic myeloid disorders represent relatively mature proliferative disorders of the myeloid lineage and are subdivided into four major categories, including chronic myeloid leukemia (CML), the myelodysplastic syndrome (MDS), the chronic myeloproliferative diseases (CMPD), and the atypical chronic myeloid disorders (ACMD). Among the chronic myeloid disorders, CML is the easiest to identify because of its specific association with the Philadelphia chromosome or its molecular equivalent (bcr/abl translocation). The morphologic demonstration of dyserythropoiesis strongly suggests MDS; it is also characterized by granulocyte and megakaryocyte dysplasia. In addition, patients with MDS often display peripheral blood cytopenia(s), while those with CML and CMPD display peripheral blood cytosis.

The current classification of the CMPD includes essential thrombocythemia (ET), polycythemia vera (PV), and agnogenic myeloid metaplasia (AMM). At present, there is

not one specific diagnostic marker for any of these three clinico-pathologic entities, and a working diagnosis is formulated by a set of laboratory and clinical features. The fourth category of the chronic myeloid disorders, ACMD, is reserved for a miscellaneous group of myeloid disorders that do not fit into the other three categories. These include mast cell disease, hypereosinophilic syndrome, chronic neutrophilic leukemia, juvenile myelomonocytic leukemia, chronic myelomonocytic leukemia, and undifferentiated MDS/CMPD.

EPIDEMIOLOGY

In a population-based study from Olmsted County, Minn., annual incidence rates were 2.5/100,000 for ET, 2.3/100,000 for PV, and 1.3/100,000 for AMM (1–3). As is true for most hematologic malignancies, the incidence rates were significantly higher in the older age groups. However, as many as 20% of patients with ET and 7% of those with PV are younger than 40 years, and approximately 10% of those with AMM are younger than 50 years. Women are overrepresented (1.6:1) in ET, whereas men have a slight predominance in both PV and AMM. In all three disorders, the median age at diagnosis is approximately 60 years. In general, the connection between disease incidence and exposure to environmental factors has not been strong.

PATHOGENESIS

Studies based on analyses of glucose-6-phosphate dehydrogenase isoenzyme patterns and X-linked DNA analyses have supported the stem cell origin of the clonal process in the CMPD. New evidence suggests that both B and T lymphocytes may also be clonally involved in AMM (4). Recent studies have focused on the pathogenetic role of genes regulating the production and expression of lineage-specific growth factors (erythropoietin in PV and thrombopoietin in ET). So far, genetic lesions involving erythropoietin, thrombopoietin, or their receptors have not been recognized in either PV or ET. In all CMPD but primarily in PV, there is an abnormal growth factor response during *in vitro* myeloid colony growth including both growth factor-independence and hypersensitivity. Bone marrow fibrosis is often demonstrated in AMM and also may develop in the later stages of PV and ET. The process appears to be reactive; circumstantial evidence and animal experiments suggest the role of megakaryocyte- and/or monocyte-derived growth factors, including transforming growth factor- β , in its pathogenesis (5).

CLINICAL FEATURES AND PROGNOSIS

Essential Thrombocythemia

Essential thrombocythemia is a chronic state of increased platelet count. Although the disorder does not significantly compromise life expectancy during the first decade of the disease (1), the clinical course may be complicated by frequent vasomotor and thrombohemorrhagic events. Vasomotor symptoms result from platelet-mediated endothelial injury in small vessels and include headache, erythromelalgia (burning pain and erythema of the hands or feet), paresthesia, and visual symptoms. Although defective platelets are believed to contribute to the abnormal thrombosis and bleeding associated with ET, the risk has not been correlated with detectable qualitative or quantitative platelet abnormalities.

Most patients with ET are asymptomatic. Approximately one-third of patients have vasomotor symptoms, leukocytosis, or palpable splenomegaly. Bleeding complications are infrequent (5%) and usually inconsequential. Thrombotic complications are more frequent (15%) and can be life-threatening. The types of thrombotic complications are similar to those in PV (see later in this chapter). The risk for thrombosis is highest in patients with a prior history of thrombosis (31% per patient-year) and in those who are older than 60 years (15% per patient-year) (1). In the absence of these two risk factors, the risk for thrombosis is low (3%). It is important to note that the degree of thrombocytosis has not been correlated with thrombotic risk.

Polycythemia Vera

At presentation, patients may have symptoms and signs related to hyperviscosity and splenomegaly. These include headaches, dizziness, visual symptoms, paresthesias, fatigue, abdominal discomfort, weight loss, and night sweats. Pruritus after bathing is a frequent but poorly understood complaint (6). Clinical examination may reveal plethora (facial fullness and erythema), retinal vein distention, and palpable splenomegaly. More than half of all patients have associated leukocytosis or thrombocytosis. Microcytosis is frequent and indicates iron deficiency from phlebotomy or occult gastrointestinal blood loss. Nonspecific additional laboratory abnormalities include increases in the leukocyte alkaline phosphatase score and in the serum vitamin B₁₂ and uric acid levels.

Thrombotic events are frequent (20%) in PV and include stroke, transient ischemic attack, retinal vein thrombosis, central retinal artery occlusion, myocardial infarction, angina, pulmonary embolism, hepatic and portal vein thrombosis, deep vein thrombosis, and peripheral arterial occlusion. Similar to the situation in ET, thrombotic risk correlates with advanced age and history of thrombosis (2). In addition, the increased blood viscosity associated with the increased red cell mass contributes to thrombosis. Bleeding in PV is less frequent than in ET, and tends to occur in the gastrointestinal system. In addition, patients may experience vasomotor disturbances. Compared with ET, PV is more likely to undergo transformation into acute leukemia and myelofibrosis.

Agnogenic Myeloid Metaplasia

The median survival in AMM may be as long as eight years or as short as one year, depending, respectively, on the absence or presence of anemia and leukocytosis (7). Causes of death include heart failure, infection, and leukemic transformation; the latter occurs in approximately 10% of patients. Most patients experience progressive anemia requiring frequent red blood cell transfusions, massive hepatosplenomegaly, and the hypercatabolic symptoms of profound fatigue, weight loss, night sweats, and low-grade fever. In addition, in some patients, extramedullary hematopoiesis may develop in the spinal cord, the pleural and peritoneal cavity, and various organs. At presentation, 45% of patients will have a hemoglobin level of less than 10 g/dL, and 25% have thrombocytopenia, thrombocytosis, or leukocytosis.

DIFFERENTIAL DIAGNOSIS AND INITIAL EVALUATION

Once a chronic myeloproliferative disease is suspected, the initial step is to exclude the possibility of reactive thrombocytosis in cases of ET (Table 95.1 and Figure

TABLE 95.1
CAUSES OF REACTIVE THROMBOCYTOSIS

Acute conditions

- Immediate postsurgical period
- Acute bleeding
- Acute hemolysis
- Infections
- Tissue damage (acute pancreatitis, myocardial infarction, trauma, burns)
- Coronary artery bypass procedure
- Rebound effect from chemotherapy or immune thrombocytopenia

Chronic conditions

- Iron-deficiency anemia
- Surgical or functional asplenia
- Metastatic cancer, lymphoma
- Inflammatory disorders (rheumatoid arthritis, vasculitis, allergies)
- Renal failure, nephrotic syndrome

TABLE 95.2
CAUSES OF ACQUIRED SECONDARY POLYCYTHEMIA

Appropriate erythropoietin response

- Chronic lung disease
- Arteriovenous or intracardiac shunts
- High-altitude habitat
- Continuous carbon monoxide exposure (smoking)

Pathologic erythropoietin production

- Tumors (liver, kidney, cerebellum)
- Uterine fibroids
- After renal transplantation

95.1), apparent or secondary polycythemia in cases of PV (Table 95.2 and Figure 95.2), and other causes of bone marrow fibrosis in cases of AMM (Table 95.3). After the possibility of a reactive process is ruled out, the next step is to classify the chronic myeloproliferative disease accu-

rately. Accordingly, *all patients in whom a reactive process cannot be identified require a bone marrow examination with cytogenetic studies.*

With regards to the diagnosis of ET, one should first determine the duration of thrombocytosis; acute onset suggests reactive thrombocytosis while chronicity suggests ET. Initial laboratory tests should include measurement of serum ferritin and a peripheral blood smear examination (Figure 95.1). A low serum ferritin level is diagnostic of iron deficiency, which is associated with reactive thrombocytosis.

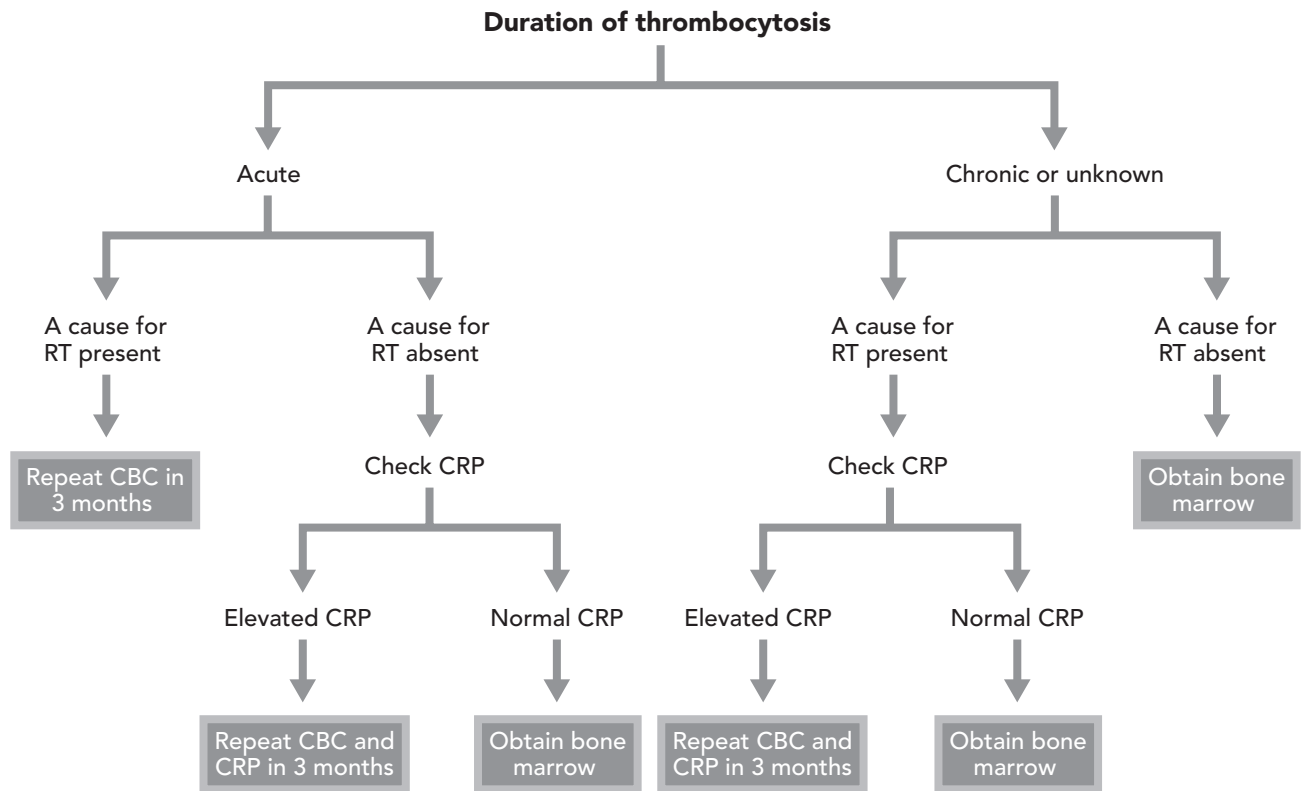

Figure 95.1 Diagnostic approach to the asymptomatic patient with thrombocytosis. *CBC*, complete blood cell count; *CRP*, C-reactive protein; *ET*, essential thrombocythemia; *RT*, reactive thrombocytosis.

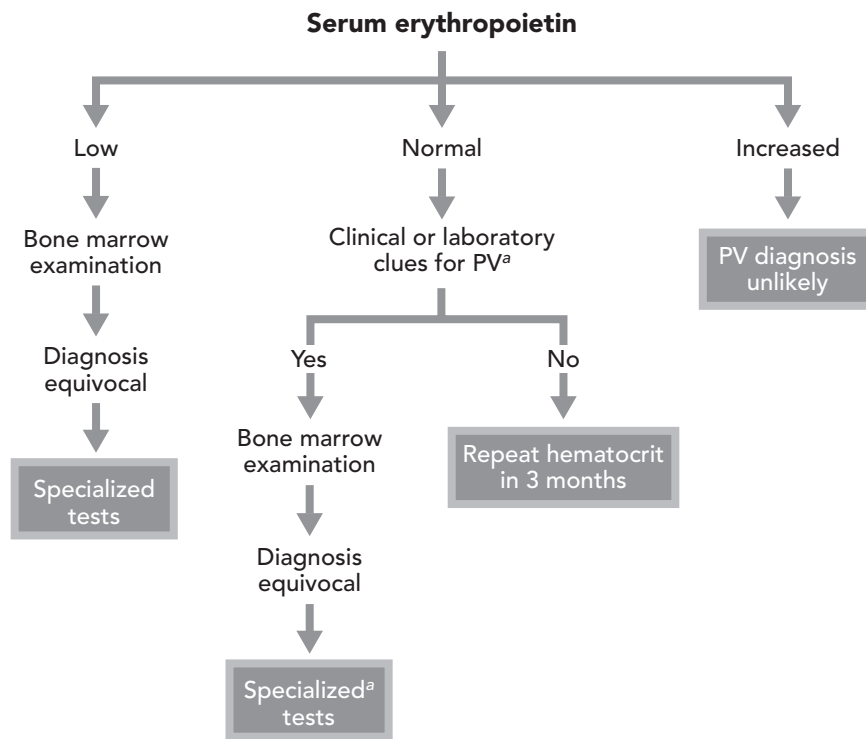

Figure 95.2 A practical algorithm for the diagnosis of polycythemia vera (PV). ^aSpecialized testing includes bone marrow immunohistochemistry for the thrombopoietin receptor (c-Mpl), reverse transcriptase-polymerase chain reaction (RT-PCR) for neutrophil expression of polycythemia rubra vera (PRV)-1 gene, and spontaneous erythroid colony assay.

However, a low serum ferritin does not exclude the possibility of ET. Similarly, the demonstration of Howell-Jolly bodies in the peripheral blood smear suggests reactive thrombocytosis associated with functional or surgical hyposplenism. Measurement of the serum C-reactive protein level helps address the possibility of an underlying occult inflammatory or malignant process. C-reactive protein level should be normal in uncomplicated ET and increased in most cases of reactive thrombocytosis. If all of these tests are unrevealing, a bone marrow examination is indicated; the characteristic finding in ET is megakaryocyte clusters.

In regards to PV diagnosis, it is no longer necessary to perform red cell mass and plasma volume measurements in view of the current availability of PV-characteristic biologic tests. Similarly, the Polycythemia Vera Study Group criteria (which utilized measures of red cell mass, leukocyte alkaline phosphatase, and vitamin B₁₂ levels) are neither essential nor accurate in the diagnosis of PV. Instead, it is much more practical to follow a diagnostic algorithm that utilizes clinical and bone marrow biopsy information in combination with one or more pertinent special laboratory tests (Figure 95.2).

The first step in the diagnostic evaluation of “polycythemia” is to determine whether or not PV should be suspected. PV should be suspected if the hemoglobin level in a male Caucasian is above 17.5 g/dL (or the corresponding sex- and race-adjusted value for females or African-American males). It should also be suspected if a high-

normal hemoglobin is associated with either a PV-characteristic clinical feature or a documented increase from an individual’s baseline hemoglobin level. Otherwise, a repeat blood count in three months should suffice.

In the presence of one of the above mentioned criteria for suspecting PV, the next step is to measure the serum erythropoietin level. Unlike all other causes of erythrocytosis, the erythroid proliferation in PV is erythropoietin-independent, and therefore it down-regulates erythropoietin production. As a result, serum erythropoietin levels are usually low, occasionally normal, but *never increased* in PV (Figure 95.2). Accordingly, PV should remain in the differential diagnosis in the presence of either low or normal EPO level. The next step is bone marrow examination with cytogenetic studies. An experienced hematopathologist is able to identify the histologic features of CMPD in general and PV in particular in the majority of cases. Occasionally, the diagnosis remains uncertain despite the information from bone marrow biopsy. In such instances, depending on availability, specialized tests may be utilized for further clarification.

The presence of substantial bone marrow fibrosis requires that other causes of fibrosis be excluded before AMM is diagnosed (Table 95.3). In this regard, particular attention should be paid to the possibility of either CML or MDS, since their prognosis and treatment are substantially different. The rates of cytogenetic abnormalities are 12% in untreated PV, 6% in ET, and 30% in AMM.

Non-hematologic disorders

Metastatic cancer
 Connective tissue disease
 Infections
 Vitamin D-deficiency rickets
 Renal osteodystrophy
 Gray-platelet syndrome

LONG-TERM MANAGEMENT

Essential Thrombocythemia

The use of acetylsalicylic acid (aspirin) in low doses (81 mg/d) is effective in controlling vasomotor symptoms. The use of platelet-lowering (cytoreductive) agents is primarily for prevention of thrombosis. The risk for thrombosis is very low in patients less than 60 years of age who do not have a history of thrombosis. Therefore, these patients may not require cytoreductive therapy. The use of these drugs in low-risk women of childbearing age is particularly discouraged.

In high-risk patients (prior history of thrombosis or age >60 years), hydroxyurea has been shown to reduce thrombotic events significantly, when compared with no treatment (8), and therefore its use is reasonable in this population. There is no hard evidence that hydroxyurea is leukemogenic when used in ET. Two other drugs, oral anagrelide and subcutaneous interferon- α , might also be used to lower platelet counts in patients with ET. With anagrelide therapy, side effects occur in one-third of patients and include headache, fluid retention, dizziness, palpitations, tachycardia, diarrhea, and rarely congestive heart failure. The response rate is more than 90%, and response occurs at a median time of 3 weeks. Anagrelide does not significantly affect the leukocyte count, but may cause severe anemia in approximately 25% of treated patients (9).

Interferon- α controls thrombocytosis, splenomegaly, and disease-associated symptoms in approximately 80% of patients with ET. The average response time is 12 weeks. Side effects include a transient influenza-like syndrome associated with fever and chills, myalgias, headache, and arthralgias. Chronic side effects include fatigue, nausea, anorexia, weight loss, diarrhea, increase in liver transaminases, altered mental status, and depression. Currently, hydroxyurea is the first line choice of drug therapy in ET regardless of age unless in women of childbearing age. In this regard, a recent randomized study demonstrated a significantly better anti-thrombotic as well as anti-hemorrhagic effect with hydroxyurea than with anagrelide. Furthermore, patients treated with anagrelide had a higher risk of transformation into myelofibrosis (10). Regardless of the particular platelet-lowering agent used, it is recommended that the platelet count be kept below 400,000/ μ L (9).

Polycythemia Vera

Based on currently available information, recommendations for the management of patients with PV are as follows: all patients should undergo phlebotomy to keep the hematocrit below 45% in men and 42% in women. Approximately 500 mL of blood may be removed daily (in symptomatic patients) or weekly (in asymptomatic patients) until the target hematocrit level is reached. Thereafter, the frequency of phlebotomy is adjusted to maintain the required hematocrit level at all times. In addition, a recent randomized study has demonstrated the anti-thrombotic value of low-dose aspirin in all risk categories of PV (11). In patients at high risk, hydroxyurea can be used to supplement phlebotomy (2).

For patients who do not tolerate hydroxyurea because of either side effects or neutropenia, interferon- α is a reasonable alternative. Interferon- α may also be considered as an alternative to hydroxyurea in women of childbearing age. A recent study involving over 1,600 patients with PV did not show increased leukemogenicity associated with single agent use of hydroxyurea (12). Phosphorus-32 may be considered if a patient's life expectancy is less than 10 years and when compliance with medication is an issue. Low-dose acetylsalicylic acid (81 mg/d) is effective for alleviating vasomotor symptoms and can be used if other treatment indications are present.

Agnogenic Myeloid Metaplasia

In young patients with AMM, allogeneic bone marrow transplantation sometimes leads to durable remissions (Chapter 96). Otherwise, most patients are treated palliatively. The combination of an androgen preparation (fluoxymesterone, 20 mg/d) and a corticosteroid improves anemia in one-third of patients (7). After one month of

therapy, fluoxymesterone is continued in responding patients and the corticosteroid is tapered. All patients treated with androgens should undergo periodic monitoring of serum liver chemistries, and male patients should be screened for prostate cancer before therapy is initiated. In addition, the virilizing side effects should be emphasized to female patients. Periodic red cell transfusion remains the major supportive therapy in AMM. Recent studies suggest that anemia in AMM may sometimes respond to either erythropoietin (13) or a combination of low-dose thalidomide and prednisone (14).

Splenectomy is considered for patients who have symptomatic splenomegaly (mechanical discomfort, refractory thrombocytopenia, hypercatabolic symptoms, or portal hypertension) (15). If laboratory evidence of disseminated intravascular coagulation is noted before splenectomy, the risk for perioperative bleeding may be increased, and it is recommended that the operation be postponed until the abnormalities are corrected. At experienced centers, the mortality rate for splenectomy should be less than 10%. Postsurgical complications include intraabdominal bleeding, subphrenic abscess, sepsis, thrombosis of large vessels, extreme thrombocytosis, and accelerated hepatomegaly. Thrombocytosis and hepatomegaly may be transiently controlled with hydroxyurea.

After splenectomy, almost all patients experience relief of hypercatabolic symptoms and portal hypertension. In addition, approximately one-third of the patients with refractory anemia benefit from splenectomy. In poor surgical candidates, the alternative to splenectomy is splenic irradiation, which usually provides a transient (3–6 months) benefit. Radiation therapy is most useful in the management of extramedullary hematopoiesis (16).

ISSUES DURING HOSPITALIZATION

The major indications for hospitalization of patients with PV and ET are thrombosis and bleeding. In AMM, indications for hospitalization include severe cachexia, extramedullary hematopoiesis involving the central nervous system, and scheduled splenectomy. Infrequent indications for hospitalization include acute leukemic transformation and life-threatening infections. Clinical situations that do not require hospitalization include asymptomatic thrombocytosis, erythrocytosis, leukocytosis, or marked hepatosplenomegaly. However, if these conditions are associated with bleeding, thrombosis, or severe pain (the latter may accompany splenic infarction), then hospitalization may facilitate prompt cytapheresis and pain control.

In the patient with thrombosis or bleeding, initial evaluation should include a complete blood cell count and determination of the prothrombin and activated partial thromboplastin times and bleeding time. (See Chapter 98 for a discussion of the more detailed evaluation of patients

with abnormal thrombosis or bleeding.) When a patient with myeloproliferative disease is bleeding or has prolonged prothrombin or partial thromboplastin times, measurement of coagulation factors may reveal an acquired factor V deficiency. In the patient being prepared for splenectomy, tests for disseminated intravascular coagulation are recommended because an elevated D-dimer level may be associated with increased perioperative bleeding. The imaging tests of choice are ultrasonography for suspected thrombosis of abdominal large vessels (portal and hepatic vein thrombosis), computed tomography for suspected central nervous system thrombosis or bleeding and for splenic infarcts, and magnetic resonance imaging for suspected extramedullary hematopoiesis involving the central nervous system.

Thrombosis

Patients with thrombosis should be anticoagulated unless there are contraindications (see Chapters 52 and 53 for general discussions regarding the initiation of heparin and warfarin therapy). Oral hydroxyurea should be started at the following dosages: 1 g four times a day for three days if the platelet count is more than 1 million/ μL ; 1 g two times a day if the count is 600,000/ μL –1 million/ μL ; and 500 mg two times a day if the count is 400,000/ μL –600,000/ μL . In addition, the blood bank should be contacted for immediate platelet apheresis if the platelet count is more than 800,000/ μL . In patients with PV, phlebotomy should be performed daily until the hematocrit is less than 45% in men and 42% in women. Oral allopurinol should be started at a dose of 300 mg/d (100 mg/d if the creatinine value is >2 mg/dL) if the leukocyte count is more than 30,000/ μL .

Heparin therapy is discontinued after a 5 day overlap with warfarin. In general, thrombocytosis and erythrocytosis are considered reversible risk factors for thrombosis, and warfarin therapy is continued for three months (target international normalized ratio of between 2.0 and 3.0) after the thrombotic event. In the presence of additional prothrombotic traits, more prolonged warfarin therapy may be required. After the first three days, the dose of hydroxyurea is adjusted to keep the platelet count below 400,000/ μL without reducing the leukocyte count to below 2,000/ μL . If a low leukocyte count does not allow the use of hydroxyurea, oral anagrelide at a dosage of 0.5 mg four times a day may be used instead. A high leukocyte count not associated with a high blast percentage does not require cytapheresis.

Bleeding

The first step in the management of bleeding complications is to discontinue the use of any antiplatelet agent. If the platelet count is less than 10,000/ μL , platelet transfusion is recommended. Initial laboratory evaluation should

include an evaluation for disseminated intravascular coagulation and coagulation factor deficiency. Acquired factor V deficiency is treated with fresh frozen plasma infusion or platelet concentrates. Occasionally, extreme thrombocytosis is associated with acquired type II von Willebrand's disease because of abnormal platelet adsorption of circulating von Willebrand's factor multimers. As such, platelet apheresis is recommended for bleeding associated with thrombocytosis. Concomitantly, therapy with a platelet-lowering agent should be started. See Chapter 98 for a fuller discussion of the management of abnormal bleeding.

Extramedullary Hematopoiesis

Extramedullary hematopoiesis can occur at several locations, including the spleen, liver, lymph nodes, peritoneum (causing ascites), pleura (causing pleural effusions), lung, bladder, and paraspinal and epidural spaces (causing spinal cord and nerve root compression). A patient with new-onset back pain should be evaluated for possible spinal cord compression. Neurologic symptoms and signs of spinal cord compression include paresthesia, motor weakness, hyperreflexia, and bladder or bowel incontinence. Magnetic resonance imaging with gadolinium is the preferred initial diagnostic test. If the clinical data are highly suggestive of cord compression, the patient should receive 10 mg of oral dexamethasone even before imaging is performed. If the test supports the diagnosis, dexamethasone should be continued at 4 mg orally four times a day until definitive treatment with irradiation is started. The steroid dose should be tapered during the course of radiation therapy. Extramedullary hematopoiesis is best treated with low-dose irradiation (1,000 cGy) in 5 to 10 fractions. Occasionally, a laminectomy may be required.

COST CONSIDERATIONS

Patients with chronic myeloproliferative diseases are usually managed in the outpatient setting. Attention to laboratory details prevents inadequate disease control and reduces the incidence of complications requiring hospitalization and other costly measures such as emergency cytapheresis. In addition, anticoagulant therapy for thrombosis with subcutaneous low-molecular-weight heparin may be administered on an outpatient basis.

There are substantial cost differences among the currently available platelet-lowering agents. The three most frequently used agents (hydroxyurea, anagrelide, and interferon- α) are similar in their ability to lower platelet counts but differ significantly in their side effect profile and cost. At the time of this writing, the annual drug costs for the

usual doses of these agents are \$1,700 for hydroxyurea, \$6,300 for anagrelide, and \$8,600 for interferon- α .

KEY POINTS

- The chronic myeloproliferative disorders represent relatively mature proliferative disorders. They include chronic myelogenous leukemia, essential thrombocythemia, polycythemia vera, and agnogenic myeloid metaplasia.
- Patients with essential thrombocythemia are usually asymptomatic but may have vasomotor symptoms, bleeding, or thrombosis. Patients with polycythemia vera are more commonly symptomatic and more often suffer thrombotic events. Patients with agnogenic myeloid metaplasia are often symptomatic; they usually have progressive, transfusion-dependent anemia.
- In general, chronic myeloproliferative disorders are diagnosed by bone marrow examination, performed after reactive disorders have been excluded.
- The following are key principles in the management of patients with essential thrombocythemia and polycythemia vera:
 - The patient should avoid smoking and using high doses of aspirin or nonsteroidal agents.
 - Aspirin (81 mg/d) is safe and effective for treating vasomotor symptoms.
 - Asymptomatic young women may not require platelet-lowering agents.
 - In patients older than 60 years and in those with a history of thrombosis, the platelet count should be kept below 400,000/ μ L in both essential thrombocythemia and polycythemia vera.
 - In patients with polycythemia vera, the hematocrit should be kept below 45% in men and 42% in women. This is accomplished by phlebotomy, supplemented by hydroxyurea in patients at high risk for thrombosis.

Transplantation

Frederick R. Appelbaum

INTRODUCTION

Biology of Hematopoietic Cell Transplantation

Bone marrow transplantation was the generic term used to describe the collection and transplantation of hematopoietic stem cells for therapeutic purposes. With the increasing use of peripheral blood and umbilical cord blood as sources of stem cells, *hematopoietic cell transplantation* has now become the preferred generic term for this procedure. The basic technique of hematopoietic cell transplantation is relatively straightforward. Following an appropriate pretreatment evaluation and identification of a source of stem cells, patients are first treated with a high-dose "preparative" regimen. This serves to eradicate the disease being treated and induce a sufficient degree of immunosuppression for the patient to be able to adequately accept the marrow graft. Following the preparative regimen, hematopoietic stem cells from an appropriate donor or previously harvested from the patient, are administered intravenously. After transplantation, patients require intensive supportive care until marrow function has been restored. Although simple in concept, transplantation is a complex procedure and is best carried out at centers specializing in the approach.

Several characteristics of the hematopoietic stem cell make transplantation possible and broadly applicable. First, it is amenable to cryopreservation, a relatively straightforward freezing and rethawing process. Second, the hematopoietic stem cell has enormous regenerative capacity and gives rise to a wide variety of mature progeny. In humans, transplanting as little as a few million highly purified stem cells can result in complete and sustained engraftment.

This occurs with subsequent production of all of a patient's red cells, granulocytes, and T- and B-cells, in addition to pulmonary alveolar macrophages, Kupffer cells of the liver, osteoclasts, Langerhans cells of the skin, and microglial cells of the brain. Finally, the remarkable homing capacity of the hematopoietic stem cell greatly simplifies the process of transplantation. Following intravenous infusion, a substantial proportion of hematopoietic stem cells collect in the bone marrow.

The source of hematopoietic stem cells used for transplantation can be defined by the relationship between the donor and the recipient, and also according to their anatomic source.

Donor-Recipient Relationship

The three broad categories defined by the relationship between donor and recipient are *syngeneic* (identical twins), *autologous* (self-harvest), and *allogeneic* (genetically dissimilar individuals). The source of first choice is an identical twin (syngeneic transplant). In syngeneic transplantation, there is no risk that stem cells will be contaminated with tumor, as can happen in autologous transplantation, and there is no risk for the development of *graft-versus-host disease* (GVHD), as there is in allogeneic transplantation. Autologous transplantation may be appropriate if the primary purpose of the transplant is to administer higher doses of chemotherapy or systemic radiotherapy than would be possible without transplantation. Autologous transplantation also has the advantage of avoiding GVHD. Nonetheless, an autologous transplant carries the dual disadvantages of lacking a *graft-versus-tumor effect* and of possibly being contaminated with the patient's tumor. Allogeneic transplantation is considerably more complicated

than syngeneic or autologous transplantation. It carries the related risks of graft rejection and GVHD. Because the donor and the recipient are genetically different, the immune system of the patient can reject the transplanted marrow. At the same time, the immune-competent cells developing from, or transplanted with, the stem cell inoculum can react against the new host, causing GVHD.

Matching

For an allogeneic transplant to be successful, a close, if not identical, match of HLAs (human leukocyte antigens) is necessary. With greater HLA disparity between donor and host, there is greater immunologic reactivity between the two. This immunologic reactivity is, for the most part, mediated by T-cells reacting with histocompatibility antigens encoded by genes of the major histocompatibility complex (MHC). The HLAs produced by the genes of the MHC are a group of molecules that bind endogenous or exogenous antigenic peptides and present them on the cell surface, an important step in mediating an immune response. The HLA molecules themselves are termed *major determinants*. If T-cells are exposed to cells of a different HLA type, they will react vigorously to the mismatched HLA antigens on the cell surface. T-cells exposed to cells from HLA-matched but nonsyngeneic individuals may also react, although less vigorously, because endogenous proteins presented by the HLA molecules differ. Such differences are termed *minor determinants*.

The probability of success in allogeneic transplants is greatest when siblings are HLA-identical. For any given patient, the likelihood that a specific sibling will be HLA-identical is one in four. Given the average size of American families, *approximately 35% of patients have an HLA-identical sibling*. The results when a transplant from a family member donor mismatched for a single antigen is used are nearly equivalent in terms of survival, although there is a higher incidence of GVHD. Results using matched unrelated donors are approaching those seen using matched or single antigen-mismatched family member donors, although the incidence of GVHD and graft rejection may be somewhat higher using unrelated donors (1). In most studies, the use of transplants from donors mismatched for two or more antigens has resulted in a substantially higher incidence of fatal GVHD or graft rejection and lower posttransplant survival. The HLA antigens are extremely polymorphic; therefore, the likelihood that any two unrelated persons would match is extremely low—less than 1 in 10,000. Finding an HLA-matched *unrelated* donor is possible because of the formation of various donor registries, through which more than 7 million normal persons have volunteered to provide stem cells for an unrelated patient. Currently, the odds of finding an HLA-matched unrelated donor are approximately 60%. On average, it requires three months from the time a search is initiated to identify a donor and schedule the transplant.

Location of Harvested Stem Cells

The source of stem cells can also be categorized according to their anatomic location. Traditionally, the source of stem cells has been the bone marrow. Marrow is usually obtained by multiple aspirations from the anterior and posterior iliac crests. Hematopoietic stem cells also circulate in the peripheral blood, although at very low numbers. The concentration of stem cells in peripheral blood increases dramatically during recovery from cytotoxic therapy or following administration of a hematopoietic growth factor, such as granulocyte colony-stimulating factor (G-CSF) or granulocyte-macrophage colony-stimulating factor (GM-CSF). With such pretreatment, sufficient stem cells for autologous or allogeneic engraftment can be obtained by leukapheresis. Use of *peripheral blood stem cells* is generally associated with a more rapid engraftment than is seen with the use of bone marrow. Umbilical cord blood contains a high concentration of hematopoietic stem cells, and cord blood can be used as a source of stem cells for transplantation (2). Cord blood is relatively devoid of mature T cells. As a consequence, the risk for GVHD is less with cord blood, but the risks of graft rejection tend to be higher. Because of the limited numbers of stem cells within cord blood, engraftment tends to be slower than when peripheral blood stem cells or marrow are used.

INDICATIONS FOR HEMATOPOIETIC CELL TRANSPLANTATION

As outlined in Table 96.1, hematopoietic cell transplantation can be used successfully in children with congenital immunodeficiency states. The technique is also widely used to provide a normal lymphohematopoietic system to patients with severe but nonmalignant disorders of hematopoiesis. *Aplastic anemia* is readily curable with marrow transplantation. With use of the optimal preparative regimen, cure rates of 90% have been reported following HLA-matched sibling transplantation. Hematopoietic cell transplantation is also used in the treatment of patients with *hemoglobinopathies*. Cure rates of 70%–90% have been reported in the treatment of thalassemia major, with the best results seen in patients undergoing transplantation before the development of hepatomegaly or portal fibrosis. Similar results have been reported in the treatment of *sickle cell anemia*, although fewer patients have been studied (3).

Hematopoietic cell transplantation plays a major role in treating a variety of malignant diseases by allowing for the administration of far higher doses of chemotherapy and systemic radiotherapy than would be possible without marrow support. In addition, in the allogeneic setting, cells derived from the transplant provide an immunologic graft-versus-tumor effect. Although the antitumor effects of the dose escalation and graft-versus-tumor reaction provided by the transplant are considerable, they are not sufficient to

TABLE 96.1
DISEASE-FREE SURVIVAL AFTER BONE MARROW TRANSPLANTATION

Disease	5-year disease-free survival (%)
Severe combined immunodeficiency disease	90
Aplastic anemia	90
Thalassemia major	70–90
Sickle cell disease	70–90
Fanconi's anemia	50–70
Acute myeloid leukemia	
First remission	40–70
Second remission	30
Acute lymphocytic leukemia	
First remission	40–70
Second remission	30–50
Chronic myeloid leukemia	
Chronic phase	60–70
Accelerated phase	30–40
Blast crisis	15–20
Myelodysplastic syndrome	45
Non-Hodgkin's lymphoma, first relapse	40–50
Hodgkin's disease, first relapse	40–60
Multiple myeloma	35
Breast cancer	
High-risk stage II	70
Chemotherapy-responsive stage IV	10–30

allow for meaningful responses in tumors that are completely refractory to standard-dose treatment. Thus, the major utility of transplantation has been in the treatment of hematologic malignancies and other chemotherapy-responsive tumors.

Hematopoietic cell transplantation is the only curative therapy for patients with *acute myeloid leukemia* who have failed initial induction chemotherapy, and it is generally considered to be the treatment of choice for patients who relapse after an initial complete response (Chapter 93). Whether patients should undergo transplantation while in first remission is a topic of considerable study. The bulk of recent evidence from randomized controlled trials favors allogeneic transplantation, especially for patients with high-risk AML as determined by cytogenetic risk factors. The evidence for autologous transplantation for AML in first remission is more equivocal (4). The indications for transplantation for adult acute lymphoblastic leukemia are similar to those noted above for AML, except that there is less evidence addressing the role of transplantation for adult patients with acute lymphoblastic leukemia in first remission (5).

Allogeneic and syngeneic transplantation are the only therapies capable of curing patients with *chronic myelogenous leukemia* (CML). Five-year disease-free survival rates of 60%–70% for patients who undergo transplantation during chronic phase, 30%–40% for transplantation during

accelerated phase, and 15%–20% for transplantation during blast crisis can be expected. The best results with transplantation have been obtained when the procedure is carried out within the two years of diagnosis. However, recommendations for early transplantation are complicated by the development of imatinib mesylate, a very effective, relatively nontoxic oral agent. Because imatinib does not generally result in complete molecular remissions in CML, allogeneic transplantation remains an important option for younger patients with matched donors. Older patients and those without matched donors should generally be treated initially with imatinib. Results of transplantation for the treatment of *myelodysplastic syndrome* in many ways mirror those seen in chronic myelogenous leukemia. Although transplantation is the only curative therapy for myelodysplastic syndrome, patients with refractory anemia can live with their disease for a long period, which makes recommendations about early versus delayed transplantation complex.

Patients with disseminated intermediate- or high-grade *non-Hodgkin's lymphoma* who fail to achieve an initial complete remission or who relapse after first remission should be considered for transplantation (Chapter 94). In one study, the 5-year disease-free survival of patients who underwent autologous transplantation for recurrent non-Hodgkin's lymphoma was 46%, compared with 12% for patients undergoing chemotherapy (6). The role of transplantation for patients with high-risk non-Hodgkin's lymphoma in first remission is unsettled. In general, the results with *Hodgkin's disease* mirror those seen in non-Hodgkin's lymphoma, but large randomized trials comparing results of transplantation with those seen with chemotherapy have not been reported.

Allogeneic transplantation results in approximately 35% survival for patients with *multiple myeloma* who have failed first-line therapy. Because of substantial morbidity and mortality associated with the procedure, most experts do not currently recommend allogeneic transplantation during first remission. Autologous transplantation provides less potential for cure but is considerably safer. In one large trial, autologous transplantation during first remission substantially improved disease-free and overall survival (7). A novel approach of autologous transplantation followed by nonmyeloablative allogeneic transplantation shows great promise in the treatment of myeloma.

The role of high-dose chemotherapy followed by autologous transplantation in the treatment of breast cancer is controversial. Although promising phase II results were reported both in patients with stage IV disease and in patients with high-risk stage II disease, the early results of randomized trials have been more equivocal. High-dose chemotherapy followed by autologous transplantation has also been studied in a variety of other chemotherapy-sensitive solid tumors, including neuroblastoma, testicular cancer, ovarian cancer, and pediatric sarcomas, but randomized trials have not yet been reported.

HOSPITAL CARE OF THE HEMATOPOIETIC CELL TRANSPLANT PATIENT

Preparative Phase and Early Posttransplant Issues

Chemotherapy, radiation therapy, or both are administered during the preparative phase of the pretransplant period. To optimize the safety and effectiveness of the preparative regimen, the physician must be aware of the unique features of each of the drugs used in the preparative regimen. Specific chemotherapy toxicities are discussed in Chapter 90. General guidelines relating to the care of patients in the preparative phase are presented in the following sections.

General Supportive Care

Nausea and vomiting are frequent immediate side effects of the chemotherapy and radiation used in most preparative regimens. Prevention of nausea and vomiting is far preferable to reacting to symptoms once they develop. High-dose cyclophosphamide and cisplatin are highly emetogenic, whereas melphalan, thiotepa, busulfan, paclitaxel (Taxol), etoposide, and total body irradiation (TBI) are moderately so. The use of intravenous antiemetics before and during the administration of highly emetogenic agents can control nausea and vomiting in 70%–90% of cases. Oral antiemetics are often sufficient if the agents used in the preparative regimen are of low-or-moderate emetogenic potential. See Chapter 90 for a discussion of therapeutic options.

Patients who began the transplant preparative regimen with hematologic malignancies in relapse are at risk for the development of the acute tumor lysis syndrome. See Chapter 94 for a complete discussion of the prevention and treatment of this entity.

Total Body Irradiation

Total body irradiation can be administered as a single dose, fractionated over several days with single fractions given daily, or hyperfractionated with multiple doses given two or more times a day for several days. TBI is generally administered at a slow rate (7–15 cGy/min), so that single-dose TBI may require 2–3 hours, whereas individual fractions may take 15–30 minutes. Single-dose TBI is more toxic and no more effective than fractionated TBI. Patients receiving fractionated TBI become nauseated later in the day if not given antiemetics. Parotitis and pancreatitis are rare early complications of TBI. Mucositis, diarrhea, alopecia, and severe pancytopenia are expected complications that develop during 1–2 weeks following TBI.

Stem Cell Collection and Infusion

Marrow is usually obtained by multiple aspirations from the donor's (or in the autologous setting, the patient's) anterior and posterior iliac crests. A total marrow volume of 10–15 mL/kg of donor weight is usually obtained. The number of marrow cells infused correlates with survival following allogeneic marrow transplantation, with a higher number of cells being associated with a more favorable outcome. Following donation, pain at the site of aspiration invariably occurs but is usually manageable with oral analgesics. Serious complications are uncommon and usually limited to local hematomas or infection. If peripheral blood stem cells are to be used, the donor is generally treated with a hematopoietic growth factor for 4–5 days. Following this, leukapheresis is performed over 1–3 days depending on the collection yield. The bone pain sometimes caused by the high doses of myeloid growth factors used for mobilization usually responds well to hydrocodone or similar oral analgesics (Chapter 18).

Stem cells are generally infused shortly after the preparative regimen has been completed, usually within 24–48 hours, depending on the amount of time needed to clear the last chemotherapeutic agent. In cases of ABO incompatibility, the red cells or plasma from the marrow may need to be removed before transplant to prevent transfusion reactions. Possible complications of fresh stem cell infusions include volume overload, mild transfusion reactions, and occasional allergic reactions to plasma proteins or other marrow components. Occasionally, a patient may complain of dyspnea, chest pain, and cough during marrow infusion. Slowing of the infusion and administration of oxygen usually relieve these symptoms. For autologous transplantation, the marrow or peripheral blood has been cryopreserved, usually with dimethylsulfoxide. Reactions are common following infusion of previously cryopreserved stem cells, both because many cells lyse during thawing and because some patients are sensitive to dimethylsulfoxide. Nausea, vomiting, and hypotension are the most frequently seen complications. To lessen these symptoms, premedication with diphenhydramine and dexamethasone is often given.

Prophylaxis for Graft-versus-Host Disease

Patients undergoing allogeneic transplantation generally require some form of GVHD prophylaxis. The most commonly used regimens have included a combination of methotrexate administered on post-transplant days 1, 3, 6, and 11, together with cyclosporine given daily from the time of transplant until day 50 and then tapered. Although it is sometimes difficult to administer methotrexate soon after transplant to patients with severe mucositis, studies have demonstrated that omission of methotrexate doses results in an increased incidence of GVHD. Cyclosporine is usually administered intravenously at a dose of 1.5 mg/kg every 12 hours, or orally at a dose of 6 mg/kg every

12 hours. Cyclosporine is a potent immunosuppressant and has a number of significant side effects (Chapter 102). If GVHD develops and a patient's blood levels of cyclosporine are low, increasing the cyclosporine dose is appropriate. Other agents sometimes used as GVHD prophylaxis include prednisone, tacrolimus and monoclonal antibodies directed at T-cells or T-cell subsets.

EARLY COMPLICATIONS (DAYS 1 TO 21 AFTER TRANSPLANT)

Figure 96.1 summarizes posttransplant complications in terms of time of onset.

Neutropenia
