

Hospital Medicine

SECOND EDITION

Hospital Medicine

SECOND EDITION

EDITORS:

■ **ROBERT M. WACHTER, MD**

Professor and Associate Chairman
Department of Medicine
University of California, San Francisco School of Medicine
Chief of the Medical Service
UCSF Medical Center
San Francisco, California

■ **LEE GOLDMAN, MD**

Julius R. Krevans Distinguished Professor and Chair
Department of Medicine
Associate Dean for Clinical Affairs
University of California, San Francisco School of Medicine
San Francisco, California

■ **HARRY HOLLANDER, MD**

Professor
Department of Medicine
Director, Internal Medicine Residency Program
University of California, San Francisco School of Medicine
San Francisco, California

Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

About the Cover

An engraving of the Pennsylvania Hospital ("The Building by the Bounty of Government and many Private Persons was proudly founded for the Relief of the Sick and Miserable. Anno 1755"). Artist, William Strickland; Engraver, Samuel Seymour; 1811. The Pennsylvania Hospital is the oldest hospital in the United States. Its first patient was admitted in 1752; its original mission was to care for the "sick poor" and the insane. Benjamin Franklin was co-founder of the hospital (along with Dr. Thomas Bond), and served on its first Board. Reproduced by permission of the American Philosophical Society.

Preface to the First Edition xxi

SECTION I: GENERAL ISSUES IN HOSPITAL MEDICINE 1

- 1 **Models of Hospital Care** 3
Robert M. Wachter
- 2 **The Economics of Hospital Medicine** 11
David Meltzer and Chad Whelan
- 3 **Practice Management in Hospital Medicine** 17
John R. Nelson
- 4 **Hospital Interfaces** 23
Winthrop F. Whitcomb and John R. Nelson
- 5 **Hospital Discharge** 31
Preetha Basaviah and Mark V. Williams
- 6 **Bayesian Reasoning and Diagnostic Testing** 37
Warren S. Browner
- 7 **Decision Analysis** 43
Warren S. Browner
- 8 **Evidence-Based Medicine** 51
Holger J. Schünemann and Gordon H. Guyatt
- 9 **Cost-Effectiveness** 59
Joel Tsevat
- 10 **Hospital Information Systems** 63
Saverio M. Maviglia, Gilad J. Kuperman, and Blackford Middleton
- 11 **Effective Clinical Teaching in the Inpatient Setting** 71
Karen E. Hauer and David M. Irby
- 12 **Assessment and Improvement of Quality and Value** 79
Robert M. Wachter and Niraj L. Sehgal
- 13 **Practice Guidelines and Clinical Pathways** 87
Scott Weingarten
- 14 **Patient Satisfaction with Hospital Care** 93
Haya R. Rubin

- 15 **Nutritional Issues in the Hospitalized Patient** 99
Annette Stralovich-Romani and Christopher R. Pennington
- 16 **Approach to the Hospitalized Older Patient** 111
C. Seth Landefeld, C. Bree Johnston, and Mary Anne Johnson
- 17 **Ethical Issues in the Hospitalized Patient** 119
Steven Z. Pantilat and Bernard Lo
- 18 **Pain Management in the Hospitalized Patient** 129
Robert V. Brody
- 19 **End-of-Life Care in the Hospital** 139
Daniel J. Fischberg, Paolo Manfredi, and Diane E. Meier
- 20 **Patient Safety in the Hospital Setting** 147
Kaveh G. Shojania
- 21 **Medication Safety in the Hospital** 157
David W. Bates

SECTION II: CRITICAL CARE MEDICINE 161

- 22 **Approach to the ICU Patient** 163
Neal H. Cohen
- 23 **Ventilator Management** 173
Stephen E. Lapinsky and Arthur S. Slutsky
- 24 **Acute Respiratory Failure** 183
Mark R. Tonelli and Leonard D. Hudson
- 25 **Hypotension, Shock, and Multiple Organ Failure** 191
Bradley D. Freeman and Charles Natanson
- 26 **Sepsis Syndrome** 201
Todd W. Rice and Gordon R. Bernard
- 27 **Procedures in Hospital Medicine** 207
Rachel L. Chin

SECTION III: MEDICAL CONSULTATION 233

- 28 **Medical Consultation** 235
Geno J. Merli and Howard H. Weitz

- 29 **Key Principles of Anesthesiology** 241
Neal Cohen
- 30 **Preoperative Evaluation** 249
Joshua S. Adler
- 31 **Postoperative Care** 261
Richard H. Savel, Jeanine P. Wiener-Kronish, and Michael A. Gropper
- 32 **Medical Complications of Pregnancy** 271
Jeffery Pickard, Linda A. Barbour, and Raymond O. Powrie
- 33 **Care of Special Populations: Psychiatry** 279
David F. Gitlin and Bernard Vaccaro
- 34 **Trauma** 287
Deborah M. Stein, Ronald Rabinowitz, and Ellis Caplan

SECTION IV: CARDIOVASCULAR MEDICINE 295

- 35 **Signs, Symptoms, and Laboratory Abnormalities in Cardiovascular Diseases** 297
Randall H. Vagelos, Rachel Marcus, and J. Edwin Atwood
- 36 **Diagnostic Tests in Cardiology** 315
Karen P. Alexander and Eric D. Peterson
- 37 **Angina and Unstable Angina** 329
Daniel B. Mark
- 38 **Acute Myocardial Infarction** 343
Daniel I. Simon, James C. Fang, and Naomi Kenmotsu Rounds
- 39 **Heart Failure** 359
Carey D. Kimmelstiel, David DeNofrio, and Marvin A. Konstam
- 40 **Heart Transplantation** 373
Maria Ansari and Teresa DeMarco
- 41 **Valvular Heart Disease** 381
Richard A. Lange and L. David Hillis
- 42 **Atrial Fibrillation, Atrial Flutter, and Other Supraventricular Tachyarrhythmias** 393
Leonard I. Ganz
- 43 **Ventricular Arrhythmias and Cardiac Arrest** 409
Graham Gardner, H. Leon Greene, and Peter Zimetbaum
- 44 **Syncope** 423
Wishwa N. Kapoor and David J. McAdams

- 45 **Bradycardia and Pacemakers** 431
Richard H. Hongo and Nora F. Goldschlager
- 46 **Pericardial Disease** 441
Fady Malik and Elyse Foster

SECTION V: VASCULAR MEDICINE 453

- 47 **Signs, Symptoms, and Laboratory Abnormalities in Peripheral Arterial Disease** 455
Stanley G. Rockson
- 48 **Urgent and Emergent Hypertension** 463
William B. White
- 49 **Aortic Intramural Hematoma and Dissection** 471
Lee Goldman
- 50 **Aortic Aneurysm** 479
Frank A. Lederle
- 51 **Peripheral Arterial Disease** 485
Eric P. Brass, William R. Hiatt, and Mark R. Nehler
- 52 **Deep Venous Thrombosis** 495
David A. Garcia and Mark A. Crowther
- 53 **Pulmonary Embolism** 505
Thomas M. Hyers

SECTION VI: PULMONARY MEDICINE 515

- 54 **Signs, Symptoms, and Laboratory Abnormalities in Pulmonary Medicine** 517
Meshell D. Johnson and Paul G. Brunetta
- 55 **Chronic Obstructive Pulmonary Disease** 531
Matthew B. Stanbrook and Kenneth R. Chapman
- 56 **Exacerbations of Asthma** 539
Homer A. Boushey
- 57 **Interstitial Lung Disease** 549
Talmadge E. King, Jr.
- 58 **Lung Transplantation and Lung Volume Reduction Surgery** 561
Steven G. Peters and David E. Midthun
- 59 **Pulmonary Hypertension** 569
Lewis J. Rubin
- 60 **Pleural Effusion and Pneumothorax** 577
Steven A. Sahn and John E. Heffner
- 61 **Pulmonary Nodules and Mass Lesions** 587
Michael K. Gould and Glen A. Lillington

SECTION VII: INFECTIOUS DISEASES 595

- 62 Signs, Symptoms, and Laboratory Abnormalities in Infectious Diseases 597
Richard A. Jacobs and Karen C. Bloch
- 63 Infections in Immunocompromised Hosts 613
Nesli Basgoz
- 64 Parenteral Antibiotics and Antibiotic Resistance 623
Lisa G. Winston and Henry F. Chambers III
- 65 Community-Acquired Pneumonia 633
Ethan A. Halm and Michael J. Fine
- 66 Hospital-Acquired Pneumonia 645
Donald E. Craven, Catherine A. Fleming, and Kathleen A. Steger Craven
- 67 Tuberculosis 655
Charles L. Daley and Phillip C. Hopewell
- 68 Urinary Tract Infection 667
Thomas M. Hooton
- 69 Cellulitis and Necrotizing Fasciitis 675
Dennis L. Stevens
- 70 Meningitis 683
Allan R. Tunkel and W. Michael Scheld
- 71 Endocarditis 693
Paul M. Sullam
- 72 Catheter-Associated Infection and Bacteremia 703
Isaam I. Raad and Hend A. Hanna
- 73 Bioterrorism 711
Thomas E. Terndrup and Sarah D. Nafziger

SECTION VIII: HIV DISEASE 719

- 74 Signs, Symptoms, and Laboratory Abnormalities in HIV Disease 721
Harry Hollander
- 75 Pulmonary Manifestations of HIV Infection 729
Laurence Huang and Philip C. Hopewell
- 76 Neurologic Complications of HIV Disease 739
Christina M. Marra

SECTION IX: GASTROENTEROLOGY 749

- 77 Signs, Symptoms, and Laboratory Abnormalities in Gastrointestinal Disease 751
Kenneth McQuaid

- 78 Acute Gastrointestinal Bleeding 767
Jonathan P. Terdiman and Peter K. Lindenauer
- 79 Esophageal Disorders 781
Asyia Ahmad and James C. Reynolds
- 80 Peptic Ulcer Disease and Stress-Related Mucosal Disease 789
Brennan M. R. Spiegel and Gareth S. Dulai
- 81 Inflammatory Bowel Disease 799
Stephen B. Hanauer and Sunanda V. Kane
- 82 Acute Hepatitis and Liver Failure 809
Marina Berenguer and Teresa L. Wright
- 83 Cirrhosis and Its Complications 819
Don C. Rockey
- 84 Disorders of The Biliary System 829
Douglas B. Nelson, Paul Druck, and Martin L. Freeman
- 85 Liver Transplantation 839
Rapheal B. Merriman
- 86 Acute Pancreatitis 849
Douglas A. Corley
- 87 Other Abdominal Emergencies: Appendicitis, Diverticulitis, and Ischemic Bowel 859
Lily C. Chang and E. Patchen Dellinger
- 88 Ileus and Obstruction of the Gastrointestinal Tract 873
Daniel T. Dempsey and Sean P. Harbison

SECTION X: HEMATOLOGY-ONCOLOGY 883

- 89 Signs, Symptoms, and Laboratory Abnormalities in Hematology-Oncology 885
Hope S. Rugo
- 90 Principles of Chemotherapy 897
Robert J. Ignoffo
- 91 Principles of Transfusion Medicine 907
Susan A. Galel and Edgar G. Engleman
- 92 Oncologic Emergencies 917
Judith A. Luce
- 93 Leukemia 929
David A. Rizzieri, Gwynn D. Long, and Nelson J. Chao
- 94 Lymphoma 937
Ranjana H. Advani, Steven M. Horwitz, and Sandra J. Horning
- 95 Chronic Myeloproliferative Disorders 947
Ayalew Tefferi

- 96 Hematopoietic Cell Transplantation 955
Frederick R. Applebaum
- 97 Sickle Cell Disease 965
Martin H. Steinberg and Harrison W. Farber
- 98 Hemorrhagic and Thrombotic Disorders 975
Julie Hambleton and Marc Shuman

SECTION XI: RENAL DISEASE 993

- 99 Signs, Symptoms, and Laboratory Abnormalities in Renal Disease 995
Rudolph A. Rodriguez and Burl R. Don
- 100 Acute Renal Failure 1007
Ravindra L. Mehta and Frank Liu
- 101 Management of the Hospitalized Patient on Dialysis 1017
Glenn M. Chertow
- 102 Renal Transplantation 1027
William J.C. Amend, Jr. and Flavio Vincenti
- 103 Renal Stone Disease and Obstruction 1037
David S. Goldfarb and Fredric L. Coe
- 104 Common Electrolyte Disorders 1045
Kerry C. Cho
- 105 Common Acid-Base Disorders 1055
Orson W. Moe, Daniel Fuster, and Robert J. Alpern

SECTION XII: ENDOCRINOLOGY 1067

- 106 Signs, Symptoms, and Laboratory Abnormalities in Endocrinology 1069
Kenneth A. Woeber
- 107 The Management of Hyperglycemia and Diabetes Mellitus in Hospitalized Patients 1079
Harold E. Lebovitz
- 108 Acute Presentations of Thyroid Disease 1093
Leonard Wartofsky
- 109 Adrenal Insufficiency and Crisis 1103
David G. Gardner

SECTION XIII: RHEUMATOLOGY 1109

- 110 Signs, Symptoms, and Laboratory Abnormalities in Rheumatology 1111
Jeffrey Critchfield

- 111 Vasculitis 1121
Gary S. Hoffman, Carol A. Langford, and Leonard H. Calabrese
- 112 Acute Presentations of Selected Rheumatic Disorders 1135
Kenneth H. Fye and Kenneth E. Sack
- 113 Acute Arthritis 1143
John H. Stone and David B. Hellmann
- 114 Back Pain 1153
Jerry D. Joines and Nortin M. Hadler

SECTION XIV: NEUROLOGY AND PSYCHIATRY 1161

- 115 Signs, Symptoms, and Diagnostic Tests in Neurology 1163
John W. Engstrom
- 116 Stroke 1175
Wade S. Smith
- 117 Central Nervous System Hemorrhage and Increased Intracranial Pressure 1185
Ellen Deibert and Michael N. Diringer
- 118 Seizures 1199
Paul A. Garcia
- 119 Depression in the Hospitalized Patient 1209
Richard J. Goldberg

SECTION XV: TOXICOLOGY AND ALLERGY 1219

- 120 Allergic Reactions and Anaphylaxis 1221
Neil Winawer and Mark V. Williams
- 121 Drug Overdoses and Dependence 1229
Josef G. Thundiyil, Jon K. Beauchamp, and Kent R. Olson
- 122 Acute Alcohol Intoxication and Alcohol Withdrawal 1243
Robert H. Lohr

Preface to the Second Edition

It seems remarkable that a decade has passed since we first described our vision of a generalist physician specializing in hospital care: the *hospitalist* (1). Although a handful of such physicians were scattered around the United States at the time, by 2005 there were more than 10,000. Their ranks are likely to swell to more than 20,000 in the United States in the coming decade (2), and they have linked with similar physicians in Canada, South America, Europe, and even China.

Although we correctly predicted the growth of hospitalists, we (and most other observers) failed to appreciate fully the other winds that would buffet hospital care during the last 10 years. Even though capitation declined in popularity, the mandate for efficiency grew as hospitals filled to the brim, forcing many emergency departments into double duty as mini-wards. A major nursing shortage further constrained hospital capacity, while a shortage of critical care doctors generated a need in many institutions for other physicians who could provide high quality ICU care. And limits on residents' duty hours created the demand for alternative providers in teaching hospitals. All of these forces further promoted the growth of the hospitalist model (3,4).

Meanwhile, the pace of medical progress continued to accelerate. New noninvasive imaging studies and new blood tests, such as troponin, C-reactive protein, BNP, and galactomannan, reshaped our diagnostics strategies for disorders ranging from pulmonary embolism to *Aspergillus* infection. New medications, such as low-molecular-weight heparin and activated protein C, caused us to rethink our management of thrombosis and sepsis, and we also found new uses for old medications, such as spironolactone and N-acetylcysteine. Prevention, once considered the exclusive domain of ambulatory medicine and public health, emerged as a key paradigm in hospital medicine, as the virtues of prophylaxis against thromboembolism, tight glucose control, and strategies to prevent hospital-acquired infections were documented by a steady drumbeat of studies.

Even more striking was the emergence—finally!—of a genuine and sustainable quality movement in health care. Galvanized by two reports from the Institute of Medicine on patient safety (5) and quality (6), patients and payers increasingly demanded that their hospital care be demonstrably safe and effective. In fact, in preparing the second edition of *Hospital Medicine*, we were struck that as much as the clinical chapters had changed, the chapter that changed

the most was the one on quality and value (Chapter 12). In the first edition (2000), we described an embryonic movement to measure quality and wondered whether it would ultimately impact inpatient care. At the time, there were only two inpatient quality measures (the use of aspirin and beta blockers in acute myocardial infarction) and only one organization doing the measuring (the National Committee for Quality Assurance). Pay-for-performance ("P4P") was a twinkle in some health economist's eye.

Five years later, scores of inpatient quality measures are being promulgated by organizations ranging from behemoths, such as the Center for Medicare and Medicaid Services (CMS) and the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO), to groups that barely existed in 2000, such as the Leapfrog Group and the National Quality Forum. Not only is hospital care being measured and reported publicly, but early pay-for-performance experiments herald an era in which quality will be demanded, measured, and rewarded. The quality and safety movements are also catalyzing the "wiring" of the American hospital. Because processes of care and outcomes will now be measurable at the click of a button, information technology will increase the pressure on providers to deliver high quality, evidence-based care. Fortunately, the same technology will also facilitate the delivery of such care. Despite a number of tricky learning curves to traverse, it is difficult to view these sea changes as anything but welcome news for patients.

We approached the second edition of *Hospital Medicine* with all of this in mind. The entire book has been updated, and more than 10% of the chapters and 20% of the authors are brand new. More than ever, we emphasize a practical, evidence-based approach to the management of hospitalized patients. Even with all the changes, feedback from readers of the first edition persuaded us to retain the underlying organizing framework of the book: *approaching common hospital disorders and presentations from the perspective of the hospital physician*, with a particular emphasis on the temporal flow of care in the hospital (e.g., "Issues at the Time of Admission," "Issues at the Time of Discharge"). This approach remains unique to *Hospital Medicine*.

Although we expect that many of our readers will be hospitalists, the book remains agnostic regarding who the provider of hospital care is or should be. We were gratified that so many primary care physicians, nurse practitioners, physician's assistants, inpatient pharmacists, residents, and

students found the first edition useful, and we prepared this new edition hoping that it would continue to appeal to this broad audience. Regardless of our readers' roles and pedigrees, we hope that *Hospital Medicine* helps them deliver the high quality, evidence-based care that their patients deserve and supports them in their roles as clinicians, teachers, and leaders in making their hospitals safer and better.

Preface to the First Edition

As the American healthcare system lurched toward managed care at the close of the twentieth century, there surfaced a prevailing notion that the institution we know as the hospital was a vestige of the old system and was doomed, along with long-playing records and bell-bottom pants, to the wastehap of history. In the New Medicine, went the mantra, pressures for efficiency would lead to a medley of home care, surgicenters, telemedicine, multi-specialty practices, disease management, and mass prevention strategies, all of which would render the hospital an expensive and needless albatross. Those who watched trends in hospital utilization in the late 1980s and early 1990s, particularly in highly managed care markets, had ample evidence to support this scenario.

As the new century dawns, it is clear that this script was wrong. The aging of the population, the growth of new technologies, and the efficiency of having a site for diverse specialists who focus on the care of sick patients, have all led to an *increase* in hospital utilization. With this increase has come a growing recognition that the hospital continues to be the focus of one-third of U.S. health expenditures (accounting for 5% of America's Gross Domestic Product), of the majority of deaths and virtually all births, and of staggering technological innovation and perhaps equally staggering iatrogenesis. In other words, what happens in hospitals matters.

As we began to refocus on hospital care, we were struck by the absence of a clinical textbook that *used the hospital admission as the unit of analysis*. Our goal, therefore, was to produce an authoritative, evidence-based, and practical book that focuses on key issues in the care of the hospitalized adult. In doing so, we cover most of the major issues that arise in inpatients (e.g., end-of-life care, nutritional issues, clinical decision making) as well as 75 of the most common conditions leading to hospital admission. Some signs, symptoms, and laboratory abnormalities are critically important in hospitalized patients, but do not fit into a specific disease framework. We have included these three topics within introductory chapters that precede each of the organ-based specialty sections. Our goal is to be more useful than comprehensive: very unusual diseases or presentations may not be covered in depth, but common ones certainly are. Similarly, fundamental skills such as reading

electrocardiograms are not addressed in detail, as we assume a basic level of clinical knowledge and such information can be found in many other sources.

We wrote this book for the physician caring for the hospitalized adult patient. Notwithstanding our interest in the hospitalist model, except for an introductory chapter on "Models of Hospital Care," the book makes no assumptions about who is the inpatient provider, nor judgments about who it should be. Thus, we hope that *Hospital Medicine* will serve the needs not only of practicing hospitalists, but also primary care physicians and specialists caring for inpatients, inpatient nurse practitioners and physician assistants, internal or family medicine residents, and junior or senior medical students on inpatient rotations. There is a strong emphasis on appropriate care and resource use, so *Hospital Medicine* will also be helpful to inpatient case managers and others involved in hospital quality improvement, utilization management, and discharge planning.

We thank our contributors for their superb work and for presenting their information in an evidence-based and practical way. We also are indebted to Mary Whitney, Leah Hayes, Carol Kummer, Amy Markowitz, and Steven Martin for their invaluable assistance in the production of the book. Susan Gay and Tim Hiscock of Lippincott Williams & Wilkins were extremely helpful at all stages of the project. So were our faculty and housestaff colleagues at the University of California, San Francisco, who often found themselves the subjects of impromptu focus groups as we grappled with difficult clinical or organizational questions. Finally, our deepest gratitude goes to our families, who had to tolerate our absences (and sometimes our presence) while we attempted to bring this concept to reality as quickly as possible. We hope that the information contained herein will improve the quality and efficiency of care for an extraordinarily important but vulnerable population, hospitalized adults.

General Issues in Hospital Medicine

Models of Hospital Care

1

Robert M. Wachter

INTRODUCTION

The past decade has brought great changes in the organization of hospital care in the United States. Although “inpatient specialists” have long provided inpatient care in Europe and Canada, the United States has only recently considered the potential advantages of a system using dedicated hospital physicians, known as hospitalists. This new model for hospital care has both advantages and disadvantages in comparison with more traditional models of inpatient care.

In the decade since the editors first described the concept of the hospitalist in the medical literature (1), the growth of the model has been remarkable. In many U.S. markets, the majority of hospital care is now delivered by hospital-based physicians. The Society of Hospital Medicine, the professional society for hospitalists, has grown to more than 5,000 members, and published projections point to an ultimate hospitalist workforce of about 20,000, approximately the same size as that of cardiology (2). Although the notion of a site-defined (rather than an organ-, population-, or disease-defined) specialty seems novel, it is not: American medicine embraced the seeming oxymoron of the “generalist specialist” when it codified the specialties of emergency medicine and critical care medicine (Table 1.1) about 40 years ago. What is new, at least in the United States, is the approach of using a site-defined specialist on the main hospital ward.

DEFINITION OF HOSPITALIST

Hospitalists were initially defined as physicians who spend at least 25% of their professional time serving as the physicians of record for inpatients and accepting

hand-offs of hospitalized patients from primary care providers; the patients are returned to the care of their primary providers at the time of hospital discharge (3). Although the Society of Hospital Medicine has embraced a more inclusive definition (“physicians whose primary professional focus is the general medical care of hospitalized patients”), focusing on the initial definition allows a discussion of two key elements of the transition from the old model of inpatient care (in which primary care physicians served as the hospital physicians of record) to the hospitalist model. The first is the hand-off—a purposeful discontinuity of care between the outpatient and hospital providers. The second is the notion that some minimum amount of hospital time is necessary for one to meet the spirit of the hospitalist concept.

The hand-off, or referral, is fundamental to the hospitalist model. In fact, the discontinuity is responsible for one of the real strengths of the hospitalist model—the presence of a physician in the hospital throughout the day who is able to coordinate inpatient care and react to clinical data in real time. However, this same discontinuity leads to the two greatest potential liabilities of the model. The first concerns a potential “voltage drop” in information as one moves from office to hospital ward and back to office. The second relates to the potential dissatisfaction of patients associated with the assignment of a new doctor—often a stranger—to care for them at their time of greatest need.

To some extent, the “voltage drop” can be minimized. Computerized or digitized information is easy to transmit from office to hospital and back to office again. This does not mean that this is currently being done in many systems, or that a linked office–hospital information system would entirely solve the problem. A filtering function is needed; otherwise, the vast amounts of computerized data will be simply ignored. Nevertheless, it seems reasonable to posit

TABLE 1.1
EXAMPLES OF SPECIALTIES, DIVIDED BY THEIR ORGANIZING PRINCIPLE

Defined by organ-system	Defined by patient population	Defined by disease	Defined by technical skill	Defined by site of care
Cardiology	Pediatrics	Oncology	Surgery	Hospital medicine (Hospitalists)
Gastroenterology	Geriatrics	Infectious diseases	Anesthesiology	Critical care medicine
Rheumatology	Family medicine		Radiation oncology	Emergency medicine

that most systems will find ways to successfully transmit computerized data from hospital to outpatient provider over the next decade (although few have done so as of this writing).

However, the hospitalist model is most vulnerable in terms of information that cannot be captured electronically—namely, the patient’s life story, values, and preferences regarding end-of-life care. These “soft” data are probably best communicated through personal contact between the hospitalist and the primary physician, at least at the time of admission, discharge, and any important change in patient status. The bottom line is that the hospitalist and the primary physician must act as a team to care for the patient effectively across the continuum of care (Chapter 4).

The other major concern raised by the transfer of care to the hospitalist relates to the potential dissatisfaction of patients when they do not see “their doctor” in the hospital. This legitimate concern has generally been refuted by surveys showing that the level of patient satisfaction under a hospitalist’s care is at least as high as that under the old primary physician-based system (4,5). These results indicate that patients may be willing to trade familiarity (of their primary doctor) for availability (of the hospitalist) when it comes to hospital care, particularly if they perceive a strong communication link between the two providers. Some health care systems have also noted that the hospitalist model leads to improvements in outpatients’ satisfaction with their primary physicians, who can now be more predictably available to their office patients.

In addition to the purposeful discontinuity, implicit in the hospitalist concept is a minimum time requirement that the physician spends in caring for hospitalized patients. This time commitment has several advantages. First, it should allow the hospitalist to become expert in the care of common inpatient disorders. Next, it should lead to the hospitalist better recognizing outliers and anticipating problems. Third, the hospitalist will become familiar with all key players in the hospital (Chapter 4) and become sufficiently invested in the system to be accountable for its cost and quality. The hospitalist will thus be able to lead quality improvement efforts in this setting (Chapter 12).

STAGES OF HOSPITAL CARE

Four distinct stages of hospital care help explain many of the forces driving the emergence of the hospitalist model (3) (Table 1.2). In stage I, the *primary care provider stage*, all patients admitted to the hospital for nonspecialized medical problems that fall within the usual expertise of an internist (e.g., community-acquired pneumonia or gastrointestinal bleeding) are cared for in the hospital by their own primary care physician. Of course, some patients may be cared for by other physicians for specialized problems during any stage (e.g., an obstetrician during childbirth or a urologist during a prostatectomy). Stage I was the dominant mode of hospital care in the United States until 10 to 20 years ago. It continues to be popular, albeit in a rapidly dwindling number of regions. The system worked best when the primary physician had many patients in the hospital at any given time, when such patients were not terribly ill, when the hospital was next door to the physician’s office, and when no one was measuring (or particularly concerned about) hospital or office availability or efficiency. However, the disadvantages of stage I have become evident, particularly in markets with significant cost pressures. In these areas, primary care physicians may have on average only one or two patients in the hospital at any given time, and these patients are likely to be extremely ill and require attention throughout the hospital day. In the meantime, the office is packed with patients to be seen at 15-minute intervals. Interestingly, although primary care physicians were ambivalent (at best) about the hospitalist concept in the early years, many have now recognized the economic inefficiency of providing their own hospital care because revenues from the care of their hospital patients now fail to compensate for the inefficiency of the commute and the disruption to their office practice. In some markets, such physicians have become major supporters of the hospitalist model.

Stage II, the *hospital rotation stage*, attempts to deal with the problem of physician inaccessibility in the hospital by rotating hospital coverage among the members of a medical group. In this model, one member at a time serves as the

TABLE 1.2**ADVANTAGES AND DISADVANTAGES OF VARIOUS MODELS OF HOSPITAL CARE**

	Description	Potential advantages	Potential disadvantages
Stage I: Primary care provider stage	Every PCP follows own patients into the hospital.	Inpatient–outpatient continuity. Patient satisfaction from seeing “my doctor.” PCPs retain acute care skills and possibly job satisfaction.	PCPs may lack hospital skills and experience to maximize quality and efficiency. PCPs not available throughout hospital day. Hospital care pulls PCPs away from office patients. PCPs unlikely to be accountable for and invested in hospital quality improvement.
Stage II: Hospital rotation stage	Physicians in the group rotate so that members take turns covering the hospitalized patients of the other members.	“Hospital PCP” now available throughout hospital day. Other PCPs freed to be in office all day. Patients may know rotating hospital physician from the office (who may even be the patients’ PCP from time to time).	Introduction of an inpatient–outpatient discontinuity. With infrequent rotation intervals (e.g., 1 week in 8), PCPs are still unlikely to develop acute care skills to produce the best outcomes at the lowest cost, or to be invested in improving the hospital system.
Stage III: Voluntary hospitalist stage	Dedicated hospitalists are hired; PCPs may choose to use them or not (there may be incentives to use the hospitalist).	Hospitalist now available throughout hospital day to review results and see patient, family, consultants. Hospitalist hones acute care skills (including communication with PCPs). Hospitalist accountable for hospital quality and cost and is invested in leading improvement.	With outpatient–inpatient discontinuity, potential for information loss. Potential patient dissatisfaction from not seeing “my doctor” in the hospital. Potential PCP loss of acute care skills. Potential hospitalist burnout over time.
Stage IV: Mandatory hospitalist stage	All patients must be handed off by their PCPs to hospitalists for inpatient care.	Same advantages as in moving from stage II to III, except true for all patients. System may now focus on mitigating potential disadvantages by the following: Developing better communication links (both personal and infrastructural). Promoting social visits or calls by PCPs, and other methods to enhance patient satisfaction. Developing CME or other mechanisms to prevent PCPs from losing acute care skills. Developing mechanisms (CME, some outpatient or nonhospitalist work, adequate reimbursement, vacation) to prevent hospitalist burnout.	Same disadvantages as in moving from stage II to III, except true for all patients and providers. Potential decreased incentive for hospitalists to be superb communicators with PCPs (under stage III, PCPs could choose to manage their own inpatients if not completely satisfied with the hospitalist). Potential problems if system has been adopted without buy-in by medical staff. PCP endorsement of both the system and the hospitalists themselves is vital.

CME, continuing medical education; PCP, primary care physician.

Reprinted from Wachter RM. An introduction to the hospitalist model. *Ann Intern Med* 1999;130:338–342, with permission.

physician of record for the inpatients of the others. In many private practice settings, these rotations typically occur at a frequency of about one week per eight-week period (during which time the hospital primary physician—these days, often incorrectly called the “hospitalist of the week”—may be sta-

tioned in the hospital for all or a large part of the day). In the academic setting, it is common for such rotations to take place at a frequency of one month per every 12-month period (the “ward attending” month). In either case, the rotating primary care physician is not in the hospital enough to be a true

hospitalist. In comparison with the stage I system, this system has the disadvantage of introducing a new inpatient–outpatient discontinuity, but it does ensure better availability of the rotating physician for inpatients (Table 1.2).

In stage III, the *voluntary hospitalist stage*, a dedicated hospitalist is hired (paid by either the hospital, a medical group, a managed care organization, or a free-standing private practice), but primary physicians retain the option to manage all or some of their own inpatients. The decision by some physicians to continue to manage their hospitalized patients may be influenced by financial incentives. For example, a fee-for-service system may influence primary care physicians to continue to provide hospital care, whereas a capitated system, in which physicians are paid solely based on panel size, may encourage the use of the hospitalist.

Finally, a few systems have moved to stage IV, the *mandatory hospitalist stage*, in which all inpatients must be handed off to hospitalists. Although the advantages of the hospitalist model are now applied to all patients (Table 1.2), political costs may be incurred in moving to this stage. The mandatory hand-off alienates some primary care physicians who want to retain the option to provide hospital care. For this reason, stage IV is most common in systems that have strong institutional control of physician practices, whereas stage III is more prevalent in looser physician–hospital affiliations, such as those in many independent practice associations.

It is important to add a few caveats regarding the four stages. First, the stages *do not* imply a hierarchy of desirability (i.e., that stage IV is necessarily better than stage III, which is always better than stage II). Each stage has advantages and disadvantages, and many physicians and health systems will find that a stage III (or II) system serves their needs well. Second, movement up the stages is not inexorable; not all systems ultimately arrive at stage IV, although there is a clear national trend in moving from stage I or II to stage III or IV. Nor will progression necessarily be orderly; some systems, especially those under significant market pressure, have jumped directly from stage I to stage IV.

EVIDENCE REGARDING THE HOSPITALIST MODEL

Early transitions to the hospitalist model were largely driven by the theoretical attractiveness of the concept rather than any specific data addressing the potential advantages and disadvantages. Over the past decade, though, a significant amount of literature has emerged regarding the impact of the hospitalist model on costs and outcomes.

Efficiency

More than 20 studies have compared hospitalist care to that delivered by primary care physicians or traditional aca-

demically ward attendings. With few exceptions, the studies have found significant decreases in both length of stay and hospital costs, averaging nearly 15% (5,6). Although concerns have been raised that some of these cost savings are simply transferred to the outpatient setting (7) or consumed by the costs of operating the hospitalist program itself, the magnitude of the savings and the rapid growth of the model nationally (often driven by return-on-investment considerations) argue against this hypothesis. Precisely how hospitalists achieve their efficiencies is not entirely clear. It is probably some combination of anticipating patients' trajectories, better and more rapid deployment of hospital resources, and greater focus on efficiency as an important goal. Some studies have found a learning curve, with hospitalists achieving their ultimate efficiencies only in their second year of practice (8).

Quality

Although it is logical to believe that hospitalists improve the quality of inpatient care (mediated through both "practice makes perfect" and their on-site availability), most studies have found no effect on blunt measures of quality (such as readmissions and mortality rates). Two studies, however, have found significant decreases in inpatient mortality rates associated with hospitalist care (8,9). Another study found lower readmission rates (10), and a fourth found better documentation of end-of-life discussions (11). These studies are promising, but additional research is needed to unequivocally prove a hospitalist quality advantage if, in fact, one exists.

Teaching

Hospitalist programs are now operating in most of the nation's teaching hospitals, driven in part by limitations in resident work-hours implemented in 2003 by the Accreditation Council on Graduate Education. Several studies have compared hospitalist teaching evaluations with those of comparable non-hospitalist ward attendings, and all have found significant advantages for the hospitalists (12–15). Given that many residents were anxious about their potential loss of autonomy under the hospitalist model, these results are reassuring. They support both the hospitalist model itself and the more general premise that additional teaching and oversight should improve, and not harm, medical education (Chapter 11).

ROLES OF THE HOSPITALIST

Under stages III and IV, the hospitalist may begin by caring for some (stage III) or all (stage IV) of the inpatients on a medical service. Additional roles for hospitalists may soon surface (16), depending on the nature of the medical

group, the dominant reimbursement methods, and the competitiveness of the market (Table 1.3).

In some settings, the hospitalist will serve as a passive acceptor of inpatient admissions from primary care physicians or the emergency department. Such a passive role avoids conflict about the decision to hospitalize and may serve an institution well when most patients are admitted under a payment system utilizing diagnosis-related groups (DRGs). (The main financial incentive of a DRG is to shorten the length of stay rather than decrease the number of hospitalizations.) Under a capitated system or in a hospital operating at full capacity, however, hospitalists may feel pressure to become involved in the *admission decision*, approving outpatients for admission and even evaluating patients in the emergency department and suggesting possible alternatives to acute hospital admission.

Similarly, in an environment in which the system is at risk for the costs of *out-of-network care*, hospitalists may be involved in efforts to transfer such patients back to their home hospitals. These efforts may involve speaking by telephone with the patient's physician at the outlying site, confirming appropriateness of and stability for transport, and organizing the logistics of the transfer. Even in the absence of such managed care-driven arrangements, hospitalists are often engaged in managing interinstitutional transfers, a challenging area that saw little physician involvement in the past.

The interface between the hospital ward and the *intensive care unit* is interesting to consider in light of the hospitalist model. A number of studies have demonstrated the

advantages of a closed intensive care unit (in which dedicated critical care specialists are utilized, with patients handed off from the primary physician to the critical care physician at the time of intensive care unit admission), instead of an open unit in terms of outcomes and efficiency (17). The average primary physician's lack of availability and experience in caring for critically ill patients is another example of the advantages of the discontinuity between the hospital ward and the intensive care unit (with separate critical care providers staffing the latter). Under a hospitalist system, the need for this discontinuity may be offset because a competent and busy hospitalist will have a large intensive care unit volume, be available throughout the hospital day, and understand the critical care system well enough to manage it correctly. As a result, the imposition of an outpatient-hospital discontinuity may render a hospital-intensive care unit discontinuity less important and even counterproductive (Figure 1.1). The presence of critical care specialists will remain important, even when hospitalists are admitting to an open unit, when such specialists manage ventilators, perform procedures, and act as consultants on other critical care issues. Nevertheless, the large national shortage of intensive care specialists (18) means that hospitalists will be called upon to perform these complex functions in many institutions. The UCSF Medical Center has a hybrid model, in which hospitalists serve as physicians-of-record for ICU patients but all such patients automatically receive a consultation from an intensive care specialist. The intensivist has the primary role in managing the ventilator and sedation. The model appears to work well but is, as yet, unstudied.

In some institutions, hospitalists are beginning to serve as the *physicians-of-record for surgical patients*. Just as the hospitalists' availability throughout the day enables the primary care physician to manage patients in the office without interruption and provides each patient with a coordinator of hospital care, the hospitalist's involvement in the care of surgical patients during the preoperative and postoperative phases enables the surgeon to be in the operating room all day while ensuring that the floor patient is receiving appropriate care. Only one study has examined the outcomes associated with hospitalist comanagement of surgical patients; it found a modest advantage (19). Clearly, further studies are needed.

Many hospitalists will also choose to have a major role in *hospital quality improvement*, including the development of pathways, guidelines, and reengineering projects (Chapter 12). Hospitalists have already made impressive contributions in patient safety and end-of-life care, areas that clearly benefit from their systems focus, comfort with interdisciplinary collaboration, and alignment with hospital goals. In the same vein, many hospitalists will naturally evolve toward leadership roles in areas related to hospital operation, including the development of hospital policies and procedures, formulary and utilization management, and credentialing.

TABLE 1.3
POTENTIAL ROLES FOR HOSPITAL-BASED PHYSICIANS

Core activities

- Care of medical inpatients
- Traditional medical consultation

Potential additional activities

- Involvement in emergency department triage
- Facilitating transfer of patients from/to other facilities
- Management or comanagement of patients in the intensive care unit^a
- Management or comanagement of nonmedical patients in the hospital^a
- Development of palliative care unit and/or consultation service^a
- Management or comanagement of patients in skilled nursing facilities, hospice, other settings^a
- Major role in hospital-based quality improvement, patient safety activities^a
- Major teaching role (in teaching hospitals)^a
- Research into relevant topics (common inpatient clinical disorders, outcomes, costs, quality, safety, etc.)^a
- Hospital administration^a

^a Hospitalist may benefit from additional training.

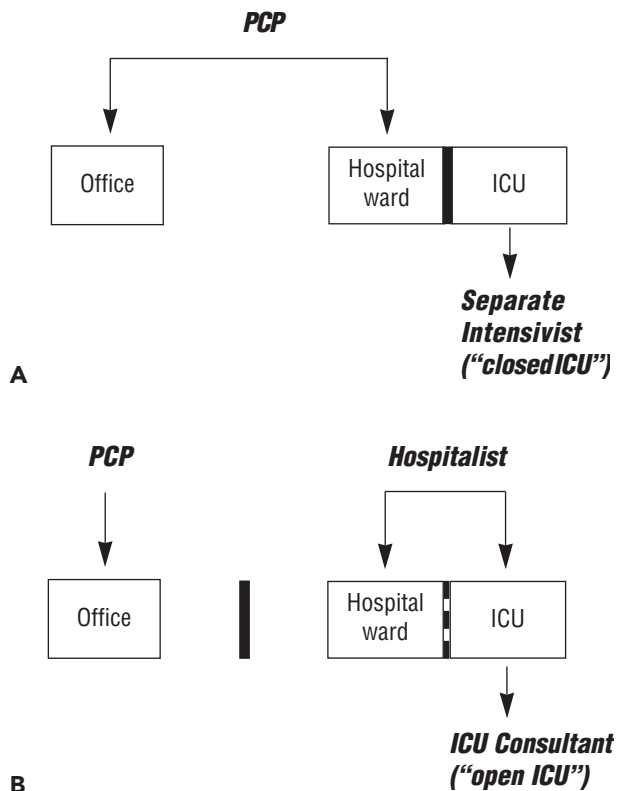

Figure 1.1 Potential impact of a hospitalist on the relative merits of a closed versus an open intensive care unit (ICU). **A.** In stage I, the potential lack of ICU expertise and a certain lack of availability of the primary care physician (PCP) create advantages for a hospital ward–ICU discontinuity (“closed ICU”). **B.** In stage III or IV, the presence of a hospitalist (and outpatient–hospital discontinuity) may obviate the need for hospital–ICU discontinuity (“open ICU”). Even in this circumstance, an ICU consultant will often considerably enhance patient care.

CONCLUSIONS

The emergence of the hospital model of care has been characterized by rapid growth and accompanied by a reassuring amount of data supporting the premise that hospitalists improve the value (quality divided by cost) of inpatient care. Nevertheless, for the foreseeable future, American hospital care will remain a highly pluralistic system in which the organization of care is determined by quality and cost considerations in the context of local culture and preferences. The method of hospital care chosen by each institution and group of physicians should be the one that promotes the best clinical outcomes and highest patient satisfaction at the lowest costs for both hospitalized and ambulatory patients.

KEY POINTS

- Hospitalists are physicians who accept hand-offs of inpatients from primary care physicians, returning the patients to the primary providers upon hospital discharge.

- Hospital care can be separated into four distinct stages: stage I (primary care providers provide hospital care), stage II (primary care providers rotate responsibility for hospital care), stage III (voluntary hand-offs to hospitalists), and stage IV (mandatory hand-offs to hospitalists).
- Potential advantages of the hospitalist model include increased availability, increased hospital expertise, and increased commitment to hospital quality improvement.
- Published data support the premise that the use of hospitalists leads to lower costs, shorter stays, at least equivalent (and possibly improved) outcomes, and higher teaching evaluations.
- Potential disadvantages of the hospitalist model include an information “voltage drop” when patients move in and out of the hospital, and patient dissatisfaction. The former can be minimized through better personal and computerized communications, and the latter seems not to be a major problem based on emerging data.

The Economics of Hospital Medicine

David Meltzer *Chad Whelan*

INTRODUCTION

Hospital care is expensive and is influenced by complex institutional structures and incentives. In 2003, the United States spent over 14% of gross domestic product—\$1.6 trillion—on health care (1). Of that, 32%, or \$512 billion, went to hospitals. Moreover, a sizeable fraction of the 22% of total spending on physicians went for hospital care. Given these large expenditures, the federal government and other major payers have enacted policies designed to control hospital expenditures. These policies often create incentives that may lead to conflicts of interest between payers, hospitals, physicians, and patients. Hospital physicians must understand the nature of these incentives and the potential for these conflicting interests in order to be most effective as agents for both their patients and the hospitals in which they work.

The fact that the United States medical economy is complicated and differs in important ways from the traditional market model (2) makes attempts to understand the effects of cost-control policies more difficult. Differences from the traditional model include the multiple organizational forms hospitals take (for-profit, not-for-profit, government-funded), multiple payers and payment systems (direct consumer payment, fee-for-service private insurance, capitated insurance, government insurance), pervasive state and federal regulations, and the complex interactions among these factors (e.g., cost for payers versus health for patients).

HOSPITAL ORGANIZATION AND HOSPITAL–PHYSICIAN RELATIONS

Hospitals are of three major types: not-for-profit, for-profit, and government-funded. All these systems have key com-

ponents that drive their organizational behavior and influence the behavior of those who regularly interact with the hospital, including physicians. Many of the key stakeholders in each system are similar. They include the hospital leaders, physicians, hospital employees (sometimes including physicians), patients, and payers. Each stakeholder may have different goals—some may hope to increase revenue, and others may hope to decrease costs. These organizational frameworks may differ in how they value the needs and priorities of various stakeholders.

Not-for-profit hospitals are the most common type in the United States. They earn their name because of the requirement that they not distribute profits to shareholders, as would typically happen in a for-profit firm. Although not-for-profit hospitals usually receive the vast majority of their revenue from patient care, they may also receive donations or service in kind from an affiliated organization (e.g., a church) and government subsidies through exemption from corporate taxes. In exchange for subsidies, they must regularly demonstrate evidence of community benefit, such as providing uncompensated care or other programs that benefit the health of the community.

Even not-for-profit hospitals usually aim to have revenues that exceed costs. When they are successful, the excess income is reinvested in the hospital in the form of savings, capital investment, higher payments to physicians and/or employees, or greater spending on uncompensated care, research, or other aspects of the hospital's mission. Physicians may be employees, yet they are generally paid independently (through professional fees) and face different incentives from those of the hospital administration (3). In the not-for-profit system, the hospital administration's goals include increasing revenue, decreasing costs, improving quality of care, having high employee satisfaction, and enhancing the reputation of the hospital. Physicians and other

employees may share many of these goals but place different weight on them. For example, hospital administrators may want lower costs, and hospital employees may want higher earnings. Similarly, physicians may want the newest facilities and excess hospital capacity if it benefits them or their patients because the hospital bears the cost of those expenditures. In contrast, hospital administrators may want as little excess capacity as possible.

Because physicians are critical to determining where a patient will be hospitalized and can choose to affiliate themselves with many hospitals, hospitals often compete for physicians. Thus, the relative bargaining power of physicians and hospitals in the not-for-profit setting may have important effects on how care is provided. This bargaining may produce incentives that make care more expensive if hospitals overinvest in infrastructure in an attempt to attract physicians. Efficiency of care may also be impaired by the internal structure of the hospital, which usually includes relatively independent management of services such as nursing, pharmacy, and information services. In the absence of strong central leadership or a culture of cooperation, this can result in a "silo mentality" that complicates efforts for cooperation among these services (Chapter 4).

In *for-profit hospitals*, profits can be returned directly to the stockholders. In theory, this may improve efficiency because stockholders will be less willing to tolerate lost profits than managers will be in a not-for-profit hospital. In practice, however, greater efficiency in for-profit hospitals has not been widely demonstrated (4). There are several reasons for this. Even though profits become an important goal, for-profit hospitals must still compete with not-for-profit hospitals for patients, payers, physicians, and employees. Therefore, they must also respond to the interests of these stakeholders, which leads them to resemble not-for-profit hospitals more than would otherwise be expected. For-profit hospitals are more likely to employ physicians as salaried employees, and so they may have greater power to align physicians' incentives to promote the efficient use of hospital resources, either through exerting influence on individual practice patterns or by increasing the efficiency of hospital infrastructure. However, not-for-profit hospitals are also recognizing that systems and systems improvement are important in optimizing the cost and quality of care. They are also realizing, along with for-profit hospitals, that compensating physicians for these roles and practice patterns can be a critical investment.

Hospitals may also be owned by *federal, state, or local governments*. These hospitals generally receive direct budgetary support that enables them to provide care to patients who would not be covered in other hospitals (such as veterans in the case of VA hospitals or uninsured persons in the case of public hospitals). As a result, these hospitals may not compete as directly with other types of hospitals for patients or payers. Nevertheless, government-owned hospitals may also care for patients with private or other government insurance (such as Medicare), which subjects them to competitive pressures to some degree. Like for-profit hospitals,

government hospitals generally employ physicians as salaried employees. This often gives administrators greater ability (in principle) to direct physician activities, whether with respect to clinical practice or investment in hospital infrastructure. Whether these administrators effectively exercise this ability may be determined by the incentives the administrators face in the organization and the discretion they are given in allocating resources. The size and complexity of bureaucracies in government-funded hospitals may markedly influence the impact of administrators on hospital physicians' activities.

HOSPITAL REIMBURSEMENT

Reimbursement for care in hospitals other than government-owned hospitals has historically been based on a fee-for-service model, in which hospitals bill payers (whether an insurer or the patient) based on the services provided. Except in government-funded and HMO-owned hospitals (where physicians are on salary), physicians generally bill separately, reflecting the historical dominance of the not-for-profit model of care in the United States, with its associated separation of hospital and physician interests. These payment systems are examples of *retrospective reimbursement systems*, which pay based on either the precise services provided or on a proxy for resource use, such as length of stay. Because these systems pay more to hospitals and doctors when resource use is greater, they can provide incentives for greater resource use.

Prospective reimbursement systems contrast with retrospective systems by paying a fixed amount for some episode of care regardless of the amount of care provided. The best example of a pure prospective payment system is a capitated health care system, such as a health maintenance organization, in which a fixed payment is made to provide care for an individual for a given period of time, usually via a monthly or annual premium. In hospital care, prospective payment systems more commonly involve a fixed payment for a single hospitalization for a given cause. Among these systems, the most important is the Medicare prospective payment system, which pays hospitals a fixed amount per episode of hospital care for a specific illness. The diagnosis-related group (DRG) of the patient's primary diagnosis in large part determines the level of compensation. For example, DRG 89 is community-acquired pneumonia.

Hospital reimbursement systems can have important implications for the cost, quality, and organization of care. For example, after the institution of Medicare's prospective payment system, hospital lengths of stay decreased because additional days of hospital care did not yield additional revenue for hospitals. Evidence is reasonably clear that patients were discharged "quicker and sicker," but there is less evidence that outcomes were adversely affected, although some studies suggest small effects on short-term mortality (5,6). Other studies suggest that prospective payment systems may have the largest adverse effects on the sickest patients be-

cause these are the least profitable patients under such systems (7). For this reason, it is important that prospective payment systems have reimbursement categories narrow enough to ensure adequate incentives for patients with all diagnoses to receive care. More generally, the concern that prospective payment systems may provide incentives to reduce care makes the ability to measure quality of care especially important in these systems (Chapter 12).

Payment systems also have implications for the organization of care. For example, when hospitals are prospectively paid, the increased incentives for early discharge tend to result in an increase in the use of skilled nursing facilities after discharge (Chapter 4). Likewise, there may be incentives to postpone non-urgent tests, such as endoscopy in patients with stable GI bleeding, until after discharge. Decisions such as these may pit the interests of patients against those of hospitals (Chapter 17). Such conflicts often reflect fundamental tensions that arise because of the need to control health care costs, but they can clearly be exaggerated in systems that do not create incentives to ensure quality while controlling costs. Medical ethics, the threat of malpractice litigation, and circumspect hospital administration can all limit the influence of the lack of cost and quality incentives, but awareness of cost issues is critical to ensuring that they do not harm the quality of care. Integrated health systems, such as HMOs or the VA system, seem to be less likely to suffer from suboptimal incentives, in part because they have strong incentives to focus on integrating services across transitions of care.

Competition among hospitals has the potential to modify many of these relationships among the system of hospital reimbursement and the cost and quality of care. For example, when hospital care is retrospectively reimbursed, having a greater number of hospitals in an area can result in greater competition among hospitals for doctors. This, in turn, can cause hospitals to overinvest in infrastructure, increasing costs in what is sometimes called a “medical arms race” (8). In contrast, greater competition among hospitals under prospective payment generally decreases costs by driving inefficient practices out of the market. Competition under prospective payment may also have a less desirable outcome because it can make it more difficult to cross-subsidize the care of costly patients with payments for the care of less costly patients in the same categories (9). This can happen because hospitals have increased incentives for devoting resources to selectively attracting the healthiest (and most profitable) patients within a diagnostic category. For example, a hospital may decide it is more profitable to redecorate the lobby of the hospital than to modernize the ICU.

HOSPITAL ECONOMICS IN PRACTICE

Because hospitalists can assume important management positions within their hospitals, they are often asked to help their institutions address economic concerns. Such concerns are usually most acute when a hospital’s prof-

itability is jeopardized. However, because profits can always be used to meet institutional goals, the pressure to increase profits is ubiquitous. Because profit is defined as revenue minus cost, the essential components of improving profits are increasing revenues and decreasing costs.

Increasing Revenues

Hospital revenues come from patient care, direct government payments (e.g., to VA hospitals), donations, or research support. For all hospitals other than government-owned hospitals, most revenue comes from patient care. Revenue is, therefore, determined primarily by the price and quantity of care provided.

A hospital may receive different prices for the same service from different payers—including sometimes no reimbursement when it is unable to collect on a bill that it issues to a patient or insurer. Therefore, the *payer mix* can have a major effect on revenue. Sixty percent of hospital care is paid for through public funds, mostly through Medicare and Medicaid. Reimbursement rates often vary by hospital, across clinical services, and over time, but public payers tend to reimburse at lower levels than private fee-for-service insurance, with Medicaid paying less than Medicare. The private funding sources are patient self-payment and private insurance. Self-payment is steadily decreasing; it now accounts for less than 20% of all health care costs, down from almost 35% in 1980. Private insurance reimbursement may be fee-for-service or capitated.

Hospitals generally try to develop the best payer mix to maximize revenue. Although simply accepting only the highest-paying private insurance would provide the best payment for a given service, the hospital must also attract enough patients to keep sufficiently busy to cover the costs of running the facility (“covering its fixed costs”). The optimal payer mix for a hospital reflects the available payers, the local environment, the size of the hospital, and more. All these factors must be taken into account when the hospital negotiates contracts.

Billing and collections can significantly affect revenues and are remarkably complex. Rules for billing are highly regulated and increasingly strictly enforced. It is important for a health care organization to bill efficiently and accurately, as this is its major source of funding. Investment in infrastructure to maximize appropriate billing may significantly improve revenues (e.g., assuring that visits that should be reimbursed at a higher level, such as “Pneumonia, pseudomonas” are billed at that level as opposed to being billed at the lower level of, for example, “Pneumonia, not otherwise specified, or NOS”).

The quantity of care provided is the other major determinant of revenue. Hospitals influence this by attracting patients, physicians, and payers and by making services available to them when they need them. Quality of care, both actual and perceived, the availability of specialized services, convenience, and amenities such as decor may all be important in attracting patients (Chapters 12 and 14).

Physicians may guide their patients to hospitals based on these same factors but have additional interests relating to their own personal convenience—ranging from the responsiveness of the nursing staff and the availability of clinical services such as radiology to the transit time from their office and the convenience of parking. Hospitals can also increase revenue by adding new resources, such as building a new hospital or more heavily using existing resources. Maintaining a high hospital occupancy rate (e.g., greater than 90%) is the most important factor in assuring high use of existing resources.

Decreasing Costs

The other component of the profit equation is costs. Costs can be conceptualized in several ways, but one of the most important distinctions is between variable and fixed costs. *Variable cost* is the incremental expenditure associated with providing a service, especially in the short run, when basic infrastructure or overall staffing levels are fixed. For example, the variable costs for administering a medication would include the cost of the IV tubing, solution, medication, and gloves worn by the nurse when administering the medication. *Fixed costs* are the remaining portion of the hospital's expenditures after variable costs are removed. These fixed costs are then attributed by an accounting system to the different activities in which the hospital engages. For example, the cost of staffing the pharmacy would be distributed among the number of medication doses provided. Because the vast majority of hospital costs are fixed (more than 80% in some studies (10)), understanding how a cost-saving intervention will affect fixed costs is essential. Assigning costs to a specific activity is often difficult in practice, so hospitals sometimes describe costs in terms of "direct" and "indirect" costs. Direct costs are costs that can be directly identified as being associated with an intervention, for example, the cost of the IV tubing, solution, and medication in the instance noted above. Indirect costs are those costs not identifiable but nevertheless associated with an intervention, for example, the nurse's gloves in the example above (because there is no mechanism to identify that the gloves were used for that particular purpose).

Of particular importance is that fixed costs may become variable costs over a period of time. For example, if more medications are ordered, it may be necessary to hire additional pharmacists. As a result, it can be very difficult to determine the true incremental cost associated with a treatment, and an intervention that reduces costs in one setting may not in another. For example, an intervention that saves pharmacists time may not reduce costs unless pharmacist staffing can be reduced. This may not be possible in a small hospital that has only one person working at a time but might be more likely in a larger hospital that can reduce staffing in proportion to the decrease in workload.

This last example illustrates *economies of scale*, which occur when the cost of producing an output falls as the quantity of

outputs provided rises. The most common reason for economies of scale in hospitals is the large component of fixed costs. For example, the fixed-cost component of an MRI scanner that costs \$3 million per year to operate while providing 3,000 scans per year is \$1,000 per scan. In a smaller hospital in which only 1,000 scans per year are done, the fixed cost would be \$3,000 per scan. Even large hospitals often cannot fully exploit economies of scale, providing a major incentive for hospital growth, consolidation, and specialization. Economies of scale can also occur when a larger organization gains experience in providing a given service and that experience results in better outcomes or lower costs (11). Diseconomies of scale can occur as well, as when a hospital becomes too large to manage effectively. Managing such economies of scale is a key part of good hospital leadership. In the earlier pharmacist example, a good manager might recognize that increasing the efficiency of the pharmacist could allow the hospital to implement a more intensive program reviewing medication appropriateness. This manager might also recognize that improving pharmacists' workflow may improve their satisfaction and make it easier to retain excellent pharmacists at more moderate salaries.

Length of Stay

In practice, reducing length of stay (LOS) is often the most significant way in which hospitalists can reduce costs (12,13). The business case for LOS reduction depends on its effects on both revenues and costs, with complex interaction between issues such as reimbursement system and hospital occupancy. For example, under prospective payment, reducing length of stay enables the hospital to obtain added revenue by admitting more patients using the same fixed resources. However, under retrospective per-diem reimbursement, shorter lengths of stay may not translate directly into either added revenue or improved profits. A good example of this is the incentive to discharge patients to a skilled nursing facility at the end of a hospitalization. Under prospective reimbursement, this clearly reduces hospital costs and allows additional revenue to be generated. Under per-diem reimbursement, patients who can be discharged to a skilled nursing facility may be far less expensive to care for than the average hospital patient, making it profitable to keep them in the hospital.

CONCLUSIONS

Hospital economics are influenced by the organizational form of the hospital, the relationship between hospitals and physicians, and complex interactions between reimbursement systems and market competition. In practice, these forces interact with local phenomena relating to reimbursement mechanism, payer mix, and cost structure to determine how changes in hospital operations affect profits through both revenues and costs. Hospitalists (and

others) can be most effective when they understand the components of the equation and how to effectively operate within the system.

KEY POINTS

- Hospital care is expensive and is often reimbursed by prospective payment systems that may create incentives to limit care.
- Hospitals have different organizational forms, including not-for profit, for-profit, and government-owned.
- These organizational forms produce incentives that influence both the relationship between physicians and hospitals and the effects of reimbursement systems on the cost of care.
- In practice, hospitals attempt to increase revenue by improving payer mix and billing practices, by increasing the volume of care provided, and by decreasing costs by identifying variable and fixed costs that can be reduced in the short run or long run.
- Decreasing length of stay is an important way hospitalists can help hospitals increase revenues and decrease costs.

Practice Management in Hospital Medicine

John R. Nelson

INTRODUCTION

The increasing pace and complexity of hospital care has led to new approaches to providing that care. This chapter explores these approaches, with a particular emphasis on organizational and financial issues for hospitalist programs.

ISSUES RELATED TO CONTINUITY OF HOSPITAL CARE

The hospitalist model of care involves a discontinuity of care between the primary care physician (PCP) and the hospitalist. Hospitalist groups are thinking carefully about ways to mitigate the potential adverse effects of this discontinuity through effective communication strategies among the PCP, patient, and hospitalist (1). However, an issue often overlooked is the continuity of care between patient and hospitalist during a single hospitalization or across multiple hospitalizations over time. One can speculate that a patient could benefit from seeing the same hospitalist each day of a hospital stay and during future hospitalizations. However, perfect hospitalist–patient continuity, such that the same doctor *always* sees a patient, is unrealistic because it requires that the doctor be constantly available. Thus, it is important for each group to find an appropriate balance between competing needs of continuity and physician lifestyle.

Patient–hospitalist continuity is most often discussed in relation to a single episode of hospital care. Many practices schedule doctors in blocks of days, such that a significant number of hospitalized patients will be cared for by a single physician during the patient’s entire stay. The following simple formula offers a way to estimate the optimal length of these blocks:

$$C = \frac{D - (L - 1)}{D} \times 100$$

where C is the percentage of patients having only one hospitalist during a hospitalization (“continuity”), D is the average duration of hospitalist shifts, and L is the average length of stay in days.

For example, the formula tells us that, in a program that uses five-day hospitalist shifts and has a median length of stay of five days, only 20% of patients will see the same hospitalist each day ($C = 20\%$). Increasing the shift length to eight days improves continuity to 50%. The schedule that provides the best continuity (i.e., highest value for C) while still ensuring a reasonable and sustainable lifestyle for the doctor is probably the best choice.

Continuity between patient and hospitalist across multiple hospital stays (admissions) is somewhat more complicated and less often discussed when considering hospitalist schedules. While no data has been published to inform this discussion, it seems reasonable to speculate that having a patient see the same hospitalist during each admission might facilitate a closer bond between patient and physician and reduce the risk of clinical information “falling through the cracks.” However, the author’s anecdotal experience suggests that most hospitalist practices find this difficult, and typically a patient is assigned to whichever hospitalist is on duty for admissions despite the theoretical benefits of admission-to-admission continuity.

When thinking about how to optimize continuity from one hospital stay to the next, three approaches are attracting interest:

1. For patients readmitted in a short period of time (e.g., less than seven days), have the hospitalist who cared for the patient during the prior stay see the patient again. If that doctor is away at the time of the patient’s return, a partner could care for the patient until the original attending hospitalist is back on duty. For patients readmitted after a longer period (and thus somewhat less likely to be returning for the same reason as the original

admission), the attending hospitalist would be the one on duty at the time of the patient's return. Many hospitalist groups take this approach.

2. A patient is paired with a hospitalist at the first admission to the hospitalist practice, and the same doctor sees that patient during every future admission. The only exception would be that a partner hospitalist sees the patient when the patient's main hospitalist is away. Such a system means that each hospitalist essentially builds his or her own patient population in much the same way an office-based doctor does. While this approach may sound ideal, it is unusual because of many complexities. For example, one hospitalist could be extremely busy with patients while a partner hospitalist might have little work to do. This is not a good way to distribute the practice manpower. Additionally, because most hospitalist practices are still relatively new, they are experiencing growth (adding doctors) and turnover. Last, this system is of little value for groups that work a modest number of days per year (e.g., a seven-days-on/seven-days-off schedule) or often use part-time doctors, because there is less chance a given patient's main hospitalist will be working at the time of any future admission.
3. An alternative to the above approach is to pair each hospitalist with an individual referring physician such that any patient referred by that doctor would always see the same hospitalist. This system should have similar advantages and drawbacks to that described above, with one additional advantage. The referring doctor and hospitalist could get to know each other even better and develop a relationship that is close to a true partnership. However, because of the same complexities described above, and because unassigned patient admissions from the emergency department would fall outside this protocol, this approach to continuity is in use in only one practice of which the author is aware.

NIGHT-TIME HOSPITALIST COVERAGE

The ideal system of night coverage for a hospitalist practice varies significantly from one practice to the next. Most small groups of five or fewer doctors use traditional call schedules with one member of the group on call for any night work. However, with larger groups, the burgeoning night work makes it increasingly difficult for a doctor to work the day before and day after being on night call. This leads many to adopt a separate system of night coverage staffed by dedicated doctors who work only at night (colloquially referred to as "nocturnists"), non-hospitalist moonlighters, or members of the hospitalist group rotating responsibility for night coverage for several consecutive nights without accompanying daytime responsibility. In practices with significant

amounts of night work, such systems seem likely to provide for more sustainable careers and reduced risk of burnout.

In addition to the potential benefits for physician lifestyle, a system of dedicated night coverage might provide a number of other benefits, including better patient care. It is easy to imagine that an on-call doctor might handle patient care issues differently at night than a dedicated night-shift doctor who is in the hospital and expecting to work rather than worrying about how to get some rest before the next working day. For example, nurses may be more willing to call a night doctor who is awake and in the building than a sleep-deprived on-call physician. Additionally, a dedicated night-shift doctor is likely to form better working relationships with the night nursing staff, and this could translate into improved work satisfaction for all parties. It is possible that dedicated night coverage by hospitalist practices will become one of the key interventions to improve the quality of care and sustainability of the practice.

Successive surveys of hospitalists show that call-based schedules are increasingly being supplanted by shift-based schedules (2). In 2002, 40% of hospitalists responding to a survey reported having no on-call hours (3). Taken together, these results suggest an increasing prevalence of dedicated night coverage. Still, such systems are far from universal, and the barriers to their universal adoption include the following:

- Difficulty in financially supporting the night position
- For small hospitalist groups, a volume of night work that does not justify a dedicated night system
- Difficulty in recruiting doctors willing to work solely or primarily at night

Of these, the issue of financial support for the position can be the most difficult to overcome. The most economically productive time for a hospitalist is daily rounds, and night doctors do not conduct them. At night, the hospitalist might admit several patients, see a few "floor" patients, and field a number of calls from the nursing staff, but these activities seldom generate enough professional fee revenue to provide adequate compensation. Two common solutions can help ensure economic viability of the night system. First, and most commonly, in many health care systems the hospital or a payer (e.g., a managed care organization) sees enough value in a dedicated night system that it provides the funding to make up the difference between collected fees for work at night and the doctor's salary. Second, the night doctor can seek additional revenue sources, such as providing call coverage to doctors outside the hospitalist practice for a fee and then billing for the visits made.

As hospitalist practices mature in the coming years, it appears likely that night on-call systems will be replaced by dedicated systems of night coverage. A number of other specialties—including emergency medicine and hospital-based radiology—have seen a similar evolution or are experiencing it now.

HOSPITALIST CAREER LONGEVITY AND BURNOUT

No clear statistics are available, but anecdotal evidence suggests that physician turnover in hospitalist practice might be higher than in other specialties. A number of organizational and individual characteristics might influence hospitalist career longevity, but one major factor in a higher turnover rate for hospitalists is probably the relatively low barrier to entry to this type of practice. When compared with other generalist careers, hospitalist practice may be an attractive choice because it seems similar to how most residents spent a great part of their training (i.e., caring for hospitalized patients). Moreover, one can join a hospitalist practice and be busy on the first day rather than spend months building a primary care practice. Finally, leaving a hospitalist practice might be less disruptive to colleagues (and patients) because the practice has no regular patients that might leave or need to be reassigned to other doctors. All these factors could increase the chance that doctors might pursue hospitalist practice as a temporary stop before moving on to other training or practice settings.

These factors contribute to physician turnover independent of many other issues related to career longevity, such as professional satisfaction, income, and burnout. Surveys designed to assess these latter features show that most hospitalists are satisfied with their work and intend to remain hospitalists for the foreseeable future (Table 3.1).

TABLE 3.1

HOSPITALIST JOB SATISFACTION

Hospitalist satisfaction, 2000	
Very satisfied	58%
Satisfied	35%
Somewhat dissatisfied	6%
Very dissatisfied	2%
Hospitalist work attitudes, 1999	
Level of job burnout:	
Burned out	12.9%
At risk of burnout	24.9%
No current risk of burnout	62.2%
Years intending to remain a practicing hospitalist	
0–3	17.5%
4–7	18.3%
>7	64.2%

Hoff TH, Whitcomb WF, Williams K, Nelson JR, Cheesman RA. Characteristics and work experiences of hospitalists in the United States. *Arch Intern Med* 2000;161:851–858.

TABLE 3.2

FACTORS ASSOCIATED WITH HOSPITALIST BURNOUT

- Perception of restricted autonomy
- Working for an institution (e.g., hospital or health maintenance organization) rather than self-employed or working in group practice
- Poor “occupational solidarity”
- Poor integration with non-MD co-workers
- Poor recognition by patients/families for job that is done
- Inability to treat entire range of patient problems

Interestingly, the following were not shown to correlate with burnout:

- Number of new patients (admissions and consultations) seen per month
- Portion of compensation linked to financial incentives
- Perceived pressure to contain costs

Hoff TH, Whitcomb WF, Williams K, Nelson JR, Cheesman RA. Characteristics and work experiences of hospitalists in the United States. *Arch Intern Med* 2000;161:851–858.

Many remain concerned about the issue of hospitalist burnout. As Table 3.1 shows, 38% of hospitalists were either burned out or at risk of burnout in 1999 (2). These percentages become even more worrisome considering that 85% of survey respondents had been hospitalists five or fewer years (46%, two or fewer years). More research is needed to learn the factors that increase and prevent burnout, but the 1999 survey highlighted several variables associated with burnout (see Table 3.2).

Clearly, more study is needed regarding maximizing satisfaction with the hospitalist career and preventing burnout. The single study in 1999 does not provide enough information to serve as the basis of definitive guidelines for the optimal practice structure. Information from similar specialties such as emergency medicine and critical care medicine may be helpful because they have burnout rates of 40%–60% (4,5). In the absence of definitive guidelines, each practice must carefully consider the available information and the preferences of its doctors to arrive at decisions about operating the practice. It seems clear that such an approach leads many groups to modify their practice schedules frequently.

FINANCIAL VIABILITY OF HOSPITALIST PRACTICE

Survey data from 2002 show that 75% of hospitalists receive some financial support in addition to the collection of professional fees (3). This support usually comes from the hospital served by the hospitalists, but it may come

from other sources, such as a managed care organization or a large group medical practice. The median amount of this support was 30% of professional fee revenue for the practice (3). The entity providing this support is usually in the position of benefiting financially from the increased efficiency hospitalists bring about. Hospitalist practices often require this additional support for several reasons, including the following:

- Hospitalists can usually command a salary that is 5%–15% higher than that of doctors with the same training in the same market. For example, an internal medicine-trained hospitalist might make 5%–15% more than an internist in traditional practice in the same area. This is because in most areas the demand for hospitalists exceeds the supply (a situation that may change in a few years as an increasing number of residents seek careers as hospitalists). Additionally, hospitalists usually have more night and weekend responsibilities than PCPs in traditional practice.
- Hospitalists are often asked to care for unassigned patients admitted through the emergency department, a patient population that is usually associated with lower levels of reimbursement.
- The amount of work to be done at night might be such that a traditional on-call schedule is unreasonable and a dedicated system of night coverage is needed. Typically, the night work fails to generate enough professional fee revenue to support the night position, and additional support might be needed.

Despite these factors, the survey indicates that 25% of groups do *not* receive additional financial support (3). However, many of these groups do receive support over and above the prevailing reimbursement rates for the local market. This support comes through a variety of mechanisms, including local payer(s) approving hospitalist fee schedules that are higher than the prevailing rates, or through nonfinancial support (such as a hospital paying for a system of night coverage using moonlighters). Groups that receive such support might indicate on a survey that they receive no money beyond their collected fees, yet they do depend on support beyond prevailing reimbursement rates.

Clearly, some hospitalist practices operate solely with professional fee collections (at the prevailing market rates). The author's experience suggests that these groups either work at a difficult and potentially unsustainable pace, pay salaries below those of hospitalists in other practices, or both.

It is difficult to predict whether support in addition to professional fee revenue will remain a typical part of hospitalist practice in the future, but it does seem unlikely that professional fees (at least those paid via government programs such as Medicare) will increase to make this financial support unnecessary.

HOSPITALISTS AND HEALTH SYSTEM EFFICIENCY

Efficient patient care delivery is one of the most well-studied attributes of hospitalist practice. Nearly all studies that have examined this issue have found that hospitalist care is associated with reductions in length of stay (LOS) and cost per case of about 15%–20% when compared with care delivered by non-hospitalists (6). Data are beginning to accumulate that this improved efficiency does not come at the expense of quality of care; in fact, hospitalist care may be associated with improved patient outcomes (7,8).

Many hospitalist practices carefully measure efficiency-related statistics such as LOS and costs, as well as a number of clinical quality measures. However, these metrics may fail to capture some additional value that the practice might provide to the hospital or health system. For example, a hospitalist practice might increase a hospital's market share of referrals through good relationships with physicians and smaller hospitals in the outlying areas.

Another, and increasingly important, way hospitalists can increase hospital efficiency is by influencing the time of day that a patient is discharged. As hospitals have become increasingly full in the past few years, they have become more dependent on early patient discharges (e.g., approximately 11 AM) so that beds can be made available for scheduled and emergency admissions. Late discharges pose less problems for hospitals that are not full, but those hospitals still incur the cost of needing more nursing staff on the afternoon/evening shift than if patients were discharged early in the day.

The following example illustrates the issue of early discharge and hospital bed availability for full hospitals. Imagine a 100-bed hospital that is full in the morning. Of the 20 discharges that will take place that day, three are delayed until late in the afternoon for nonmedical reasons. That leads to the cancellation of three elective admissions planned for that day. If those delayed patients were discharged early in the day, the hospital might avoid canceling the elective admissions, thereby serving more patients with the same number of beds. In other words, with early discharge, it is as though the hospital has access to three more beds without having to construct them or add new staff to provide care.

Some hospital administrators speak in terms of expediting throughput by reducing LOS and discharging patients earlier in the day. For a 300-bed hospital, a 0.25-day reduction in LOS for all patients would have the effect of making 12 "new" beds available and freeing approximately nine nursing full-time equivalents. Hospitalists are well positioned to address these issues by providing efficient care, by letting patients and families know the anticipated date of discharge as early in the hospital stay as possible, and by visiting patients potentially ready for discharge very early in the day. Of course, the hospital needs to do its part: ensuring that clinical data used to make discharge decisions are

made available to the physician early in the day and eliminating hospital-related bottlenecks that lead to the patient remaining in the room unnecessarily after the discharge order is written.

While obvious, it is worth mentioning again that medical issues must take precedence in deciding the day and time of discharge. Some patients cannot be appropriately discharged until late in the day, after their evaluation and treatment is completed. While these patients may first appear to be delayed discharges, they might in fact be very *early* discharges—by being released late in the day rather than the next morning, as might have occurred years ago.

CONCLUSIONS

As the care of hospitalized patients continues to evolve, ongoing clinical and economic challenges will require adjustments in the care delivery system to ensure the provision of high-value care. Information from research studies will help determine the most effective ways to improve care delivery, but published research is unlikely to answer all questions about how physicians and hospitals should be organized. Innovation will always be needed in response to local strengths and challenges.

KEY POINTS

- While the hospitalist model of care involves a discontinuity between inpatient and outpatient providers, thoughtful arrangements of the hospitalist's work schedule can maximize patient-hospitalist continuity while preserving a sustainable lifestyle for the doctor.
- The on-site presence of a night hospitalist who does not also work the day before or after the night shift may have important benefits for patient care and hospitalist longevity. However, there are significant challenges to implementing such a system.
- Few data are available to answer questions about hospitalist career longevity and burnout, but they may be similar to what is seen in fields, such as emergency medicine or critical care medicine. Physician turnover in hospitalist practice may be much higher than in other

primary care roles because of the comparatively low barrier of entry to hospitalist practice.

- For many reasons, most hospitalist practices require a source of financial support in addition to the collection of professional fees. This is an area that may see significant changes in the future.
- When medically appropriate, discharge of patients early in the day can have a significant impact on the number of patients that the institution can serve. Discharge early in the day can be valuable to a hospital, but that value does not appear in commonly tracked statistics such as length of stay or cost per case.

Hospital Interfaces

4

Winthrop F. Whitcomb John R. Nelson

INTRODUCTION

In our increasingly complex health care system, patients receive care from a staggering number of providers. This is particularly true in the hospital, where the average patient sees dozens of health care personnel every day. Not surprisingly, fragmentation among various departments and providers is an important obstacle to high-quality and efficient care (1) and has led some to examine how best to manage the myriad hospital interfaces. This chapter explores key physician interfaces, both within the hospital setting and across the care continuum. In addition, the chapter discusses the interactions between physician and nonphysician members of the hospital care team. Specific strategies related to hospital discharge are further considered in Chapter 5.

Rapid advances in information technology aimed at linking the hospital and other care settings will significantly improve the physician's ability to care for patients effectively. However, technology will not diminish the importance of the time spent communicating with and examining the patient, nor will it obviate the need for physicians to properly manage the dozens of personal interactions that frequently determine the outcomes and cost of care.

TERMINOLOGY

As discussed in Chapter 1, a variety of arrangements among physicians are emerging for the provision of hospital care. Whether hospital care is provided under the traditional approach (stage I), a non-hospitalist rounder system (stage II), or a dedicated hospitalist model (stages III and IV), many of the interface issues for the physician in the hospital are the same. Accordingly, this chapter uses the term *hospital physician* regardless of model for hospital care and the term *referring physician* to denote the physician who refers the patient to be cared for by the hospital physician. The referring

physician may be a primary care physician or a subspecialist. The hospital physician may be a hospitalist or a traditional physician with significant outpatient responsibilities.

CARE OF THE HOSPITALIZED PATIENT

Physician–Patient Interface

Admission to a hospital can mean that a patient and a physician are meeting each other under stressful circumstances, often for the first time. Hospital physicians should begin by introducing themselves and describing their role, and they should use an empathic interview style to provide both patient and family with a sense of comfort and confidence. An approach to establishing rapport is summed up by the mnemonic PEARLS, for *partnership, empathy, apology, respect, legitimation, and support* (see Table 4.1) (2).

Referring physicians can help build a patient's confidence in a separate hospital physician by explaining the reasons for the referral, letting the patient know that they will be communicating with the hospital physician frequently during the hospitalization, and explaining that they will be the patient's primary doctor after discharge. One Baton Rouge physician captured the essence of the referring physician–hospital physician relationship by using a local metaphor:

An analogous role [to that of the hospitalist] is performed by Mississippi river pilots. River pilots board all ocean liners as they enter the deceptive and changing currents of the Mississippi River. They guide the vessel safely to and from port, returning the controls to the ship's captain for the homeward voyage. Their collaborative efforts yield navigational quality that neither could attain alone (3).

It is helpful to provide the patient with a written brochure introducing the hospital physician and explaining when the patient can expect to be seen, how the family can contact the hospital physician, and how communication between physicians will occur.

TABLE 4.1
KEY STEPS TOWARD ESTABLISHING RAPPORT (PEARLS)

Element of the approach	Settings and examples
Partnership	<i>(With a chronically ill patient in the ER about to be admitted for unstable angina)</i> “We’re going to have some difficult decisions to make. I’ll need to work with you and your family to provide the best care and the care most consistent with your values and beliefs.”
Empathy	<i>(With an elderly patient traveling alone through your town, admitted with pneumonia)</i> “You look sad. I can only imagine how hard it must be being ill here, without your family or your own doctor to help you.”
Apology	<i>(With an HMO patient angry about being admitted by the hospitalist, not his or her PCP)</i> “I’m very sorry that the system doesn’t allow your own doctor to care for you here, and that you and I don’t have a close relationship. Still, I’d like to try to get to know you, and, after speaking with your doctor on the phone, take as good care of you as I know she would.”
Respect	<i>(With a patient readmitted for COPD, still smoking after many attempts to quit)</i> “You know, Mr. Jones, I know how hard it is to quit. But even though you’re still smoking, you never seem to give up trying to quit.”
Legitimation	<i>(With a patient suspicious of your motives in not consulting a specialist)</i> “Many people these days are unaware of the skills of internal medicine (family practice, etc.) and have come to equate quality care with subspecialists like cardiologists. I can imagine you’d have some questions about how qualified I am to care for this problem.”
Support	<i>(With a patient about to enroll in hospice)</i> “Hospice does not mean giving up. The hospice nurses and your family doctor will be with you in the coming months, and if they have questions for me, or if you have questions for me, the hospital operator can page me and I’ll call you back as soon as possible.”

Adapted from Barnes PB. Rapport and the hospitalist. *Am J Med* 2001;111:31S–35S, with permission.

If meeting the patient for the first time, the hospital physician carries the dual burden of building a relationship with the patient and family and learning the pertinent medical and psychosocial details. The latter task requires a review of prior medical records. In many systems, outpatient records are separate from hospital records, so the hospital physician must request records from outpatient providers and other hospitals. Because this record request is a regular part of the hospital physician’s work, it is worth developing a protocol such as the one shown in Figure 4.1 to streamline the process. The hospital physician can complete the form and include it with the admitting orders. Additionally, referring offices should develop similar protocols to provide records to the hospital physician when a patient is admitted. The referring office can send the entire office chart (although transporting it between office and hospital risks losing it), or it can furnish copies of recent records, including (at a minimum) results of the last comprehensive history and physical examination plus medical problem and medication lists.

With medical-surgical lengths of stay averaging less than five days in many regions of the United States, part of the admission process should include initial discharge planning. Early assessment by the physician, nurse, and case manager should elicit the preadmission functional status and social support structure. As the hospital course progresses, new information emerges that can influence the discharge plan, and the patient’s need for other services,

such as physical and occupational therapy, is frequently revealed. Patient and family satisfaction with the discharge plan has been shown to depend on factors related both to the discharge planning process and to the discharge destination (4).

Hospital discharge is a point at which important communication issues arise for all physicians. The challenge of organizing effective posthospital care is greater for a hospitalist because a different physician provides follow-up with the patient. Detailed conversation between the hospital physician and patient during the final hospital visit, accompanied by written instructions, is helpful (5). For a hospitalist, a phone call to the patient between 24 hours and two weeks after discharge is an excellent opportunity to reinforce discharge instructions, review the results of tests that may have been pending when the patient left the hospital, answer the patient’s questions, and remind the patient of the importance of follow-up (6). Follow-up phone calls by nurses, case managers, or clinical pharmacists may also be effective (7). When appropriate, providing the patient and family with a copy of the discharge summary can also serve to reinforce the findings of the hospital stay and the follow-up plans. Finally, some hospitalist programs have established a follow-up service, whereby the patient may be seen once after hospital discharge by the hospital physician before returning to the referring physician (8). Chapter 5 contains further information on hospital discharge.

Figure 4.1 A model record request form. A form such as this one can be completed by the admitting physician and included with the admitting orders. It can then be faxed to the office or institution from which records are sought. A section at the bottom documents the patient's consent to provide the records and avoids the need to complete and fax a separate consent form.

Hospital Physician–Referring Physician Interface

Hospital physicians need to establish effective communication links with referring physicians, both to transmit information and to collaborate on inpatient care decisions. They can use each other as telephone consultants in de-

termining whether to admit or discharge, and they should continually educate each other about the strengths and limitations of care in their respective settings. In this regard, there may be advantages to systems in which the hospital physician maintains some outpatient contact and the referring physician some contact with the inpatient setting.

Situations can arise in which neither physician should make unilateral decisions about the care of a patient, sometimes including the decision to admit or discharge. For example, if a hospital physician decides the patient can be treated with an intravenous antibiotic as an outpatient, the referring physician or another outpatient physician must agree and be ready to assume this responsibility. The list of illnesses once requiring hospitalization that can now be managed in the outpatient setting grows each year, and the hospital physician must involve the referring physician in the decision to employ outpatient treatment.

As a gap between hospital and outpatient care emerges in the United States, concerns have arisen regarding a potential loss of information at the hospital threshold (9). In an Australian survey of 350 outpatient physicians, 84% were not notified of their patients' admission to the hospital; 87% were not notified of major changes in their patients' condition, including death; and 75% were not notified of patient discharge from the hospital (10). Preliminary results from American hospitalists seem more favorable: more than 90% state that they do communicate with referring physicians at discharge (11).

The frequency and nature of contact between the hospital physician and referring physician during the patient's hospital stay can vary a great deal. At a minimum, the hospital physician should notify the referring physician when any significant or unexpected changes in the patient's condition develop and when decisions are made in the hospital that will significantly affect subsequent outpatient care (e.g., starting a complex therapy such as parenteral nutrition that will be continued on an outpatient basis). Additional contact can be tailored to the interests and desires of each physician. Some referring physicians choose to make "continuity visits" to their hospital patients or to contact the patients by telephone. These important contacts, which the hospital physician should encourage, facilitate discussion about psychosocial and ethical issues, assure patients of the referring physician's continued involvement, allow for the referring physician's endorsement of the hospitalist, and bridge the gap in clinical information between hospital and non-hospital settings (12).

At discharge, the hospital physician should give the referring physician a detailed discharge summary that incorporates the usual components of a summary in addition to features commonly found in consultation reports. The summary should include a specific section listing the tests pending at discharge, follow-up studies needed (e.g., repeated chest roentgenogram to follow a lung lesion or coagulation studies to monitor warfarin therapy), a list of medications, and instructions given to the patient. All discharge summaries should have the same format regardless of the physician who prepared them; this ensures that the reader can quickly find pertinent information. Summaries should be provided to the referring physician and other

caregivers in a timely manner to help with the transition in care. Many institutions have a summary dictated and transcribed on the day of discharge and faxed to the referring physician the same day. In addition, some referring physicians prefer a phone call from the hospital physician on the day of discharge (13). When patient care is being transferred from hospitalist to primary physician, the principles outlined in Table 4.2 (14) should be kept in mind.

Hospital Physician–Emergency Department Physician Interface

The role of the emergency department (ED) physician is to institute a timely diagnostic and therapeutic plan for patients in the ED. In those who require hospital admission, early involvement of the hospital physician can be an advantage for all parties. Because of their increased or continuous presence in the hospital, hospitalists have the opportunity to become involved in the care of ED patients earlier than primary care physicians can. Early contact with the hospital physician to provide admission services may improve patient flow through the ED, decrease costs, and increase patient satisfaction.

Some patients can be admitted directly to the hospital without involving the ED. Hospital physicians can help facilitate direct admissions by encouraging referring physicians to call them about patients who will require admission rather than send patients to the ED for initial evaluation. Of course, unstable patients should always be seen in the ED first.

Clinical guidelines to coordinate the efforts of ED and hospital physicians are proliferating. By defining each physician's role for a given condition, guidelines can minimize gaps in care and duplication of effort. Creating successful guidelines requires the participation of both ED and hospital physicians on the clinical guideline authoring team. Successful implementation of such guidelines can lead to more rational divisions of labor, with the ED and hospital physicians able to focus on their respective care settings.

TABLE 4.2
SIX PILLARS OF THE HAND-OFF

1. Communicate, but do not irritate.
2. Consult the primary physician.
3. Timeliness is next to godliness.
4. Partner with the patient.
5. Make it clear that you are the patient's advocate.
6. Pass the baton as graciously as you received it (or even better, more graciously).

Hospital Physician–Intensive Care Unit Physician (Intensivist) Interface

The role of the hospital physician in the ICU is highly variable and depends on hospital size, setting, and organization of care. Evidence suggests that ICUs in which dedicated intensivists play a primary role in patient management outperform ICUs in which primary care physicians play such a role (with no or optional intensivist consultation), with regard to both outcomes and efficiency (15). As a result of caring for many ICU patients, some hospitalists may be more comfortable and competent in ICU procedures than primary physicians with the same training background. This increased skill, along with greater availability during the day, will allow some hospitalists to feel comfortable managing patients both in and out of the ICU. Although hospitalists who are not intensivists will never replace physicians trained in critical care, their presence may result in a decreased need for closed ICUs and their associated discontinuity. Moreover, if the hospital physicians are more readily available than the intensivists, they can provide preliminary critical care services (e.g., airway management or fluid resuscitation) until the intensivists arrive to deliver comprehensive critical care services. Finally, the growing national shortage of intensivists will require that other physicians, usually hospitalists, fill the vacuum (16).

Because hospitalists and non-hospitalist intensivists are readily available within the hospital, both are naturally suited to provide leadership on hospital and medical staff committees concerned with inpatient settings, such as ethics committees, quality improvement committees, and clinical guideline committees. Guidelines developed by members of both disciplines can streamline care (e.g., antibiotic selection) as patients move out of the ICU to a step-down unit or an acute medical floor. Early transfer of patients out of the ICU can be facilitated by a hospital physician, whose presence and expertise may improve patient flow and bed availability in the ICU.

Hospital Physician–Observation Unit Interface

Observation units are present in many hospitals. They go by a variety of names, including emergency department observation units, clinical decision units, rapid diagnostic and treatment units, or others. These units, commonly located within or near the emergency department (ED), are most often used for ED patients who require diagnostic evaluation or urgent treatment beyond the typical scope of ED care but who do not clearly require hospital admission. Common problems managed this way might be chest pain, asthma, cellulitis, and dehydration. During the patient's time in the observation unit, a decision is made regarding discharge or admission to an inpatient unit of the hospital. Because of their availability, ED physicians most commonly serve as the patient's attending physician during the

observation unit stay, but if the unit is in a location remote from the ED, then hospitalists or other members of the medical staff might serve as attending (17).

For the hospital physician, the presence of an observation unit is likely to significantly decrease the number of inpatient admissions (18). It might also change the nature and acuity of patients admitted after an observation unit stay because they will have undergone more workup and treatment than patients admitted directly from the ED. Physicians in the observation unit and hospital physicians need to work together closely to develop protocols regarding observation unit versus direct hospital admissions from the ED. Both physicians also need to work with hospital administration to correctly designate patients as being on "observation status," per Medicare regulations. Both groups should be comfortable with the time of day that patients are transferred from the observation unit to the inpatient ward and care transferred to the hospital physician. For example, if care is routinely transferred to the hospital physician as the workday begins (e.g., 7 AM), the patient's observation unit attending physician might have left work already, and the hospital physician might be busy discharging patients. A protocol regarding transfer of care should specify that the transfer occur at the optimal time of day for all involved and provide for seamless transfer of the patient's clinical and social history.

Hospital–Skilled Nursing Facility Interface

The hospital–skilled nursing facility interface is a demanding area for practitioners, both in maintaining high-quality care and in preventing loss of pertinent clinical information. Yet physician training in this area has been inadequate. A survey of 389 hospitalists revealed a perception of inadequate residency training in "coordination of care between settings," "prescribing the appropriate level of care," and "knowledge of therapeutic capabilities of nursing homes" (19).

A growing body of literature suggests that hospital physicians can be most effective when discharging patients, including those who will go to a skilled nursing facility, by working with a multidisciplinary team (20). A team approach allows assessment of functional status and evaluation of home supports so that skilled nursing facility transfer can be anticipated early in the hospital course. Upon discharge, the chief concern is the appropriate transmission of patient information across settings. Table 4.3 lists important documents to be sent with the patient at the time of transfer to a skilled nursing facility.

The Hospital Team

The increasing acuity of hospitalized patients requires the hospital physician to carefully orchestrate the delivery of

TABLE 4.3
INFORMATION TO BE SENT TO SKILLED NURSING FACILITY AT TIME OF HOSPITAL DISCHARGE

- Concise yet detailed discharge summary
- Medication and allergy list
- Pertinent doctor, nurse, and therapist progress notes and care plans
- Consultant notes including history and physical exam
- Key diagnostic and lab tests
- Advance directive, including do-not-resuscitate forms
- Fact sheet and demographic information

care. This coordination process applies equally to interactions with both consulting physicians and nonphysician members of the hospital team.

A variety of collaborative initiatives is replacing the traditional fragmentation of hospital disciplines. Many institutions have implemented multidisciplinary patient rounds, integrated medical record documentation, and clinical guidelines involving the entire hospital team. Proponents of such collaborative systems point to the reduced duplication of effort and gaps in care as primary benefits. Lessons from multidisciplinary approaches in ICUs support the hypothesis that this approach improves outcomes (21).

Nursing

The nurse–physician interface is, in many ways, the central relationship affecting the day-in, day-out care of inpatients. The continuous presence of the nurse on the floor provides a comprehensive perspective of the patient’s condition, including medical, emotional, and psychosocial concerns. Trust in the hospital team is highly dependent on the physician, who is viewed as its leader, but its foundation is often the patient–nurse relationship because of the close contact between them. Because the physician’s time with the patient is limited, the flow of information between nurse and physician must be optimized. Additionally, the physician serves as a vital resource for the nurse in clarifying the care plan and providing important social information about the patient.

This interdependence creates the need for a close working relationship between nurse and physician. The old approach of having the head nurse make rounds with the physician was extremely effective in promoting care that was coordinated and informed and that engendered the trust of the patient, who witnessed and often participated in the exchange of information between the two caregivers. Although this model has been largely abandoned because of the limited availability of both physicians and nurses, the inefficiency of fragmenting care has become apparent, and the idea of coordinated bedside rounds is now regaining favor in some institutions.

The nurse provides the general coordination of patient care from hour to hour, often conveying information from other members of the hospital team to the physician, including consultant recommendations, therapist evaluations, and laboratory or radiographic data. Finally, because of ongoing availability to the patient, the nurse serves as a primary liaison with family members.

Case Management

The hospital physician–case management interface revolves around placing the patient into the appropriate care setting at the appropriate time. The case manager plays a central role in discharge planning. As such, the case manager is usually the first nonphysician to speak with the patient and family about the discharge process, including location (e.g., skilled nursing facility or home), follow-up, and special services needed. Effective models of hospital case management involve regular meetings between the physician and case manager beginning soon after admission to allow for the exchange of important social and medical information, including patient and family needs. These interactions facilitate early involvement of the other members of the hospital team. For example, if a patient with a newly diagnosed stroke has a good family support structure, the patient may be able to go home once physical and occupational therapy, home health care, and transportation services have been arranged.

At or soon after hospital admission, the case manager must often supply payers or the hospital with information regarding the appropriateness of the decision to admit. Case managers obtain this information through physician documentation in the medical record or verbal communication with the physician. In addition, the case manager performs a utilization review function or works closely with the utilization review nurse. In either case, regular determinations of the suitability of a given care setting are made. If the case manager determines that a patient should be moved to a less acute setting, the physician is notified.

Social Services

The work of the social services department complements that of the case manager in many ways. The social worker uses information from the physician to access community resources appropriate for a given patient’s needs. Through collaboration, the physician becomes aware of the possibilities for community support for the patient, and the social worker learns of specific medical issues that need to be addressed. Resources that may then be used include medical or psychiatric care, home services, child or adult day care services, post-acute care, support groups, substance abuse programs, public assistance, and protective services.

With the rise of case management as a discipline, social workers in many hospitals are focusing on bedside relations with the patient, fulfilling a critical mental health

role. The social worker can provide crisis intervention and counseling to patients and their families during an acute illness. Through an understanding of psychosocial issues, the social worker can assist the physician in dealing effectively with patient–family dynamics.

Pastoral Care

As the emphasis on patient satisfaction grows, the need to understand patients' spiritual and emotional needs has become more apparent. Frequently, the physician is privy to the most telling cues regarding a patient's emotional state. Body language or verbal communication from the patient can alert the physician that a patient is angry, scared, indifferent, or resentful. The role of the pastoral care worker is to assist the patient in exploring personal faith and in managing the gamut of emotions experienced during an acute hospital illness. The physician can most effectively utilize the skills of pastoral care providers by involving them early in the hospital course rather than calling on them only when a patient's demise is imminent.

The physician and pastoral care provider can meet with families to help align disparate views regarding an appropriate course of action in the event the patient has lost decision-making capabilities. In contemplating withdrawal of life support, for example, loved ones must integrate medical with emotional and spiritual information in making a decision. Physician–pastoral care collaboration can most effectively support this process (see Chapter 19).

Pastoral care can also serve the important role of supporting the caregiver. For example, if a patient dies, an event many physicians perceive as professional failure, the pastoral care provider can help explore such feelings and bring them to resolution (22).

Therapy Departments

Departments of physical, occupational, and speech therapy interact with the hospital physician in several important ways. By performing functional assessments, they provide information that is used to determine appropriate acute treatment, timing of patient discharge, and selection of care setting. These departments guide patient recovery through exercise, education, and other measures. The therapist can often detect patient deficits and notify the physician, which allows for timely evaluation and further treatment.

Pharmacists

The role of clinical pharmacists is described in Chapter 21.

CONCLUSIONS

Hospital physicians must establish roles and systems that ensure a good flow of clinical and psychosocial information

among all members of the health care team. An examination of the many hospital interfaces sheds light on potential problems and opportunities for improved communication and collaboration. Innovations in computerized real-time and online medical record technologies can assist these efforts, but they will never supplant effective personal interactions among multidisciplinary providers.

KEY POINTS

- The increasing complexity of hospital systems requires careful attention to the management of physician and nonphysician interfaces.
- Communication between the hospital and non-hospital physician depends on the use of existing technologies (telephone, fax, electronic mail) and the development of new ones (e.g., electronic medical record). Protocols for exchanging records between these providers can strengthen this interface.
- Physician leadership of multidisciplinary hospital care teams, including nurses, case managers, social workers, pastoral care providers, pharmacists, therapists, and others, is critical to inpatient care.
- Improving hospitalists' interaction with patients after discharge is likely to improve both quality and patient satisfaction.

Hospital Discharge

5

Preetha Basaviah *Mark V. Williams*

INTRODUCTION

The timing of and events surrounding hospital discharge can have a significant impact on patient satisfaction, patient safety, and the outcomes and cost of care. A growing body of research on optimizing discharge strategies and improving communication at discharge can inform the discharge decision. Several strategies, including structured patient education, predischARGE checklists, multidisciplinary discharge planning teams, postdischarge telephone follow-up, and improving communication methods between inpatient and outpatient providers during discharge, have been shown to enhance the discharge process.

With the average day in an American hospital costing from \$1,600 to \$2,200, there is no doubt that unnecessary hospital days drain health care resources (1,2). However, the motive for timely discharge is not limited to cost considerations. For many patients, the simple unpleasantness of the average hospital room, the lack of privacy, and the human desire to sleep in one's own bed are motivation enough. In addition, patients and families have become aware that the risks of medical errors and nosocomial infections (3) make the hospital a potentially dangerous place.

Of course, discharging patients from the hospital as quickly as possible has its own risks. The subsequent period—from hospital discharge to full recovery—is often traumatic and confusing for both patients and families. After discharge, many patients still feel unwell and yet are expected to follow complex medication regimens and return for follow-up visits and tests. The growth of the hospitalist model means that the inpatient and outpatient providers are often different individuals, which may lead to miscommunication between providers and add to the patient's anxiety over the transition out of the hospital. Finally, for many patients, the costs of hospital care are fully borne by third-party payers, while the costs of skilled

nursing or home care must be covered partially or completely with personal resources.

In the past, a physician's decision to discharge a patient was often governed by intuition and experience. In the past decade, high-quality studies have come to provide a scientific basis for many discharge decisions. This chapter illustrates principles of research on the timing and process of hospital discharge, focusing on optimizing the hospital discharge process in four general areas: (1) implementing disease-specific strategies in the form of guidelines or educational initiatives; (2) improving patient safety; (3) enhancing communication and follow-up; and (4) facilitating discharge planning.

EVIDENCE-BASED, DISEASE-SPECIFIC APPROACHES TO DISCHARGE

Community-acquired pneumonia (CAP) probably has the best-elucidated discharge criteria and processes of all the disorders that physicians treat in the hospital (see Chapter 65 for further information on management of CAP). Several studies have tested whether the use of practice guidelines or decision support improves the efficiency and quality of care for patients with CAP (4–6). Most studies show that practice guidelines promoting early identification of low-risk patients and evidence-based choice of antibiotics can lead to earlier discharge with maintained patient outcomes and satisfaction.

Hospitalized patients with CAP can be discharged when they are clinically stable, and the time required to reach clinical stability is more rapid than previously appreciated. Among patients with vital sign abnormalities on presentation, the median time to stabilization of the heart rate (≤ 100 bpm) and systolic blood pressure (≥ 90 mm Hg) is two days (7). The average patient achieves a stable respiratory rate (≤ 24 breaths/min), oxygen saturation ($\geq 92\%$),

and temperature ($\leq 99^\circ\text{F}$ (37.2°C)) on hospital day three. The time to overall clinical stability, defined as stable vital signs, baseline mental status, and ability to eat, varies depending on the pneumonia severity on presentation: it averages three days for low-risk patients (Pneumonia Severity Index risk class I through III), four days for moderate-risk patients (risk class IV), and six days for high-risk patients (risk class V) (8).

Such explicit criteria defining when a patient is medically stable for discharge may standardize the physician's approach to patients with common medical problems. Evidence-based guidelines and algorithms that help guide the discharge decision are also available for upper gastrointestinal bleeding (9), congestive heart failure (10), asthma (11), and stroke (12). (See also Chapters 78, 39, 56, and 116.)

While such disease-specific discharge criteria and cost effectiveness analyses may help guide lengths of stay, other clinically important factors must be considered. For example, hospitalization beyond three days for patients with uncomplicated myocardial infarction is not cost effective (13). However, when implementing any early discharge guidelines, it is important to measure quality, patient satisfaction, and long-term follow-up to ensure that short-term benefits (in decreased costs caused by shorter lengths of stay) are not associated with detrimental long-term outcomes. In the coming years, clinicians can expect to see more information, much of it computerized, available at the point of care and tailored to their patients' clinical presentation. This information will help inform the discharge process for an array of hospital diagnoses.

PATIENT SAFETY

Hospital discharge is often a chaotic and potentially dangerous time for both patients and providers, ripe with opportunities to improve both patient outcomes and satisfaction. Functional limitations may persist and make patients especially vulnerable to injuries with the increased activity of the peridischarge period. Particularly in hospitalist systems, the transition from inpatient to outpatient care may become fraught with miscommunication and inadequate follow-up.

Many of the adverse events that occur frequently during the post-hospital period are preventable or ameliorable (14). The most common events are adverse drug events, but harm may also come from unaddressed laboratory abnormalities. Changes in system design can improve patient safety during the peridischarge period and should focus on four areas: (1) evaluating patients at the time of discharge; (2) educating patients about drug therapies, side effects, and actions to take if specific problems occur; (3) strengthening monitoring of therapies; and (4) improving monitoring of patients' overall condition.

STRATEGIES FOR EFFECTIVE DISCHARGE

To optimize the effectiveness of the hospital discharge, *communication* at discharge and follow-up must be enhanced. Communication gaps are common at the time of hospital discharge, yet physicians and nurses tend to overestimate patients' comprehension of discharge treatment plans. In one study, physicians believed that 89% of patients understood the potential side effects of their medications, but only 57% of patients confirmed that they understood (15). A similar gap occurred regarding patients' understanding of when to resume normal activities (16).

Although communication is a core skill for physicians, many patients have difficulty understanding what physicians tell them. This is particularly a problem for patients who have inadequate *health literacy*. Health literacy has been defined as the ability to read and comprehend prescription bottles, appointment slips, and written discharge instructions (17). Several strategies, including structured patient education, postdischarge telephone follow-up, communication improvement between inpatient and outpatient providers, and multidisciplinary discharge planning teams, have been shown to improve communication at the time of discharge and may yield more satisfied patients (see Table 5.1).

TABLE 5.1
POTENTIALLY EFFECTIVE DISCHARGE STRATEGIES

Strategy	Comments
Intensive postdischarge care	<ul style="list-style-type: none"> • Contacting patients after discharge • Improving access
Telephone follow-up	<ul style="list-style-type: none"> • Following up on missed visits (41) • Substituting for routine clinic follow-up (42) • Using pharmacists/focusing on medication compliance (23)
Patient education and communication	<ul style="list-style-type: none"> • See Table 5.2
Predischarge checklist	<ul style="list-style-type: none"> • List of requirements for equipment, services, benefits, and follow-up (43)
Multidisciplinary discharge planning/discharge coordinator	<ul style="list-style-type: none"> • Multidisciplinary task force, comprising planner, social worker, nurse, dietician, chaplain, therapist, and utilization review nurse; discusses patients (44)
Home visits	<ul style="list-style-type: none"> • Collaborative discharge planning and home follow-up (including telephone and home visits by advanced practice nurses for four weeks after discharge) provided to elders hospitalized with common medical and surgical cardiac conditions (45)

Structured Patient Education

Hospital discharge is a critical transition zone, from a time when all care is delivered by hospital staff to one in which the patient, and possibly family, are entirely responsible. Making this transition safely depends on high-quality, structured patient education. Too often, however, such education is neglected, in part because unrecognized barriers interfere. Hospital physicians need to appreciate patients' capability to assimilate discharge instructions. Although providers usually assume patients comprehend their written and oral explanations of illness, several studies have shown that health literacy is often worse than providers think (18). Many health materials, including patient education brochures, discharge instruction sheets, and informed consent documents, are written at levels far exceeding patients' reading abilities. More than one third of patients age 65 and older have inadequate or marginal health literacy (19).

The terminology or language health care providers use in communicating with patients is a significant barrier for patients who have inadequate health literacy. Physicians' facile overuse of medical terms, combined with patients' limited health vocabulary, results in inadequate and even confusing communication. Unfortunately, patients with low health literacy tend to ask fewer questions, even though they may feel overwhelmed with information and lack understanding.

Checking to ensure that the patient's history is accurate and that the patient understands the physician's instructions are the most important interviewing skills. Unfortunately, they are also the least utilized. In one study of audiotaped encounters, primary care physicians assessed patients' understanding only 2% of the time (20). Written materials can be used to augment patient education, but video and computer multimedia programs are even more powerful interventions. Pictographs (simple pictures that represent ideas) markedly enhance recall of spoken medical instructions among all patients. Using pictographs as visual aids (e.g., simply drawing a picture related to what you want the patient to remember) can more than quadruple patients' ability to recall important medical information (21).

Based on published research and the authors' experience in caring for patients, the following six simple steps for structuring patient education are recommended (see Table 5.2) (17). First, slow down and take time to assess patients' health literacy skills. Second, use "living room" language that patients can understand, taking care either to avoid medical terminology or to explain medical terms when they must be used. Third, show or draw pictures to enhance understanding and subsequent recall. Fourth, limit the quantity of information given to patients at each interaction, and repeat instructions several times. Enrolling family members in the process may allow more information to be disseminated and retained. Fifth, use a "teach back" or "show me" approach to confirm comprehension. Ask

TABLE 5.2

SIX STEPS TO ENHANCE UNDERSTANDING AMONG PATIENTS WITH LOW HEALTH LITERACY

- Slow down and take time to assess patients' health literacy skills.
- Use "living room" language instead of medical terminology.
- Show or draw pictures to enhance understanding and subsequent recall.
- Limit information given at each interaction, and repeat instructions.
- Use a "teach back" or "show me" approach to confirm understanding.
- Be respectful, caring, and sensitive, thereby empowering patients to participate in their own health care.

patients to demonstrate their instructions (i.e., teach back to you how to take their medications or when they should follow up) to ensure that you have done an adequate job of instruction. Never ask, "Do you understand?" because patients will typically acquiesce and say, "Yes." Last, be respectful, caring, and sensitive to the plight of patients who have low health literacy. This six-step approach will enhance patient satisfaction and empower patients to optimize their participation in their health care.

Postdischarge Telephone Follow-Up

Telephone follow-up with discharged patients has been proposed as one way to mitigate discharge communication problems (see Table 5.3). Although this approach is intuitively appealing, surprisingly few studies have been conducted of telephone follow-up at the time of hospital discharge. Telephone follow-up after emergency department visits has improved patient satisfaction and compliance with follow-up instructions and appointments (22). In one small study, a postdischarge follow-up call by a pharmacist involved in the care of hospitalized patients led to enhanced patient satisfaction, fewer returns to the emergency department, and frequent resolution of medication-related issues (23). Postdischarge telephone follow-up may also improve adherence, inform the hospital physician about the results of treatment or of adverse outcomes, and enable hospitalists to receive feedback from the patient and family (24).

Improving Communication Between Inpatient and Outpatient Providers

Appropriate transfer of information at the time of hospital discharge reduces rates of readmission, medication errors, and medical costs (25). Discharge summaries or letters and telephone interchange are the key tools to optimize communication during these hand-offs and to reinforce continuity of care.

TABLE 5.3
STRATEGIES TO IMPROVE COMMUNICATION BETWEEN THE INPATIENT AND OUTPATIENT PHYSICIANS AT DISCHARGE

Intervention	Pros (positive outcomes)	Cons
Telephone follow-up with patients (24)	<ul style="list-style-type: none"> Improves adherence Informs the inpatient physician about the results of treatment or of adverse outcomes Permits hospitalists to receive feedback from the patient and family 	<ul style="list-style-type: none"> Time May interfere with role of PCP Not reimbursed
Telephone communication between providers (29)	<ul style="list-style-type: none"> Provides continuity Clarifies history or diagnosis Provides information about chronic problem management Clarifies psychosocial and cultural factors (30) 	<ul style="list-style-type: none"> Time Not reimbursed
Optimization of conventional discharge summaries (26)	<ul style="list-style-type: none"> Enhances PCP satisfaction and continuity of care through timely and concise documents Facilitates follow-up care, especially when focused on relevant discharge-related information 	
Discharge information cards/letters (28)	<ul style="list-style-type: none"> Draws favorable response from PCPs and patients Better informs patients about their illnesses and treatments 	
Electronic discharge summary (27)	<ul style="list-style-type: none"> Enables timeliness, increased PCP satisfaction, cost effectiveness, efficiency, and clinical auditing Reduces error rates Increases efficiency, supports continuity of care 	<ul style="list-style-type: none"> Higher systems costs
Patient-delivered discharge summary (28)	<ul style="list-style-type: none"> Compels inpatient physicians to complete summaries early, while information is fresh Keeps PCPs up to date with discharge details Saves money on postage costs 	<ul style="list-style-type: none"> Some patients may have difficulty traveling to hand-deliver their summaries

Despite its documented deficiencies, including delays and inadequacies in information transfer, the discharge summary or discharge letter remains the main means of communication between inpatient physicians and primary care providers. Physicians rate discharge summaries highly if they are timely, concise, and contain focused discharge information. This information includes admission diagnosis, relevant physical examination findings, laboratory results, procedures, hospital complications, discharge diagnoses, discharge medications, active medical problems, and follow-up (26). Using computerized discharge summaries promotes timeliness, increased PCP satisfaction, cost effectiveness, efficiency, reduced error rate, and easier clinical auditing (27). Discharge information cards and associated discharge letters are favorably received by patients and providers, and they better inform patients about their illness and treatment than traditional discharge processes (28).

Interphysician communication by phone can contribute substantially to continuity and quality of patient care

during the discharge process. In a survey of family physicians, primary care physicians overwhelmingly stated their preference to communicate with hospitalists by telephone (77%), particularly at admission and discharge (29). Not surprisingly, primary care physicians who are personally contacted are more likely to make hospital visits and help provide continuity, particularly by clarifying history, diagnosis, psychosocial, and cultural factors (30).

Facilitating Discharge Planning

The cumulative impact of communication gaps and other coordination problems leaves patients less satisfied with hospital discharge planning than with any other aspect of hospital care (31). Discharge planning is defined as the development of an individualized discharge plan for a patient in anticipation of leaving the hospital for home or other postdischarge facility. The old adage that discharge planning starts upon admission seems more important today than ever.

Although the concept of advance discharge planning is intuitively attractive, the literature reveals mixed results, possibly reflecting the variable study populations and different means of implementing site-specific interventions. A Cochrane review did not demonstrate that discharge planning was effective in reducing unplanned hospital admissions (32). Yet some evidence suggests that discharge planning may lead to decreased hospital length of stay (33–36) and, in some cases, reduced readmission rates (35,37). Further, discharge planning may improve patient satisfaction (33). Notwithstanding the sparse evidence, the authors believe all hospitalized patients should receive individualized discharge plans in light of the enhanced patient satisfaction and the increasing complexity of treatment regimes.

Disease-specific management teams improve discharge planning, especially among patients with diabetes. Multidisciplinary diabetes teams, typically comprising endocrinologists, nurse-educators, nutritionists, and social workers, bridge the inpatient and outpatient environments, enhance coordination of care, clarify goals of care for patients and team members, provide more consistent patient instructions, and promote involvement of patients and families in their own care (38). Such teams can also reduce hospital length of stay, improve glycemic control, and decrease readmissions. Combining this team approach with a nursing case management model and referral links to podiatry and ophthalmology also reduces length of stay and cost while improving glycemic control and readmission rates (39,40). The applicability of this model to other chronic diseases is under study.

CONCLUSIONS

One of the most important changes in the paradigm of modern medicine is the recognition that high-quality and efficient practice depends as much on the system of care as on the competence of the physicians. This principle is rarely more applicable than at hospital discharge. Patients benefit when discharge planning begins soon after admission, when discharge decisions are informed by evidence, and when patients are cared for in a system that promotes an effective discharge process. Such a system should be designed to make errors less likely, encourage teamwork across disciplines, and facilitate communication across the inpatient-outpatient divide. Improving the discharge process should be an important goal of all health care workers and systems.

KEY POINTS

- Adverse events occur frequently in the peridischarge period, and many can be prevented or ameliorated with simple strategies that improve communication and follow-up at discharge.

- Patient education about conditions, medications, actions to take if symptoms develop, and follow-up care is a critical component of the discharge process.
- Improving communication between inpatient and outpatient providers at the time of hospital discharge is critical to optimizing patient care.

Bayesian Reasoning and Diagnostic Testing

Warren S. Browner

INTRODUCTION

Making clinical decisions often involves using diagnostic tests to determine whether a patient has a particular disease. Some of the best diagnostic tests—such as listening for rales or asking patients whether they have chest pain while walking uphill—are performed during the history and physical examination. The same principles that apply to the interpretation of these customary tests also apply to the interpretation of more sophisticated tests, such as measurement of the serum ceruloplasmin value or ultrasonography to detect an abdominal aortic aneurysm.

Bayesian reasoning is a formal way of doing explicitly what most clinicians do implicitly, that is, interpreting the results of a diagnostic test in light of the clinical situation. The basic paradigm is simple:

What was thought before the test was done & the test result → what is thought after the test result

The ampersand sign (&) indicates that this is not a simple problem in addition. The mathematics, developed by an 18th-century amateur mathematician, Thomas Bayes, are known as Bayes' theorem.

For example, suppose a clinician believes that a particular disease (e.g., appendicitis in a young man with gastrointestinal symptoms, fever, and right lower quadrant pain) is likely before ordering a diagnostic test. If the test result is positive (say, an abnormal result on an abdominal computed tomogram), the clinician will be almost certain that the patient has appendicitis (Chapter 87). On the other hand, if the clinician thinks that appendicitis is unlikely before ordering the test, and the test result is negative,

the clinician will be almost certain that the patient does not have appendicitis. If the clinical impression and the test result differ, or if the clinician was not sure before and the test result is borderline, then the situation remains uncertain.

Clinicians seek the perfect test, or *gold standard*, such that a negative test result rules out the diagnosis and a positive result rules it in. Few tests are perfect, especially because human and machine fallibility mean that even gold standards, such as excisional biopsies, can be tarnished. For nearly all tests, one must be satisfied that a negative result reduces the likelihood of a disease (e.g., normal chest radiographic findings in a case of possible pneumonia), whereas a positive result increases the likelihood of the disease (e.g., a lobar infiltrate on the chest radiogram in a patient with suspected pneumonia).

Many clinicians use time as the gold standard, assuming that all diseases will "declare themselves" given adequate follow-up. Even if this were true, a more efficient diagnostic strategy would involve selecting tests with results sufficiently definitive to affect a patient's management. Not ordering an expensive diagnostic test to save money is rarely an efficient strategy in a hospitalized patient.

A QUALITATIVE APPROACH TO TEST INTERPRETATION

This basic idea can be refined further, as most tests have more than two results. Thus, a highly negative result greatly decreases the probability of a disease, whereas a highly positive result greatly increases the probability. Intermediate results have intermediate effects (see Table 6.1).

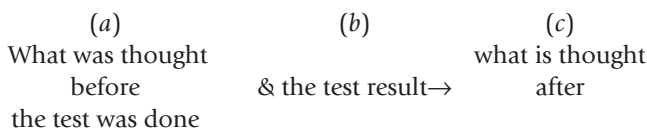

TABLE 6.1
EFFECTS OF A TEST RESULT ON THE PROBABILITY OF A DISEASE

Test results	Example (1)
Very negative, greatly decreases the probability of the disease	Ferritin = 300 mcg/L in the patient in whom iron deficiency anemia is being considered
Slightly negative, slightly decreases the probability of the disease	Ferritin = 100 mcg/L and iron deficiency anemia
Borderline, does not affect the probability of the disease	Ferritin = 30 mcg/L and iron deficiency anemia
Slightly positive, slightly increases the probability of the disease	Ferritin = 20 mcg/L and iron deficiency anemia
Very positive, greatly increases the probability of the disease	Ferritin = 5 mcg/L and iron deficiency anemia

Adapted with permission from Guyatt GH, Oxman AD, Ali M, Willan A, McIlroy W, Patterson C. Laboratory diagnosis of iron-deficiency anemia: an overview. *J Gen Intern Med* 1992;7:145–153. (Published erratum in *J Gen Intern Med* 1992;7:423.)

A QUANTITATIVE APPROACH

To express the probability of a disease quantitatively, the elements of the basic paradigm must be converted into numbers:

The concept of “what was thought before” (a) is the *prior probability* of the disease. It estimates how likely it is that the patient has the disease. The prior probability must be estimated before the test result is known. Prior probabilities vary from 0% to 100%. They replace vague terms such as “very unlikely,” “probable,” and “almost certain.” Prior probabilities are sometimes called *pretest probabilities*.

When setting prior probabilities, remember that the patient’s problem must have an explanation. Thus, *the sum of all of the prior probabilities for the diagnostic possibilities should be 100%*. It is not adequate to decide—in a patient with dyspnea—that the probability of pneumonia is 1%, of pulmonary embolism 1%, of asthma 2%, of congestive heart failure 3%, and of other conditions even lower percentages.

“The test result” (b) is expressed as a *likelihood ratio* (LR). A test does not have a single LR. Rather, each possible result of the test has its own LR for the disease in question. The LR for a test result is between zero and infinity (see Table 6.2).

The LRs have been determined for many common diag-

nostic tests and diseases. For coronary artery disease (CAD) (defined as an obstruction of 75% or more in at least one artery), typical angina (exertional substernal chest pressure that is relieved by nitroglycerin or rest within minutes) has an LR of 120! Even atypical angina (in which one of these features is not present) has an LR of about 15 (2). On the other hand, musculoskeletal chest pain (pain that can be reproduced by pressing on the chest) has an LR of about 1. (A more familiar, but less useful, approach expresses the test result in terms of the *sensitivity* and *specificity* of a test; this approach is discussed later.)

“What is thought after” (c) is called the *posterior probability*, an estimate of the likelihood that the patient has the disease, made after the test result is known. Posterior probabilities vary from 0% to 100%. They are sometimes called *posttest probabilities*.

If the LR is greater than 1, then the posterior probability is greater than the prior probability. If the LR equals 1, then the posterior probability is the same as the prior probability. And if the LR is less than 1, then the posterior probability is less than the prior probability.

More precisely, Table 6.3 can be used to combine the prior probability with the LR for the test result to estimate the posterior probability. For example, consider a 62-year-old man with hypertension and diabetes who presents with a one-month history of substernal chest pain when climbing hills, relieved in minutes by rest. His serum cholesterol level is 240 mg/dL. Assume that the prior probability of CAD (based on sex, age, and risk factors) is about 20% to 40% (2). The diagnostic test in this case is the history; the result of “typical angina” has an LR greater than 100 for CAD. Use Table 6.3 and look across from the LR of 100; the posterior probability of CAD is between 96% (looking down from a prior probability of 20%) and 99% (looking down from 40%). This example demonstrates that it is

TABLE 6.2
EXAMPLES OF LIKELIHOOD RATIOS AND THEIR EFFECTS ON THE PROBABILITY OF A DISEASE

Likelihood ratio	Effect on probability of the disease
Zero (0)	Test result rules out the disease.
Very small (e.g., 0.01)	Test result greatly decreases the probability of the disease.
<1 (e.g., 0.5)	Test result decreases the probability of the disease.
One (1)	Test result has no effect on the probability of the disease.
>1 (e.g., 2)	Test result increases the probability of the disease.
Very big (e.g., 50)	Test result greatly increases the probability of the disease.
Infinite (∞)	Test result rules in the disease.

TABLE 6.3
CONVERTING PRIOR PROBABILITIES AND LIKELIHOOD RATIOS INTO POSTERIOR PROBABILITIES^a

^aThis table is based on a three-stage process that combines prior probabilities and likelihood ratios to yield posterior probabilities. The mathematics involve converting the prior probability to a prior odds [= Prior Probability ÷ (1 – Prior Probability)], then multiplying the prior odds by the likelihood ratio to obtain the posterior odds, and then converting those posterior odds back to a posterior probability [= Posterior Odds ÷ (1 + Posterior Odds)].

often unnecessary to make a precise estimate of the prior probability. Although there is a twofold difference between 20% and 40%, the posterior probabilities are similar.

On the other hand, suppose that the patient is a 23-year-old woman with a two- to three-week history of left-sided chest pain after swimming that sometimes lasts seconds and sometimes an hour or two. Movement of her arms exacerbates the symptoms. The prior probability of CAD (based on sex and age) is, at most, 0.1%. Because her diagnostic test result (history consistent with musculoskeletal chest pain) has an LR of 1.0 for CAD, her posttest probability is not changed from her pretest value.

WHERE DO LIKELIHOOD RATIOS COME FROM?

The LRs are the ratio of two likelihoods of obtaining a particular test result:

$$\text{LR for a Test Result} = \frac{\text{Likelihood of Test Result in Patients with Disease}}{\text{Likelihood of Test Result in Patients without Disease}}$$

(The mnemonic is *WOWO*, for “with over without.”) The LRs are determined by making a column of the number (and percentage) of patients with the disease who have each possible result of a diagnostic test; a similar column is also made for patients without the disease. Table 6.4 shows such results for the exercise stress test (Chapter 36).

For example, the LR for ST segment depression of 2 mm or more is determined as follows:

$$\begin{aligned} \text{LR} (\geq 2 \text{ mm}) &= \frac{\text{Likelihood of } \geq 2 \text{ mm in CAD}}{\text{Likelihood of } \geq 2 \text{ mm in no CAD}} \\ &= \frac{30\%}{1\%} \\ &= 30 \end{aligned}$$

In the same way,

$$\begin{aligned} \text{LR} (1.5 - 1.9 \text{ mm}) &= \frac{20\%}{5\%} = 4 & \text{LR} (1 - 1.4 \text{ mm}) &= \frac{24\%}{10\%} = 2.4 \\ \text{LR} (\text{trace}) &= \frac{16\%}{24\%} = 0.67 & \text{LR} (\text{none}) &= \frac{10\%}{60\%} = 0.17 \end{aligned}$$

TABLE 6.4
CALCULATING LIKELIHOOD RATIOS FOR ST SEGMENT DEPRESSION DURING EXERCISE STRESS TESTING^a

	N	%	N	%
≥2 mm	15	30	2	1
1.5–1.9 mm	10	20	10	5
1–1.4 mm	12	24	20	10
Trace (<1 mm)	8	16	48	24
None	5	10	120	60
Total	50	100	200	100

^aSimplified for ease of calculation.

USING LIKELIHOOD RATIOS IN SEQUENCE

One attribute of LR_s is that they can be used in sequence as long as the test results are independent.¹ That is, one can keep modifying the posterior probability based on a series of results.

- Prior & LR Test Result No. 1 →
- Posterior & LR Test Result No. 2 →
- New Posterior & LR Test Result No. 3 → etc.

For example, consider a 35-year-old man who presents with a chief complaint of dyspnea and pleuritic chest pain. He reports a “vein problem in my legs that was treated with a blood thinner for a few months last year.” A chest radiograph shows a patchy infiltrate in the left upper lung field. A room air arterial blood gas specimen has a PO₂ of 92 mm Hg, with a PCO₂ of 38 mm Hg, for an alveolar-to-arterial (A-a) gradient of $[147 - (1.25 \times 38) - 92] = 7$ mm Hg.

You assess the prior probability of pulmonary embolism as the cause of dyspnea in a population of 35-year-old men as about 5%. How helpful are the patient’s history and examination and laboratory findings? About 25% of patients with pulmonary embolism have a history of venous throm-

¹ Mathematically, independence of test results means that the results of one test convey no meaningful information about the results of another test. Independence may best be understood conversely; totally dependent results convey the same information—for example, measuring someone’s temperature with two thermometers, one centigrade and one Fahrenheit, or filling two blood culture vials with blood from the same syringe and needle.

boembolic disease (3), which occurs in about 0.8% of healthy middle-aged men (4), for a likelihood ratio of 25% divided by 0.8%, or about 30. Pleuritic chest pain and abnormal chest radiographic findings are not particularly more common in pulmonary embolism than in other disorders confused with it, so their LR_s are about 1 (5). An A-a gradient of 7 mm Hg has an LR of about 0.1 for pulmonary embolism (3).

If you assume that all these test results are independent, then their combined LR is simply the product of the individual LR_s, or $30 \times 1 \times 1 \times 0.1 = 3$. Thus, if the prior probability that this patient has a pulmonary embolism was about 5%, then the posterior probability is about 15%, according to Table 6.3. This value is in the range that requires an additional diagnostic test, such as a spiral CT scan (6) or a ventilation–perfusion scan (7), before the appropriate treatment can be determined (Chapter 53).

SENSITIVITY AND SPECIFICITY

Sensitivity and specificity are alternate ways to describe the characteristics of a test. The *sensitivity* of a diagnostic test indicates the proportion of persons with a disease who have a positive test result. The *specificity* of a diagnostic test indicates the proportion of persons without a disease who have a negative test result. Returning to the example of the exercise stress test in a patient with chest pain, with a cut-off point of 2 mm or more of ST depression (see Table 6.5), the test would have a sensitivity of only 30% (15/50) but a specificity of 99% (198/200). To improve the sensitivity, one could change the cut-off for a positive test result to 1 mm or more (see Table 6.6). This would improve the sensitivity, but the specificity would decline. The sensitivity and specificity are combined with the prior probability of a disease to estimate the posterior probability. If the test re-

TABLE 6.5
CALCULATING SENSITIVITY AND SPECIFICITY FOR ST SEGMENT DEPRESSION OF 2 MM OR MORE DURING EXERCISE STRESS TESTING (BASED ON TABLE 6.4)

ST Segment Depression	Coronary artery disease (N = 50)		No coronary artery disease (N = 200)	
	N	%	N	%
≥2 mm	15	30	2	1
<2 mm	35	70	198	99

Sensitivity (positive in disease) = $15 / 50 = 30\%$.
 Specificity (negative in health) = $198 / 200 = 99\%$.

TABLE 6.6
CALCULATING LIKELIHOOD RATIOS FOR ST
SEGMENT DEPRESSION OF 1 MM OR MORE
DURING EXERCISE STRESS TESTING (BASED ON
TABLE 6.4)

ST Segment Depression	Coronary artery disease (N = 50)		No coronary artery disease (N = 200)	
	N	%	N	%
≥1 mm	37	74	32	16
<1 mm or none	13	26	168	84

Sensitivity (positive in disease) = 37 / 50 = 74%.
 Specificity (negative in health) = 168 / 200 = 84%.

sult is positive, then the posterior probability of the disease is determined as follows:

$$\text{Posterior Probability (positive result)} = \frac{\text{Prior Probability} \times \text{Sensitivity}}{\dots}$$

The posterior probability of a disease, given a positive test result, is sometimes called the *predictive value positive*, as it indicates how often someone with a positive test result has the disease.

On the other hand, if the test result is negative, then the posterior probability that the patient has the disease is determined as follows:

$$\text{Posterior Probability (negative result)} = \frac{\text{Prior Probability} \times (1 - \text{Sensitivity})}{[\text{Prior Probability} \times (1 - \text{Sensitivity})] + [(1 - \text{Prior Probability}) \times \text{Specificity}]}$$

The posterior probability of a disease, given a negative test result, measures how often a patient with a negative test has the disease. Subtracting it from 1 yields the *predictive value negative*, which indicates the likelihood that a patient with a negative test does *not* have the disease.

Unfortunately, predictive values, positive and negative, depend on the prior probability of the disease. They are therefore most helpful when the prior probability of the disease is constant, as in the evaluation of tests that are used routinely, such as screening tests.

Sensitivity and specificity are less useful than LRs. They require that test results be either positive or negative, whereas LRs can be used for all sorts of test results. In addition, sensitivity and specificity are not independent terms; you cannot interpret one without knowing the other. By changing the threshold for a positive test result, one can arbitrarily increase the sensitivity of a test and at

the same time reduce its specificity (or vice versa). Finally, the sensitivity and specificity of a diagnostic test may look fine if borderline results are left out, but in actuality, the test may have so many borderline results that it is not of much help.

For a test with only two possible outcomes (positive or negative), a straightforward method can convert sensitivity and specificity to LRs. The LR for a positive test result is determined as follows:

$$\begin{aligned} \text{LR (positive result)} &= \frac{\text{Likelihood of a Positive Result in Someone with the Disease}}{\text{Likelihood of Positive Result in Someone without the Disease}} \\ &= \frac{\text{Sensitivity}}{1 - \text{Specificity}} \end{aligned}$$

Most tests with a very high specificity will also have a large positive LR because the denominator will be very small. For example, with a sensitivity of 70% and a specificity of 95%, the LR for a positive test result is 14 (70% / 5%).

The LR for a negative test result is determined as follows:

$$\begin{aligned} \text{LR (negative result)} &= \frac{\text{Likelihood of a Negative Result in Someone with the Disease}}{\text{Likelihood of Negative Result in Someone without the Disease}} \\ &= \frac{1 - \text{Sensitivity}}{\text{Specificity}} \end{aligned}$$

Most tests with a very high sensitivity will also have a small negative LR because the numerator will be very small. For example, with a sensitivity of 98% and a specificity of 70%, the LR for a positive result would be 0.03 (0.02 / 0.70).

LRs, or sensitivity and specificity, are sometimes referred to as the operating characteristics of a test, as in the phrase *receiver–operating characteristic (ROC) curve*. An ROC curve is a pictorial way of representing the changes in sensitivity and specificity of a diagnostic test as the threshold for calling a result “positive” is altered (8).

QUALITY OF THE LABORATORY

When evaluating the results of diagnostic tests, the clinician must also be familiar with the local characteristics of the diagnostic laboratory. Along with the obvious concerns about diagnostic colleagues who “overinterpret” or “underinterpret” abnormalities on subjective tests such as radiographs and nuclear medicine scans, clinicians should be aware that they themselves are the most important laboratory. Clinicians must account for the *precision* and *accuracy* of the diagnostic tests that they perform during the history and physical examination. (*Precision* refers to the reproducibility of a result; *accuracy* refers to whether the result actually measures the phenomenon of interest.) Taking a few extra minutes to verify an important historical detail or to reposition a patient for a better examination of the

abdomen, as well as corroborating the accuracy of physical examination findings with more definitive diagnostic tests, may substantially improve the LRs of many findings.

KEY POINTS

- The results of a diagnostic test must be interpreted in the context of the prior probability of the disease.
- Two of the best diagnostic tests are the history and physical examination.
- Likelihood ratios quantify the effect of a test result on the prior probability.
- The likelihood ratios for independent test results can be multiplied together.
- The sum of the probabilities of the various diagnostic possibilities must equal 100%.
- The precision and accuracy of the diagnostic laboratory (including the characteristics of the clinician in the case of the history and physical examination) should always be considered when interpreting the results of a diagnostic test.
- An appreciation of quantitative reasoning and Bayesian analysis allows clinicians to make more rational and ultimately more correct decisions in caring for their patients.

Decision Analysis

7

Warren S. Browner

INTRODUCTION

Decision analysis is a formal method to estimate the result of a clinical decision by assigning numeric values to the potential outcomes of that decision and to the probabilities of those outcomes. Analyses of many common clinical problems have been published (1–4). Decision analysis is most useful when uncertainty exists about the best course of action. One does not need a decision analysis to determine whether to obtain blood cultures in a patient with rigors, fever, and a new heart murmur. However, decision analysis would be an appropriate way to determine which antibiotics to use to treat that patient. Indeed, it would be an ideal situation for decision analysis; the clinical scenario is relatively common, and clinical trials have not definitively answered the question.

The process of decision analysis assumes that it is possible to rate the outcomes of a decision on a quantitative scale from best to worst. Thus, decision analysis is sometimes called a *normative process*; given the assumptions in the model, a “best” answer must exist. An analysis can be only as good as the abilities of the decision analyst and the quality of the data used. When little is known about a clinical problem, or when the decision analysis has been prepared by someone who is not familiar with what is known, even the most sophisticated analysis is unlikely to provide much that will be useful in caring for patients.

Although decision analysis is not the only way to approach a clinical problem, it has advantages compared with other methods of decision making under uncertain circumstances, such as dogmatism (“This is the best way to do it.”), policy (“This is the way we do it around here.”), nihilism (“It doesn’t really matter what we do.”), deferral to experts or patients (“What do you want us to do?”), and catastrophe avoidance (“Whatever else we do, let’s be sure

to not do that.”). Especially when the correct decision is too close to call, small changes in one or two assumptions can change the results. The process of creating a decision analysis can often identify key pieces of clinical information that are unknown but essential to determining the best course of action. Decision analysis—because it assigns patient-specific values to the outcomes of clinical decisions—highlights the importance of patient preferences in physician decision making.

BASIC STRUCTURE OF A DECISION TREE

Decision analysis begins with a *clinical decision*, such as whether a patient with chest pain should be admitted to the hospital. The decision, of course, needs analysis only if the course of action is uncertain. Under many circumstances, as when a patient is severely ill, no uncertainty exists: admission to the hospital, not a formal decision analysis, is needed. For certain patients, however, the best decision is not clear.

A decision analysis is usually portrayed as a *tree structure*, progressing from the decision on the left to the outcomes on the right (Figure 7.1).

In general, the *decision* should be framed in terms of the clinical options and the characteristics of the patient and setting. Making a decision about hospitalization for chest pain will be different for a 75-year-old patient with known coronary artery disease than for a 35-year-old patient who runs 3 miles a day without symptoms. Suppose the clinical problem of interest concerns a patient between the ages of 50 and 59 years with new, but resolved, substernal chest pain. This patient has normal electrocardiographic findings and does not live alone. The decision is whether to admit the patient to the hospital or to treat at home with close

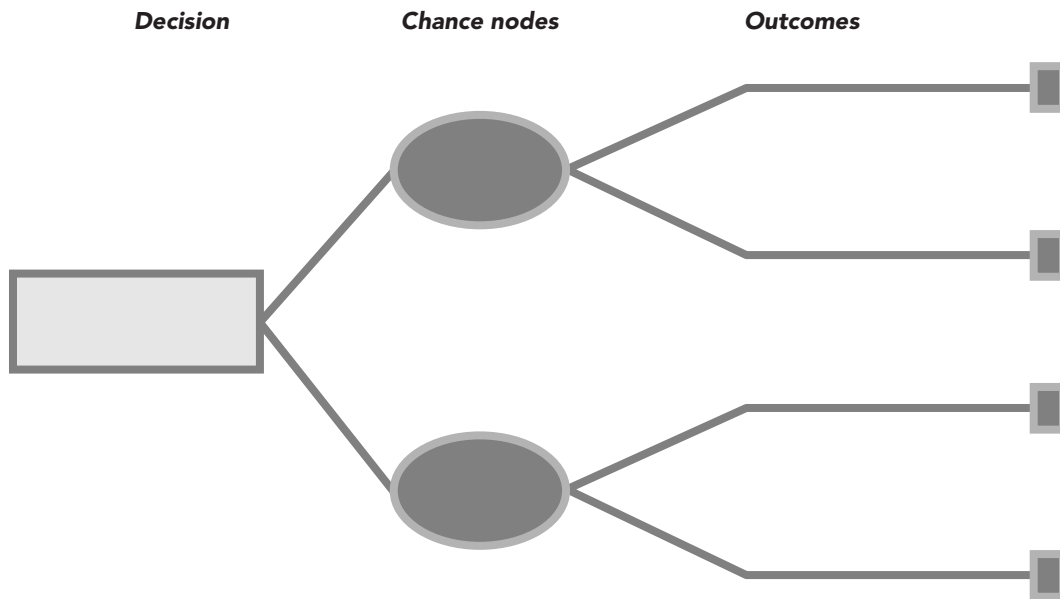

Figure 7.1 Basic structure of a decision tree.

follow-up. The outcome of interest is whether the patient survives the episode. By convention, the decision itself is placed in a rectangle, where each branch represents a different decision. Usually, a decision entails only two options, but additional choices are certainly possible, such as a brief admission to an observation unit. The same principles and techniques would hold.

After the decision node come the *chance nodes*, indicated with circles, which are used whenever clinical uncertainty exists. However, uncertainty from the clinical point of view may not be what matters in a decision analysis. For example, it may seem that the key uncertainty in deciding whether to admit a patient with chest pain is whether the pain is actually cardiac in origin. A more for-

mal approach, though, may indicate that the actual uncertainties that matter are whether the patient has a problem that will get worse with outpatient treatment and how much more likely improvement is to occur with hospital admission.

A simple analysis of this decision (Figure 7.2) might begin with one set of chance nodes—the probability that a life-threatening problem will develop. A decision analysis ends with the *outcomes* of the different possibilities. In this case, four outcomes are possible: admitted and died, admitted and survived, treated at home and died, and treated at home and survived.

This simple tree does not reflect the clinical situation. A more realistic tree (Figure 7.3) needs at least one additional

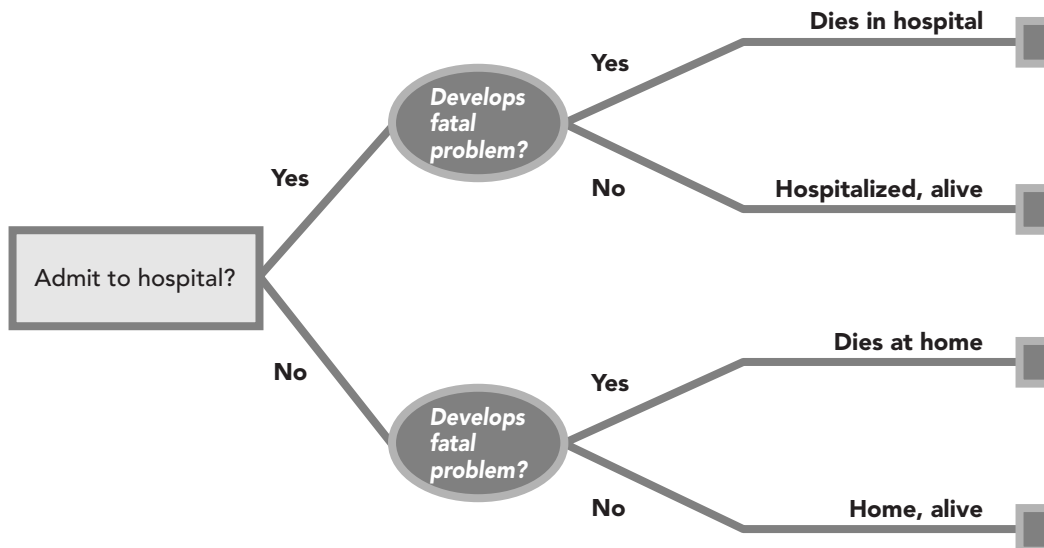

Figure 7.2 A simple decision tree for chest pain.

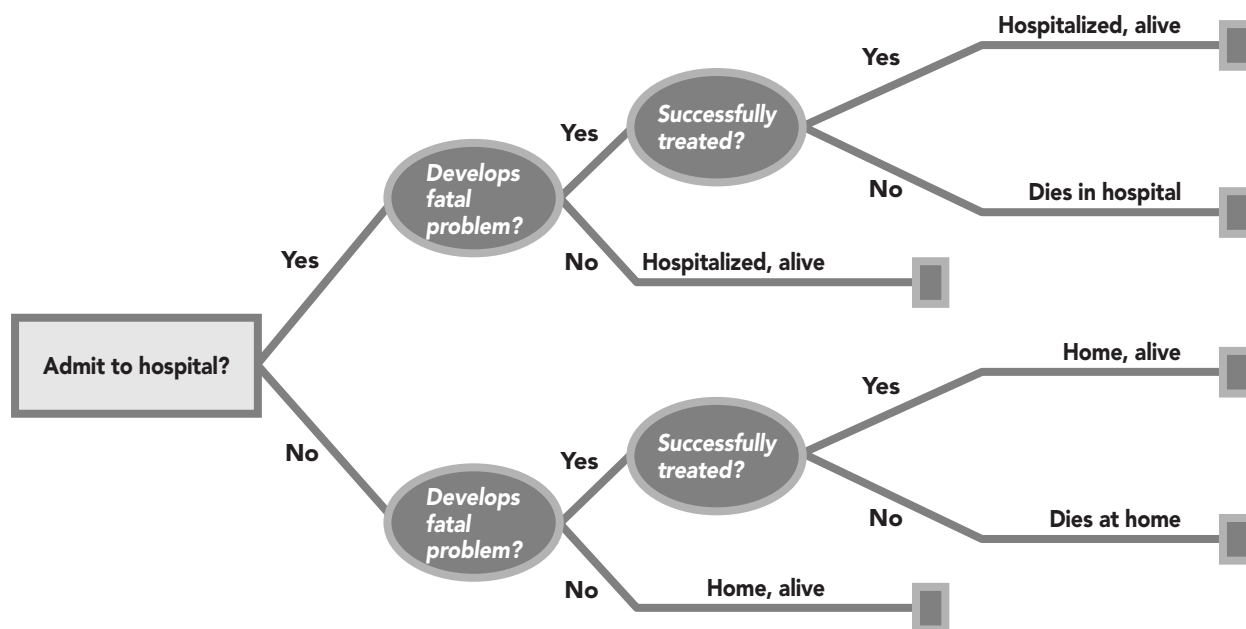

Figure 7.3 A more realistic tree.

layer of complexity—the likelihood that the potentially fatal problem can be prevented by therapy or detected and treated in time to prevent a fatal outcome. That likelihood is presumably greater if the patient is admitted to the hospital; if not, then hospitalization has no benefit, and no uncertainty exists about the right decision, which is to send the patient home.

In this more elaborate tree, the new set of chance nodes reflect the different probabilities. The chance nodes indicate the probability that a potentially fatal complication is destined to develop. This probability is independent of the decision; its likelihood is not influenced by the decision to admit the patient. This concept—that *the decision does not affect the likelihood that a patient already has a particular condition*—is essential to understanding decision analysis. If the patient is not destined to have a life-threatening complication, then the patient will survive whether admitted to the hospital or treated at home.

FILLING IN THE DECISION TREE

After the tree structure has been outlined, the next step in a decision analysis is to assign *probabilities* to the various branches leaving each chance node. The total probability at each chance node must sum to 100%. These probabilities can be obtained by a thorough review of the literature, from original data, or by asking experts. Although the most valid estimates of the effects of treatment are obtained from trials, these are not available for many decisions. Indeed, one of the strengths of formal decision analysis is that it is useful when a randomized trial is not practical or available.

In the example, let us arbitrarily assume that the likelihood that a life-threatening problem would have developed is 5%; thus, the likelihood that such a problem would not have developed is 95%. Next, one must estimate the likelihood of preventing or detecting and successfully treating this problem both at home and in the hospital. Let us assume that this likelihood is 80% if the patient has been hospitalized but only 50% if the patient is at home.

Numeric values must now be assigned to each outcome. These values are called *utilities*. For convenience, the best outcome (in this case, alive and at home) is usually assigned 100 points, and the worst outcome (in this case, dead) is assigned zero points. But how should the utility of the outcome of “alive and in the hospital” be valued? Some “disutility” must be assigned to hospitalization; otherwise, the best decision would be to hospitalize everyone, no matter how small the probability of the development of a life-threatening problem. This disutility results from the cost and inconvenience of hospitalization and from the possibility that the patient will suffer a hospital-related complication. Arbitrarily, let us assume that admission to the hospital for a condition that could have been managed on an outpatient basis has a disutility of two points; thus, the outcome of “alive and admitted” is worth 98 (100 – 2) points.

An important question to ask before assigning utilities is, “Whose utility?” Usually, the perspective for a clinical decision analysis is that of the patient. For example, a physician may view a death that occurs at home as being worse than a death that occurs in the hospital (in the sense that the death at home might have been avoidable had the patient been admitted). From the perspective of the patient, however, it is usually reasonable to assume that a

fatal outcome has the same utility whether or not the patient was hospitalized.

ESTIMATING THE UTILITY OF EACH DECISION

After completing the anatomy of the tree and estimating all the probabilities and utilities (Figure 7.4), the decision analyst must determine the expected utility of each alternative decision. The expected utility of a decision is the average utility of all the possible outcomes of that decision, weighted by the likelihood of arriving at each outcome. The decision with the greatest expected utility is the best decision.

This process begins at the most distal nodes of the decision; the expected values at these nodes are determined by multiplying the utility of each outcome by the probability of the twig leading to that outcome. Then one sums the expected values of each twig. For example, a 20% chance of an outcome that is worth zero points and an 80% chance of an outcome that is worth 100 points has an expected value of 80 points, or $(20\% \times 0) + (80\% \times 100)$. This value becomes the expected utility of that chance node, which is then multiplied by the likelihood of arriving at that chance node. The process progresses centrally (from right to left) until the expected values of the original decisions, at the *base case* for the probabilities and utilities, are determined. In this example (see Figure 7.5), the decision to treat the patient at home results in an expected utility of 97.5, whereas admission to the hospital has an expected utility of 97.02 when using the base case assumptions about probabilities and utilities. Thus, the analysis indicates that treating the patient at home

will have a marginally (less than a half point) greater expected utility.

SENSITIVITY ANALYSIS

The decision analyst next varies the assumptions in the model to determine how these changes affect the expected utilities of alternative decisions. This process is known as *sensitivity analysis* because its purpose is to determine whether the value of a decision is sensitive to the assumptions. Decisions that are not greatly affected by a probability or utility are said to be *robust* to that assumption. Sensitivity analyses alter the probabilities at each chance node as well as the utilities through a reasonable range. If only one assumption is varied, the process is known as a one-way sensitivity analysis. If several probabilities and utilities are varied simultaneously, these are called, for example, two-way or three-way analyses. Sensitivity analyses are especially important when the model contains several critical variables and there is disagreement about what the base case values should be.

One potentially confusing aspect of most sensitivity analyses is that the expected utilities of alternative decisions usually decline as the probability of an adverse outcome increases (Figure 7.6). For example, the value of admitting a patient with chest pain and the value of treating the patient at home both decline as the probability increases that a life-threatening complication will develop. That is because complications are usually a result of severe disease; even patients who are hospitalized may have adverse outcomes. However, a comparison of the expected values of the two choices shows that as the likelihood of

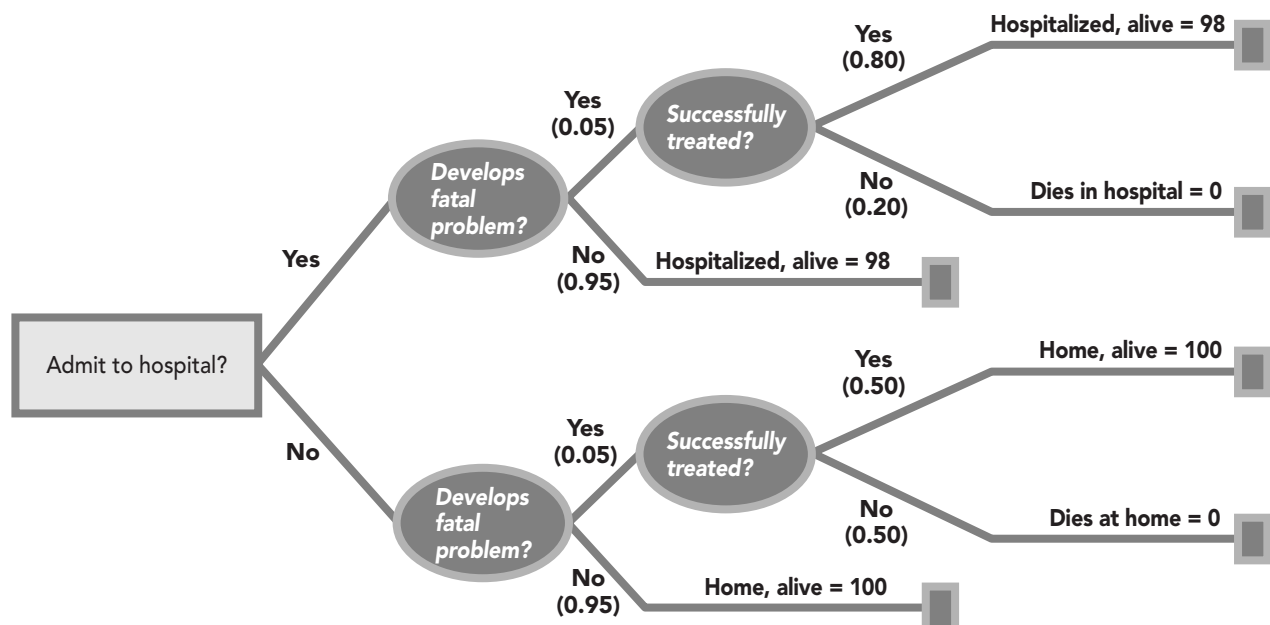

Figure 7.4 The tree with probabilities and utilities added.

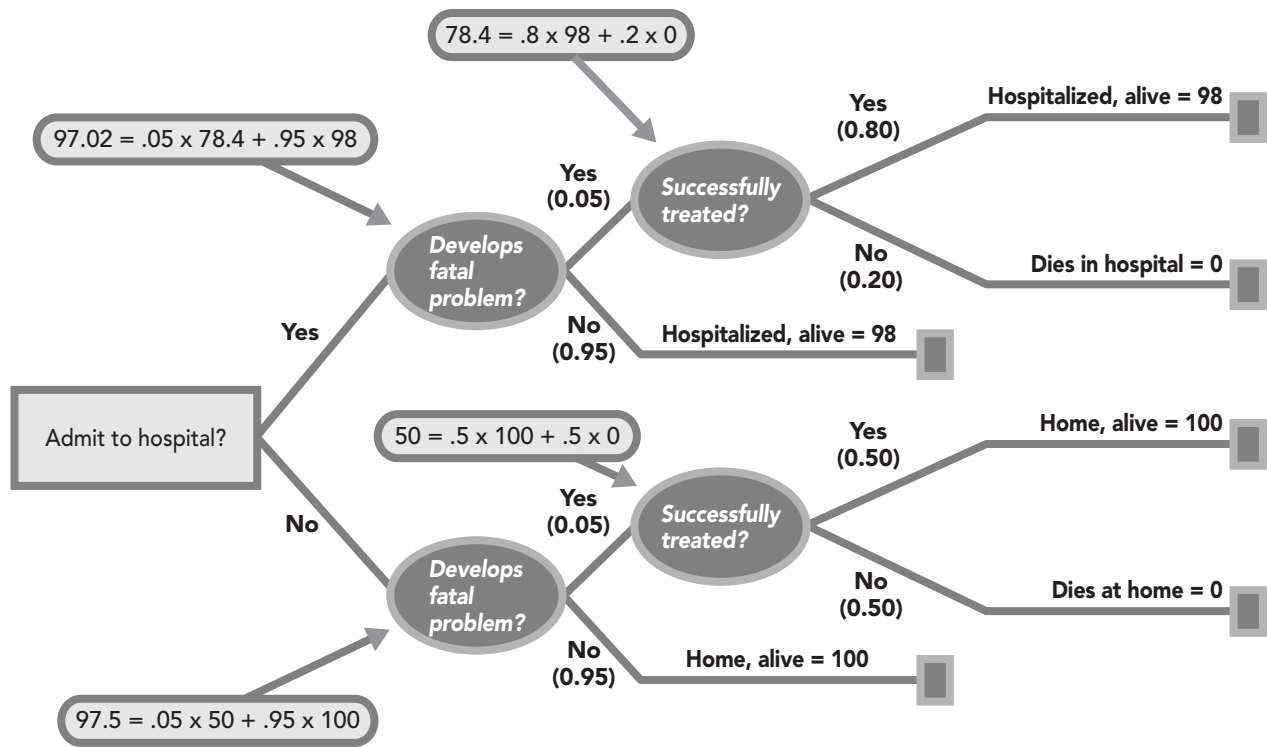

Figure 7.5 The tree with expected utilities (elongated ovals) added.

complications increases, the difference between the two therapies becomes more favorable to admission as the two lines diverge.

The point at which the expected values of alternative decisions are identical is the *toss-up* (5). In the example, this occurs when the probability of a complication is 6.6%. When the probability that the patient has a life-threatening

condition is less than 6.6% (e.g., a 5% risk, as in the base case assumptions), treatment at home is preferred, albeit not by much. At probabilities greater than 6.6%, hospitalization is the better decision.

SETTING UTILITIES

One of the most difficult aspects of decision analysis is setting the utilities for the expected outcomes (6-9). Sometimes the utilities are obvious—for example, if there are only two of them (such as life and death). At other times, the utilities can be set in years of life expectancy under alternative decisions, such as survival with medical or surgical therapy in patients with left main coronary artery disease. However, for many situations, it is necessary to determine the utilities for one or more intermediate outcomes by using some sort of scale—the higher the utility, the greater the value to the patient.

Consider the following example. You are trying to help a patient determine whether to have femoral–popliteal artery bypass surgery for claudication. The patient is able to walk one block on level ground. The condition has been stable for the past year, during which time the patient has quit smoking. If the surgery is successful, the patient will be able to resume previous activities—walking several blocks a day—without pain. This is the best outcome, and it is assigned 100 points. The main complication of surgery is perioperative death. This is the worst outcome, and it is

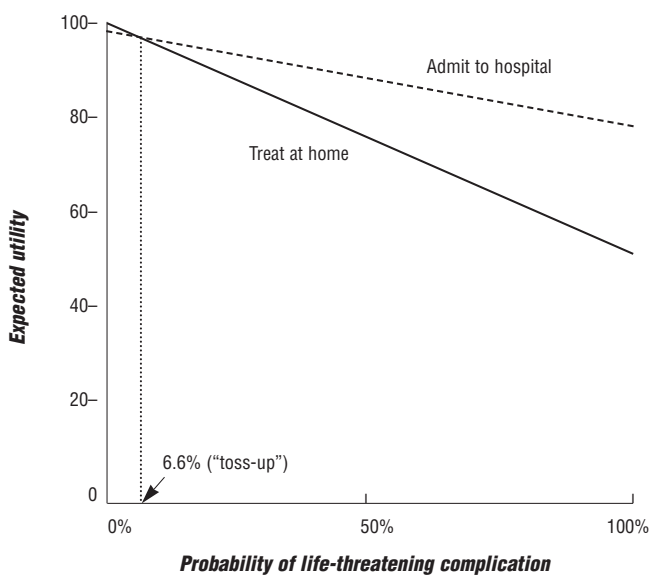

Figure 7.6 One-way sensitivity analysis of expected utilities of treating at home or admitting to the hospital, as a function of probability of life-threatening complication.

Figure 7.7 The linear utility scale.

assigned zero points. Assume that surgery is otherwise without problems. The utility that needs to be determined is that of the intermediate outcome—being “able to walk one block on the level.”

One way to set this utility is to ask the patient, “On a scale of zero (death) to 100 (able to walk without pain for several blocks), how would you rate the current situation, with limited activity? Place a mark on the line that indicates your choice” (Figure 7.7). This is then the patient’s utility.

Another way of assessing utilities is known as the *standard gamble* (Figure 7.8), in which the patient is offered two hypothetical scenarios. The first scenario is the intermediate outcome (e.g., living with claudication). The second involves balancing a chance of the best outcome (revascularization and pain-free ambulation) against the alternative of the worst outcome (death). When the chance of the best outcome is low enough that the patient has a difficult time deciding which scenario is more attractive, you have determined the utility of the intermediate outcome. This can be portrayed as a simple decision analysis to determine the probability of surviving a successful procedure that would make the decision a toss-up.

The patient needs to estimate the chance of surviving the procedure that would make the decision a difficult one (a toss-up). At that probability (P), the patient has determined the utility of the intermediate outcome because $P \times 100 + [1 - P] \times 0 =$ claudication utility. One can estimate this probability by beginning with a very high likelihood of surviving surgery and reducing it until the patient no longer

chooses surgery. (“Suppose that surgery could restore your walking back to several blocks without discomfort. Would you choose to undergo surgery if the chance of surviving was 999,999 in a million? 999 in 1,000? 99 in 100? 49 in 50? 1 in 10? 1 in 2?”) Alternatively, one can begin with a low surgical risk and increase it. (“Would you choose surgery with a risk for death of 1 in a million? 1 in 1,000? 1 in 100? 1 in 50? 1 in 10? 1 in 2?”) If a patient is willing to take no more than a 1 in 20 chance of dying at surgery (at least a 95% chance of a good outcome), that implies that the patient has assigned the value of 0.95 to the utility of living with claudication.

Utilities derived from the standard gamble tend to be greater than those estimated using a linear scale; intermediate outcomes such as claudication tend to cluster close to those for good health. This happens because patients are risk averse and especially because they are death averse. Many are not willing to risk death to improve their current condition.

The standard gamble assumes that patients value a 95% chance of a perfect outcome the same as a 100% chance of an outcome that has a utility of 0.95. Some patients, however, may not like the uncertainty of not knowing and prefer a sure thing, even to the point of overvaluing it.

Often, utilities obtained from a linear scale or the standard gamble combine with life expectancy to yield *quality-adjusted life-years* (QALYs, pronounced “qwallyes”). If claudication has a utility of 0.9, then the outcome of “alive for 10 years with claudication” would be equivalent to nine quality-adjusted life-years; so would nine years in perfect health (with a utility of 1.0) or 20 years with a health condition that had a utility of 0.45.

Another way to set utilities is by making time trade-offs to estimate the utility of a year of life in the intermediate state. In this method, the patient is asked to balance time in the current situation with time in a state of perfect health. For example, patients are asked whether they would be

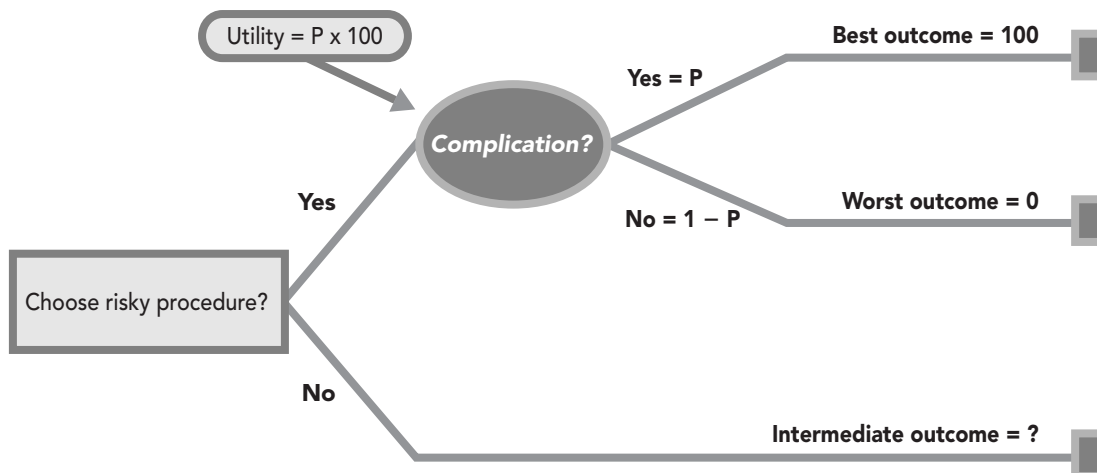

Figure 7.8 The standard gamble.

willing to trade 10 years of life with claudication for Y years of “revascularized” life (and death immediately thereafter). In this situation, patients are estimating the quality of life with claudication (e.g., on a scale of 0% to 100%):

$$100\% \times Y \text{ Years} \\ = \text{Quality of Life with Claudication} \times 10 \text{ Years}$$

If a patient chooses eight years, this indicates that the current quality of life is 80%:

$$80\% \times 10 \text{ Years} = 100\% \times 8 \text{ Years}$$

In general, time trade-offs give values for utilities that are between those of a linear scale and those of a standard gamble. This occurs because patients, especially young patients, tend to devalue time given away in the future. They are more willing to give some away for the chance of feeling better.

Setting utilities from other perspectives can yield different results in a decision analysis. From the perspective of an insurance company or an overworked physician, admitting a patient to the hospital for five days of treatment for pneumonia has a major disutility, whereas from the patient’s perspective, it may have only a minor disutility (or even none at all). Physicians may not value quality of life with a disability, such as the need for long-term dialysis, as highly as patients themselves do.

EVALUATING PUBLISHED DECISION ANALYSES

Before accepting the validity of a decision analysis, one must determine whether it is relevant to the clinical situation. First, are the alternative decisions actually available, or do they involve specialized or unavailable tests or procedures? Second, are the probabilities—both of outcomes and of the effects of treatment—valid in the particular clinical situation in which you find yourself? Were they based on referral populations? Were there other important differences, such as in age, gender, race, or stage of disease, in comparison with patients for whom you care? Were the relevant outcomes considered, and were they valued appropriately?

A well-performed decision analysis should also provide the exact structure of the decision tree that was used. If you cannot re-create the calculations involved in a complex model, then it is difficult to be certain that the authors did them correctly. A decision analysis that is not explicit about the tree structure can hide many branches and may have arrived at the wrong results.

Published analyses should provide the values for each probability for the base case and the ranges of probabilities for the sensitivity analyses, as well as references to the sources of probabilities. More importantly, an analysis should verify their relevance to the clinical situation. A decision analysis, for example, that concludes that anticoagulation is always the best course of action for patients with atrial fibrillation who have a risk for bleeding that varies

between 1% and 10% a year would not be relevant for a patient who has had three gastrointestinal hemorrhages in the previous month.

Utilities should be appropriate. They are often set arbitrarily or by consulting with a few physicians, and thus they bear little resemblance to what patients might say. Bear in mind that most patients value life, even with disability or disease, highly, and that short-lived events (such as hospitalization) have only a minor effect on the quality of life for an entire year.

The advantages of decision analysis—that it requires an explicit structure of the decision, that probabilities and utilities must be estimated, and that a point of view must be adopted—also point to some of its key disadvantages. These requirements are time consuming and often not practical when a decision must be made in real time. However, formal decision analyses are available for many common clinical decisions, and many have been done well (1–4). The process of decision analysis, by highlighting the key uncertainties, may suggest areas in need of research. Many difficult decisions are toss-ups, and the process of decision analysis reminds clinicians of the importance of patient preference in these circumstances. Small changes in the utility of an outcome, such as a preference not to undergo an invasive diagnostic test, may greatly affect the preferred decision.

KEY POINTS

- Decision analysis is a formal method of evaluating clinical decisions made under circumstances of uncertainty.
- The process assumes that it is possible to rank outcomes from best to worst and to assign them numeric values, called utilities.
- The expected utility of a decision is determined by multiplying the utilities of each possible outcome of that decision by the likelihood of reaching that outcome.
- The best decision is the one that leads to the greatest expected utility.
- A decision is a toss-up when the expected utilities of alternative choices are similar.
- Sensitivity analyses determine the effects of changes in the assumptions of a decision analysis on the expected utilities.
- Different methods of setting utilities can result in different values.

Evidence-Based Medicine

8

Holger J. Schünemann **Gordon H. Guyatt**

INTRODUCTION: THE HISTORY AND PHILOSOPHY OF EVIDENCE-BASED MEDICINE

When one of the authors first introduced the term *evidence-based medicine (EBM)* in an informal residency training program document, it was described as “an attitude of enlightened skepticism toward the application of diagnostic, therapeutic, and prognostic technologies in their day-to-day management of patients” (1). In the following years, the term and its philosophy became well known through a series of articles (later published in a collection) by the EBM Working Group (2). A MEDLINE search of the term *EBM* in January 2005 revealed seven citations for the year 1993 and approximately 2,500 citations in 2004.

The need to solve clinical problems has stimulated the evolution of EBM. In contrast to the traditional paradigm of clinical practice, EBM emphasizes that intuition, unsystematic clinical experience, and pathophysiologic rationale are not sufficient for making the best clinical decisions. Although EBM acknowledges the importance of clinical experience, it deems the evaluation of evidence from clinical research as a prerequisite for optimal clinical decision making (3). Moreover, it holds that clinicians must use a formal set of rules to interpret and apply evidence from clinical research results effectively. Another fundamental principle of EBM is the explicit inclusion of patients’ and society’s values and clinical circumstances in the clinical decision-making process (see Figure 8.1) (4). Patients, their proxies, or (if a parental approach to decision making is desired) the clinician must always weigh the benefits, harms, and costs associated with alternative treatment strategies, and values and preferences always influence those trade-offs.

For clinicians, integrating research evidence in their practice requires an understanding of what constitutes higher-quality versus lower-quality evidence. For instance, a case report describing an “effective” intervention makes one less certain than when evidence about the intervention is summarized in a systematic review of large, randomized controlled trials. EBM teaches that confidence in research results should be greatest when systematic error (bias) is lowest and that confidence should fall when bias is more likely (see Figure 8.2).

SETTING CRITICISM OF EBM STRAIGHT

Although randomized study designs provide the highest-quality evidence, EBM does not neglect other study designs. In fact, EBM acknowledges explicitly that a large body of state-of-the-art evidence comes from observational studies because higher-quality evidence often is unavailable or experimental study designs are infeasible. For instance, consider the role of smoking in the development of lung cancer. Randomizing individuals to smoke or not smoke is infeasible (and unethical), and, thus, the highest-quality evidence comes from observational data. The practice and application of EBM requires an understanding and critical evaluation of all study designs and their appropriateness for specific clinical questions. In addition to study design, rules for formal assessment of evidence allow critical appraisal of whether studies are executed and analyzed correctly. The next sections consider how to develop a clinical question and identify and appraise evidence.

Figure 8.1 Model for Evidence-Based Decision Making. Clinical expertise balances and integrates the “clinical state and circumstances,” “patient preferences and actions,” and “research evidence,” dealing with not only the traditional focus of assessing the patient’s state but also the pertinent research evidence and the patient’s preferences and actions before recommending a course of action. (Reproduced from Haynes RB, Devereaux PJ, Guyatt GH. Clinical expertise in the era of evidence-based medicine and patient choice. *ACP Journal Club* 2002;136:A11, with permission).

EBM IN ACTION: A CLINICAL SCENARIO

Imagine you are a busy hospitalist in a university-affiliated county hospital, working late at night after admitting several patients over the course of the day. You just admitted a 66-year-old Caucasian man who presented to the emergency room that morning with 15 minutes of left-sided chest pain radiating to his left arm. The pain was severe enough to awaken him, and he reports that he had to sit up in his bed because of difficulties in catching his breath. Finally, his symptoms became so severe that he called an ambulance. A second episode of similar pain in the ambulance was relieved within a few minutes by 0.4 mg nitroglycerin given under his tongue, and he has been free of pain since then. An ECG in the emergency room was unremarkable, and cardiac enzymes drawn at ER arrival were borderline elevated (troponin I 1.0 mcg/l; the hospital’s indeterminate range is 0.4–2.0 mcg/l). His chest radiograph was normal.

The patient has a history of hypertension. He takes a diuretic, and his primary care provider had given him 325 mg of aspirin daily to prevent a heart attack. Now, a few hours after his ER arrival, you recheck his laboratory values, and you find that his second troponin I level has risen to 4.8 mcg/l. At this point, you feel that a myocardial infarction without ST segment elevation (a non-ST segment elevation MI) is the most likely diagnosis, and you need to decide what to do after admitting the patient. The patient

Study Design

- Randomized controlled trials
- Controlled trials (controlled before and after studies)
- Case-control studies and cohort studies
- Cross-sectional studies
- Case reports and case series

Figure 8.2 The Hierarchy of Quality of Evidence. As the research design becomes more rigorous (moving from bottom to top), the quality of evidence increases, and the likelihood of bias decreases.

had already received aspirin and low-molecular-weight heparin in the ER, but you wonder about the best action to prevent further cardiovascular events. (The patient refuses any invasive cardiac procedure, including catheterization.) Apart from management of the patient’s lipids and lifestyle modifications, you know that cardiologists and neurologists in your hospital often use a second antiplatelet agent (clopidogrel) to prevent further ischemic events. However, you wonder how large the potential benefits and harms are. You are particularly concerned about the risk of bleeding.

You develop the following clinical question according to Table 8.1 (5): *In patients with acute coronary syndromes without ST segment elevation, what is the impact of early and*

TABLE 8.1
FORMULATING THE CLINICAL QUESTION

Component	Explanation
Population	Who are the relevant patients?
Interventions or exposures	What are the management strategies clinicians are interested in (for example, diagnostic tests, drugs, toxins, nutrients, surgical procedures, etc.)?
Comparison (or control) intervention or exposures	What is the comparison, control, or alternative intervention clinicians are interested in? For questions about therapy or harm, there will always be a comparison or control (including doing nothing, placebo, alternative active treatment, or routine care). For questions about diagnosis, there may be a comparison diagnostic strategy (for example, troponin I compared with creatine kinase MB in the diagnosis of myocardial infarction).
Outcome	What are the patient-important consequences of the exposure clinicians are interested in?

long-term use of clopidogrel plus aspirin versus aspirin alone on cardiovascular events and bleeding risk?

While the patient is transferred to the floor, you go to your office and search for appropriate studies. You can find the answer to your question in several ways, including asking a colleague. However, you want to solve this question now because it has come up before but you have always been too busy to answer it.

You consider the resources you have available. First, you could obtain the relevant evidence in the form of published original research and critically appraise these studies yourself. Second, you could rely on prefiltered evidence provided by others with experience in critical appraisal of primary studies. In view of available time and your entirely clinical training, you decide to focus on the latter.

SOURCES OF EVIDENCE

For many hospital-based physicians, the most accessible resources are online. Most resources require use of a computer with a World Wide Web connection, but many have CD-ROM versions available. (For a comprehensive list, see McKibbin et al. (5).) Online or computer-based resources are easy and relatively quick to search. Although there are a number of such resources, no formal comparison in terms of efficiency and patient outcomes exists. This chapter describes some of these resources. The question framed in the previous section is one of therapy, and several sources address questions about therapy.

Prefiltered Medical Information Resources for Hospital-Based Clinicians

The best starting point to look for answers to clinical questions is a systematic review. Systematic reviews are rigorous and all-inclusive summaries of evidence; they often include statistically pooled summary measures of effect called meta-analysis. The best source for systematic reviews and summaries of systematic reviews are the Cochrane Library (6), *ACP Journal Club/Evidence-Based Medicine* (7), and *Clinical Evidence* (8)—all of which are available in CD-ROM versions or on the World Wide Web. The Cochrane Collaboration, an international organization that aims to produce, maintain, and disseminate high-quality systematic reviews of health care interventions, produces the Cochrane Library. *ACP Journal Club* and *Evidence-Based Medicine* contain prefiltered appraisals of primary research and systematic reviews. *Clinical Evidence* provides concise accounts of the current state of knowledge (updated biannually) primarily based on searches for systematic reviews. Another source of prefiltered evidence is *UpToDate* (9), a comprehensive online or electronic textbook updated every four months. The advantages of *UpToDate* include the provision of background knowledge of clinical topics for quick review and its comprehensiveness. Although *UpToDate* does not describe

the methodology used to obtain and appraise the evidence, its editors are working toward being increasingly evidence-based.

Looking for Evidence

You start the search by looking at the OVID collection called “EBM Reviews,” which includes *ACP Journal Club* and the Cochrane databases. You know that few studies on clopidogrel exist because of its relatively recent introduction. You type the keyword “clopidogrel” first and then “myocardial infarction OR acute coronary syndrome.” You then combine these searches with an “and,” yielding a list of 31 references that you review in less than five minutes. Reference number 20 is a *hit* (10), providing an appraised summary of the CURE trial: “Effects of Clopidogrel in Addition to Aspirin in Patients with Acute Coronary Syndromes without ST-Segment Elevation Trial” (11). You decide that you cannot spend the 20–25 minutes reading the primary article, both because you have other patients waiting and because of your limited training in critical appraisal. Just as critically appraising the primary articles addressing a clinical question can be unwieldy, searching for primary evidence using MEDLINE, an electronic database of more than 4,500 biomedical journals, can be inefficient. If searches of preappraised sources prove fruitless, however, one must fall back on MEDLINE.

MEDLINE

MEDLINE is a bibliographic database created and updated by the U.S. National Library of Medicine (NLM). In many hospitals, MEDLINE is available through commercial vendors (such as OVID) that purchase licenses from NLM. Clinicians can also access MEDLINE directly through the NLM PubMed World Wide Web site (<http://www.pubmed.org>). MEDLINE is helpful in answering focused clinical questions. However, because of its size and complexity, searching MEDLINE can be difficult, time consuming, and frustrating. Using the same keywords described above, your MEDLINE search returns 292 citations. Screening this list of citations will be infeasible for those who need an answer quickly. Therefore, the authors recommend initial use of MEDLINE only when searches of other sources—particularly those that contain prefiltered summaries of evidence—have been unrewarding. In general, for common questions, such as the one in the scenario, the prefiltered databases described above are more useful.

EVIDENCE-BASED CARE FOR THE HOSPITALIZED PATIENT

The *ACP Journal Club* article summarizing the CURE trial provides you with sufficient information about the study to answer typical questions about therapy (see Table 8.2). *ACP Journal Club* provides this assessment for clinicians in

TABLE 8.2
CRITICAL APPRAISAL OF STUDIES ABOUT THERAPY

Question	Therapy or prevention
Study design and execution—evaluation of bias	I. Are the results of the study valid? <ol style="list-style-type: none"> 1. Were patients randomized? 2. Was randomization concealed? 3. Were patients analyzed in the groups to which they were randomized? 4. Were patients in the treatment and control groups similar with respect to known prognostic factors? 5. Were patients aware of group allocation? 6. Were clinicians aware of group allocation? 7. Were outcome assessors aware of group allocation? 8. Was follow-up complete?
Results and random error	II. What are the results? <ol style="list-style-type: none"> 1. How large was the treatment effect? 2. How precise was the estimate of the treatment effect?
Application and uptake	III. How can I apply the results to my patient care? <ol style="list-style-type: none"> 1. Were the study patients similar to my patients? 2. Were all clinically important outcomes considered? 3. Are the likely treatment benefits worth the potential harms and costs?

summary format. You learn that the study was a randomized, blind, and placebo-controlled trial with 12 months of follow-up. The investigators randomized patients to clopidogrel or a placebo, but all patients received aspirin as standard therapy. You know that randomized studies have a lower risk of yielding biased outcomes compared with observational studies because known prognostic factors often influence clinicians' or patients' decision about certain therapies. Properly conducted randomized, controlled studies will eliminate the imbalance of known and unknown risk factors. You also know that randomized trials have often led to different results from those of observational studies or commonly held medical opinion. For example, based on a number of observational studies, the use of hormone replacement therapy was thought to prevent coronary heart disease in postmenopausal women, but results of a large randomized controlled trial showed an increased risk for cardiovascular events in patients receiving hormone replacement therapy (12).

EXPRESSING TREATMENT EFFECTS: RELATIVE RISK REDUCTION, ABSOLUTE RISK REDUCTION, AND NUMBER NEEDED TO TREAT

The CURE study included 12,562 patients from 28 countries, and all patients were included in the final analysis. Approximately half the patients received an immediate loading dose of oral clopidogrel, 300 mg, followed by 75 mg daily for 3–12 months; the remaining patients received a placebo resembling clopidogrel; and all patients received aspirin, 75–325 mg daily. Patients were followed for 12 months.

The main outcomes were a composite of death from cardiovascular causes, nonfatal myocardial infarction (MI), or stroke, and a composite of death from cardiovascular causes, nonfatal MI, stroke, or refractory ischemia. Safety outcomes included major and minor bleeding. The focus here is on the latter composite endpoint. Patients in the clopidogrel group had a *relative risk* (RR)—the proportion of the baseline risk in the control group that still is present when patients receive the experimental treatment (in this case, clopidogrel)—of 0.86 (see Table 8.3 for a glossary of key terms in EBM). The easiest measure of risk to understand is the *absolute risk*. In the CURE trial, the absolute risk for the combined primary outcome of recurrent nonfatal myocardial infarction, stroke, death from cardiovascular disease, or refractory ischemia was 16.5%. The absolute risk for this outcome in the control group was 18.8%. One can express treatment effects as the *absolute risk reduction* (ARR) or the risk difference—the difference between the absolute risks in the experimental and control groups. This effect measure represents the proportion of patients spared from the unfavorable outcome if they receive the experimental therapy (clopidogrel) rather than the control therapy (placebo). In the CURE trial, the absolute risk reduction is 2.3% (18.8%–16.5%).

However, the most commonly reported measure of dichotomous treatment effects in clinical studies is the complement of this RR, the *relative risk reduction* (RRR). One can obtain the RRR easily from the RR because it is the proportion of baseline risk that is removed by the experimental therapy, equivalent to $1.0 - RR$. It can be expressed as a percentage: $(1 - RR) \times 100 = (1 - 0.86) \times 100 = 14\%$ for this scenario. A relative risk reduction of 14% means that clopidogrel reduced the risk of the combined outcome

by 14% relative to that occurring among control patients. The greater the RRR, the more efficacious the therapy.

Distinguishing between RRR and ARR is important. Assume that the absolute risk of experiencing the combined outcome doubled in both groups in the CURE trial. This could have happened if the investigators had conducted a study in patients at much higher risk of experiencing the endpoint, such as much older patients. In the clopidogrel group, the absolute risk would then become 33% compared with 37.6% in the control group. As a result, the ARR would increase from 2.3%–4.6%, whereas the RR (and therefore the RRR) would remain identical at 0.86 ($33\% \div 37.6\% = 0.86$), and the RRR would remain approximately 14%. As this example makes clear, doubling of those experiencing the endpoint in both groups leaves the RR (and the RRR) unchanged but increases the ARR by a factor of 2.

Although 14% reduction in the relative risk of the combined endpoint may not sound impressive, its impact on patient groups and practice may be large. The *number needed to treat* (NNT), the number of patients who must receive an intervention during a specific period to prevent

one additional adverse outcome or produce one positive outcome, provides a guide to this impact (13). The NNT is the inverse of the ARR and is calculated as $1 / \text{ARR}$. Therefore, in the hypothetical example above (with an ARR of 4.6% expressed as a proportion, 0.046), the NNT would be 22 ($1 / 0.046\%$). It was 44 ($1 / 0.023\%$) in the CURE trial.

With this concept in mind, imagine a young patient with no other risk factors for adverse outcomes. Such a patient may carry a much lower baseline risk (say, 4%), and thus the NNT skyrockets to 179 [$1 / (0.14 \times 4\%)$]. Given the duration, potential harms (absolute risk increase of 2.7% and 1% for minor and major bleeding, respectively), and cost of treatment with clopidogrel, withholding therapy in this lower-risk patient would be reasonable.

EXPRESSING TREATMENT EFFECTS: CONFIDENCE INTERVALS

Results of any experiment, such as a randomized controlled trial, represent only an estimate of the truth. The true effect of treatment actually may be somewhat smaller or larger than what researchers found. The *confidence interval* (CI) tells, within the bounds of plausibility, how much smaller or greater the true effect is likely to be. The results provided in *ACP Journal Club* show that the CI in the CURE trial around the point estimate of the RRR of 14% ranges from approximately 6%–21%. Both the point estimate and the CI itself help answer two questions. First, what is the single value most likely to represent the true difference between treatment and control; and second, given the difference between treatment and control, what is the plausible range within which the true effect might lie? The smaller the sample size (number of patients in a trial) or the number of events in an experiment, the wider the CI. As the sample size gets larger and the number of events increases, investigators become increasingly certain that the truth is not far from the point estimate calculated from the experiment, and, therefore, the CI is narrower.

One can interpret the 95% CI as the range within which, 95% of the time, the true effect will lie. However, how does the CI facilitate interpretation of the results from the CURE trial? As described above, the CI represents the range of values within which the truth plausibly lies. Accordingly, one way to use CIs is to look at the lower boundary of the interval (the lowest plausible treatment effect) and decide whether the action or recommendation would change compared with assuming that the point estimate represents the truth. The most likely value for the RRR with clopidogrel is 14%, but the true RRR may be as high as 21% or as low as 6%. Values progressively farther from 14% will be less and less likely. One can conclude that patients receiving clopidogrel are less likely to experience the combined endpoint (because even the lower bound of the RRR is greater than zero)—but the magnitude of the difference may be either quite small (and not outweigh the increased

TABLE 8.3 GLOSSARY OF KEY TERMS IN EVIDENCE-BASED MEDICINE

Absolute risk increase (ARI): Used as a measure of harm when an investigational therapy causes more harm than good. It is the difference between the absolute risks in the experimental and control groups and represents the proportion of patients that suffer from the unfavorable outcome if they receive the experimental therapy rather than the control/comparison therapy. Conceptually similar to the ARR but indicating an *increase* in risk from the investigational therapy.

Absolute risk reduction (ARR): The difference between the absolute risks in the experimental and control groups. This effect measure represents the proportion of patients spared from the unfavorable outcome if they receive the experimental therapy, compared with those in the control/comparison group.

Confidence interval (CI): The range within which, 95% of the time, the true effect of an intervention will lie.

Evidence-based medicine (EBM): EBM deems the evaluation of evidence from clinical research as a prerequisite for optimal clinical decision making but acknowledges the importance of clinical experience. EBM requires that clinicians use a formal set of rules to interpret and apply evidence from clinical research results effectively. Another fundamental principle of EBM is the explicit inclusion of patients' and society's values and clinical circumstances in the clinical decision-making process.

Number needed to harm (NNH): The number of patients who must receive an intervention during a specific period to cause one additional harmful outcome. Inverse of the ARI.

Number needed to treat (NNT): The number of patients who must receive an intervention during a specific period to prevent one additional adverse outcome or produce one positive outcome during that time period. Inverse of the ARR.

Relative risk reduction (RRR): The proportion of baseline risk that is removed by the experimental therapy, equivalent to $1.0 - \text{relative risk (RR)}$.

risk of bleeding and/or the cost) or quite large. This way of understanding the results avoids the yes/no dichotomy of testing a hypothesis.

EXPRESSING HARMS AND TOXICITIES: ABSOLUTE RISK INCREASE AND NUMBER NEEDED TO HARM

The chief toxicity of clopidogrel that concerned the authors of the CURE trial was bleeding. They found that the *absolute risk increase* (ARI) (conceptually similar to the ARR but indicating an *increase* in risk associated with the investigational therapy) for major bleeding was 1% (an increase from 2.7% in the placebo group to 3.7% in the clopidogrel group). The investigators defined major bleeding as substantially disabling bleeding, intraocular bleeding or the loss of vision, or bleeding necessitating the transfusion of at least two units of blood. One can also calculate the number of patients who must receive an intervention during a specific time to cause one additional harmful outcome (analogous to the NNT). The *number needed to harm* (NNH) for major bleeding in the CURE trial is equal to $1 / \text{ARI}$, or $1 / 0.01 = 100$. The authors also provided the information for minor bleeding, which they defined as hemorrhages that led to interruption of the study medication but that did not qualify as major bleeding. The risk for minor bleeding was 5.1% in the clopidogrel group compared with 2.4% in the placebo group. Thus, the NNH for minor bleeding was $1 / 0.027 = 37$. Clinicians should keep in mind that estimates of harm also come with uncertainty; therefore, *ACP Journal Club* provides confidence intervals around these harmful effects.

APPLYING EBM PRINCIPLES TO YOUR PATIENT

You now want to know whether you can apply these results to your patient. You examine the study population included in the CURE trial and the associated exclusion criteria. In terms of age, your patient is similar to the study population (66 vs. 64 years), the study included a large proportion of men, and your patient does not fulfill any exclusion criteria. In addition, the study addressed all relevant outcomes. So the study does seem applicable to your situation.

You discuss the option of clopidogrel therapy with your patient, who is now feeling better and appears to have a good understanding of the information you are providing. You explain that—based on your assessment—the benefits and harms of clopidogrel are finely balanced: for every 44 patients treated for one year in the CURE trial, there was one less occurrence of the combined endpoint (the NNT). However, for every 100 patients treated with clopidogrel for one year, one additional patient suffered a

major bleeding episode, and for every 37 patients treated for one year, there was one additional minor bleeding episode (the NNH). You also explain that because these are only estimates, the true benefits and harms might be somewhat smaller or larger. The decision regarding taking clopidogrel thus depends on the patient's values and preferences regarding preventing the combined endpoint vs. incurring additional risk of bleeding (see Figure 8.1). Your patient states that he does not care about the risk for minor bleeding and that he feels the risk for major bleeding is less threatening for him than the risk of the recurrent pain of a heart attack and its subsequent impact on his long-term prognosis. Thus, he would like to use clopidogrel. Uncertain of clopidogrel's cost, you now call the hospital pharmacist. She informs you that the cost is approximately \$90 per month and that at least one analysis has suggested the drug is not cost effective (14). The patient tells you that he has a minimal copayment for most medications and remains interested in taking the medication. Thus, you start the patient on a 300 mg loading dose of clopidogrel and continue with 75 mg daily.

CONCLUSIONS

Evidence-based medicine provides an approach to addressing clinical problems. In contrast to the traditional paradigm of clinical practice, EBM emphasizes that intuition, unsystematic clinical experience, and pathophysiologic rationale are not sufficient for making the best clinical decisions. Although EBM acknowledges the importance of clinical experience, EBM's philosophy is that the evaluation of evidence from clinical research provides for the best clinical decision making. Clinicians need to understand a few basic methodological concepts to practice EBM, including developing searching skills and applying the results of clinical studies to their own practice circumstances. A large number of resources facilitate evidence-based clinical practice. Optimal clinical practice includes making the time for obtaining and applying the evidence.

KEY POINTS

- The first step to practicing evidence-based medicine is to develop focused clinical questions.
- Searching for evidence can be simple and efficient.
- A number of electronic and print resources are available for obtaining evidence.
- A basic understanding of risk, measures of effect, and outcomes (both benefits and harms) is necessary to practice or apply EBM (see Table 8.3).
- Patient values and preferences bear on the decision-making process.

Cost-Effectiveness

9

Joel Tsevat

INTRODUCTION

Physicians are facing increasing pressures to practice medicine efficiently. To many involved in hospital medicine, efficiency implies avoiding hospitalization when possible, minimizing hospital length of stay for those who need hospitalization, and eschewing expensive tests and treatments. In contrast, the cost-effectiveness paradigm is not to provide as little care as possible but to derive as much value as possible from the limited resources available. Thus, economic analyses in health care often seek to answer the question “How much bang are we getting for our buck?” rather than “How can we spend the fewest bucks possible?”

ECONOMIC ANALYSES

Economic analyses in health care compare two or more diagnostic or treatment modalities. There are several types of economic analyses (1) (Table 9.1). The simplest, *cost-minimization analysis*, assumes that the clinical outcomes of the alternatives under question are equivalent, so the analysis seeks to determine the least costly alternative. For example, one cost-minimization analysis determined the potential savings to a hospital (\$2,973 per patient at 12 months) derived from treating patients who have multivessel coronary artery disease by angioplasty and stenting vs. by coronary-artery bypass surgery (2). Cost-minimization analysis is useful for identifying costs but not for evaluating the yield (health benefits) from the expenditures.

A second type, *cost-benefit analysis*, compares the consequences of alternative modalities in common units, usually

dollars. For example, cost-benefit analyses of influenza vaccination have found that vaccination and treatment costs were more than offset by savings from reduced morbidity and mortality (3,4). Here, clinical outcomes were expressed in monetary units to compare them directly with the cost of the vaccination program. The principle in cost-benefit analysis is to adopt a program if it is cost-saving, or if it has a more favorable benefit-to-cost ratio than its alternatives.

The most common form of economic analysis is *cost-effectiveness analysis*. Because most choices in health care involve changes in the level or extent of an activity (e.g., ordering an expensive antibiotic vs. a less expensive antibiotic, or ordering computed tomography vs. ultrasonography), cost-effectiveness analysis addresses marginal or incremental changes. Thus, cost-effectiveness analyses examine the net cost (expenditures minus savings) per net unit of effectiveness for one alternative relative to another (5). Effectiveness is usually expressed as *years of life saved*, *quality-adjusted life-years (QALYs) saved*, or *lives saved*. QALYs factor in quality-of-life weights for years of life in various states of health; the weight ranges from zero (representing dead) to 1 (representing full health). The weights are derived by using utility measures, such as (a) the *standard gamble*, which assesses one’s willingness to risk a bad outcome, such as death, in exchange for a chance at full health; or (b) the *time trade-off method*, which assesses how much (if any) time a person would be willing to trade in exchange for a shorter but healthy life (6). Cost-effectiveness analyses that express outcomes as the incremental cost per QALY gained are also called cost-utility analyses. Cost-effectiveness ratios can also be expressed in terms of “intermediate outcomes,” such as cost per hospital day averted, but use of a “definitive” common denominator such as

TABLE 9.1
COMMON TYPES OF ECONOMIC ANALYSES IN HEALTH CARE

Type	Compares	Expressed In	Comments
Cost-minimization analysis	Costs of alternative strategies	Dollars	Assumes equivalent clinical outcomes
Cost-benefit analysis	Costs and benefits of alternative strategies	Dollars	Benefits converted into dollar savings
Cost-effectiveness analysis	Incremental costs per unit of benefit of alternative strategies	Dollars per year of life saved, per QALY saved, or per life saved	<\$50,000 per QALY often considered cost-effective

QALY, quality-adjusted life-year.

QALYs facilitates comparisons among a wider variety of interventions.

Cost-effectiveness analysis is too complex to perform at the bedside, but familiarity with its methods is useful for interpreting published studies. An important distinction is the difference between costs and charges (7). Costs represent the actual consumption of resources that could have been used otherwise, and as such, they are usually the relevant measure. Charges (patient bills), on the other hand, are subject to the vicissitudes of the health care system, such as type (or lack) of insurance, and may bear little resemblance to true resource use (see Chapter 2).

Several types of costs may be germane to an analysis. For example, fixed costs, such as building overhead, do not change during the short term and are thus usually excluded from analyses; on the other hand, variable costs—those directly related to the number of services provided—should be included. In general, costs appropriate to include in the numerator of a cost-effectiveness ratio include the following:

- Costs of health services (so-called direct health care costs, such as medications and laboratory tests)
- Cost of patient time expended while undergoing care (travel time, waiting time, and time actually receiving treatment)
- Costs associated with providing home care for the patient or for obtaining child care while the patient seeks care

In practice, many cost-effectiveness analyses include only direct medical costs. Occasionally, they include income lost because of morbidity or premature death (although such “indirect costs” are more appropriately captured in the denominator of the cost-effectiveness ratio) (8).

Besides which costs are considered, published cost-effectiveness analyses vary in other fundamental areas, such as *perspective* (e.g., that of society, the patient, the hospital, or the insurer), *time horizon*, and *discount rates* (discounting is a method of converting future costs, years of life, or both to their present value). Variability in methodology limits comparison across studies, and this limitation is significant because interventions cannot be considered cost-effective

or not cost-effective *per se*—they must be viewed in relation to alternative uses of health care resources. As such, attempts have been made to rank interventions by their cost effectiveness (9,10). Although no official consensus exists regarding an acceptable incremental cost-effectiveness ratio, a *de facto* benchmark of \$50,000 per QALY has emerged. Interventions that cost less than \$50,000 per QALY are often characterized as worthwhile, whereas those costing more than \$50,000 per QALY are often considered to be inefficient.

CARE OF THE HOSPITALIZED PATIENT

Cost-effectiveness analysis is generally regarded as an aid for health policy formulation. Given the premise that we as a society do not have unlimited funds to provide all beneficial health care—no matter how marginally beneficial or how expensive—to everyone, cost-effectiveness analysis can theoretically help to allocate resources to large groups of patients more efficiently.

At the bedside, however, the story may be different. Patients rightfully expect their health care providers to put the patients’ own best interests first, not those of society or their insurer. Health care providers often find themselves serving two masters with opposing paradigms.

What then, should a health care provider do? Ubel and Goold (11) contend that bedside rationing of care that is not economically worthwhile does not violate patients’ best interests. They argue that physicians should play a role in limiting access to marginally beneficial health care services, especially those that patients would not be willing to pay for themselves in cash or in extra insurance premiums. To do this, they state, physicians need to be trained to identify such marginally beneficial services. If one accepts and extends that viewpoint, then it is probably reasonable for physicians to withhold tests and treatments with incremental cost-effectiveness ratios that greatly exceed accepted benchmarks. Table 9.2 lists the cost-effectiveness ratios of some common inpatient practices.

TABLE 9.2**COST-EFFECTIVENESS RATIOS FOR SOME HOSPITAL-BASED INTERVENTIONS**

Problem	Finding	Reference	Comments
Radiofrequency ablation for supraventricular tachycardia	Saves costs and QALYs	13	Comparison is with antiarrhythmic therapy.
Early invasive treatment for unstable angina and non–ST-segment elevation myocardial infarction	\$12,739 per year of life saved	14	Comparison is with conservative treatment (catheterization reserved for recurrent ischemia or positive stress test). Productivity costs included.
Gastric bypass for severe obesity (body mass index 40–50 mg/kg ²)	<ul style="list-style-type: none"> For women: \$5,000–\$16,100 per QALY For men: \$10,000–\$35,600 per QALY 	15	Comparison is with no treatment. Used payer's perspective.
Annual lung cancer screening with helical computed tomography	<ul style="list-style-type: none"> For current smokers: \$116,300 per QALY For quitting smokers: \$558,600 per QALY For former smokers: \$2,322,700 per QALY 	16	Comparison is with no screening.

QALY, quality-adjusted life-year.

CONCLUSIONS

Cost-effective is a buzzword in today's practice of medicine, but the term is often misused and misconstrued (12). Health care practices must be subjected to formal economic analysis before they can be considered to be cost-effective or not cost-effective, and then only when compared with other interventions or consensus standards. When conducted and applied rigorously, cost-effectiveness analysis can aid health care systems in allocating resources as efficiently as possible.

KEY POINTS

- Economic analysis is a tool to allocate limited health care resources efficiently.
- Of the several forms of economic analysis applied in health care, cost-effectiveness analysis is the most commonly used.
- In cost-effectiveness analysis, the relevant evaluation involves the incremental cost per additional benefit received; benefits are usually expressed as years of life or quality-adjusted life-years gained.
- Several types of costs, rather than charges, are germane to cost-effectiveness analysis.
- Published cost-effectiveness analyses may differ with respect to their methodology, which may, in turn, limit comparisons between or among studies.
- Although clinicians have a fiduciary obligation to do what is in their patients' best interests, some argue that withholding marginally beneficial care (or care that is not economically worthwhile) does not violate that obligation.

INTRODUCTION

Electronic information systems are critical to the functioning of today's hospitals. Although there is immense heterogeneity in the clinical information systems (CIS) used by hospitals, almost all hospitals use computers to manage financial and patient registration data such as patient demographics and insurance information, to control bed allocation, and to schedule visits, tests, and procedures. While such systems are often implemented as tightly integrated modules, or as independent but cooperative systems, the same cannot be said for the clinical information systems utilized by individual departments within hospitals. Each separate department, such as the laboratory, radiology, pharmacy, and telecommunications, usually has its own system(s) to manage intradepartmental processes and clinical data.

Unfortunately, the rule rather than the exception is that these departmental systems employ different methods to represent clinical data, making information exchange between them difficult. In fact, the institutions with the most advanced information systems are commonly not those with the most computerized processes, but those with computerized processes that are the most integrated, where added value is derived from sharing and cross-referencing data, in order to detect actionable patterns and trends.

This chapter will focus on advances in CIS that are most directly related to providing care to hospitalized patients. These can be broadly classified into two categories, basic and advanced.

BASIC CLINICAL INFORMATION SYSTEMS

Basic clinical information systems are essentially passive tools that increase access to clinically relevant patient information. In the typical hospital, most ancillary departments (such as laboratory, blood-bank, microbiology, radiology, etc.), use their own departmental information systems. These systems manage the local workflow, such as accounting, scheduling, ordering and resulting of tests and procedures performed in the department. Clinical data from these systems are aggregated into a clinical data repository that allows the clinician to have an integrated view of clinical information without the necessity of going to several individual results terminals (Figure 10.1). More sophisticated results viewers augment the informational value of the presented data by co-displaying related results or graphically trending results.

Another example of a basic CIS application is the *report generator*, which is a tool for viewing data across multiple patients. Traditionally utilized by hospital administrators to focus quality improvement or cost reduction efforts, it also is tremendously useful to the rounding physician for keeping track of his or her patients. It can also reduce errors, as demonstrated by one computerized "coverage list" application that standardized the information exchanged between physicians on sign-out, a problem list, medications, and active issues (1, 2). Often, the quality of these reports can make or break a roll-out of a new CIS because, unlike with lab results that

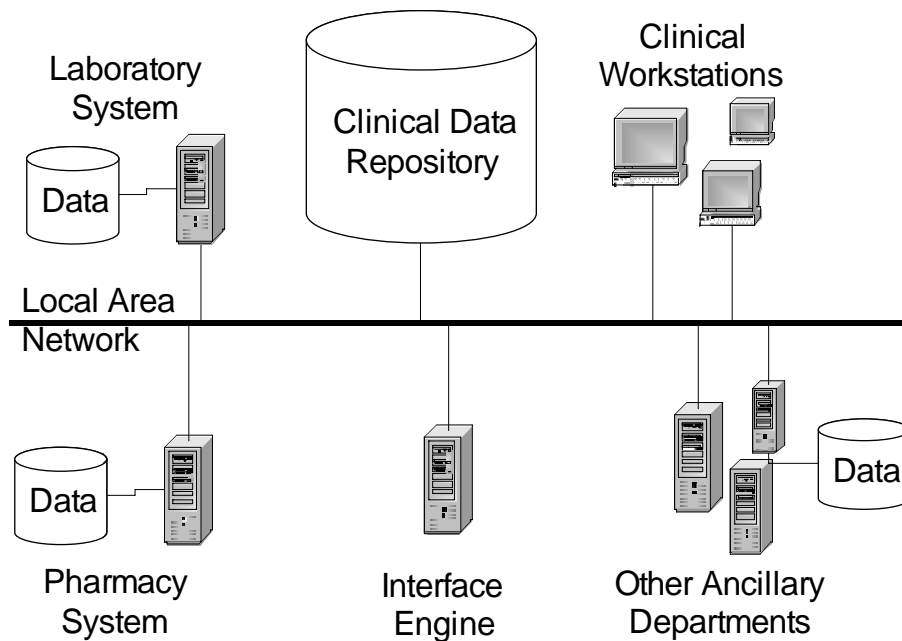

Figure 10.1 Basic hospital clinical information system.

continue to be printed and inserted into the paper chart, there are often no back-up mechanisms to make up for deficiencies in patient tracking. Nothing irritates physicians more than not knowing for which patients they are responsible, where they are located, and what their test results are.

When different types of results viewers are integrated under a single shell, the result begins to form the foundation for an *electronic medical record* (EMR). With an EMR, clinicians can review (to varying degrees), the entire medical history (remote and recent) of the hospitalized patient, along with additional functionality to support clinical decision making. As with hospital information systems in general, the more information that is stored, and the more integrated the data, the more impact an EMR can have on patient care. While typical EMRs record patient allergies, medications, and patient encounter reports (such as consultations, admission history and physicals, discharge summaries, and operative reports), these data elements are usually stored as free-text entries, which restricts how effectively the CIS can impact patient care, as discussed below.

In addition to convenient access to patient information, basic CIS also can provide convenient and quick access to reference information. The Internet has revolutionized the manner by which patients and physicians look up facts, figures, and opinions. As libraries and publishers offer more of their offerings in electronic formats, simply providing terminals with Web access throughout hospitals effectively provides clinicians with a virtual mobile library. Many hospital CIS offer an intranet portal to this material, which can include textbooks, drug information compendiums,

medical journals, medical literature search engines, and locally developed or authored material, such as clinical guidelines, manuals, policies and procedures, forms and formularies, bulletins and newsletters. All members of the hospital staff, not just physicians, commonly and regularly visit these portals (3, 4). Furthermore, such portals have great potential to be unifying forces, especially for integrated delivery networks distributed across multiple institutions and regions.

ADVANCED CLINICAL INFORMATION SYSTEMS

Advanced CIS are characterized by increased interaction with the physician or care provider in return for decision-support, or patient-specific recommendations and guidance about therapy or diagnosis. This usually requires that the clinician contribute data to the system. The most common example of this is computer-based provider order entry, but other advanced CIS include event monitoring, electronic documentation, and barcoding.

Computer-Based Provider Order Entry

With computer-based provider order entry (CPOE), orders for medications, tests, or procedures are entered into the hospital CIS and dispatched to the appropriate departments, either electronically in integrated environments, or printed/faxed. At the least, the computer ensures that

orders are legible and complete. Order sets can further simplify and speed up the ordering process for common scenarios (5). The real advantage of computerized orders is that they can be checked against the patient’s allergies, current medications, and recent lab results, triggering alerts when a potentially dangerous order has been entered, such as a medication to which a patient is allergic or perhaps cross-sensitive, a medication that has a dangerous drug interaction with another agent that the patient is taking, or a medication whose dose must be adjusted because of impaired renal or hepatic function.

The data on which any computerized decision support intervention runs must be represented in a coded form. This requires that the provider enter allergies, medications, and other data into the system in a computable form, not as free-form text. This can be done in a variety of ways, the most common being a look-up function or “quick-pick” list of one form or another. Although structured data entry is unavoidably time-consuming, many objective studies of well-designed order entry systems show that only a minimal extra time investment is required, and, in the long run, they may in fact be time saving (6,7). But even if they do take a bit more time, this must be balanced against the potential positive impact on patient safety, particularly in the hospital setting (8). For example, one CPOE system, with limited decision support, prevented 55%–86% of serious medication errors that otherwise would have reached the patient (9, 10). Decision support tied to CPOE can also reduce costs (11, 12).

One way that hospitals have tried to ensure successful implementations of computerized order entry is by delegating the time-intensive burden onto clerical staff rather than

physicians—physicians write orders by hand in the usual way, and then a unit secretary transcribes the orders into the computer. Although this technique can still prevent errors in the transmission of orders to ancillary departments, decision support is sabotaged because the opportunity to interact with the decision-maker is bypassed.

CPOE is only half the equation when it comes to implementing effective decision support. The other half is crafting, testing, and maintaining the knowledge base of rules that fire and provide corrective recommendations (13,14, Table 10.1). Some rules are readily agreed upon and rarely change (such as *when* to alert on critical lab results), but deciding (and encoding) *who* to alert (physician, nurse, or pharmacist; and which particular one) and *how* (text page, e-mail, or phone call) can be difficult and politically charged (15–17). Even implementing basic drug-allergy checking requires the maintenance of accurate and ever-expanding drug and allergen families (18,19). Even more complicated and labor-intensive is the compilation and maintenance of rules which drive drug-drug (20), drug-disease, and drug-lab interaction checking.

An emerging problem at institutions where extensive rules are implemented is how to reconcile when multiple conflicting rules are triggered—for example, a rule that suggests a formulary change to another medication to which the patient is allergic, or a renal-based dosing rule which suggests a dose that violates an age-based dosing rule. In such cases, more complicated meta-rules must be crafted, tested, and maintained, quickly leading to a situation where the behavior of the CIS system as a whole is difficult to predict and test.

EXAMPLES OF DECISION SUPPORT RULES

Type	Example	References
Drug-allergy	Warn of possible cross-sensitivity when physician orders “Keflex” for patient allergic to “amoxicillin.”	19
Drug-drug	Not allow a clinician to concurrently order linezolid and pseudoephedrine because of the risk of severe hypertension.	21, 22
Drug-lab	Warn physician of danger when ordering “digoxin” for patient with a recent potassium level under 3.0.	15, 16, 17
Drug-disease	Warn of a possible adverse event when ordering lovastatin in a patient with cirrhosis.	23
Therapeutic/route substitutions	Suggest switching from intravenous to oral formulation, or from proton-pump inhibitor to an H2 antagonist.	10, 24
Dosing	Suggest lower dose of a drug for patient with renal insufficiency, or an alternative medication in an elderly patient (oxazepam instead of diazepam).	25, 26
Computerized practice guidelines	Suggest appropriate diagnostic or therapeutic steps for a patient admitted with community-acquired or ventilator-associated pneumonia.	27–30

Event Monitoring

An event monitor is a computer program that continually reviews information transactions (or events) that occur within a CIS. As depicted in Figure 10.2, an event monitor or alerting system “listens” for clinical events by monitoring the data transactions occurring across the network. An event that activates a rule is called a *trigger event*. A trigger event may prompt notification of the appropriate clinician with an e-mail or page, depending on the severity of the event. Examples of trigger events are a new lab result for a patient, a new patient registration, a new order, or documentation of a patient encounter. The event monitor examines the new data and decides which, if any, of a database of rules applies to this new piece of data.

A rule usually is encoded as a simple logical statement. For example, “if the patient has a diagnosis of coronary artery disease and the patient is not currently taking aspirin, then remind the physician to order aspirin for the patient,” or “if the patient has a new serum potassium result of less than 3.1 meq/liter and the patient is receiving digoxin, then generate an alert notifying the physician about the new lab result.” These examples are represented in free text form, but actually must be translated into very precise logical operations on coded concepts in order to have meaning to the CIS.

Rules may require that the event monitor look up other patient-specific data, and so the event monitor must have access to the clinical data repository. When rules are evaluated as “true,” some consequent action results. The result of a true rule can be a new monitored event that

might trigger another round of rule evaluation, or an unmonitored event, such as the sending of a text message by page or the generation of a report of a possible adverse event (31, 32).

When it comes to impacting patients’ care, an event monitor is only as good as the events which can invoke it, the database(s) of rules which it computes, the set of other CIS components with which it can communicate, and the breadth of effects or mechanisms at its disposal (e.g., sending e-mail, paging physicians, generating printed reminders, etc.). However, even simple monitors can be quite effective, especially for critical lab values, for which event monitors have been shown to increase the rate and pace of appropriate care, as well as to reduce morbidity, and even decrease length of stay (33–35).

Electronic Charting and Documentation

Having clinical information in electronic form is valuable for a variety of reasons. Most notably, electronic data can be made available remotely, so the physical limitations of the paper chart are removed. Also, data in coded form are available for clinical decision support (event monitoring). Coded data can also be used for billing, research, management and quality assurance analyses. Clinicians’ documentation of the clinical encounter, if represented electronically, could be a boon to quality and safety improvement efforts (see Chapters 12 and 20).

Traditionally, the clinical encounter has been captured on paper, or as transcribed dictation. Although transcription makes the data available for remote viewing (assum-

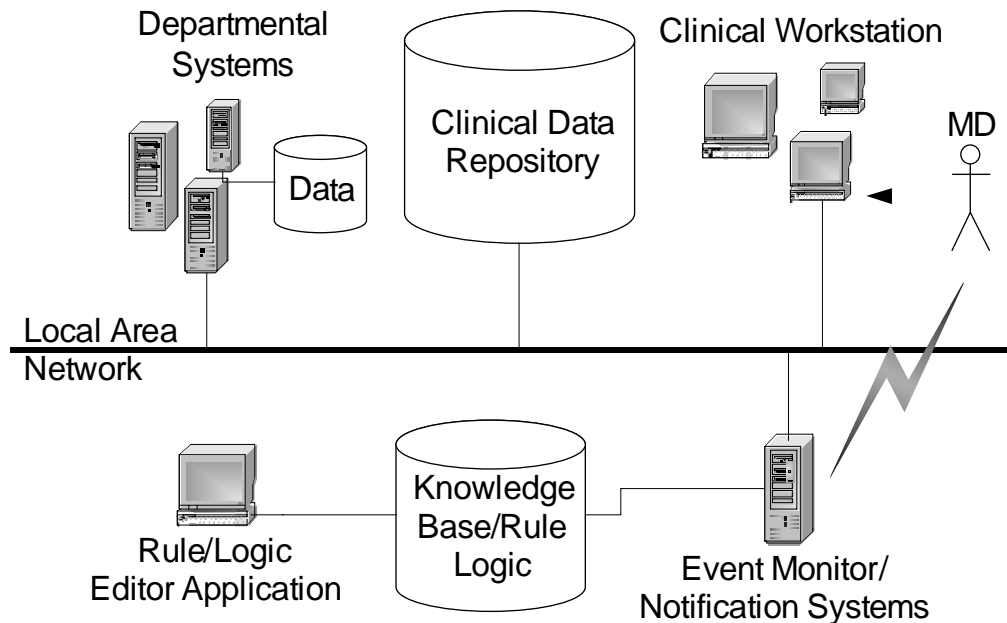

Figure 10.2 Architecture of an event monitor.

ing the appropriate electronic interfaces are in place), the data are not represented in coded form and so are not available for clinical decision support. Many efforts over the last 10–20 years have focused on how to capture encounter information directly from clinicians. As physicians have become increasingly comfortable with typing, many providers now type their encounter notes into the computer themselves. This eliminates the need for transcription (and results in large cost savings); however, it does not result in coded data.

Capturing coded data from clinicians is complex (36). As the requirements for structuring data increase, the flexibility of the data input and expressiveness of the resulting documentation may decrease, thus decreasing physician satisfaction and willingness to use such systems. How best to encode medical concepts involved in documentation (e.g., signs, symptoms, diseases, problems, etc.) is also complex and still lacks a standard solution (37, 38). With the recent free availability of SNOMED (39) (a controlled terminology that attempts to cover these domains), progress towards a more robust and standardized representation of clinical concepts in a computer should proceed more rapidly, which should result in more useful structured physician documentation programs.

Barcoding

Medication errors have been shown to be common (40, 41), and a large proportion (61%) of them occur in the dispensing, transcribing and administering stages (42), after CPOE has had its chance to eliminate them. Barcode technology, in conjunction with an electronic medication administration record system, has been proposed as a promising way to reduce medication errors at these stages (43). However, its efficacy for reducing medication error rates, its acceptance by staff, and its cost-benefit ratio have yet to be evaluated (see Chapter 21).

OTHER CLINICAL INFORMATION SYSTEMS ISSUES

Success Factors for Implementation

The successful implementation of a clinical information system requires more than just a suite of applications that provide the functionality of reviewing test results, entering orders, and guiding decisions. Even systems that perform these functions well may fail to gain the acceptance of their intended users, most notably physicians (44). The problem is that any implementation requires changing practice habits, and such change is difficult even when there is excellent evidence to support the change (45, 46).

There appear to be several factors associated with successful implementation of electronic medical records and decision support. These include both application-dependent characteristics (those that are quick, anticipate the clinician's needs and behaviors, integrate as much as possible into the current workflow, minimize data entry, and guide rather than prevent action) (47) and organization-specific factors (motivation/vision, clinical and administrative leadership, involvement of clinical users, adequate training and support, and responsiveness to user feedback) (48, 49).

Security

All hospital information systems must protect the privacy and confidentiality of clinical information, and the security of their systems. Recent regulations, codified in the Health Insurance Portability and Accountability Act (HIPAA), have defined privacy and security requirements for clinical information systems (50). Typically, hospital information systems operate behind an enterprise “firewall” which guards against intrusions from the outside. Within the hospital environment, access privileges to the information systems are often controlled at the departmental level, or sometimes by the information systems or medical records department. In any case, information security is maintained by requiring users to employ a two-step login procedure (user name and password) to identify themselves and gain permission to use appropriate functions or systems within the environment. Biometric identification (e.g., fingerprint scan) is rarely used today, but may become more common in the future as the reliability of these technologies improves.

Once authenticated into a CIS, a “role-based” security model is often employed to allow users to access information systems applications appropriate for their role. For example, a physician may be permitted to review all clinical data, but a scheduling clerk may be only allowed to access patient demographics and scheduling information. Selected patient-specific information within the CIS environment may also be partitioned off for medical-legal reasons. For example, in some states, HIV test results require special access provisions. Also, in certain settings, mental health-related clinical information might require additional permissions to access. In most settings, however, system designers allow authorized clinical personnel to access any and all clinical information on a patient in an emergency condition, although such access is usually logged.

Hospital Information System Architectures

Most hospital information systems deliver clinical data and functionality to desktop personal computers connected to

the hospital network. As depicted in Figure 10.1, ancillary departmental systems communicate via the hospital network to a clinical data repository that aggregates clinical data for presentation to the end user. An interface engine transfers data from one system to another. Additionally, personal computer desktop clinical applications, or Web-based applications, may access the clinical data repository data to present it in useful ways for the end user. For example, as described above, a results viewer application may format clinical laboratory data pooled in the clinical data repository in a way that facilitates rapid review of electrolytes, hematology values, or other data. The most common architecture in use today is a “client-server” architecture that consists of a “back-end” database hosted on a computer (the server), communicating via a secure network to a “front-end” desktop application or Web page (the client), which is viewed by the end user. This approach affords a flexible approach to both front-end and back-end systems design, implementation, and maintenance. Newer approaches may use “application servers” to provide application functionality via Web-based technologies on the client desktop. Additionally, as newer technologies emerge, the front-end may be delivered via wireless network connections that allow the user to access clinical information while mobile, using laptop personal computers, handheld devices, or even cellular phones (51–53).

THE ROLE OF THE HOSPITALIST IN CLINICAL INFORMATION SYSTEMS

The hospitalist can play a unique and pivotal role in the development, implementation, and support of the hospital’s clinical information system. First, as a prime consumer of the services provided by CIS, hospitalists are extremely motivated to make sure that the CIS is effective. Because they are at the point of care on a day-to-day and minute-to-minute basis, hospitalists are well positioned to understand the problems of the current health care system and the ways that information technology can help improve matters.

Second, as systems-oriented providers well versed with the processes already at work within the hospital, hospitalists are valuable sources of insight to the developers and implementation team about what will or will not work. They should understand the potential benefits and limitations of information technology to improve care, and mechanisms should be created to regularly elicit their opinions about these matters.

Third, as respected members of the hospital staff and effective communicators, hospitalists can provide leadership in these efforts. One way to promote this is to have hospitalists play an active role in developing and maintaining rules. But, even putting aside specific operational roles,

hospitalists should be advocates for the use of IT as an important way to improve care, and be intimately involved in developing and implementing such systems to ensure that they achieve their intended goals of improving patient care processes, work flow, and outcomes.

CONCLUSIONS

Hospital information systems are critical to the functioning of the modern hospital. They are central to almost all core hospital activities, not just to patient care. Hospital information systems are varied, and the system as a whole can be hampered by the lack of interoperability between subsystems. However, effective hospital information systems can improve patient outcomes, reduce costs, and increase satisfaction among providers. Hospitalists can play a pivotal role in ensuring the success of their hospital’s information system.

KEY POINTS

- Hospital information systems are critical to the functioning of today’s hospitals, but are limited by poor interoperability and uncoded data entry.
- Effective hospital information systems can improve patient outcomes, reduce costs, and increase satisfaction among providers, largely through clinical decision support provided during order entry, and notification to providers of “panic” or other abnormal test results.
- Successful implementation of advanced hospital information systems requires not just good computer programs, but all the systems, processes, and values that go into changing practice patterns and managing user expectations.
- Hospitalists are uniquely positioned to help develop and implement successful hospital information systems, which can increase their own efficiency and ability to provide high quality care to their patients.

Effective Clinical Teaching in the Inpatient Setting

Karen E. Hauer David M. Irby

INTRODUCTION

Inpatient physicians at academic medical centers and teaching hospitals face the opportunity and challenge of combining a busy clinical practice with teaching responsibilities. Attendings can serve as powerful role models and expert instructors of inpatient care for trainees, potentially leading to better future performance and greater interest in internal medicine as a career. Trainees who work with the most highly rated clinical instructors have been shown to perform better on standardized examinations and to be more likely to pursue the specialty of their most valued teacher (1, 2). Highly effective clinical teachers share common traits—they are enthusiastic, they actively involve learners in the educational process, and they plan carefully prior to teaching (3).

In this chapter, we will outline the planning strategies, teaching methods, and reflective practices that inpatient attendings or residents can use to teach and lead a team successfully (Table 11.1). With many academic health centers now employing hospitalists, the inpatient attending role is becoming the responsibility of fewer, more highly experienced physicians (4). Nevertheless, the principles described in this chapter apply to all inpatient team leaders. The *planning* step involves jointly setting expectations with team members, establishing a positive learning climate, and planning for instruction. A variety of *teaching methods* are needed to meet the multiple learning needs of the team in a patient-centered environment. *Reflection* is the process of making sense out of experience and is pro-

moted through thoughtful self-evaluation by learners. This chapter will describe how to apply these three steps with an inpatient team.

PLANNING STRATEGIES

The norms of a group are set at the outset, so attendings should take time to clarify expectations for the team and create a positive learning climate at the start of the rotation. The team will function more effectively and efficiently when responsibilities and roles are clear and consistent.

Jointly Set Expectations

Rounds and Patient Care. Defining expectations at the outset can mitigate later confusion about what was expected or whether a learner has satisfactorily met the requirements of the rotation. Specifically, behaviorally focused expectations are better than generalities. The attending could start this discussion with, “I’m going to share with you the day-to-day expectations I have for all of you to help the team run smoothly; let me know if you have other suggestions.” Expectations should be addressed regarding rounds, presentations, workload, communications with the attending, and days off.

Structure of Rounds. Define the relative allocation of time devoted to patient care versus didactics or other teaching. For 90-minute attending rounds, the attending might suggest, “I’d like to devote no more than 30 minutes to

TABLE 11.1
STRATEGIES FOR SUCCESSFUL
INPATIENT TEACHING

Planning

- Team planning
 - Set clear expectations and provide a rationale for them.
 - Establish learning goals.
 - Create a positive learning climate.
 - Describe the feedback, evaluation, and grading process.
- Plan for teaching

Teaching Methods

- General principles
 - Be learner-centered.
 - Make the same thing count twice by integrating teaching and feedback with patient care.
- Specific methods
 - Teach at the bedside and actively involve the patient and learners.
 - Target teaching to learner needs using the “One Minute Preceptor” model (Table 11.3).
 - Develop and use teaching scripts to address common inpatient illnesses (Table 11.4).
 - Use clinical reasoning in conference room teaching.
 - Promote pattern recognition for classic presentations.

Reflection

- Encourage learners to self-assess and to reflect on their performance.
- Provide frequent, behaviorally focused feedback.
- Include areas for improvement with feedback.
- Schedule periodic meetings for formal feedback.

updates on the patients on the service, and leave the last hour for didactic teaching or more in-depth discussion of our toughest case of the day. You can expect that I will have pre-rounded on all the patients, so your presentations can be short and focused.”

Presentations. Outline the format and length of presentations for attending rounds and work rounds, and the amount of detail to be provided to the attending versus the resident (Table 11.2). For example, for hospitalists, the traditional model of post-call attending rounds, with the attending first learning about new patients when trainees recite detailed oral presentations, may need to be modified (4). Instead, the attending, who has already seen many of the new patients on call, may prefer to focus on specific teaching points about a case, or on certain patients who raise complex management questions. The resident who leads work rounds should also clarify how much information should be presented for each patient. For example, student presentations can be streamlined with advice such as, “Be sure to update your problem list each day, omitting problems that have been resolved,” and “You only need to present labs from the past 24 hours, and only those that are abnormal.”

Presentations lasting under 5 minutes are desirable for both trainees and attendings. Trainees may find delivering briefer, more targeted presentations to be challenging, since they lack the background to identify which information to omit after spending hours with the patient and a thick medical record. Learners may be inclined to talk faster or to guess what the attending wants (5). Instead, shorter presentations should prompt the presenter to identify the most pertinent positive and negative data in advance of the assessment. So that trainees are not left guessing what type of presentation the attending will want each post-call day, the attending should state at the start of the month, or on each call day, his/her expectations regarding presentation format. For instance, the attending might say during an on-call phone conversation with the resident, “It looks like we’ll cap tonight with 10 new admissions, so please ask each student to be prepared to present a case in no more than 5 minutes, focusing the H & P on the pertinent positives and negatives, and discussing only the main one or two problems in the assessment and plan.”

Number and Complexity of Patients To Be Followed. It is particularly important to define this expectation for students.

Communications with the Attending. Tell the team members when to consult or page the attending (such as with critical changes in patient status or possible DNR orders). Explain how best to communicate with the attending (phone versus pager) and the types of clinical situations that warrant immediate communication (versus waiting until rounds). Define regular check-in points throughout the day (e.g., morning rounds with the team and afternoon phone rounds with the resident), and plan for how and when the attending will be involved with new admissions.

TABLE 11.2
GUIDELINES FOR INPATIENT ORAL
PRESENTATIONS

- No more than 5 minutes long
- Focus on pertinent positives and negatives—the data that support the differential diagnosis
 - Chief complaint
 - HPI: chronologic, begins with prior medical evaluation and treatment of current problem (if relevant), then current symptoms, then pertinent positive and negative review of symptoms
 - Medical history: major or relevant medical problems
 - Medications: list only without doses
 - Allergies
 - Social history, family history if relevant
 - Exam: vital signs, general appearance, pertinent positives and negatives
 - Laboratory data: abnormal values, pertinent normal values
 - Assessment: differential diagnosis, linking findings above to the most likely diagnoses
 - Plan for each major problem

Adapted from McGee SR, Irby DM. Teaching in the outpatient clinic. Practical tips. *J Gen Intern Med* 2001;16:308–314.

Days Off. Describe the coverage system for team members on days off. For continuity of patient care, it is optimal to have some team members in house every day, by staggering the days off among the team members.

Establish Learning Goals

At the start of the rotation, discuss individual and group learning goals. The attending can initiate this discussion by saying, “I’d like to learn a bit about your interests and goals, so that we can make this month as valuable as possible.” Housestaff and students may have initial trouble identifying learning goals—“I’ll learn about whatever you want to teach”—but the attending can help team members identify types of learning opportunities in the inpatient setting. For example:

- Clinical skills: physical diagnosis, physical exam of ICU patients, functional assessment of elderly patients
- Diseases and symptoms: evaluation of rash, approach to acute chest pain
- Evidence-based use of diagnostic testing
- End-of-life care
- Role of the physician in the hospital: time management and prioritization, teamwork with ancillary health providers, discharge planning

Create a Positive Learning Climate

The first attending rounds begin with introductions, including interests and goals. In this session, the attending seeks to establish a learning climate that is participatory and respectful of learners at all levels. He or she signals that the team will collaborate in patient care and in the education of one another. He or she role models the enthusiasm, humor, and personal commitment that will support the team’s education, motivate performance, and promote teamwork. By inviting questions and suggestions from all team members, the attending also fosters critical thinking and sets the stage for interactive learning, trying to avoid a passive climate in which the attending does most of the talking.

Explain the Process for Feedback, Evaluation, and Grading

Learners should be alerted to the feedback and evaluation process at the start of the rotation. It is important to set a schedule for feedback so that learners will know when to expect feedback and recognize it when they are receiving it. For instance, students will want to know when they will receive feedback on their new patient presentations—immediately after the presentation, later that day, or the next day away from the whole team. The attending might say, “I will plan to give you feedback on your new patient presentations on the post-call day; and if I haven’t given

you feedback, it’s your job to remind me by the end of the day.”

The first attending rounds is also a good opportunity to set a schedule for the three key feedback meetings of the rotation—a first meeting to set expectations and discuss learning goals, a mid-rotation meeting for feedback on progress to date and to decide on priorities for the remainder of the rotation, and a final meeting at the end of the rotation to discuss the evaluation.

For evaluation, the attending should define the attending role: what form or procedure is used, and when it will occur, particularly for students who may be graded on the experience. Students should also be informed of others who may provide input into their final grade.

Plan for Teaching

Attending rounds teaching by necessity is a combination of prepared material and improvised discussion of patients. Attendings who only present prepared didactic material may be perceived as inflexible, and—if their material is only peripherally related to patient care—irrelevant. Alternatively, attending rounds that are focused solely on patient discussions may seem like a disorganized repetition of work rounds. Effective clinical teachers choose one of a number of planning strategies (and often make this choice explicit to the team at the orientation):

- Seeing patients before rounds to expedite presentations and allow for more teaching time
- Reading and preparing handouts before rounds
- Checking in with the resident the day or night before to learn about new patients and solicit topics of interest to the team

Work rounds are the main format for resident teaching and the critical time for most patient care decision-making. To plan for work rounds, the resident should review the patient list each night to identify three to five relevant topics (diagnoses, test results, responses to treatments) to address as teaching points on work rounds the next day. Writing these topics on the patient data cards or in the handheld patient log will remind the resident about these teaching points during discussion of the corresponding patient.

TEACHING METHODS

Highly rated clinical teachers share common characteristics that make their instructional style effective and well received. They are *enthusiastic* about their work and teaching. Inpatient attendings, and hospitalists in particular, have the opportunity to model enthusiasm for inpatient generalism, distinguishing it from ambulatory and subspecialty care. For many housestaff, the presence of dedicated inpatient attendings validates the many months they spend on

inpatient rotations by presenting it as a viable and exciting career option. *Flexibility* is a key skill used by effective teachers to adapt their content and teaching style to learners. For instance, a flexible attending will recognize that a post-call intern may not be inclined to generate a long differential diagnosis for chronic abdominal pain, preferring to focus on “what tests do I need to order today.” Effective clinical teachers *embed their teaching in the context of cases*, helping learners to retain more information. A particularly powerful learning tool is comparing and contrasting. The attending can stimulate analytic comparisons with questions like, “How does the cardiac exam in this case of shortness of breath differ from the one in the patient we admitted last week with congestive heart failure?” and “What are the key features of each patient’s illness?”

Teach at the Bedside and Actively Involve the Patient and Learners

The traditional model of bedside teaching involves the attending shepherding the entire team to the bedside to demonstrate or teach one aspect of physical examination. This process can be quite time-consuming. It can also be difficult to involve all learners actively with one finding or exam technique, often relegating interns or students to the back of the room while others auscultate a murmur. Because many inpatient attendings now aim to see patients on the day of admission, traditional post-call bedside rounds may not synchronize with clinical events, and patient findings may even have resolved.

Attendings who periodically join the team’s work rounds (e.g., post call or on the resident’s day off) can teach at the bedside while conducting real-time patient care. However, the frequency of such participation in rounds must be carefully planned to maintain the balance between housestaff autonomy and supervision, and the team should be notified in advance of attending participation.

A practical way to implement bedside teaching during the attending’s own walk rounds is for the attending to periodically bring one or two learners, particularly students. With the first patient, the learners can observe the attending doing a focused interview and exam. The attending should prepare the learner in advance for what he or she will model at the bedside (6). For example, “I’m going to discuss code status with this patient; watch how the patient responds to my questions,” or “My plan is to discuss the risks and benefits of a biopsy versus empiric treatment; see how well you think the patient understands these options.” This process can be enhanced by debriefing the learner afterward about general strategies used to address similar problems, or principles the case illustrates. With the next patient, the learner can take the lead, allowing the attending to observe and provide feedback.

For the resident leading work rounds, a major teaching method used at the bedside or in the hallway is *questioning*:

asking interns and students to interpret findings, share their assessment, or suggest a management plan. In general, starting with the junior students and working up to interns allows everyone to participate. Questions should be open-ended to stimulate critical thinking (“How would you put these two findings together?”) rather than closed-ended (“What is the most common cause of . . . ? What is the definition of . . . ?”). The other fundamental form of resident teaching is bedside teaching of clinical skills, via modeling of appropriate interaction with patients and verification of clinical findings. The resident should keep in mind that sloppy bedside technique, such as a superficial examination through the patient’s gown, while time-efficient, sends a powerful implicit (and unhelpful) message to learners.

Target Teaching to Learner Needs Using the “One Minute Preceptor” for Case Presentations

For daily case presentations, the “One Minute Preceptor” model (Table 11.3) is a useful format that actively involves the learner and incorporates immediate feedback (7). Developed for the ambulatory setting, it can be readily adapted to hospital teaching. After a learner presents the patient data, the model suggests an alternative to a long, meandering discussion of a broad differential diagnosis. Instead, the One Minute Preceptor asks focused questions that help “diagnose” both the patient *and* the learner: “What do you think is going on with this patient?” or “What do you want to do for the patient? What led you to this conclusion?” Based on the answers to these questions, the attending teaches a general point, provides positive feedback, and recommends improvements.

Learners should be advised in advance whether new patient presentations will occur in the hallway or at the bedside. Trainees often prefer conference room or hallway presentations, because bedside presentations may seem intimidating and time-consuming. Bedside presentations nonetheless have advantages: patients may enjoy the attention and information, and bedside presentations ensure some role modeling of bedside care (8). A reasonable balance can be achieved by selecting a few of the most clinically active patients with easily demonstrated physical findings for bedside presentation.

Develop and Use Teaching Scripts to Address Common Inpatient Illnesses

Effective clinical teachers have teaching scripts for common and/or important clinical symptoms and presentations (9). A teaching script is an outline that includes the goals for instruction on a given topic, key teaching points and teaching methods, and learners’ typical conceptions and challenges in mastering the topic (Table 11.4). An inpatient attending

TABLE 11.3
THE ONE MINUTE PRECEPTOR—5 EASY STEPS

One minute preceptor steps	Example
The learner presents a case.	A 40-year-old woman with 3 days of shortness of breath and pleuritic chest pain.
1. Get a commitment: What do you think is going on with the patient?	"What do you think is going on with this woman?"
2. Probe for supporting evidence: What led you to that diagnosis?	"What led you to think of PE in this case?"
3. Teach general rules.	"When clinical suspicion of PE is high, heparin should be started prior to obtaining an imaging study."
4. Reinforce what is done well: positive feedback.	"You did a nice job eliciting the potential risk factors for PE."
5. Correct errors.	"A normal oxygen saturation does not rule out PE, particularly in a previously healthy patient without underlying cardiopulmonary disease."

From Furney SL, Orsini AN, Orsetti KE, Stern DT, Gruppen LD, Irby DM. Teaching the one-minute receptor. A randomized controlled trial. *J Gen Intern Med* 2001;16:620–624.

might do well to develop a "toolbox" of 10 to 20 teaching scripts for the most common inpatient symptoms and diagnoses.

Teach Clinical Reasoning in Conference Room Rounds

The explosion of information related to inpatient medicine means that trainees can no longer be expected to have memorized all of the diagnostic criteria and diagnostic steps for every patient presentation. More important than sharing factual knowledge is facilitating the opportunity for critical thinking and self-directed learning. The attending can model critical thinking with every admission. What pertinent information from the history and physical examination led to this diagnostic hypothesis? How were tests interpreted, and how accurate are the tests that were obtained? Although every attending will have his or her

own style and technique, the most effective inpatient clinical teachers have been shown to use the following principles to promote active learning (10):

First, instruction should be *anchored in clinical cases*. Learner interest and retention will be highest when material is presented in the context of a fascinating or compelling case. The inpatient setting, with the constant stream of new patients, high acuity, and immediately available diagnostic information, provides a rich opportunity for case-based instruction. Adapting teaching scripts can be a very useful strategy here.

Second, *actively involve the learners*. In the conference room, ask each team member to read about a portion of a case (a lab value, physical finding, or item on the differential diagnosis) in advance of the next day's attending rounds. At the bedside, rather than demonstrating a physical finding on a new admission, ask the intern or student to model the exam for the group, and then solicit suggestions from other group members.

Third, *model professional thinking and action*. Although the focus of inpatient teaching is often the didactic attending rounds presentations, much of the teaching and learning occurs in the real-time management of patients. Some of the best teaching comes when the attending talks through a clinical case, sharing the clinical thought process and modeling inpatient expertise. The learner will also then see how the attending deals with uncertainty—how he or she works through different diagnostic possibilities, resolves ambiguous test results, and explains clinical situations to patients and families.

Promoting pattern recognition. Something that looks, sounds, and behaves like your Aunt Minnie is likely to be your Aunt Minnie—there is little need to systematically consider other possibilities (11). In the inpatient setting, where disease often presents in fulminant, dramatic fashion, this teaching principle can be used to highlight

TABLE 11.4
A TEACHING SCRIPT FOR THIRD-YEAR MEDICAL STUDENTS: GI BLEED

- **Goals for instruction:** understand the differential diagnosis and management of a patient with GI bleed
- **Key teaching points:** distinguishing upper from lower GI bleed, identifying the major causes of GI bleed, initiating a diagnostic workup, and stabilizing the patient
- **Teaching methods:** interactive, based on case admitted to the team
- **Knowledge of learners' typical conceptions of and difficulties in mastering specific content:** students typically have difficulty using clues from the history to distinguish causes of GI bleeding, and integrating information to risk-stratify the severity of the bleed

From Irby DM. Three exemplary models of case-based teaching. *Acad Med* 1994;69:947–953.

classic cases. Instead of asking learners for an extensive case presentation, attendings can request a presentation of the patient's identifying information, chief complaints, or reasons for hospitalization, followed by the working diagnosis. The discussion would then focus on the confirming and disconfirming findings and data.

For example, consider the case of a patient with metastatic cancer who presents with abdominal complaints, altered mental status, dehydration, and worsened bone pain—all hallmarks of hypercalcemia of malignancy (see Chapter 92). Rather than an analytic discussion of differential diagnosis, this method focuses on those key features that learners will remember vividly. Of course, experienced clinicians also expedite their patient assessments by relying on their memory of prototypical case examples, so this method has the additional advantage of introducing trainees to this technique.

REFLECTION

Promoting Reflection in Learners

To encourage self-improvement among trainees, the attending should promote self-assessment and reflection (12). Feedback and evaluation meetings should generally begin with, "I'd like to start by hearing how you think you're doing on the rotation." Rather than telling learners how they've done, or worse yet having them find out the attending's impressions when they read their written evaluation months later, the goal is to create an ongoing dialogue. Although trainees may be reluctant to self-assess, they will feel increasingly comfortable if the attending creates an atmosphere that is collegial and nonjudgmental.

A positive, reflective learning climate is also fostered by allowing for the admission of errors and uncertainty. The attending can model the way in which he or she handles personal limitations—talking at attending rounds about any mistakes that occur in patient management, sharing how to fill in knowledge gaps, and inviting the team to analyze cases with poor outcomes.

To encourage reflection, periodically ask learners to identify one thing they learned from each patient they discharged in the prior week. This strategy is known as "Learning Rounds" (13). It can also be a useful reminder to reflect upon patients who have died, offering trainees the opportunity to learn from deaths on the service and process their emotional reactions to terminal illness (see Chapter 19) (14).

Feedback

Trainees consistently want more feedback and complain that they have not received enough. Feedback provides learners with information about their performance for the purpose of improvement. The attending and resident should create an atmosphere that promotes feedback with

careful planning. Residents in particular may not realize that giving feedback is a critical component of effective teaching. Key steps for effective feedback include the following:

- *Set the expectation for feedback* at the start of the rotation. Explicitly state, "Feedback is a priority, and it will occur on a daily basis, with more in-depth feedback meetings midway through the rotation and at the end." Demonstrate an openness to receiving (as well as giving) feedback by soliciting feedback: "I'd like to hear from you how you think I'm doing, teaching at attending rounds, and what I could do to make that time even more useful for you."
- *Immediate feedback* on a daily basis is ideal after hearing a presentation, reading a note, or observing a bedside encounter. Within 5 minutes, give the learner positive feedback to reinforce a specific behavior and make a suggestion for improvement.
- The feedback should be *behaviorally focused*—a description of the specific action performed ("The way that you followed up on the history of alcohol use by quantifying the amount the patient drinks was helpful in revealing the potential impact of alcohol abuse on the cirrhosis") rather than generalizing with adjectives such as "great history" that do not reinforce specific behaviors.
- Feedback should be *based on direct observation* whenever possible. Because residents conduct daily walk rounds

TABLE 11.5 GIVING CONSTRUCTIVE FEEDBACK AND MAKING RECOMMENDATIONS FOR IMPROVEMENT

- **Ask the learner to self-assess.** Questions like "How did you feel about your code discussion with the patient?" encourage reflection and often prompt the learner to articulate concerns shared by the attending.
- **Focus on behaviors, not the person.** Instead of saying, "Your presentation style is too slow," feedback could be phrased: "By identifying the pertinent positives and negatives in this patient's physical exam, you can omit the other parts of the exam, like the neurological and skin, to shorten your presentation."
- **Label the feedback "constructive" instead of "negative."** Highly skilled trainees may not have any negative aspects of their performance, but all clinicians at any level of training can make improvements with guidance.
- **Suggest a plan for improvement.** Critical feedback is more readily accepted if it is made as a recommendation for improvement and phrased in the future tense rather than as a reprimand. For example, "Next time you encounter a problem like this, I have found it helpful to do" This phrasing turns feedback into teaching.
- **Use the feedback sandwich to give frequent feedback that routinely includes reinforcing comments and a suggestion for improvement.** By making constructive comments a regular part of your feedback, you help learners to expect a useful tip along with praise.

TABLE 11.6
GIVING FEEDBACK BASED ON LIMITED INFORMATION

Take the following steps with the learner:

1. Describe the information you received tentatively and avoid drawing conclusions.
"I heard from Mrs. Jones' daughter that she was frustrated that she wasn't told that her mother was being discharged today, and she was worried it might be too soon for her mom to leave the hospital."
2. Invite joint interpretation of the information.
"Can you tell me what happened from your perspective? Why do you think her daughter was upset?"
3. Identify areas for positive feedback.
"You're managing a large service very well, with great attention to detail for each patient."
4. Identify areas of disagreement and develop a plan to collect information to determine if there is really a problem.
"I understand that you had asked Mrs. Jones' daughter to relay the plans to the family. However, with major changes in the care plan, it's important to make sure the primary spokesperson for the family is fully informed. I have a few suggestions for how you can keep patients and families aware of the plans you're making throughout the day so that they aren't caught by surprise. How about if we start by going to Mrs. Jones' room now and meeting with the family together?"

Gordon MJ. Cutting the Gordian knot: a two-part approach to the evaluation and professional development of residents. *Acad Med* 1995;2:876–880.

with interns and students, residents are ideally situated to observe the team members' clinical skills and critical thinking, following each learner's progress over time. Attendings often hear about and discuss patients in a conference room, and then infer a trainee's history and physical examination skills from the way that findings are presented. By directly observing their interaction with the patient, the resident and attending learn how the information was obtained and can give specific feedback in real time.

- *Frequent feedback* will increase the effectiveness by allowing trainees to quickly modify their behavior before the next observation.
- *Establish a schedule for more formal feedback.* Schedule periodic (e.g., every two weeks or midway through a rotation) longer meetings to give more detailed feedback that serves as a summary of the work to date and an opportunity to set future learning goals. Focus feedback on key objectives of the clerkship or rotation, as well as general areas of inpatient performance. The final feedback meeting doubles as an evaluation of the rotation and feedback for upcoming rotations.
- The *feedback sandwich* is a time-honored format to ensure balanced inclusion of both positive and constructive feedback—begin with positive and reinforcing comments, follow with correction of any errors and sugges-

tions for improvement, and end with praise. It has its place, but effective teachers also find opportunities for unambiguous reinforcing and, when needed, constructive feedback to their trainees (15). Many teachers find it uncomfortable to give constructive feedback. Teachers may feel guilty, or worry that the negative feedback may generate more work in dealing with learner resentment. Steps to make the process of constructive feedback more routine are described in Table 11.5.

- Another challenge confronted by teachers is learning of a trainee's problems second-hand—from another team member, nurse, patient, or family member. The attending may be tempted to dismiss the situation because he or she didn't directly witness it or because it will be uncomfortable to address, thereby missing a key learning moment. The challenge is to use the concern as an opportunity for teaching and feedback without seeming to take sides or misinterpret limited information (Table 11.6).

CONCLUSIONS

The successful inpatient team leader, whether attending or resident, provides a carefully planned experience infused with enthusiasm and active learning. Clarification of expectations at the outset establishes a fair and respectful team dynamic. Highly effective inpatient teaching methods promote critical thinking through bedside interaction and feedback, carefully worded probing questions, and teaching scripts. Self-assessment is a crucial skill that the attending and resident can instill by providing frequent feedback and ensuring that learners reflect on their own performance.

KEY POINTS

- The inpatient attending should set clear expectations with the team at the start of the rotation regarding patient care, learning, and feedback.
- Teaching methods on the inpatient wards should stimulate critical thinking and actively involve learners.
- The attending can promote reflection among learners by prompting self-assessment and by providing frequent, behaviorally focused feedback.

Assessment and Improvement of Quality and Value

12

Robert M. Wachter **Niraj L. Sehgal**

INTRODUCTION

The search for value, best described as quality divided by cost, dominates our purchasing decisions. When searching for a car, who would want the cheapest car if there were no guarantee that it was reasonably reliable? Conversely, who could afford the highest quality car if it cost hundreds of thousands of dollars? The goal is to optimize value by weighing quality and cost while being mindful of monetary constraints. The same approach is generally used when planning a vacation, choosing a college, and deciding where to have dinner.

The fact that health care purchasing decisions have not been made on the same basis is an anomaly, primarily explained by the fact that health insurance traditionally insulated both physicians and patients from the cost of care. As a result, it was not until payers—primarily business and government in the United States—decided that health care was too expensive that serious efforts were undertaken to rein in the denominator of the value equation. As for the numerator, the system had neither the tools nor the resources to measure quality effectively. The dominant assumption among patients and purchasers was that all doctors and hospitals provide high quality care, despite the reality that most physicians could easily name colleagues and institutions that they would never consider using, especially if they were sick.

This chapter begins by defining value and its elements, including quality. It highlights problems in health care value, describes how value can be measured, and ends with discussion about how it can be improved.

DEFINING VALUE

One way to consider quality in the context of health care is to separate it into two components—*clinical quality* and *patient satisfaction* (Figure 12.1). This dichotomy produces two entities that are easier to measure and ultimately more amenable to improvement efforts.

The pioneering work of Donabedian (1) on the quality of health care further refined the concept of clinical quality by dividing it into three elements—structure, process, and outcomes. *Structure* refers to *how care is organized*: Does the hospital use hospitalists or primary care physicians to provide inpatient care? Is the intensive care unit open or closed? Is there a designated stroke service? How are the physicians compensated? *Process* refers to *what was done*: Did the patient receive a β -blocker and aspirin after the myocardial infarct? Was the asthma teaching record completed at discharge? *Outcomes* refer to *what happened*: Did the patient live or die? Was the glucose controlled? Did the vessel remain patent? Structure, process, and outcomes are all important in understanding clinical quality, but each has certain advantages and disadvantages when used as a measurement tool (Table 12.1).

The measurement and improvement of patient satisfaction are discussed in Chapter 14. It is worth noting that an assessment of value might consider the satisfaction of “customers” in addition to that of patients. For example, a hospital trying to market its services to a group of primary care physicians would be well advised to survey such physicians. Similarly, a teaching hospital may need to consider how best to optimize not just clinical quality but also education,

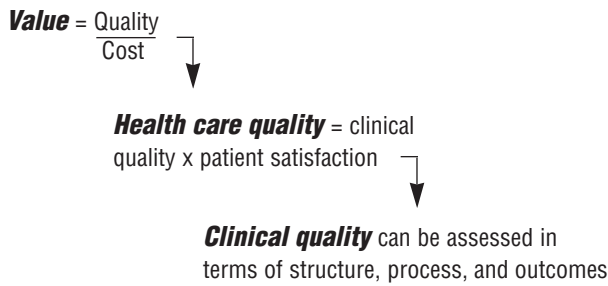

Figure 12.1 The health care value cascade.

and so it should survey its trainees regarding their satisfaction (2). Finally, in light of the large national nursing shortage, increasing numbers of hospitals now pay considerable attention to the satisfaction of their nursing workforce (3).

MEASUREMENT OF QUALITY AND VALUE

The innovative studies of Wennberg and Gittelsohn (4), which demonstrated wide and clinically indefensible variations in clinical care, coupled with a breathtaking health care inflation rate throughout the 1970s and 1980s, led many to question the quality and value of health care in the United States. Concerns were further heightened by the publication of data demonstrating a high rate of iatrogenesis and avoidable error in hospital care (5) (Chapter 20). These concerns led to a new emphasis on measuring the elements of value to allow for more informed consumer choice, catalyze quality improvement efforts, and meet regulatory demands. The measurement efforts were given even more urgency by the growth in capitation in the 1990s, a payment model that can provide strong incentives to withhold potentially beneficial care from patients (6).

Prompted by these forces, the health care industry has developed standard “report cards” that measure the elements of value (7). The first influential report card, the Health Plan Employer Data and Information Set (HEDIS), developed by the U.S. National Committee for Quality Assurance, largely focused on process measures in the ambulatory environment (8). The focus on process was understandable: when compared with outcomes, processes are easier to measure, take far less time to develop, and are less demanding of case-mix adjustment (9) (Table 12.1). It is relatively easy to measure whether all diabetics had glycohemoglobin tests and all women had Papanicolaou smears and mammograms at the appropriate ages and intervals. It is far more challenging, costly, and time-consuming to assess the quality of diabetic care by measuring outcomes, such as incidence of renal dysfunction or blindness.

HEDIS’s focus on the ambulatory environment was also understandable. In hospitalized patients, even determining what outcomes to measure is problematic. Commonly measured outcomes in complex hospitalized patients, such as mortality and readmission rates, are important but clearly capture only a small part of the picture. Moreover, in the case of mortality, a well-orchestrated death in the hospital may in fact reflect a superb quality of care (Chapter 19).

Over the past few years, a growing number of organizations committed themselves to developing and disseminating quality measures for hospital care. This practice is of particular interest because patients may care more about how a system or physician cares for them when they are sick compared to when they are relatively well (10). The organizations involved in inpatient quality measurement include regulatory agencies [such as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO)], payers [such as the Center for Medicare and Medicaid Services (CMS) and several large private insurers], joint public-

TABLE 12.1
A COMPARISON OF THE THREE TYPES OF CLINICAL QUALITY MEASURES

Measure	Short definition	Advantages	Disadvantages
Structure	How was care organized?	<ul style="list-style-type: none"> • May be a highly relevant variable in a complex health system 	<ul style="list-style-type: none"> • May fail to capture the quality of care provided by individual physicians • Difficult to determine the “gold standard”
Process	What was done?	<ul style="list-style-type: none"> • More easily measured and acted on than outcomes • May not require case-mix adjustment • No time lag—can be measured at the time care is provided • May directly reflect quality (if carefully chosen) 	<ul style="list-style-type: none"> • All may not agree on “gold standard” processes • May promote “cookbook” medicine, especially if physicians and systems try to “game” the report card
Outcomes	What happened?	<ul style="list-style-type: none"> • What we really care about 	<ul style="list-style-type: none"> • May take years to occur • May not reflect quality of care • In need of case-mix and other adjustment

private partnerships [mainly the National Quality Forum (NQF)], and representatives of business coalitions (best illustrated by the “Leapfrog Group,” a healthcare advocacy group representing many of the Fortune 500 companies). As one can imagine, although each group shares a commitment to promoting quality, each has a slightly different agenda and a different set of carrots and sticks with which to promote it. For example, while JCAHO measures tend to be process-oriented, emphasize patient safety, and carry the threat of regulatory action for noncompliance, Leapfrog measures tend to be structural (for example, does the hospital have computerized physician order entry?), focus on both safety and quality, and carry little weight of enforcement but the possibility of shifts in market share (and ultimately differential payment) based on performance. Not surprisingly, hospitals that generally lack a tradition of (or infrastructure for) quality measurement and transparency suddenly find themselves struggling to keep up with burgeoning reporting requirements and to prioritize their nascent quality improvement efforts.

Table 12.2 shows some of the existing inpatient quality measures. Although it is a selected list, its scope and breadth reflects how far the inpatient quality initiative has come in a short period. A perusal of the table demonstrates several trends. First, whereas prior quality measures focused on processes, an increasing number of outcome measures are being added. The degree to which such measures reflect true quality will depend on the adequacy of case-mix adjustment. Second, process measures are rapidly being developed for common inpatient diagnoses, building on the successful experience of cardiology (e.g., β -blockers and aspirin in patients with MI) to add process measures for disorders such as pneumonia, stroke, and asthma. Third, the notion of prevention, previously considered exclusively to be an ambulatory issue, is now increasingly being tied to hospital care. Partly because such prevention strategies are easy to understand and do not require case-mix adjustment, many new quality measures seek documentation of smoking cessation counseling, appropriate vaccinations, and prescriptions for preventive medications, such as statins, during a hospital stay. Finally, the list illustrates the chaotic state of quality measurement from the standpoint of the individual hospital, and why many hospitals are reeling trying to keep up with the reporting demands.

The science of *risk adjustment* has advanced to the point that it now adequately accounts for differences in complexity in stereotypic patients undergoing single procedures such as coronary artery bypass grafting (11), although even well-constructed adjusters may be greeted skeptically by clinicians (10). Far more difficult is trying to capture the quality of hospital care for patients with multiple medical disorders, such as those with both diabetic ketoacidosis and community-acquired pneumonia. Although notable progress has been made in the science of risk adjustment and outcomes measurement, much more remains to be done (9). An inadequate methodol-

ogy of risk adjustment gives hospitals and health systems a potent incentive to recruit healthy patients (“cherry picking”) or a ready-made excuse for poor outcomes (“my patients are older and sicker”).

The methodologic issues in the measurement of cost and resource use are covered in Chapter 9. Two issues bear emphasis. The discussion of risk adjustment presented above is relevant to the consideration of costs as well as outcomes. A group of physicians caring for sicker patients than another group of comparable quality and efficiency would be expected to have both higher costs and poorer outcomes. An effective adjustment method would be needed to level the playing field in terms of both the numerator and denominator of the value equation. Secondly, the issue of cost shifting needs to be considered in assessing the value of certain services. For example, an intervention that led to shorter hospital stays and lower hospital costs might appear to improve health care value (assuming stable outcomes and satisfaction); however, if the intervention led to costs that were simply displaced to the skilled nursing facility or home, the savings might be illusory. Integrated systems, in which care is delivered across a continuum within the same organization (Chapter 4), may have an advantage in their ability to detect such cost shifting and ensure that overall value has truly been improved.

QUALITY AND VALUE IMPROVEMENT

Changing Physician Behavior

Although physician salaries make up 15% of the American health care dollar, their activities generate 85% of the expenditures, leading to the maxim that “the physician’s pen is the most expensive piece of technology in the hospital.” Greco and Eisenberg (12) described six ways to change physician behavior: education, feedback, administrative rules, financial incentives, financial penalties, and participation by physicians in efforts to bring about change. All are relevant to efforts to improve value in the hospital.

Educational efforts include continuing medical education, dissemination of practice guidelines, and “academic detailing.” In general, studies have shown that continuing medical education leads to no changes in patient outcomes and relatively small changes in practice behavior. Well-designed practice guidelines, especially if locally developed and implemented, can influence physician behavior significantly (Chapter 13). Similarly, academic detailing—in which specific physicians are engaged in the process of educating their peers—can be quite effective, especially when such physicians are opinion leaders in their institutions (13). The degree to which physician participation in continuing education and/or demonstration of up-to-date knowledge (as evidenced by board recertification) reflects

quality is the subject of ongoing debate; there is little doubt, however, that the public perceives it as such (14).

Feedback involves providing physicians with information about their performance in an effort to improve their performance. Often, there is an implied “gold standard” or “benchmark” against which physicians are compared. The number of national and regional benchmarks related to outcomes and resource utilization that are available for comparison is increasing. Examples include the University HealthSystem Consortium’s clinical database, the Centers for Disease Control and Prevention’s National Nosocomial Infection Surveillance System (NNIS), and the number of bed-days per thousand population recorded by most managed care organizations. Evidence regarding feedback shows that it can influence practice patterns but its effect is often short-lived. Feedback loops embedded in computerized information systems are likely to have more lasting effects (Chapter 10).

Administrative rules are increasingly being used to influence physician behavior and promote structural changes. Managed care organizations were early adopters of such rules to control costs and decrease variations. As the public became more concerned about the impact of aggressive cost cutting, a spate of governmental regulations emerged covering everything from hospital stays for childbirth to emergency department admissions criteria. Such rules may influence behavior but carry the risk of increasing the “hassle factor” for practicing physicians, and displacing patients from their usual sources of care. Examples of administrative rules include utilizing high-volume providers to perform procedures (15) and reorganizing hospital or critical care services to improve availability and expertise (2,16,17).

Financial incentives and penalties are also used increasingly to modify physician behavior. Although payment methods that motivate physicians to withhold care raise considerable concern (such as capitation arrangements with shared-risk pools), the incentives in fee-for-service arrangements also represent a cause for concern, since physicians are paid more to do more. Controversy continues to exist about whether managed care and capitation harm or improve overall quality and value (6), although it is clear that reimbursement changes do influence practice behavior (18).

Perhaps the most important method of achieving sustainable change in health care practices is to encourage *providers to participate* themselves. This notion was recognized long ago by W. Edward Deming, who promoted the concept of *continuous quality improvement (CQI)*, predicated on a continuous flow of information from the process to the providers. These concepts have been adapted to the health care system during the past decade. In this conceptual model for quality improvement activities, all the participants engage in a continuous cycle of changing, measuring, and changing again (19) (Figure 12.2). In a stunning example of CQI in action, 23 cardio-

thoracic surgeons participated in a three-component intervention that included training in CQI techniques, feedback on outcome data, and site visits to other medical centers. As a result, there were 74 fewer deaths (a 24% reduction) than the expected rate following the intervention period (20).

Pay for Performance

As noted earlier, the last few years have seen an explosion in public quality reporting efforts. Such efforts try to motivate change by dint of transparency: the hope is that by simply reporting comparative performance on quality metrics, organizations and providers will seek to improve their performance. The evidence that this strategy is effective in motivating change is mixed (21, 22).

However, discouraged by the slow pace of change and evidence of poor performance on many quality measures (23), a newer trend goes beyond public reporting to linking compensation to quality performance. (24) As of this writing, an estimated 40 pay-for-performance (PFP) programs have been developed or implemented by health plans and employer coalitions. (25) Most programs involve a “report card” to evaluate providers and groups around designated quality standards, including rates of screening for cervical and breast cancer, markers of management for patients with diabetes and heart disease, and specific patient-satisfaction scores. A number of different incentive strategies have been employed, ranging from paying a “quality bonus” to providers who achieve certain performance goals to linking patients’ deductible and copayments to providers’ performance (26). Perhaps the most prominent example is Medicare’s Premier Hospital Quality demonstration project, in which a group of hospitals are submitting data on patients treated for several conditions, including acute myocardial infarction, community-acquired pneumonia, and coronary artery bypass surgery. (27) Hospitals whose performance

What are we trying to accomplish?

What changes can we make that will result in an improvement?

Figure 12.2 Berwick’s model for quality improvement, emphasizing the iterative process of change. (From Berwick D, Nolan T. Physicians as leaders in improving health care: a new series in *Annals of Internal Medicine*. *Ann Intern Med* 1998;128:289–292.)

matches evidence-based performance standards will receive an extra 2% in Medicare payments per condition. Many similar programs are under consideration.

The impact of PFP programs is as yet unstudied. We believe that, depending on the extent of their spread and the magnitude of the incentives, they are likely to motivate improved performance by individual providers and systems. The latter issue is extremely important: physicians whose practices are supported by electronic medical records with automatic alerts and robust decision support are likely to perform better, especially on relatively straightforward, algorithmic metrics such as ordering certain tests or medicines at the right time (Chapter 10). Of course, such PFP programs may have the perverse effect of lowering reimbursements to healthcare systems that lack information technology, making it even less likely that the systems will be able to afford the purchase of the needed computers and infrastructure. It will be vital to study the impact of PFP systems to ensure that they are achieving their intended effects.

Other Recent Trends in Quality Improvement

Whether motivated by a professional desire to change, comparative report cards, or pay for performance, hospitals and physicians have come to recognize the inadequacy of traditional, education-based quality improvement strategies. Increasingly, systems are embracing more active and engaging endeavors to impact practice behaviors. Many successful projects have begun by recognizing that reliance on a physician's memory fails to ensure uniform adoption of evidence-based practices. Instead, such projects focus on "hard-wiring" quality improvements. Examples include the use of computer-generated clinical decision-support in antibiotic selection for patients admitted with pneumonia, automatic reminders to provide tobacco cessation counseling and influenza vaccinations, and ventilator management algorithms that are independently executed by respiratory therapists (28). Finding the right balance of "hard wired" approaches to ensure flawless execution of quality strategies while preserving physician autonomy in more complex and less algorithmic situations will be one of medicine's great challenges over the next decade.

CONCLUSIONS

Former *New England Journal of Medicine* editor Arnold Relman (29), writing in 1988, predicted that the American health care system was leaving the eras of expansion of care (1940s to 1970s) and cost containment (1980s) and entering a third era of assessment and accountability. This new era, he wrote, would be one in which measurement of value would become standard practice, and in which patients and purchasers would make their decisions based on such measurements. In this environment, physicians and the systems in which they work would be strongly motivated to assess

value continuously and work tirelessly to improve it. Although Relman may have been optimistic in his timing, the activities in the past few years by regulators such as JCAHO, business coalitions such as the Leapfrog Group, and payers such as the Center for Medicare and Medicaid Services (CMS) to measure, promote, and reward quality—and the extent to which hospitals and providers are increasingly participating in activities to improve value—may mean that Relman's vision may finally be realized.

The questions no longer are about whether there will be quality measurement of hospitals and their providers. Rather, they increasingly relate to the methodology of measures (what is the right combination of measures that are evidence-based vs. expert consensus-derived?), the organizational and logistical aspects of measurement (particularly, can measurement sets be consolidated to a manageable group that all stakeholders will accept?), and the appropriate combination of carrots and sticks to promote full implementation. In these chaotic early days, it can be easy to forget that the final outcome of the quality measurement movement will undoubtedly be improved patient care and better outcomes.

KEY POINTS

- Health care purchasing decisions will increasingly be made based on assessments of value, defined as quality divided by cost.
- Quality in health care may be thought of as a product of clinical quality (assessed according to structure, process, or outcomes) and patient satisfaction.
- Although outcome measurements may ultimately be more salient than process measurements, they are more difficult to acquire; furthermore, correct interpretation of outcome measures is highly dependent on adequate case-mix adjustment.
- A number of strategies (including education, feedback, regulation, and incentives) can be used to change physician behavior. Those that actively engage providers themselves in the process of change tend to be the most successful.
- There is a burgeoning trend of public reporting of doctors' and hospitals' quality measures, increasingly accompanied by economic incentives that reflect performance.
- In part to meet these demands, a new trend is to "hard wire" quality improvements by fundamentally altering the processes of care, rather than depending on the physicians' execution of the correct processes.

Practice Guidelines and Clinical Pathways

13

Scott Weingarten

INTRODUCTION

Practice guidelines and clinical pathways have been developed by scores of health care and physician organizations in many countries. The dramatic proliferation of guidelines and pathways and the widespread enthusiasm surrounding their development is fueled by the belief that the adoption of guidelines and pathways can lead to a more systematic and consistent approach to the delivery of patient care and result in improved quality and reduced health care costs. Newer approaches to clinical quality improvement, including the use of health care information technology, may be replacing paper-based strategies. Such technology may facilitate the electronic delivery of clinical pathways, practice guidelines, and clinical decision support, creating a more sustainable strategy for improving patient care for diverse populations of patients (1).

VARIATIONS IN MEDICAL CARE

In the past, the strongest influence on medical decisions was the beliefs of individual physicians, formed by their experience, medical training, and understanding of the scientific literature. However, the sheer volume of medical literature has made it virtually impossible for any physician to remain current (2). Currently, physicians spend about one third of their day reviewing, interpreting, and integrating clinical information (3). Estimates suggest that more than 100,000 medical research articles are published every month in 20,000 different medical journals, and there are more than 200,000 randomized controlled trials indexed in MEDLINE alone. It is not surprising, then, that individual clinicians are often overwhelmed by the amount of available clinical information.

A variety of studies have demonstrated frequent and unexplained *variations in medical care*. For example, lengths of stay for patients with pneumonia have been shown to vary from one geographic region to another, from hospital to hospital, and even from ward to ward within the same hospital (4). Differences in length of stay have been found to persist even after case complexity and other known patient-related factors are taken into consideration. Many of these variations are believed to result from differences in physician practice style and are unrelated to patients' medical conditions or preferences.

Although some variation in medical care may be desirable, variations can also compromise care, especially when care deviates from the best course of treatment based on the scientific evidence. For example, studies have demonstrated significant interhospital variations in the "door-to-needle" time for the administration of thrombolytic therapy in patients presenting to an emergency department with acute myocardial infarction (5). This variation may reflect differences in approaches to therapy and the time required for informed patient decision making, but delayed administration of thrombolytic therapy can increase mortality rates. Delayed administration of antimicrobial therapy for patients hospitalized with community-acquired pneumonia was associated with increased mortality, and there are wide regional variations in the time to administer antibiotics to such patients (6). Similarly, underutilization of β -blockers and aspirin among selected patients recovering from acute myocardial infarction can result in higher patient mortality. Finally, underuse of angiotensin-converting enzyme inhibitors and angiotensin receptor blockers in appropriate patients with congestive heart failure is associated with reduced survival and increased hospitalization rates. Therefore, variations in medical care can be associated with

preventable deaths, and such variations continue to provoke concern in the medical community.

DEVELOPMENT OF PRACTICE GUIDELINES AND CLINICAL PATHWAYS

A variety of approaches have been employed to reduce undesirable variations in medical care and to make medical care more consistent with the published scientific evidence. These approaches have included the creation and dissemination of *practice guidelines*, *clinical pathways*, *clinical decision support*, *protocols*, and *care maps*. Practice guidelines have been defined as “systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances” (7). Ideally, evidence-based guidelines and clinical pathways would integrate, organize, and summarize the available information for a condition and allow busy clinicians to wade efficiently through it. Additionally, the information would be updated regularly to allow even the busiest of clinicians to remain relatively current. Although the terminology and nomenclature will undoubtedly change, the basic premise of codifying and expressing a somewhat uniform approach to caring for patients that reflects the most up-to-date and relevant scientific evidence should be enduring.

Guidelines and clinical pathways are often developed for high-volume and costly medical and surgical conditions. For example, many institutions have developed guidelines and pathways for conditions such as acute myocardial infarction, congestive heart failure, acute ischemic stroke, total hip replacement, coronary artery bypass graft, and community-acquired pneumonia. The conditions are prioritized because changes in care for the most common conditions carry the greatest potential to improve patient care and reduce health care costs, and are scrutinized by regulatory organizations and payers.

Thousands of guidelines have been funded by subspecialty organizations, such as the American Heart Association and the American College of Cardiology, and countless local organizations. There are probably more than 2,000 published guidelines, and far more have been developed and disseminated within local health care organizations without wider distribution.

Many of these guidelines have been based on study of integrative articles (systematic reviews, meta-analyses, and decision analyses), thorough review of the primary literature, or both (see Chapter 8). Some guidelines rely to a greater extent on *scientific evidence*, others are primarily based on *expert opinion*, and still other guidelines blend these two approaches. Whichever method is used, it can be important to identify explicitly and grade the sources of key recommendations (Table 13.1). Different sources of and approaches to guidelines may engender different levels of confidence. For example, guidelines developed by a trusted subspecialty organization using scientific evidence may be

TABLE 13.1
AN EXAMPLE OF AN EVIDENCE GRADING SYSTEM

Grade A	Randomized, prospective, controlled trials
Grade B	Non-randomized, prospective trial
Grade C	Retrospective analyses
Grade E	Expert opinion unsubstantiated by higher levels of evidence
Grade M	Meta-analyses
Grade Q	Cost-effectiveness/decision analysis
Grade S	Systematic reviews

Adapted from Greengold NL, Weingarten SR. Developing evidence-based practice guidelines and pathways: the experience at the local hospital level. *Jt Comm J Qual Improv* 1996;22:391-402, with permission.

considered more credible by physicians than guidelines developed by a health insurance company or by persons viewed as having a significant financial stake in the course of patient care (8). In any case, guidelines rigorously based on scientific evidence may be considered more credible and less subject to bias than guidelines based solely on expert opinion.

Clinical pathways are management tools that have been used in many industries outside the health care arena (9). Traditionally, they have been employed to describe the goals of work flow processes and the sequencing of events. The perceived success of clinical pathways in these industries has led to the belief that a similar approach could improve patient care. Sometimes, they will embed practice guidelines, which include information about the appropriateness of care in addition to the sequencing of care. Clinical pathways are charted with time displayed along the x-axis. Many guidelines and clinical pathways are developed through a multidisciplinary approach, which includes physicians, nurses, pharmacists, and other ancillary personnel. In many cases, a goal of the clinical pathway is to replace existing documentation, allowing nurses (and sometimes physicians) to document care on the pathway rather than the progress notes. However, many health care providers also believe that the delivery of patient care is unique, complicated, and not readily suited to industrial strategies for automating work flow “processes.”

The purchasers of health care (e.g., employer groups) and the payers (e.g., health plans, Center for Medicare and Medicaid Services) are demanding accountability for the quality of care received by patients. Purchaser efforts to document the quality of care and outcomes include the Health Plan Employer Data and Information Set (HEDIS) measures developed by the National Committee on Quality Assurance, and several others. Some payers have asked contracting provider organizations (e.g., hospitals, physician organizations) to document their care in “pay for performance” or incentive-based reimbursement programs

(see Chapter 12). It is likely that the use of guidelines and clinical pathways will become even more common as the movement to measure and report quality indicators continues to grow.

EFFECTIVENESS OF PRACTICE GUIDELINES AND CLINICAL PATHWAYS

Although significant effort and resources have been devoted to the creation and dissemination of guidelines, relatively little is known about whether this effort has improved patient care and whether the benefits of these efforts have justified the cost of development and implementation. However, the published literature supports the hypothesis that care can be improved through the use of practice guidelines. A rigorous evaluation of 59 studies on the topic demonstrated that guidelines have led to documented improvements in patient care (10). Of the eleven studies that specifically examined patient outcomes (which reflect what happens to the patient as a result of care), nine demonstrated beneficial effects of guidelines.

There are even fewer published peer-reviewed studies evaluating the effects of clinical pathways on clinical practice or demonstrating a significant improvement in patient outcomes as a result of their implementation. Although some studies have shown reductions in length of stay following the introduction of a clinical pathway, the relative contributions of the pathway and of secular trends that may have been occurring independently of the clinical pathway are not known. Given the dearth of evidence supporting the use of pathways, at present it is unclear whether the cost of developing and implementing them can be justified.

One traditional challenge of implementing practice guidelines and clinical pathways is that paper-based strategies (e.g., paper-based standing orders, paper reminders on the front of charts) are laborious and costly to implement on an ongoing basis. Furthermore, it is difficult to “build” paper-based guidelines and pathways to encompass multiple conditions and procedures across a hospital setting. Also, many hospitalized patients have multiple comorbid conditions, and paper-based guidelines and order sets can potentially oversimplify the care of these complex patients.

One additional problem with evaluating the effects of guidelines and clinical pathways on patient care has to do with the methodologic difficulties associated with conducting scientifically credible studies. Randomized, controlled clinical trials are the “gold standard” for evaluating the safety and efficacy of drugs. Although it would be desirable to test guidelines and clinical pathways in a similarly rigorous manner, the use of clinical trials to assess “systems” of caring for patients poses significant challenges. For example, multiple changes are often instituted simultaneously, which makes it difficult to isolate the impact of guidelines or pathways on patient care. Moreover,

contamination of patient groups may occur, as it is not possible to prevent physicians caring for control patients from familiarizing themselves with the guidelines and applying them to the care of their patients.

CARE OF THE HOSPITALIZED PATIENT

The potential of practice guidelines to improve patient care may depend on whether they are based on firm scientific evidence, are easy to understand, include actionable statements, and are implemented in an effective manner. Because many guidelines express ambiguous statements, their impact on patient care is limited. For example, a guideline that recommends that patients be transferred out of the intensive care unit when they are stable will probably have little effect on patient care.

The key to improving care through the use of guidelines and clinical pathways is *successful implementation*. Many different strategies can be employed to facilitate the widespread dissemination and effective implementation of practice guidelines. For example, continuing medical education is often used to introduce guidelines, although a number of studies suggest that conventional forms of continuing education rarely produce sustained changes in clinical practice. Providing retrospective feedback to physicians, in the form of comparisons with peers or other appropriate benchmarks, may prove more helpful, but most studies demonstrate a modest impact. “Academic detailing,” or one-on-one encounters with clinicians, has been shown to change physician behavior, but is costly (11). A strategy that can be effective is when those disseminating the guidelines are regarded as “opinion leaders” by their peers. Guidelines can also be implemented through reminders from case managers or other appropriate non-physician personnel. Hospitalists who are faithfully committed to the use of guidelines and pathways and may have participated in their development can facilitate the successful implementation of guidelines by serving as effective messengers for the rest of the medical staff. Intensivists can serve in comparable roles in the critical care unit.

Many published examples have shown that guidelines, when disseminated and implemented effectively, can improve patient care. For example, a guideline was developed at Cedars-Sinai Medical Center in Los Angeles to risk-stratify patients hospitalized for upper gastrointestinal hemorrhage (12). The guideline was based on patient hemodynamic parameters, endoscopic findings, comorbid conditions, and time elapsed since the initial bleed. A retrospective study found that the guideline accurately identified patients who were at low risk for rebleeding and might not benefit from continued and prolonged hospitalization. Based on the risk information, the guideline prescribed a specific day of discharge for each patient. When tested retrospectively, the guideline would have significantly reduced hospital length of stay while preserving excellent

patient outcomes had it been applied to patient care. When the guideline was later applied in clinical practice, hospital length of stay declined from 4.6–2.9 days (mean reduction of 1.7 days per patient, $p < .001$) (12). Moreover, patient outcomes, including hospital readmission rates, emergency department visits, and health-related quality of life, remained unchanged when measured 1 month after discharge from the hospital.

Information technology has great potential to facilitate the implementation of guidelines and clinical pathways, and represents an important aspect of the future of clinical quality improvement. Studies involving computerized clinical decision support have shown important improvements in care (13). When information is made available to physicians while they are caring for patients (at the “point of care”), it becomes easier for them to apply the guidelines in the care of individual patients. Information technology is particularly helpful since most guidelines are too complex to be committed to memory, and effective guidelines undergo frequent revision based on new published evidence and local experience. Computerized entry of provider orders can integrate guidelines and other recommendations into the routine patient care work flow, and can enable deployment of multiple guidelines and pathways at the same time (see Chapters 10 and 12).

Providing *alerts* and *reminders* to physicians while they are caring for patients by using rules-based logic has often proved to be an effective strategy. For example, there is evidence that early antibiotic treatment may be beneficial for patients with community-acquired pneumonia. In the case of a patient presenting to an emergency department, clinical decision support embedded in an information system might notify a physician about the benefits of early antibiotic treatment immediately after a patient with community-acquired pneumonia is hospitalized. A similar intervention in which computer-assisted prescribing of antibiotics was used for intensive care unit patients led to significant reductions in length of stay, costs, and mortality rates (14).

Therefore, as computerized provider order entry and the electronic medical record become more prevalent, they are likely to play an even more substantial role in the implementation of practice guidelines and clinical pathways. The guidelines and pathways may be expressed electronically as clinical decision support, order sets, alerts, reminders, and structured documentation. Published studies are encouraging regarding the impact of health care information technology with clinical decision support on the quality of patient care.

Studies have also explored and demonstrated the potential pitfalls of applying guidelines. For example, if the focus of a guideline or pathway is too narrow, it may not lead to improved outcomes. A study of congestive heart failure patients that focused only on the decision regarding the most appropriate time to transfer them from the intensive care unit or intermediate care unit to an unmonitored bed found little net benefit (15). In fact, while lengths of stay in

monitored settings decreased as a result of an increased emphasis on transferring patients out of the coronary care unit, length of stay in unmonitored settings increased, and total length of stay actually increased. As more rigorous studies of guidelines and clinical pathways are published, we can expect to see more evidence regarding both their benefits and limitations.

Many clinical pathways include information on expected length of stay. However, these figures may be derived from “benchmark” information from other institutions, which may include data on length of stay but no corresponding data on quality or outcomes. For example, if shorter lengths of stay are associated with more patient readmissions, returns to the emergency department, and discharges to skilled nursing facilities rather than home, overall quality of care may have declined and overall costs may have increased (see Chapter 12). To ensure that costs are not simply displaced (“squeezing the balloon”) or quality compromised, studies evaluating the impact of guidelines and pathways should generally measure important outcome variables, such as mortality, readmission, and patient satisfaction. They should also make efforts to rule out cost shifting; this is most easily accomplished in integrated systems in which patients can be tracked across the continuum of care.

Another concern about the relevance of clinical pathways or practice guidelines to patient care is that many medical conditions afflict a fairly *heterogeneous population* of patients. For example, it may be difficult to implement guidelines in patients with multiple comorbid conditions. Consider how challenging it would be to develop a standardized course of care for a patient hospitalized with community-acquired pneumonia who also has chronic obstructive pulmonary disease, congestive heart failure, and severe depression.

Finally, there are concerns about the *medicolegal risk* associated with the use of practice guidelines and clinical pathways. The literature is inconclusive on whether guidelines and pathways increase or decrease medicolegal liability (16). One study suggested that guidelines were used more frequently by plaintiff’s attorneys against physicians than by attorneys defending physicians. Conversely, it has been difficult to quantify the number of cases in which physician adherence to a guideline resulted in an attorney’s declining to take a case. Many believe that the potential medicolegal benefits of guidelines and pathways exceed the risks, but this is an evolving field.

CONCLUSIONS

Many hospitals have supported the development or local adaptation of practice guidelines and clinical pathways. Although relatively little is known about whether clinical pathways have any effect on patient care, a burgeoning literature suggests that carefully implemented practice

guidelines can promote high-quality, efficient patient care. For practice guidelines to be beneficial, however, they must be based on sound scientific evidence and implemented in an effective manner. With the introduction of more sophisticated clinical information systems, clinicians will see an expansion in the development and application of systematic approaches to caring for hospitalized patients, including the use of practice guidelines and clinical pathways integrated into information systems.

KEY POINTS

- Practice guidelines, which are “systematically developed statements to assist practitioner and patient decisions about appropriate health care for specific clinical circumstances,” have been demonstrated to improve patient outcomes, and lower costs.
- Clinical pathways, which map out the process of work flow over time, have not been convincingly demonstrated to improve patient care.
- A key to improving care with guidelines or pathways is successful implementation.
- Although many strategies have been used to assist in implementation, embedding evidence-based guidelines within clinical information systems used by clinicians at the “point of care” holds the most promise.

Patient Satisfaction with Hospital Care

14

Haya R. Rubin

INTRODUCTION

Fifteen years ago, many physicians believed that patient satisfaction was of no particular importance, and few hospitals measured it regularly. In this era of increasing competition and patient sophistication, patient satisfaction with medical care has become an important outcome. This transformation has been driven by a number of forces, including (a) competition for market share among hospitals and health systems, especially in markets where employer coalitions are strong and managed care is prevalent; (b) availability to and use of information about patient satisfaction by medical care purchasers; (c) the strong patients' rights movement (evidenced by, among other things, informed consent laws across the nation, the Patient Self-Determination Act, the Patient Bill of Rights, and the Consumer Protection Act), which stresses the philosophical importance of patient satisfaction as an outcome; and (d) our own awareness that physicians' judgments of technical quality of care are sometimes no more informed than our patients' judgments. Because of these factors, regular measurement of patients' experiences with and evaluations of their health care, and efforts to improve care based on the results, are now commonplace among American hospitals' internal quality measures. They have also recently become part of Medicare hospital quality monitoring efforts (1).

What is referred to here as patient satisfaction, out of deference to popular nomenclature, should more properly be called patient evaluation or judgment of hospital care. Patients are usually satisfied with hospital care, but even satisfied patients have various opinions that can be influential when they are deciding between hospitals or recommending hospitals to their friends or family members.

CARE OF THE HOSPITALIZED PATIENT

Studies in the last decade have explored which dimensions of care are most important to hospitalized patients (1–3), and measurement tools reflecting these are both publicly and commercially available. Patients' judgments about nursing care correlate best with their global assessment of their hospital stay and their intentions to recommend the hospital to others (2–4). Of particular importance is how quickly nurses respond when patients call for a bedpan and toileting assistance or for pain medication. The perceived quality of physician care has usually been next, although in other countries that have long traditions of hospital-based physicians, it has sometimes come first (5). In the United States, nursing care probably was given greater weight than physician care because, in the traditional American system, the attending physician in the hospital was usually the patient's outpatient physician. This physician was not present for most of a patient's hospital day, and often was not perceived by patients as being part of the hospital staff. Except in teaching hospitals, physicians were not present enough to figure into patients' opinions about the hospital. Deficiencies in physicians' orders were often interpreted by patients as deficiencies in nursing care. As the hospitalist model grows in popularity (Chapter 1) and hospitalist physicians are available to interact more often with hospitalized patients, their behavior will likely figure more prominently into patient assessments of the hospital. Across all staff groups, sensitive, respectful treatment and clear information are highly prized by hospitalized patients.

Clinicians may be relieved to know that cosmetic changes in the hospital environment do not impress patients in the absence of high quality care. Patients do

value restful, clean, attractive environments carefully designed with the needs of physically limited, ill, or postoperative patients in mind. Reflecting this, patients' ratings of noise, cleanliness, appearance of the room and unit, design and condition of the room and bathroom, furnishings, supplies, and equipment are independently associated with their global judgments and their intentions to recommend the hospital to others. Hospitals aiming for high patient satisfaction scores should not ignore these aspects. However, health care environmental factors are more weakly associated with final judgments than are nurse and physician care and information given to patients. Therefore, unless a hospital has a very poor physical plant, *successful efforts to improve care and patient information will yield greater gains in overall satisfaction than will remodeling.* Paint, artwork, and food will not compensate for inconsiderate staff behavior or failure to respond to the call bell, nor for failure to give patients information about their medical condition, treatment, and what they should do when they leave the hospital. In contrast, patients forgive inadequate parking facilities and terrible food in hospitals that get high ratings for physicians' and nurses' skills and caring.

TECHNICAL ASPECTS OF ASSESSING PATIENT SATISFACTION

Patient evaluations of inpatient care can be obtained in a variety of ways. The two most popular are mailing surveys to or calling patients discharged within the last week or two. Surveys can also be conducted by interviewing patients or giving them a questionnaire to complete while in the hospital or at the time of discharge. However, this results in sicker patients not being able to complete the survey, does not allow patients to evaluate the completeness and clarity of instructions they receive about how to care for themselves after discharge, and does not permit an evaluation of billing services. Post-discharge surveys offer these advantages, and provide comparable evaluation results in domains that could be assessed by both methods.

The relationship between survey length and response rate is not linear. Surveys that take more than 15–20 minutes to complete are returned less often than shorter surveys. However, postcards and one-page minimal surveys are also returned less often than more comprehensive surveys because patients believe that they are trivial and do not permit useful and constructive feedback (3). Most commercial surveys obtain a 40%–50% response rate from discharged patients. Although no absolute floor for unacceptable response rates can be specified, patients who are less satisfied with their care are less likely to return their questionnaires, so as the response rate goes down differences among hospitals or units are obscured. Thus, when choosing between surveying a greater number of patients or obtaining a smaller sample and devoting more resources

to follow-up, the latter is preferable as long as at least 100 responses per group will be compared.

Item wording affects results in important ways. Patient satisfaction surveys are highly susceptible to biases created by framing effects and insensitive response scales. Items that ask patients for yes or no answers can obscure areas for improvement if the item is one in which a “no” response still could indicate a serious deficiency with care. In addition, such items are not sensitive to differences across the entire spectrum of quality. It is preferable to use response scales that allow for a wider spectrum of responses, such as one in which answers range from “excellent” to “poor,” A to F, or 1 to 10. Double-barreled questions and questions with double negatives are confusing and likely to elicit unreliable and inaccurate responses (Table 14.1). Figure 14.1 gives examples of poorly worded and well-worded questions.

Hospitals that have substantial populations of patients who do not speak English must translate questionnaires into other languages. Competent translations require bilingual translators and back-translation to check accuracy. Because of cultural and language differences in the use of rating scales, ratings obtained in another language should not be directly compared with ratings by speakers of English, but they can be used to track improvements over time for the segment of hospitalized patients who speak the second language.

INTERVENTIONS TO IMPROVE PATIENT SATISFACTION WITH CARE

Clinicians and administrators have numerous opportunities, beginning at the first moment of hospitalization, to influence and improve a patient's experience. Patients value a hospitalization in which they are admitted promptly from the emergency department or the admitting office to the inpatient unit and are treated thereafter with care and respect.

Administrators attempting to improve patient satisfaction throughout a unit or service should focus on training the staff in improving their interpersonal skills and in providing patient education procedures and materials (4). As an example, the Johns Hopkins Department of Medicine implemented a multifaceted program, the Osler Way Project, to increase patient satisfaction with inpatient services. The interventions included institution of joint rounds for nurses and physicians to improve the consistency of information provided to patients; training in interpersonal skills (“service excellence”) for nurses' aides, nurses, and house staff physicians; better coordination of the discharge process; putting housekeeping under nursing supervision on individual units; and making physical changes to the environment, such as putting up new wallpaper, adding new artwork, and closing one entry to the unit to reduce noise and improve security. Table 14.2 lists some of the 20 topics included in the “service excellence” training given to all staff categories. The proportion of excellent patient ratings

TABLE 14.1
EXAMPLES OF WORSE AND BETTER ITEMS

Worse	What's wrong	Better
The staff were courteous and respectful. Response choices: Strongly agree, agree, not sure, disagree, strongly disagree	Evaluation is in the stem of the item, allowing for only one cutoff point on the spectrum of opinion. More sensitive items place the evaluation in the response scale rather than asking for agreement.	How courteously and respectfully were you treated by the staff? Response choices: 0 (worst possible) to 10 (best possible), A (best) to F (worst), or excellent to poor
Was the information adequate? Yes/No	Yes/No items create a dichotomy that obscures the full spectrum of possible answers and obscures differences.	Adequacy of the information given (0, worst possible, to 10, best possible)
Please rate the food and how it was served by staff.	Double-barrelled item is difficult to answer if the two items differ.	Separate into two items: 1. Please rate the quality of the food. 2. How was food served by staff?
The doctors did not involve me in decisions. Response choices: Strongly agree, agree, not sure, disagree, strongly disagree	1) Double negative is confusing; 2) value of being involved in decisions is imposed on the patient, not a true patient evaluation item; and 3) agree/disagree scales limit spectrum of possible evaluation.	How much did the doctors involve you in decisions? Response choices: Way too much, somewhat too much, about right, somewhat too little, way too little, or (less informative about patient's expectations but a sound rating item): 0, worst possible, to 10, best possible

of the overall hospital stay doubled after the interventions were implemented, with the greatest improvements in specific ratings corresponding to the areas of intervention (6).

Interpersonal relations can be improved by incorporating interpersonal behavior as a criterion for employee selection and performance evaluation and by providing service excellence training for all types of staff. Patient education can be improved in similar ways, and also by providing patient education materials about common hospital diagnoses, tests, and treatments in a variety of media.

PATIENT CHARACTERISTICS RELATED TO EVALUATIONS OF CARE

Certain types of patients have a greater propensity to find a hospital stay unsatisfactory. Educated patients have higher expectations of care and generally rate their hospital care more unfavorably than do less educated patients. Those who are sicker on admission rate their care less favorably, probably because their needs are greater and therefore staff members are more likely to fail to meet them. Patients with

Poorly worded

I was not told how to take care of myself at home.

TABLE 14.2**SOME KEY ELEMENTS OF JOHNS HOPKINS MEDICINE SERVICE EXCELLENCE TRAINING**

Module name	Brief description of module
First encounters: Guess who?	Stresses the importance of all staff members introducing themselves and explaining their role; provides examples of good introductions.
First impressions: It's up to you!	Describes what leads to a good first impression, the critical importance of courteous and respectful first contact.
Anticipating customer needs	Encourages staff members to put themselves in patients' shoes and think about what they need.
Dealing with difficult people	Provides some pointers on defusing tension and handling challenging behavior.
Power of nonverbals	Discusses how body language and appearance affect patients' impressions.
How my department conserves cost	Educates staff members about service efficiency.
Moving myself from negative to positive (attitude)	Presents strategies for a constructive and cheerful outlook.
Stages of team development and stress	Gives guidance on how team morale can be improved with respectful interactions.
Choosing the right words	Scripts some common situations and gives tips on avoiding offensive language.
Innovation, my job, and me	Encourages staff members to make suggestions for better care throughout the hospital.

intermediate levels of pain or moderate needs for assistance give lower ratings than do those with the highest and lowest levels. Possibly those with the most pain or disability occupy the staff, and those with little or no pain or disability are not in need, whereas those with moderate pain and disability are more likely to find their needs unmet. Patients who are depressed are more likely to be dissatisfied with care. It is important to identify such patients, especially on medical and surgical wards, and to treat their depression along with their other conditions (Chapter 119). Patients in their twenties and thirties give lower ratings for care than do those in their forties and fifties. Relatively younger patients, especially men, may be less likely than older patients to express their needs because of embarrassment, frustration, and discomfort with revealing disability or vulnerability. It may be necessary for staff members to inquire directly to identify and meet the needs of these patients.

Studies that have examined ratings of care by different racial or ethnic groups have found inconsistent results. However, if large minority populations are present, especially if their race or ethnicity differs from that of most of the hospital care providers, it is important to survey such groups to ascertain whether specific concerns need to be targeted to improve their experiences.

The Elderly Patient

Elderly patients require special sensitivity to toileting needs, and how these are handled can greatly affect their satisfaction with care. To maintain dignity and have the best chance of maintaining continence, elderly patients need to be answered promptly when they call so that they can be taken to the bathroom, placed on a commode, or given a bedpan. When they are incontinent, sheets must be changed promptly. Bedpans are uncomfortable for frail

elderly patients with atrophic skin and should be promptly removed when they are finished using them.

Elderly patients also are more likely than others to become immobile and less physically functional in the hospital because of increased sensitivity to sedatives, opiates, anticholinergic agents, and other commonly used hospital medications. Early ambulation, restraint-free environments, and aggressive physical therapy are very important in preserving independent function. This translates into fewer demands placed on the hospital staff and greater patient satisfaction (Chapter 16).

The Dying Patient

For hospitalized patients at the end of life, patient comfort and patient and family satisfaction are the most important outcomes. Of paramount importance is prompt and effective treatment of the patient's pain and discomfort, emotional support for both patient and family, involvement of both patient and family (as desired by the patient) in treatment decisions, and communication of as much information to patient and family as they desire about the patient's condition and treatment.

Particular care must be taken with families who are unexpectedly faced with the death of a loved one, and those whose relative is receiving mechanical ventilation. Ongoing discussion about the natural history of the patient's condition and treatment options is critical. Treating physicians should set up regular times for communication with the family. One possible mechanism is for the team to designate one physician to be in charge of communicating with the family or the patient's designated advocate. This advocate can then be asked to provide information to other family members.

Family members of dying patients have great emotional needs as they struggle with the imminent loss of a

close relative. Small acts on the part of hospital staff members can have powerful long-term comforting effects that assist relatives in adjusting to a death. These may include coming into the patient's room or a family lounge to inquire about the health and emotional state of the family member rather than simply ministering to the patient, providing snacks or juice to family members who are spending many hours by the patient's bedside, communicating regularly about the illness and its treatment, and ensuring that relatives designated by the patient as proxies are involved in treatment decisions. Patients from different backgrounds have widely varied expectations and needs at the time of death, and the staff should attempt to find out early in the hospital stay whether there are any specific issues of concern to individual patients and their family members (Chapter 19).

SYSTEM CHARACTERISTICS RELATED TO PATIENT EVALUATIONS OF CARE

Most studies comparing managed care with fee-for-service care have found a lower rate of satisfaction with care in managed care environments, but these have not concentrated on the hospital environment. However, as cost pressures on hospitals increase under ever more aggressive care management and greater assumption of risk by providers, it will be important to monitor whether patients perceive their hospital stays as too short and feel that not enough instruction and education are provided in preparation for the transition to home.

Patients at large hospitals and teaching hospitals tend to be less satisfied with their care (6). Studies have suggested that this is a consequence of the relatively large number of providers involved with patients, conflicting communications, and the size and complexity of interactions, which lead to a loss of intimacy and caring. To mitigate these effects requires a concerted effort by all providers to keep primary providers and other specialty consultants informed of the care plan and of communications with patients and families, and to keep nurses informed of the care plan so that they can help to convey accurate information to patients and families. A daily goals sheet can alert all personnel to care goals for the day; in one study this simple intervention raised staff awareness of patient care goals from 10%–90% (7). Medical students, residents, fellows, and specialty consultants must be taught to treat patients and families with caring and respect no matter how brief and specialized their interactions with them. Fortunately, the American Council on Graduate Medical Education (ACGME) and several of the Residency Review Committees that accredit residency programs now require competency in communication (see www.acgme.org). Curricula are available for these purposes and are likely in the next few years to become standard parts of house staff and postdoctoral fellowship training (8). These have healthy effects on trainee interactions with patients in teaching hospitals.

CONCLUSIONS

The importance of patient evaluations of hospital care will continue to grow in our environment where hospitals increasingly become cost centers, health plans look for better value (Chapter 12), and consumers become more involved and educated about hospital choice. Hospitalized patients are often too ill to advocate for themselves, and staff members treating them must be particularly sensitive to their needs.

KEY POINTS

- Patient satisfaction is an increasingly important outcome of hospital care.
- Hospital staff can improve patient satisfaction, mostly through improving nursing response to pain and toileting needs, respectful and caring interpersonal treatment, and patient education.
- Systems can improve staff interpersonal and patient education skills by including such skills as criteria for personnel selection and evaluation, providing training in these areas, and offering patient education materials in a variety of different media.
- Family members, especially of dying patients, need a quick response to their relative's pain or discomfort, emotional support, and information, and they should be involved in decisions as appropriate.

Nutritional Issues in the Hospitalized Patient

15

Annette Stralovich-Romani *Christopher R. Pennington**

INTRODUCTION

Malnutrition is recognized as a major contributor to morbidity and mortality in hospitalized patients across a spectrum of diagnoses. Many studies of nutritional status in hospital patients, based on anthropometric data, have indicated an incidence of malnutrition of 30%–40% (1). Significant nutritional depletion occurs in the majority of patients during their hospital stay, and those who are already malnourished on admission are the most severely affected. Early identification of patients who will benefit from nutrition intervention can lead to cost-effective and beneficial outcomes. This chapter focuses on the diagnosis, prevention, and management of nutrition depletion in hospitalized patients.

EFFECTS OF STARVATION AND METABOLIC STRESS IN HOSPITALIZED PATIENTS

Food substrates lead to the synthesis of glycogen, lipid, and protein under the influence of insulin. After meals, insulin concentrations are reduced and glycogen is mobilized to supply glucose. During periods of starvation, glycogen stores are rapidly exhausted and fatty acids liberated from tissue stores by lipolysis supply the energy substrate, except

in the central nervous system, which depends on glucose. However, ketones formed in the liver from fatty acids supply some energy to the central nervous system, thus minimizing the requirement for glucose and the catabolism of muscle for gluconeogenesis. This adaptive mechanism is disrupted, however, during periods of acute illness, especially critical illness or injury.

The metabolic response associated with acute stress, critical illness, or injury is often referred to as *hypermetabolism*. Metabolic stress is triggered by the release of the counter-regulatory hormones (catecholamines, glucagon, cortisol), and cytokines (tumor necrosis factor, interleukin-1, interleukin-6). The catabolic hormones stimulate gluconeogenesis, increase net protein catabolism and cause glucose intolerance/insulin resistance. The cytokines produce a spectrum of effects, including skeletal muscle proteolysis, increased metabolic rate, release of acute phase reactants, and depression of hepatic protein synthesis (albumin, prealbumin, transferrin, retinol binding protein).

Stressed starvation has a profound effect on the nutritional status of a patient. Whereas in a previously fit person death from starvation takes about 60 days (depending on initial body stores), the nutritional decline in sick persons is influenced by their disease process and may be much more rapid.

Nutritional intervention is required long before patients become seriously malnourished. One important experiment demonstrated that many weeks are needed to restore lean body tissue, even with nutritional repletion (2). Furthermore, tissue restoration is not attainable in the context of

* Deceased.

acute illness, so that minimizing tissue loss is the nutritional objective (3). Impaired organ function can be demonstrated very early in the course of starvation, and reduced muscle strength has been shown after 5 days. Reduced muscle strength may impair mobilization of patients after surgery or illness and may also compromise other important muscle groups, notably the muscles of respiration.

The intestine may be particularly vulnerable to starvation. Besides its role in digestion and absorption, the GI tract has the distinct property of maintaining barrier function and normal bacterial flora of the intestine. Gastrointestinal tissues require direct contact with nutrients to support cell replication and the numerous metabolic and immunologic functions required for successful adaptation to stress (4). Absence of luminal nutrient stimulation, therefore, may lead to gut atrophy, which can result in bacterial translocation. The integrity of intestinal immunity, particularly during a period of physiologic stress, may therefore be helpful in preventing infectious complications and averting the development of multisystem organ failure in the critically ill.

NUTRITIONAL ASSESSMENT

Upon admission to the hospital all patients should undergo nutritional screening to identify those individuals with either pre-existing malnutrition or those who are at risk for nutritional compromise. Many types of hospitalized patients are commonly malnourished. Patients with infectious and inflammatory disorders (e.g., AIDS, cancer) often have cytokine-mediated anorexia. Patients with gastrointestinal disease may be afraid to eat due to abdominal pain or other symptoms, be unable to eat because of dysphagia, or suffer from impaired digestion and absorption resulting from pancreatic and intestinal disease. Elderly patients, those who are depressed, and patients with underlying lung disease (chronic obstructive pulmonary disease, cystic fibrosis) are especially vulnerable to malnutrition. Patients with neurological injury (stroke, subarachnoid hemorrhage, trauma) or other critical illness are also prone to nutritional compromise.

Malnutrition may develop in some patients after admission because of the nature of their illness. Patients unable to swallow as a consequence of cerebrovascular disease, those with intestinal obstruction, and those requiring frequent fasting for investigation or therapeutic intervention will all suffer from starvation unless they receive nutritional therapy.

The evaluation of nutritional status is a vital step in formulating nutritional care plans for patients. Unfortunately, most markers of malnutrition lack specificity and sensitivity. Therefore, until improved methods of identifying malnutrition are developed, it is necessary to perform a comprehensive assessment which includes carefully selected objective parameters, a nutritionally focused physi-

cal exam, and other subjective parameters. However, in daily clinical practice, the nutritional assessment process must center around assessment parameters that are clinically relevant, easy to obtain, and cost-effective (5) (see also Table 16.2).

When evaluating nutritional status, it is important to obtain subjective data from the medical history that may bear relevance on the patient's nutritional well-being. For example, acute or chronic illnesses, medications (immunosuppressive agents, corticosteroids), psychosocial history, diagnostic tests/procedures, surgeries, or other treatment modalities (chemotherapy, radiation therapy) may all significantly influence nutritional status (6). A thorough nutritional history should also be completed and include weight and appetite changes, diet information, bowel habits, chewing and swallowing abilities, and activity level.

Careful observation of physical appearance adds a dimension to the evaluation of nutritional adequacy. Severe wasting of lean body mass and subcutaneous fat stores are signs of frank malnutrition. The physical exam should also focus on edema, dermatitis, and overt signs of vitamin and mineral deficiencies (alopecia, cheilosis, glossitis, stomatitis, bleeding gums, bruising, visual changes, rickets).

Anthropometry can be used to obtain objective parameters for assessment of nutritional status. Body weight—although useful for establishing the diagnosis of malnutrition—provides only a crude evaluation of overall fat and muscle stores. *Body mass index* [weight in kilograms divided by height in meters squared (m^2)], is often used to help determine nutritional status (normal range 20–25). Values below 18 signify important nutritional depletion. Patients with values above 25 and 30 are respectively defined as overweight and obese. Usual body weight, rather than ideal body weight, is a much more useful nutritional assessment parameter in the ill population. Loss of 5% of body weight in one month or greater than 10% of body weight in the 6 months preceding admission signifies nutritional depletion. When assessing the weight status of a critically ill patient, exercise caution as to what weight is being used, for weights are influenced by fluid shifts and therefore are unreliable. Dry weights are more ideal for determining nutritional status, determining nutrient requirements, and monitoring response to nutritional therapy.

Skinfold measurements, although rarely used in the clinical setting, are indirect methods of measuring somatic protein and subcutaneous fat. These measurements have limited utility in the critical care setting due to edema/fluid shifts. Skinfold measurements tend to have more merit in the outpatient arena when nutritional status is being serially evaluated over time or in the pediatric population to assess growth.

Various serum protein levels have been used in assessment of nutritional status. Albumin, transferrin, thyroxine-binding pre-albumin, and retinol-binding protein are

most commonly used in the clinical setting. Serum albumin is best evaluated at admission because levels rarely show nutritionally relevant changes during hospitalization due to its long half-life (18–20 days). The advantages of albumin are that it is inexpensive, it is useful with long-term assessments, and it is a valuable prognostic indicator of morbidity and mortality. Serum albumin levels dramatically decrease, however, with metabolic stress and injury. Albumin levels may also change quickly as a result of non-nutritional factors, and respond slowly even with adequate nutrition support. In fact, plasma albumin levels will not increase in stressed patients until the inflammatory response remits. Therefore, little credence should be given to albumin as a marker of nutritional status or response to nutritional therapy during a period of metabolic stress.

Because of their shorter half-lives and smaller protein pools, transferrin, pre-albumin, and retinol-binding protein have been touted as better markers of status. However, like albumin, these constitutive proteins decrease independently of nutritional status during critical illness due to the preferential production of acute phase reactants over the synthesis of visceral proteins. It should not be assumed, therefore, that decreased levels of serum proteins are caused solely by malnutrition. Normal patterns of hepatic protein synthesis and degradation are altered during critical illness, making evaluation difficult (Table 15.1).

NUTRITIONAL REQUIREMENTS

Energy Requirements

The amount of energy required is a function of resting needs (those required to do daily metabolic work), with adjustments added for activity, specific dynamic action of food, healing, repair of nutritional deficits, painful stimuli, and any catabolic insult (such as trauma, sepsis, and surgery). Several methods exist to determine energy requirements. These include predictive equations, nomograms, and indirect calorimetry.

Predictive Equations

Predictive equations are most often estimated using the Harris-Benedict equation (Table 15.2), which estimates resting energy expenditure and then is multiplied by stress factors ranging from 1.2–2.0, depending on the clinical condition of the patient. The utility of this formula in critically ill patients is limited since this equation was developed from data on normal volunteers.

Indirect Calorimetry

A more accurate method to calculate energy expenditure, especially in the complex and rapidly changing setting of critical illness, is indirect calorimetry. This method can be

TABLE 15.1
SERUM PROTEINS FOR NUTRITIONAL ASSESSMENT

Serum protein	Half-life	Normal range	Comments
Albumin	20 days	3.5–5.0 g/dL	Large body pool; reliable predictor of morbidity and mortality; reflects chronic vs. acute protein depletion; responds slowly to changes in nutritional status; decreased levels with fluid overload, malabsorptive states, stress (sepsis, burns, trauma, postoperative states), and certain disease processes (liver failure, congestive heart failure); increased levels with anabolic agents, dehydration, and infusion of albumin, fresh frozen plasma and whole blood
Transferrin	8–10 days	200–400 mg/dL	Smaller body pool; sensitive to changes in nutritional status; calculated from total iron binding capacity; decreased with chronic infection, stress, uremia, iron overdose, overhydration, liver failure; increased with pregnancy, iron deficiency, hypoxia, hepatitis, dehydration, estrogens
Prealbumin (Transthyretin)	2–3 days	15–40 mg/dL	Rapid turnover rate; small body protein pool; quickly changes with changes in nutritional status; decreased levels with stress, inflammation, surgery, liver disease; increased levels with renal dysfunction
Retinol-binding protein	8–10 hours	2.7–7.6 mg/dL	Highly sensitive to changes in nutritional status; decreased levels in same states as pre-albumin, as well as in vitamin A deficiency; increased levels with renal dysfunction and vitamin A supplementation

TABLE 15.2
HARRIS-BENEDICT EQUATION FOR ESTIMATING ENERGY REQUIREMENT

Men: $REE = 66.5 + (13.75 \times W) + (5 \times H) - (6.76 \times A)$
 Women: $REE = 655 + (9.56 \times W) + (1.85 \times H) - (4.68 \times A)$
 W = Weight (kg)
 H = Height (cm)
 A = Age (years)

REE, resting energy expenditure, in kcal/day.

carried out at the bedside using portable machines that are costly and require trained personnel to operate. The premise of indirect calorimetry is that it calculates energy expenditure by measurement of respiratory gas exchange (specifically the measurement of oxygen consumption (V_{O2}), carbon dioxide production (VCO₂), and minute ventilation (VE)), and then applying the Weir equation (7). When measured energy expenditure is obtained from indirect calorimetry, some clinicians add a factor of 10%–20% to account for 24-hour variability.

Protein Requirements

The goal of protein provision is to minimize the degree of net nitrogen loss. Since protein reserves do not exist in the body, protein must be continually replenished. Under normal circumstances the recommended daily intake of protein is approximately 0.8 gm of protein/kg body weight. In critical illness, the proper provision of protein is crucial as it is the most important macronutrient with stress and/or injury. Protein requirements are high with trauma, sepsis, and also go up to meet the demands for healing of burns, necrotizing fasciitis, and other types of large wounds. In some disease states, such as renal failure and hepatic encephalopathy, protein requirements may be reduced (Table 15.3).

Nitrogen Balance

Nitrogen balance, when correctly measured and calculated, remains the best available marker of the effects of acute nutrition intervention, and the best nutritional predictor of outcomes. Urinary nitrogen losses following injury and illness tend to parallel the increased energy expenditure with increased degrees of stress. The magnitude of nitrogen loss varies with the severity of disease (8). Nitrogen balance is equal to nitrogen intake minus urinary nitrogen output plus obligatory losses from skin, stool, and respiration. It ranges from 2–4 grams per day. When there are excessive losses of nitrogen from severe diarrhea, fistula drainage,

burn exudate, ostomy output, or wounds or pleural drainage, total nitrogen content should be determined when practical.

A positive nitrogen balance correlates with net protein synthesis (*anabolic state*) and suggests adequate nutritional support. A negative nitrogen balance, on the other hand, indicates that the rate of protein breakdown exceeds the rate of protein synthesis (*catabolic state*), and therefore indicates the need to adjust the nutritional support regimen. Positive or even neutral nitrogen balance may be difficult to achieve in critically ill patients due to the effects of catabolic hormones, medications, bed rest, fever, and infection. The goal of nutrition support, therefore, is to offset the degree of catabolism rather than to achieve positive balance. Once the source of stress is resolved, an anabolic state should be attainable.

A nitrogen balance study should only be completed after the patient has been on relatively constant protein and energy intake for 3 days, thus allowing the urea cycle and gluconeogenic enzymes to adjust to protein intake. Urine should be kept on ice during the collection and analyzed within 4 hours to prevent loss of urea due to bacterial conversion to ammonia.

The major limitation of using a standard nitrogen balance study in critically ill patients is that a creatinine clearance greater than 50 mL/min is required for accurate interpretation. With liver failure, nitrogen balance studies are usually invalid due to decreased urea production.

TABLE 15.3
ESTIMATING PROTEIN REQUIREMENTS

Normal renal function

Maintenance	0.8–1.2 gm of protein/kg/day
Moderate stress	1.3–1.5 gm of protein/kg/day
Severe stress	1.5–2.0 gm of protein/kg/day

Renal Failure

Non-dialyzed	0.8–1.2 gm of protein/kg/day
Hemodialyzed	1.0–1.4 gm of protein/kg/day (may be adjusted based on frequency of dialysis)
CAPD	1.3–1.5 gm of protein/kg/day
CAVHD/CVVHD	1.6–1.8 gm of protein/kg/day

Hepatic Failure

without encephalopathy	Begin at 1.0 gm of protein/kg/day, increase as tolerated to 1.5–2.0 gm of protein/kg/day
with encephalopathy	0.8–1.0 gm of protein/kg/day (no less than 40 gm/day)

CAPD, continuous ambulatory peritoneal dialysis; CAVHD, continuous arterio-venous hemodialysis; CVVHD, continuous veno-venous hemofiltration dialysis.

NUTRITIONAL SUPPORT FOR PREVENTION OR TREATMENT OF MALNUTRITION

During periods of metabolic stress, tissue wasting should be minimized by the provision of adequate nutrition. This truism is supported by data showing that the use of early enteral feeding in postoperative patients reduces the incidence of infection. There is also abundant evidence that nutritional support and the correction of nutritional depletion, when possible, reduces mortality, morbidity, and length of hospital stay.

Patients with initially normal nutritional status should be considered for nutritional support if they will not be able to eat for more than 5–7 days, or if it is anticipated that their dietary intake will be inadequate for 7–10 days or more. Patients who are malnourished or metabolically stressed should receive nutritional support within 3 days if their oral intake is not satisfactory or if oral feeding cannot be achieved. Significant nutritional depletion should be avoided because of the early effects on organ function, the prolonged period required for nutritional repletion, and the fact that malnutrition cannot be corrected in the stressed patient.

NUTRITION SUPPORT MODALITIES

Enteral Nutrition

Enteral nutrition is the preferred modality of nutrition support because it is cost-effective and has beneficial outcomes. Perhaps the most striking clinical benefit of enteral nutrition is preservation of the gastrointestinal tract. Enteral nutrition is strongly favored over parenteral nutrition because some studies have shown that there is a significantly lower incidence of septic complications in patients fed enterally rather than parenterally.

Liquid oral nutritional supplements in various flavors may be sufficient for some patients with anorexia, failure to thrive, esophageal disease or other disorders associated with malnutrition when the normal diet is inadequate to meet their nutrient needs. Patients with severe impairment of appetite or an inability to eat because of neurologic or oropharyngeal disease will need enteral tube feeding. Tube feeding may also be indicated in patients with intestinal failure, as in Crohn's disease or short bowel syndrome. Critically ill patients will also undoubtedly require enteral nutrition support.

Technological advances in enteral feeding have significantly influenced the practice of enteral support. Improvements in placement procedures, enteral feeding devices, and nutritional products have allowed enteral nutrition to be provided to patients who previously would not have been candidates for it, and would therefore have been on parenteral nutrition.

Newer Clinical Applications for Enteral Nutrition

There are several clinical conditions now deemed appropriate for enteral nutrition support that deserve mentioning (9). The use of enteral feeding in fistula management is becoming more widespread. The ability to enterally feed is contingent upon the site and extent of usable intestine for feeding. To avoid reflux, it is necessary to feed 40 cm distal to the fistula. Spontaneous closure rates comparable to TPN have been reported. In short bowel syndrome, enteral feeding is used in conjunction with parenteral nutrition. Minimal infusion of enteral nutrition has been shown to foster intestinal adaptation/rehabilitation. Utilization of alternative substrates (glutamine, fiber, growth hormone) may promote successful adaptation.

A new alternative for providing nutrition support to the patient with acute pancreatitis has been jejunal feedings placed either nasojejurally or with an operative jejunostomy. Because the cephalic and gastric phases of digestion are bypassed, this method leads to decreased pancreatic stimulation.

Another area in which the efficacy of enteral feeding warrants in-depth investigation is in patients undergoing bone marrow transplantation. There is hope that enteral feeding in this population might help restore the GI mucosa following chemotherapy and radiation therapy, prevent bacterial translocation, maintain normal immune responses, promote smoother transition to oral feeding, and decrease cost.

Timing

Timing may be crucial when it comes to instituting enteral alimentation in critically ill or injured patients. If possible, enteral feeding tubes should be placed within 48 hours of admission to the ICU. Administration of enteral nutrition into the small bowel 8–12 hours following surgery is being practiced widely, and with good success, since peristalsis is often well maintained in the small bowel postoperatively. *Bowel sounds should not be used to indicate feasibility of enteral alimentation, but rather to indicate the adequacy of gastric emptying.* Although gastric and colonic motility are impaired in most critically ill patients, small bowel motility and absorption are usually intact.

Early administration of enteral nutrition appears to minimize gut atrophy, decrease sepsis, enhance immunocompetence, and blunt the hypermetabolic response to stress. The role of pharmacomodulation of the gut has also received increased attention. Pathologic conditions and unavoidable iatrogenic disorders that affect gut function may be able to be managed with drug therapy (octreotide, propofol, 5-hydroxytryptamine-3 receptor antagonists, erythromycin, oral naloxone) to allow enteral feeding to be used (10).

Tube Types and Location

The administration of enteral nutrition is generally accomplished by using nasogastric feeding tubes inserted into the stomach, duodenum or jejunum. Nasogastric feeding tubes are the most frequently used because they are easy to place and less costly and risky than tubes requiring surgical insertion. Small bore feeding tubes are preferred over the traditional nasogastric tubes (salem sumps) because there is less risk of tracheoesophageal fistula and aspiration, and they are more comfortable. The downside to using the small feeding tubes is that they are prone to collapse and clogging, making it difficult to check for feeding residuals.

Gastric feeding is suitable for many patients. However, in cases of altered GI motility (gastroparesis, gastric ileus, delayed gastric emptying from opiates, elevated intracranial pressure), the feeding tube should be placed transpylorically. In critically ill or postoperative patients, along with patients who have an absent gag reflex or who are on non-invasive positive pressure ventilation (BiPAP), having the feeding tube in the small bowel is essential. Jejunal feeding tubes are a must when feeding patients with acute pancreatitis.

Many bedside placement techniques for passing weighted tubes beyond the pylorus are available and usually successful. Auscultation while the patient is in the right lateral decubitus position can be used to track the tube into the small intestine. However, if this method is unsuccessful, then endoscopically or fluoroscopically guided tube placement may be indicated. Prokinetic drugs can also help

facilitate tube positioning. Upon placement of the feeding tube, radiographic confirmation is necessary before initiating the enteral feeding regimen.

Methods of Delivery

Enteral nutrition can be delivered by bolus, intermittent, or continuous feeding. *Bolus feeding* is the rapid infusion of a large volume of enteral formula over a short period of time. GI complications (e.g., diarrhea, nausea, vomiting, aspiration, distention) may result, however. *Intermittent feeding*, using either gravity drip or an infusion pump, can deliver a moderate to large volume of enteral formula over a defined period, usually from 1 to 16 hours. *Continuous tube feeding* is the infusion of a small amount of enteral formula over 24 hours using an infusion pump. *In critically ill patients and with small bowel feedings, the continuous delivery method is essential.* Continuous feedings are better tolerated than bolus or intermittent feedings, and are associated with reduced incidence of high gastric residuals, gastroesophageal reflux, and aspiration.

Formula Composition

There are many commercially available enteral products that differ in composition and proportion of nutrients, as well as cost. All formulas contain carbohydrate, fat, protein, and water, as well as vitamins, minerals, trace elements, and electrolytes (Table 15.4). Polymeric formulas contain intact

TABLE 15.4
CLASSIFICATION OF ENTERAL FORMULAS

Category	Subcategory	Comments
Polymeric	Blenderized	Real food; requires normal digestion and absorption; lactose or lactose-free; isotonic; nutritionally complete
	Standard	Intact nutrients; lactose-free; low residue; isotonic; nutritionally complete; requires normal digestion and absorption
	High nitrogen	Intact nutrients; lactose-free; isotonic; protein >15% of total kcal; nutritionally complete; requires normal digestion and absorption
	Fiber-enriched	Intact nutrients; lactose-free; isotonic; soluble and insoluble fiber; regulation of bowel function; nutritionally complete; requires normal digestion and absorption
	Calorically dense	Intact nutrients, 1.5–2.0 kcal/mL; high osmolality; use with fluid restriction; lactose-free; nutritionally complete; requires normal digestion and absorption
	Disease-specific	Intact nutrients; protein, fat, and carbohydrate source varies depending on specific disease-state formula; electrolyte content and osmolality varies; requires normal digestion and absorption; expensive; efficacy controversial
Oligomeric (partially hydrolyzed/ semi-elemental)		Hydrolyzed protein; di-tripeptides, free amino acids; fat content varies (3%–40% of total kcal); lactose-free; osmolality varies (250–700mOsm/kg); nutritionally complete; digestion required; limited absorptive surface of GI tract
Monomeric (elemental/ chemically defined)		Free amino acids; lactose-free; fat varies (1%–15% of total kcal); high osmolality; may include glutamine; nutritionally complete, minimal digestion required; limited absorptive surface of GI tract
Modular		Individual nutrient (carbohydrate, fat, protein) modules; used to modify pre-existing commercial formula to increase nutrient density or to make unique formula; requires normal digestion and absorption

nutrients and require normal digestion and absorption. Lactose-free mixtures are the basic feeding formulation, since most hospitalized patients have genetic or acquired lactase deficiency. These formulas can be isotonic or hypertonic (300–800 mOsm per kg of water). Caloric density varies from 1.0–2.0 kcal/mL, with 40%–55% of total calories from carbohydrate, 12%–20% from protein, and 30%–50% from fat. Fats are provided as long chain triglycerides (LCTs) and medium chain triglycerides (MCTs).

Oligomeric and monomeric formulas are classified as elemental and semi-elemental/peptide-based formulas. They contain one or more partially digested macronutrients and are reserved for patients with compromised GI function (e.g., critical illness, pancreatic or bile salt deficiencies, intestinal atrophy, short bowel syndrome and inflammatory bowel disease). Caloric density is usually 1.0 kcal per mL. Elemental diets have a much higher osmolality than semi-elemental diets. These formulas are considered low fat and may contain a high proportion of fat in the form of MCTs. The efficacy of elemental diets remains controversial.

Widespread use of enteral feeding and an expanding knowledge of specific disease processes has led to an explosion in the development of disease-specific formulas. These formulas have been designed for specific organ failure, metabolic dysfunction, or immunomodulation. Given the cost and questionable efficacy of these specialized formulas, they should be used judiciously. Detailed formula descriptions, clinical indications, and possible benefits are beyond the scope of this chapter.

Formula Selection

Enteral formula selection should be based on the patient's digestive and absorptive capacity, organ function, specific nutrient needs, tolerances, and allergies, and should take into account the formula composition and total calories. Attention must also be given to fluid requirements, vitamin and mineral needs, and osmolality. Most enteral formulas contain water in the general range of 700–900 mL per 1,000 mL of enteral formula. The general rule of thumb is to provide 30 mL water/kg body weight, or as clinical status permits. When provided in sufficient volume, most nutritionally complete products contain adequate vitamins and minerals to meet the U.S. recommended dietary intake (RDI). If necessary, a daily multivitamin and mineral supplement can be added.

Initiation and advancement of enteral feedings will vary with the method of administration. Bolus feedings are generally administered over several minutes and are best tolerated when given at less than 60 mL/min (e.g., 240 mL of formula every 3 hours over at least 3 minutes). Intermittent feedings are generally better received if a maximum of 200–300 mL of formula is delivered over a 30–60 minute period every 4–6 hours. Continuous feedings are introduced at 10–30 mL/hour, and advanced in 10–20 mL increments every 8 to 12 hours until the goal

flow rate is attained. For patients who are critically ill, who have not been fed for an extended period of time, and those who are receiving calorie-dense or high osmolality enteral formulas, conservative initiation and advancement rates are highly advised (e.g., 10mL increments every 12–24 hours).

Complications

Complications associated with enteral feeding may be avoided and managed with appropriate monitoring. The major goal of monitoring is to minimize the complications of enteral therapy and to maintain the patency of the small bore feeding tube. An assessment of GI tolerance (i.e., nausea, vomiting, abdominal discomfort/distention, stool pattern) is mandatory when a patient is on enteral nutrition support. Hydration status and laboratory data must also be evaluated when a patient is being enterally fed. Preventive measures should be taken to minimize the risk of aspiration. Keeping the head of the bed elevated at a 30–45 degree angle and checking for tube feeding residuals are recommended to lessen the potential for aspiration. With continuous feeding, residuals should be checked every 4 hours and should not exceed 200 mL. If the patient has a cuffed tracheostomy, the cuff can be deflated 2 hours after bolus feedings; for continuous feeds, the cuff may be deflated only when necessary to prevent tracheal complications. Routine flushing of feeding tubes with 30–60 mL of water every 4–6 hours will help extend the life of the small tubes.

Although enteral nutrition is generally safe, complications may arise. There are three types of complications: mechanical, gastrointestinal, and metabolic. *Mechanical complications* of nasoenteric tube feedings include tube obstruction, displacement, or dislodgement; nasopharyngeal irritation; and gastric rupture. Obstruction or clogging of the tube occurs most frequently from inadequate crushing of medications and from formula residue adhering to the lumen of the tube. Giving liquid medications (elixirs, suspensions) rather than pills or syrups may help to avoid clogging. Flushing with water, as previously described, will help maintain patency of feeding tubes. Following proper procedures for feeding tube placement and verifying tube position will help avoid the complication of tube displacement. Using small soft tubes, lubricating tubes for insertion, and maintaining good hygiene of the mouth and nares improves patient comfort.

The most common complications of tube feedings are *gastrointestinal*, including diarrhea, nausea, vomiting, constipation, delayed gastric emptying, and GI bleeding. The major causes of formula-related diarrhea are rapid infusion rate, formula characteristics (hypertonic, low fiber/residue, high fat), and bacterial contamination. Medications (sorbitol-containing elixirs, antibiotics, laxatives, magnesium and phosphorous supplements), pancreatic insufficiency, fecal impaction, and pathogenic bacteria (*Clostridium difficile*) can all be nonformula-related causes

of diarrhea in the tube-fed patient. Treatment of diarrhea is contingent on the etiology. Antimotility agents (lomotil, immodium, paregoric, deoderized tincture of opium) can be used in the treatment of diarrhea, provided stool cultures are negative for an infectious etiology.

High gastric residuals from delayed emptying can result from high fat and fiber formulas, rapid infusion rate, high osmolality formulas, certain disease state (e.g., diabetic gastroparesis), elevated intracranial pressure, sepsis, and certain medications (especially opiates). As previously discussed, checking feeding residuals is an essential component of the monitoring process. If patients have persistently high residuals, giving prokinetic drugs or placing the feeding tube in the small bowel should help alleviate the problem. During small bowel feedings, there should be little or no residuals obtained. If residuals are obtained, then chances are the feeding tube has relocated to the stomach, and verification of tube placement is warranted.

Constipation can result from low fiber/residue formulas, inadequate water/fluid intake, inactivity, decreased bowel motility, and medications such as phosphate binders, opiates, and calcium-channel antagonists. Neuromuscular blocking agents do not paralyze gut smooth muscle but may slow bowel motility via anticholinergic actions (11). Adequate hydration, fiber-enriched formulas, stool softeners, and bowel motility agents are helpful in improving constipation. Monitoring the stool pattern of the patient is also important for prevention of fecal impaction.

Metabolic complications that occur during enteral nutrition therapy are similar to those developed during parenteral nutrition, but are generally less severe. The most common metabolic disturbances are hyperglycemia, dehydration, and electrolyte imbalances (e.g., hyper-hypophosphatemia, hyper-hyponatremia, hyper-hypokalemia). Hyperglycemia is common in patients who are diabetic, who have poor glucose utilization due to insulin resistance from stress (trauma, sepsis), or who are on diabetogenic medications such as corticosteroids. Urine and blood glucose should be monitored at periodic intervals in all patients receiving enteral feeding. For optimal nutrient substrate utilization, blood glucose levels should be ≤ 150 mg/dL. Insulin administration will be required in patients with persistently elevated blood glucose levels. Subcutaneous administration of insulin is poorly absorbed in critically ill patients; therefore, an insulin infusion is required for the treatment of hyperglycemia. Tight glycemic control (i.e., blood glucose 80–110mg/dL) using an insulin infusion in critically ill patients has been shown to reduce mortality, bacteremia, and the number of days on mechanical ventilation (12) (see Chapter 107).

Repleting malnourished patients can result in the intracellular uptake of phosphorous, potassium, and magnesium as anabolism is stimulated, causing decreased serum levels of these electrolytes. These electrolytes should be closely monitored and replaced as needed. Thiamine supplementation is also needed in the malnourished patient.

Parenteral Nutrition

Parenteral nutrition (PN) is the intravenous administration of a hypertonic solution of carbohydrate, fat, protein, electrolytes, vitamins, minerals, and fluid. Although enteral nutrition support is the preferred modality of nutritional therapy, PN is an important technique in patients who have absolute gut failure, as with short bowel syndrome, small bowel obstruction, ischemia or ileus, severe GI hemorrhage, and fistulas not amenable to enteral feeding. Other patients who might require PN are those with severe mucositis following chemotherapy, or those in whom the use of the intestine is not possible after major excisional surgery. Additionally, PN should be initiated in any patient not tolerating full enteral nutrition support within 5–7 days.

Many patients will require only short-term parenteral nutrition. In these patients, nutrients can be infused via the peripheral veins with conventional cannulae rotated on a daily basis, or ultra-fine-bore 15-cm catheters inserted at the antecubital fossa. For more prolonged treatment, nutrients are infused into central veins through central catheters or peripherally inserted central catheter (PICC) lines. Peripheral access, however, may be limited by the dextrose concentration; a central line is necessary when infusing dextrose concentrations greater than 10%.

Formula Composition

Carbohydrate is the primary energy source in parenteral nutrition solutions. Dextrose monohydrate is the carbohydrate source yielding 3.4 calories per gram, and ranging in concentration from 5%–70%. The most frequently used dextrose concentrations for critically ill patients are 20% and 25%. The quantity of carbohydrate, however, is based on the patient's caloric requirement, optimal fuel balance, and glucose oxidation rate (i.e., hepatic oxidative capacity). Administration of no greater than 4–6 mg dextrose/kg/min per 24-hour period is recommended for optimal oxidation and prevention of fat synthesis (lipogenesis). Excessive carbohydrate provision is also associated with hepatic dysfunction and increased carbon dioxide production.

Crystalline amino acids are the form of protein currently added to PN admixtures. Standard amino acid solutions contain a balance of non-essential and essential amino acids tailored to the normal serum amino acid profile. Concentrations range from 3%–15%; they provide 4.0 calories per gram. Modified amino acid formulas contain a blend of amino acids designed to meet disease or age-specific requirements.

Intravenous fat is an aqueous dispersion containing soybean or safflower oil, egg yolk phospholipid (an emulsifier) and glycerin to achieve isotonicity. Long chain fatty acid emulsions are currently the only commercially available IV fat. They are available as either 10%, 20%, or 30% emulsions. Maintenance essential fatty acids (EFA) requirements can be met by providing 4%–10% of the total calories as fat

(2%–4% as linoleic acid). The 10% lipid emulsion provides 1.1 kcal/mL; 20% provides 2.0 kcal/mL; 30% provides 3.0 kcal/mL. IV fat is contraindicated in patients with disturbances in normal fat metabolism (i.e., triglyceride levels ≥ 400 –500 mg/dL), nephrosis when accompanied by hyperlipidemia, and severe egg allergy. For patients with pancreatitis of etiologies other than hypertriglyceridemia, intravenous fat infusions are not contraindicated. The recommended infusion rate varies depending on the lipid concentrations. For the 10% emulsion, a minimum of 8 hours is suggested. The anesthetic agent propofol is delivered in 10% intravenous fat, providing 1.1 kcal/mL. Attention must therefore be given to those patients who are on PN with lipids and on propofol.

Electrolyte requirements for patients receiving parenteral nutrition are patient-specific and influenced by nutritional status. Organ function, acid-base balance, medications, and gastrointestinal losses will also influence the electrolyte adjustments that will be needed in the PN solution to maintain electrolyte homeostasis. In stable patients, acid-base balance can, for the most part, be maintained by adding equal amounts of chloride and acetate. However, for patients with acid-base disturbances the acetate, which is metabolized to bicarbonate, and the chloride will need to be adjusted in an effort to help correct the abnormality. For example, in patients with severe metabolic acidosis, the chloride would be minimized and the acetate maximized. Vitamins and trace elements are added to PN solutions in doses consistent with the American Medical Association Nutrition Advisory Group's recommendations. Iron is absent in the multi-trace element preparation due to the fear of anaphylaxis, but iron can be given as iron dextran either in the PN formula or intramuscularly. Copper and manganese are excreted via biliary excretion. Consequently, supplementation of copper and manganese should be discontinued if baseline total bilirubin is three times the upper limit of normal or if total bilirubin triples from baseline value.

Initiation and Advancement

Parenteral nutrition therapy should be initiated at a slow rate (e.g., 30–40 mL/hour), using the final concentration planned for therapy and advanced as glucose tolerance permits until the nutrient needs of a patient are met. For critically ill patients, advancement of parenteral nutrition should be conservative (e.g., increased 20 mL every 24 hours until the goal rate is attained). Since dextrose concentration is limited in peripheral parenteral nutrition (5% or 10% dextrose), it may be initiated at the same rate as the usual peripheral IV fluids.

Monitoring

Successful administration of PN requires careful monitoring. Blood glucose monitoring via finger sticks every 4–6 hours (more frequently in the ICU) is indicated until the infusion rate has stabilized. Serum glucose should be main-

tained under 120 mg/dL in ICU patients, and under 150 mg/dL in non-ICU patients. Serum triglycerides should be checked 6 hours after the completion of the intravenous fat infusion to assess the patient's lipid clearing capacity, especially in the face of hyperglycemia and steroid therapy. Serum triglyceride levels should be ≤ 400 mg/dL. Electrolytes must be followed to assure adequate hydration, renal function and need for supplementation or restriction. Finally, liver function should be periodically monitored.

Complications

Mechanical, metabolic, infectious, and hepatic complications may occur when using parenteral nutrition support. Pneumothorax is the most common mechanical complication. Others include thrombus, catheter occlusion, and air embolus. The infectious complications seen with parenteral nutrition are typically catheter-related (see Chapter 72). Hyperglycemia is the most prevalent metabolic complication. Risk factors for hyperglycemia include metabolic stress, medications, obesity, diabetes, and excess calories and/or carbohydrate. Malnourished patients are prone to refeeding shifts. For an extensive list of the metabolic complications of parenteral nutrition and suggestions for prevention and treatment, the reader is referred to a major text on parenteral nutrition (13).

Hepatobiliary abnormalities have been identified in patients on total parenteral nutrition who have no underlying liver disease. Elevated aminotransferases, alkaline phosphatase, and bilirubin concentrations may occur days to weeks after initiation of parenteral nutrition. Enzyme levels may return to normal while a patient is on PN, but almost always normalize when it is discontinued. Steatosis (fatty liver) is the most frequent hepatic derangement that occurs with PN. High glucose infusions, exceeding 4–6 mg dextrose/kg/min, is the primary etiologic agent in the production of fatty liver. The excessive provision of intravenous fat can also result in fatty infiltration of the liver.

Gallbladder stasis (biliary sludging) is felt to be the primary cause of PN-associated biliary disease. Stimulating gallbladder contractility with enteral feedings usually reverses this process. To manage and prevent PN-induced hepatic dysfunction, use the GI tract whenever possible, avoid overfeeding, provide a well-balanced fuel mix, cycle the PN regimen, consider carnitine and glutamine supplementation, and work up alternative causes such as hepatitis, biliary obstruction, hepatotoxic drugs, and sepsis.

CONCLUSIONS

Malnutrition is common in patients who are admitted to the hospital, and the nutritional status deteriorates during the hospital stay in most patients. Nutrition, therefore, becomes of vital importance in maintaining nutritional status during illness. Fortunately, malnutrition can be prevented or treated in most patients by using nutrition support.

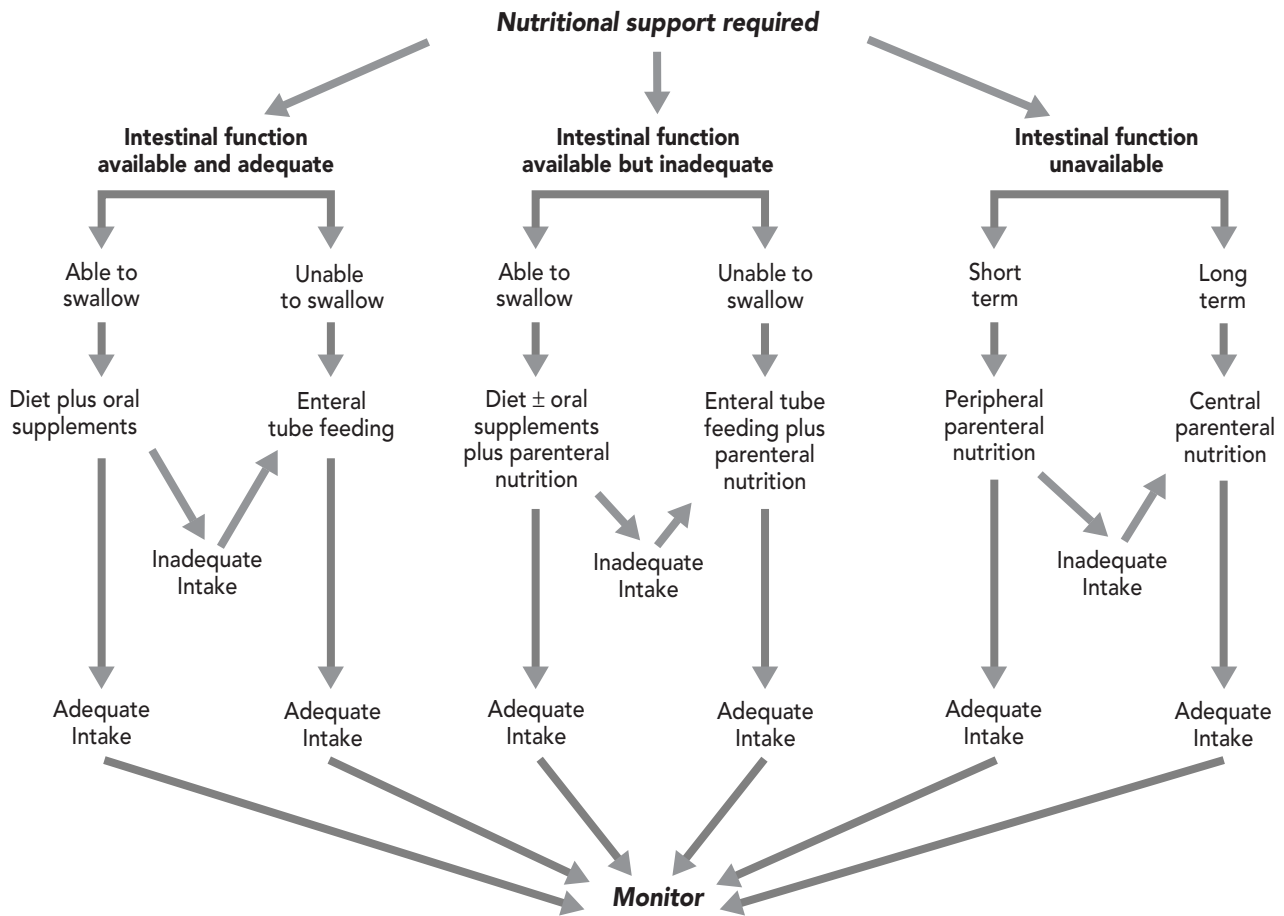

Figure 15.1 Summary of nutritional management in the hospital patient.

Although enteral nourishment is the optimal route of administration, at times it is not medically feasible or well tolerated. Under these circumstances total parenteral nutrition is indicated; however, every effort should be made to switch to enteral feeding when possible (Figure 15.1).

Unfortunately, attempts to improve a patient's prognosis through nutritional intervention can be counterproductive when nutritional therapy is poorly managed. Both enteral and parenteral nutrition (particularly the latter) are associated with serious and sometimes life-threatening complications. Thus, nutritional therapy merits the same high standard of care applied to other therapeutic modalities, and patients who do not need artificial nutrition support should not receive it.

Approach to the Hospitalized Older Patient

C. Seth Landefeld C. Bree Johnston Mary Anne Johnson

INTRODUCTION

Older people are at disproportionate risk of becoming seriously ill and requiring hospital care. Persons 65 years of age or older make up only 13% of the U.S. population but account for 35% of acute-care hospital admissions and 45% of hospital expenditures for adults. The impact of older persons on acute hospital care will increase rapidly with the aging of the population. The number of Americans 65 years of age or older is expected to double to 71 million by 2030, representing 20% of the U.S. population. Particularly striking is the projected growth in the number of persons over age 85, especially in the middle third of the century (Figure 16.1).

Once hospitalized, older patients are at high risk for loss of independence and institutionalization. Among hospitalized medical patients 70 years of age or older, nearly 15% experience a decline in their ability to perform basic self-care activities of daily living (ADL), another 20% are discharged without recovering their baseline abilities, and 15% of those admitted from home are discharged to a nursing home (1). Loss of personal independence is often promoted by the reciprocal effects of the acute illness that led to hospitalization and underlying chronic illnesses and impairments. In addition, many older patients have lost their “bounce”—their ability to recover rapidly and completely from the acute insults of illness and hospitalization to their physiologic, psychological, and social systems. Thus, optimal care for the hospitalized older patient requires the physician to manage acute illness while simultaneously intervening as necessary to promote or maintain independent functioning.

RATIONALE FOR A SYSTEMATIC APPROACH TO HOSPITALIZED OLDER PATIENTS

This chapter outlines an approach to the hospitalized older patient that incorporates systematic assessments at the level of the organ system, the whole person, and the person’s environment. This approach can identify areas in which targeted interventions may improve function or reduce risk for adverse outcomes. Although this approach has been designed specifically for older persons, a similar approach may often be appropriate in other patients with complex chronic illness.

Table 16.1 summarizes a suggested approach to the systematic assessment of 10 common problems that are frequently overlooked in hospitalized elders. Seven of these problems are primarily at the level of organ systems, two are at the level of the whole person, and one is at the level of the person’s interaction with the environment. These 10 problems were selected on the basis of their relative importance, the quality of relevant evidence, and their specificity to older persons. Other important problems (e.g., use of alcohol or tobacco, pain management, and advance directives) are not specific to older persons, and some problems specific to the elderly (e.g., age-related decline in renal function) are widely recognized.

Although this chapter focuses on addressing these problems in the hospital, it is important to recognize the importance of continuity of care before and after hospitalization. In the care of the hospitalized older patient, initial and ongoing communication between the hospital physician and the primary care physician, if these are two different

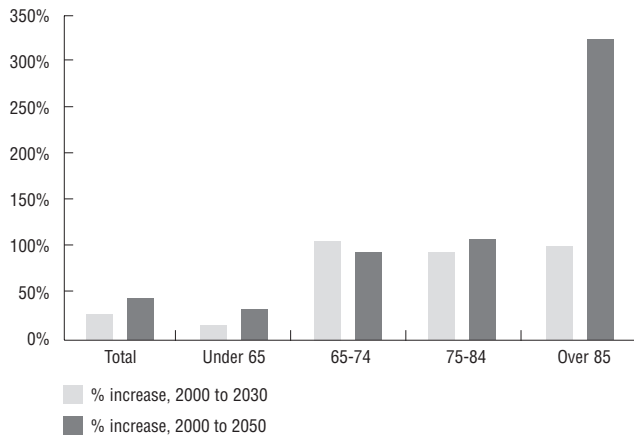

Figure 16.1 The aging of the U.S. population. Projected increase in population cohorts by age between 2000 and 2030 and between 2000 and 2050. (Source: U.S. Bureau of the Census)

persons (Chapter 1), is essential. Knowledge of the patient’s prior function, medical and psychosocial history, mental status, and values should inform decisions about acute and post-acute care. Ongoing communication throughout the hospitalization also helps ensure that there will be continuity of care after discharge.

The proposed approach requires the marshaling of resources early in the hospitalization, generally in the form

of the time of the physician, nurse, social worker, or other staff. Two types of evidence suggest that these interventions are a good investment. First, for each problem, there is compelling evidence supporting the proposed intervention, either because the efficacy of the intervention is well established (e.g., warfarin to prevent stroke related to atrial fibrillation) or because the associated problem is frequent, often overlooked, and can be relieved with a safe and inexpensive intervention. Second, these types of systematic approaches to the evaluation and management of acutely ill older persons can improve patient outcomes and reduce hospital costs (2).

MANAGEMENT OF THE HOSPITALIZED PATIENT

Assessment at the Level of Organ Systems

Problem 1. Atrial Fibrillation (Cardiovascular Function)

Rationale. Nonvalvular atrial fibrillation is present in 5% or more of hospitalized elders, often found as an incidental finding. Consistent and compelling evidence from randomized trials shows that the risk for stroke in persons with

TABLE 16.1

SYSTEMATIC ASSESSMENT OF HOSPITALIZED OLDER PATIENTS: A FRAMEWORK HIGHLIGHTING 10 COMMON PROBLEMS THAT ARE FREQUENTLY OVERLOOKED

Problem (domain of assessment)	Assessment methods	Illustrative interventions
Assessment at the level of organ systems		
1. Atrial fibrillation (cardiovascular)	Take pulse, ECG	Warfarin, treatment to maintain sinus rhythm
2. Malnutrition (gastrointestinal)	Subjective Global Assessment (Table 16.2)	Supplement water, calorie, protein intake; assess social environment
3. Influenza and pneumococcus (infection)	Ask about vaccination	Vaccination against influenza, pneumococcus
4. Cognitive impairment (neurologic)	Short Portable Mental Status Questionnaire (Table 16.3)	Evaluate for dementia or delirium; assess social environment
5. Immobility and falls (neurologic)	Ask about difficulty walking and falls	Avoid restraints and tethers; prescribe walking and physical therapy
6. Sensory impairment (neurologic)	Assess vision and hearing	Prosthetics (glasses, hearing aids)
7. Depression (psychological)	Depression screen	Attention, cognitive therapy, pharmacotherapy
Assessment at the level of the whole person		
8. Disability (activities of daily living)	Ask about help needed for basic and instrumental activities of daily living	Physical and/or occupational therapy; assess social environment
9. Suboptimal drug use (pharmaceuticals)	Assess indications for therapy, dosing, and potential interactions	Modify prescribing
Assessment at the level of the environment		
10. Maltreatment (social support)	Ask about level of social support and perceived freedom and safety	Early involvement of family and social services in planning to go home

atrial fibrillation can be reduced approximately 75% by treatment with warfarin (e.g., from 4.3% to 0.9% annually). Moreover, the beneficial effect of warfarin is maintained in persons 75 years of age or older and in those with other risk factors for stroke (3). Alternatively, comparable benefits may be attained with cardioversion and pharmacologic maintenance of sinus rhythm. Nonetheless, many older patients with atrial fibrillation are discharged from the hospital without warfarin therapy, even when warfarin is judged to be appropriate (4). Failure to prescribe warfarin is likely a consequence of underestimation of the benefit of therapy, overestimation of its potential risk, and the difficulty of implementing, monitoring, and modifying therapy to minimize adverse effects.

Recommendation. Every hospitalized older patient should be assessed for the presence of chronic nonvalvular atrial fibrillation by examination of the pulse and electrocardiogram. When atrial fibrillation is diagnosed, valvular disease and hyperthyroidism should be ruled out. In the absence of a strong contraindication, treatment should be instituted to prevent stroke, usually with warfarin. A strategy of rate control and anticoagulant therapy may have a lower risk of adverse effects than one focused on attaining and maintaining sinus rhythm (Chapter 42).

**Problem 2. Malnutrition
(Gastrointestinal Function)**

Rationale. Serious deficiencies of macronutrients and micronutrients are common in hospitalized older patients. Key macronutrients are protein, calories, salt, water, and fiber. On admission, severe protein-calorie malnutrition is present in approximately 15% of patients 70 years of age or older, and moderate malnutrition is present in another 25%. Moreover, 25% of older patients suffer further nutritional depletion during hospitalization. Even after the underlying illness, its severity, and comorbid illnesses are controlled for, malnutrition is associated with an increased risk for death, dependence, and institutionalization (5).

In addition to deficiencies of vitamins and electrolytes that may develop with protein-calorie malnutrition,

vitamin D deficiency is especially common among hospitalized elders. In one large hospital, nearly two-thirds of medical inpatients 65 years of age or older were deficient in vitamin D; vitamin D deficiency was nearly as common in inpatients without a risk factor for vitamin D deficiency and in those taking multivitamins (6). These data regarding the high prevalence of vitamin D deficiency in hospitalized elders complement evidence that vitamin D and calcium supplementation reduce by half the frequency of nonvertebral fractures in men and women 65 years of age or older (7).

Recommendation. Assessment of nutritional status is indicated by three considerations: (i) the poor prognosis of patients with malnutrition, (ii) the potential benefit of low-cost, noninvasive interventions, and (iii) increasing evidence of beneficial effects of nutritional supplementation on the outcomes of malnourished patients in other settings (8). The *Subjective Global Assessment* (9) (Table 16.2) is an inexpensive yet accurate method of systematically identifying patients who are moderately or severely malnourished based on weight loss and physical signs of malnutrition. When malnutrition is identified, remediable contributing factors should be sought and corrected, such as difficulty chewing or insufficient time or encouragement to eat. Oral feeding is preferred whenever possible (8). It remains unclear whether the benefits of invasive alimentation (alimentary or parenteral) outweigh their risks, yet they may be beneficial in situations in which prolonging survival is a central goal and the invasive approach will overcome a critical barrier to feeding (Chapter 15). In patients with a progressive terminal illness in whom prolongation of life is not a central goal of care, or in patients who would require long-term restraints for invasive alimentation, the burdens of invasive alimentation are likely to outweigh the benefits. An open and nonjudgmental discussion with the patient or surrogate decision maker can help clarify the role of nutrition within the overall goals of care (Chapters 17 and 19).

Long-term supplementation with vitamin D (1,000 IU daily) and calcium (1,000 mg daily) should be considered for every hospitalized older person.

TABLE 16.2
SUBJECTIVE GLOBAL ASSESSMENT OF NUTRITIONAL STATUS

Nutritional status	Weight loss in past 6 months	Weight loss in past 2 weeks	Physical signs of loss of subcutaneous fat or muscle
Well nourished	<5%	—	None
	>5%	None	None
Moderately malnourished	5–10%	Present	Mild
Severely malnourished	>10%	Present	Severe

From Detsky AS, Smalley PS, Chang J. Is this patient malnourished? *JAMA* 1994;271:54–58, with permission.

Problem 3. Influenza and Pneumococcus (Immune Function)

Rationale. Influenza vaccination reduces hospitalization and mortality in persons 65 years of age or older (10). Pneumococcal vaccination of persons 65 years of age or older reduces serious pneumococcal infections (11). Influenza vaccination should be administered annually in the fall, and pneumococcal vaccination should be administered at least once and probably every 5–10 years. The immune response to vaccination is not seriously compromised by hospitalization or acute illness.

Recommendation. All persons 65 years of age or older should be asked whether they have received influenza or pneumococcal vaccination. Hospitalization provides an opportunity to ensure that these important immunizations are given to those at risk for serious disease. Influenza vaccine should be administered annually in the fall. Pneumococcal vaccine should be administered to all those over 65 who have not previously been vaccinated or whose vaccination status is unknown. Those who have received the vaccine more than 5 years previously and who were under age 65 at the time of vaccination should receive another dose. Delivery of these vaccines to appropriate hospitalized patients is increasingly being assessed in hospital quality report cards, many of which are being made available to the public (see Chapter 12).

Problem 4. Cognitive Impairment (Neurologic Function)

Rationale. Underlying cognitive impairment consistent with dementia is present on admission in 20%–40% of hospitalized elders and frequently goes undetected (12).

Preexisting cognitive impairment is a risk factor for delirium, falls, use of restraints, and lack of adherence to therapy. Also, there is intrinsic value in identifying previously undiagnosed dementia so that appropriate evaluation and management strategies can be implemented after discharge. Tests of mental status are sensitive and specific for dementia. For example, in one study of hospitalized elders, three or more errors on the 10-item Short Portable Mental Status Questionnaire (13) (Table 16.3) was 87% sensitive and 99% specific for a diagnosis of dementia (14).

Delirium is present in 10%–15% of hospitalized elders on admission and develops in up to 30% during the course of hospitalization (15). Delirium is associated with increased rates of in-hospital death, nursing home placement, and prolonged length of stay, and it may worsen chronic cognitive impairment. Roughly one-third of delirium cases are preventable by appropriately managing these six risk factors: cognitive impairment, sleep deprivation, immobility, visual impairment, hearing impairment, and dehydration (16).

Recommendation. Mental status should be assessed by using an established test of cognitive function, such as the Short Portable Mental Status Questionnaire (Table 16.3) or the 30-item Mini-Mental State Exam. The diagnosis of dementia should be considered in those patients with three or more errors on the Short Portable Mental Status Questionnaire or a score of 24 or less on the Mini-Mental State Exam. When dementia is a possibility, the patient should be assessed to rule out reversible causes and to identify those for whom pharmacologic therapy and family oriented interventions are warranted.

The diagnosis of delirium should be considered when any of the following are observed: fluctuation in mental status or behavior, inattention, disorganized thinking, and

TABLE 16.3

THE 10 ITEMS OF THE SHORT PORTABLE MENTAL STATUS QUESTIONNAIRE

Item	Correct response
1. What is the date today?	Exact month, date, and year
2. What day of the week is it?	Day of the week
3. What is the name of this place?	Any correct description of the location
4. What is your telephone number?	Correct number, or consistently given number if the correct number is not known to the examiner
5. How old are you?	Stated age corresponds to date of birth
6. When were you born?	Correct month, date, and year
7. Who is the President of the U.S. now?	Last name of the President
8. Who was President just before him?	Last name of the previous President
9. What was your mother's maiden name?	Any female first name, and a last name different from the subject's
10. Subtract 3 from 20 and keep subtracting 3 from each new number, all the way down.	17, 14, 11, 8, 5, 2

From Pfeiffer E. A short portable mental status questionnaire for the assessment of organic brain deficit in elderly patients. *J Am Geriatr Soc* 1975;23:433–441, with permission.

altered consciousness. Prudent measures to prevent or ameliorate delirium include avoiding medicines associated with delirium whenever possible, treating infection and fever, detecting and correcting metabolic abnormalities, frequently orienting patients with cognitive or sensory impairment, and walking.

Problem 5. Immobility and Falls (Neurologic Function)

Rationale. Walking facilitates the performance of virtually all basic and instrumental ADL. The ability to walk briskly and the habit of regularly walking 1 mile or more daily are associated with prolonged survival (17). Immobility during hospitalization, however, leads rapidly to deconditioning and subsequent difficulty walking. The major adverse effect of walking is falling, which can lead to serious injury. Falls and fall-related injuries are associated with cognitive impairment; abnormalities of cognition, gait, balance, and the lower extremities; and multiple chronic medical conditions and depression (18, 19).

Recommendation. The ability to get up from bed, gait, balance, lower extremity strength and anatomy, cognition, and mood should be assessed during the initial physical examination. Persons able to walk independently should be encouraged to do so frequently during hospitalization. The hospital staff should assist those able to walk but unable to do so alone safely several times daily. Formal physical therapy may yield additional benefits. Risk for falls should be assessed by inquiring about a history of falls and by examination. Adopting interventions that reduce falls in other settings may also prevent falls in the hospital (20). Prudent preventive strategies include minimizing bed rest when possible and providing in-bed physical conditioning when bed rest is required, assisting with walking for those who walk with difficulty, and providing physical therapy for those with weakness or gait abnormalities. Soft-tissue and bony abnormalities of the feet should receive appropriate podiatric care. Restraints and tethers have not been shown to reduce fall-related injuries and may result in a variety of untoward consequences, including strangulation. Their use should not generally be considered a strategy to reduce falls.

Problem 6. Sensory Impairment (Neurologic Function)

Rationale. Most hospitalized elders have impaired vision or hearing, and these sensory impairments are risk factors for falls, incontinence, and functional dependence (18). Although most visual and hearing impairments are readily corrected by glasses or hearing aids, these appliances are often not brought to or lost in the hospital. Addressing sensory impairment is part of an effective strategy to prevent delirium (16).

Recommendation. Hospitalized elders should be routinely screened for visual and hearing impairments by asking if they have difficulty with seeing or hearing and whether they use glasses or a hearing aid. Physical examination should include a test of visual acuity (e.g., with a pocket card of the Jaeger eye test) and the whisper test of hearing (in which a short, easily answered question is whispered in each ear) (21). In people with visual or hearing impairments, glasses or a hearing aid should be provided (ideally brought from home), and the staff should be informed that patients may need to use an appliance to communicate effectively. Some hospital units have found it useful to have “pocket amplifiers” and magnification devices on hand to assist in communicating with older persons who lack glasses or hearing aids.

Problem 7. Depression (Psychological Function)

Rationale. Depressive symptoms in hospitalized elders are common and prognostically important, and they can potentially be ameliorated. Major or minor depression occurs in roughly one-third of hospitalized patients age 65 years or older but is often missed. The presence of depressive symptoms is associated with increased risk for dependence in ADL, nursing home placement, and shortened long-term survival, even after baseline function and the severity of acute and chronic illness are controlled for (22).

Recommendation. The possibility of depression should be considered in hospitalized older patients, who should be asked whether they feel down, depressed, or hopeless, or whether they have lost interest or pleasure in doing things (23). A positive response to any one of these questions should trigger a formal assessment for an affective disorder. In hospitalized elders, the presence of three or more of 11 depressive symptoms has been found to be 83% sensitive and 77% specific for a diagnosis of major depression (24).

Detection is the first and most important step in the management of depression, which is frequently missed in hospitalized elders. Psychotherapeutic interventions (environmental, behavioral, cognitive, and family) are safe and often effective, and they should be initiated in all patients with suspected depression. It is rarely necessary to begin pharmacotherapy during hospitalization for a medical or surgical condition, but follow-up shortly after discharge is critical. Strategies incorporating cognitive problem-solving therapy and pharmacotherapy may be most effective (25). If pharmacotherapy is initiated, selective serotonin reuptake inhibitors are often preferred because tricyclic antidepressants are contraindicated in approximately 50% of older hospitalized patients (26). Tricyclic antidepressants are probably more effective in older patients with severe depression; if tricyclic antidepressants are used, desipramine and nortriptyline have fewer anticholinergic and cardiac side effects than do other agents (Chapter 119).

Assessment at the Level of the Whole Person

Problem 8. Disability (Activities of Daily Living)

Rationale. The performance of ADL is necessary to live independently, and dependence in ADL is independently associated with worse quality of life, shortened survival, and increased resource use (27). ADL have traditionally been divided into those performed on a daily basis in the home (e.g., bathing, dressing, using the toilet, transferring from a bed to a chair, eating, and maintaining continence) and those that involve higher levels of integrative function (e.g., cooking, doing household chores, using transportation, and handling financial and medical matters). Although walking is sometimes considered an ADL, it is often considered separately because it facilitates many of the other activities but is not necessary for any one of them.

Recommendation. The ability to perform basic and instrumental ADL should be determined at the time of admission. The etiology of dependence in ADL should be determined (e.g., dependence in instrumental ADL is often associated with dementia), and strategies to maintain and improve functional capacity, such as physical and occupational therapy, should be considered. These strategies may be best implemented by ward staff (i.e., nurses or case managers) without physician consultation or referral (16). Social work consultation and early involvement of family or other caregivers is often necessary to plan post-discharge care for those dependent in ADL (see Chapter 5).

Problem 9. Suboptimal Drug Use (Pharmaceuticals)

Rationale. The number of drugs prescribed to hospitalized patients is directly proportional to their age. Moreover, hospitalization is a period of rapid turnover in drug therapies for elders. In one study, 40% of drugs prescribed before admission were discontinued during hospitalization, and 45% of drugs prescribed at discharge were started during hospitalization (28). Although older patients are at increased risk for inappropriate drug therapy, adverse drug effects, and drug–drug interactions, they may also be undertreated when effective therapies are not used or are used in inadequate doses. Thus, hospitalization is an opportunity for a thorough review of each older patient’s medications and to make adjustments as needed. In one study, 88% of older hospitalized patients had one or more clinically significant drug problems, and 22% had at least one potentially serious and life-threatening problem (29). Consultation with clinical pharmacists can lead to more appropriate prescribing and improved adherence (30) in hospitalized elders.

Recommendation. Each patient’s medications should be reviewed on admission, and those that are unnecessary or have low therapeutic indices (e.g., sedative–hypnotics)

should be discontinued. During hospitalization and discharge, medications should be reviewed in six common categories: inappropriate choice of therapy; dosage; schedule; drug–drug interactions; therapeutic duplication; and allergy. Also, neglected therapies (e.g., vitamin D and calcium) should be considered and instituted if appropriate.

Assessment at the Level of the Environment

Problem 10. Maltreatment (Social Support)

Rationale. Hospitalization of older persons is sometimes precipitated by maltreatment, which includes physical or psychological abuse, neglect, self-neglect, exploitation, and abandonment. Although elder maltreatment was not recognized in the medical literature until 1975, it is now estimated to affect 1 to 2 million Americans annually. In a large, prospective cohort study, the annual incidence of referral to protective services for mistreatment was approximately 1% among persons age 65 years or older (31). Those referred for abuse, neglect, or exploitation had a lower survival rate during 13 years of follow-up (9%) than did those referred for self-neglect (17%) and those not referred (40%). Most older persons referred to protective services because of physical abuse have been seen in hospital emergency departments, and many emergency department visits lead to hospitalization. Sociodemographic factors such as poverty, age greater than 75 years, and nonwhite race are the strongest predictors of elder maltreatment (32).

Recommendation. Universal screening for maltreatment has been recommended and can be implemented by asking each older patient, “Do you feel safe returning where you live?” However, it must be recognized that the sensitivity and specificity of this and other screening approaches are unknown. Further questions can explore the living situation and specific settings or aspects of maltreatment. The diagnosis of maltreatment should be considered when physical or psychological stigmata (e.g., unexplained injury, dehydration, malnutrition, social withdrawal, recalcitrant depression or anxiety) are present. When maltreatment is suspected, Adult Protective Services or the equivalent state agency should be contacted; such contact is required in most states.

KEY POINTS

- Older persons, the fastest-growing segment of the U.S. population, are at disproportionate risk for hospitalization. Once hospitalized, many older patients lose significant functional ability.
- A systematic approach is needed to address the problems of hospitalized older patients.
- Underdiagnosis and undertreatment of common medical problems, such as atrial fibrillation, malnutrition,

delirium, and depression, may contribute to excess mortality and morbidity.

- Efforts should be made to diagnose sensory (such as hearing and vision) and cognitive impairment in elderly inpatients.
- Hospitalization is a good time to review drug use and assess possible toxicity or interactions.
- All hospitalized older patients should be screened for maltreatment.

Ethical Issues in the Hospitalized Patient

17

Steven Z. Pantilat Bernard Lo

INTRODUCTION

Physicians commonly face ethical dilemmas in the care of inpatients. The family of an elderly Chinese man with newly diagnosed hepatocellular carcinoma asks you not to inform the patient of the diagnosis. The children of a comatose woman with end-stage cirrhosis cannot agree on code status. A patient with end-stage metastatic pancreatic cancer is admitted as a full code. The renal consultant says that it is futile to initiate dialysis on a patient with dementia. A patient who you believe is medically ready for discharge refuses to go home. Such ethical issues can be difficult to resolve, time-consuming, and emotionally draining.

In the ethical arena, primary physicians caring for their own inpatients have an advantage. A hospital physician who is not the primary provider (as in the case of a hospitalist or a house officer on an inpatient rotation) must spend time getting to know the patient and developing a relationship. In such cases, hospital physicians often benefit by learning the patient's goals, values, need for information, and specific preferences for care from the primary care physician.

PRINCIPLES OF MEDICAL ETHICS

In caring for patients, physicians should follow the fundamental ethical principles of *autonomy*, *beneficence*, *non-maleficence*, *justice*, and *confidentiality*.

Autonomy. Physicians must respect a patient's right to make decisions regarding medical care. Competent, informed patients have the right to choose among treatment options and refuse any unwanted medical interventions.

Beneficence. Physicians must act in the best interests of their patients. Patients are vulnerable because of illness and lack of medical expertise. Therefore, they rely on physicians to offer sound advice and act according to patients' best interests. In doing so, physicians must put the interests of their patients ahead of their own interests or those of third parties, such as insurers or managed care organizations. If patients lack decision-making capacity, they need to be protected from making decisions that are contrary to their best interests.

Non-maleficence. The related principle of non-maleficence directs physicians to "do no harm" to patients. Physicians must refrain from providing ineffective treatments or acting with malice toward patients. This principle, however, offers little useful guidance to physicians because many beneficial therapies also have serious risks. The pertinent ethical issue is whether the benefits outweigh the burdens.

Justice. Physicians should treat similarly situated patients similarly and allocate resources fairly. In the face of limited health care resources, physicians should practice cost-effective medicine.

Confidentiality. Physicians must maintain the confidentiality of medical information. Confidentiality respects patient autonomy and encourages patients to seek care and be candid. However, confidentiality can be overridden to protect third parties when there is the potential for serious, foreseeable harm to third parties. Legally-mandated reporting may include certain infectious diseases like tuberculosis, loss of consciousness, child or elder abuse, or domestic violence.

These ethical principles guide and inform the process of gaining consent for or confirming refusal of treatment at every stage of the patient-physician relationship, including

times when emotionally charged end-of-life decisions are being considered.

CARE OF THE HOSPITALIZED PATIENT

Decisions for Competent Patients

The centerpiece of ethical delivery of care is informed decision making. Informed, competent patients have the right to choose among, consent to, or refuse medically feasible options for care.

Our understanding of decision making and care for seriously ill hospitalized patients in the United States has been markedly enhanced by the results of the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) (1). SUPPORT was a large, multicenter, randomized controlled trial designed to study decision making at the end of life. In addition, SUPPORT aimed to facilitate communication between seriously ill patients and physicians regarding prognosis and advance directives, and also to decrease pain and eliminate unwanted interventions at the end of life. Although the intervention improved neither care nor decision making, SUPPORT did provide a wealth of information regarding the treatment of symptoms and the process of communication and decision making for seriously ill patients. Some of its important findings were that physicians are often unaware of their patients' preferences for care; that even when patients preferred to have a "do not resuscitate" (DNR) order written, physicians wrote such orders in only 49% of cases; and that half the patients suffered moderate-to-severe pain in the last 3 days of life.

Decision-Making Capacity

Patients are presumed to have the capacity to make medical decisions unless it is determined otherwise. Decision-making capacity is ascertained by considering the patient's ability to make an informed decision regarding a specific intervention, rather than by a global assessment of mental function (2). Particular diagnoses or medical conditions such as dementia, depression, or hypoxemia do not, *a priori*, mean that a patient lacks decision-making capacity. When in doubt, the physician must assess such capacity formally.

Patients are considered to have adequate decision-making capacity if they can give informed consent for an intervention. Specifically, physicians must ensure the following:

- The patient can make and communicate a choice.
- The choice is stable over time and consistent with the patient's values and goals.
- The patient appreciates the indications, benefits, and risks of the proposed intervention and the alternatives.
- The decision does not result from delusions, psychosis, or mental illness.

Primary care physicians can help assess whether patients are making decisions consistent with their values and goals and

whether their mental status differs substantially from baseline. For example, a patient with severe chronic obstructive pulmonary disease may have indicated a desire for intubation in past office discussions with the primary care physician and family. If the patient refuses intubation at the time of a severe exacerbation characterized by hypoxia and sepsis, but the hospital physician determines that the patient now lacks decision-making capacity, the hospital physician should override the patient's refusal in favor of the one expressed when the patient had full decision-making capacity.

In assessing decision-making capacity, the attending physician should explain the proposed intervention, risks, benefits, and alternatives, including the option to decline treatment. The physician should then ask the patient to paraphrase the information and try to uncover any internal inconsistencies in the patient's reasoning. For example, the physician might say to the patient who is refusing amputation of a gangrenous leg, "Help me understand. You say you want to get rid of the pain and bad smell from your leg but don't want surgery. Could you please explain that to me?" Such probing questions help clarify issues for the patient as well as the physician. Mental status testing can be helpful, but patients who score poorly on a formal mental status exam (such as in Table 16.3) may still be able to give informed consent, and patients who score well may deny their condition or change their minds frequently. In addition, although not required routinely, psychiatric consultation can help determine whether delusions, psychosis, or depression are seriously impairing a patient's capacity to decide.

Although the courts are the ultimate arbiters of whether a patient is competent to refuse medical interventions, physicians routinely assess decision-making capacity at the bedside and turn to surrogates or advance directives if they determine that patients lack this capacity. Nonetheless, it may be necessary and desirable to obtain a court order in rare cases, such as when a patient who lacks decision-making capacity and has no surrogate is actively refusing an invasive procedure or risky treatment designed to save life or function.

Informed Consent

In soliciting informed consent, physicians should provide information about the risks, benefits, and consequences of proposed treatments and alternatives. They should listen more than talk, and use language the patient can understand. Tulskey et al. (3) found that when discussing code status with hospitalized patients, medical house officers spoke more than three-fourths of the time, often used jargon, and frequently missed opportunities for empathic connection. The use of simple statements such as "tell me more about that" or simply "uh huh" may encourage patients to speak more.

Patients' desire for information may depend on their cultural background (4). For example, the family of an

elderly Chinese man who has been given a diagnosis of hepatocellular carcinoma may request that the physician not tell the patient the diagnosis. They may believe that speaking of the bad news to the patient will take away all hope and cause a poor outcome. One way of dealing with such family requests is to say to the patient, "I have information about your condition. I generally give this type of information directly to my patients, but some patients prefer that I speak to a family member or friend instead. What would you like me to do?" Even better, ask patients how they would want you to communicate information about the test results before ordering the test.

Refusal of Therapy

Most patients accept treatments recommended by their physician. However, some patients may refuse treatments that the physician believes are highly beneficial (e.g., amputation of a gangrenous leg). In such circumstances, it is appropriate for the physician to try to persuade the patient to accept beneficial treatments, although the physician should not badger the patient or misrepresent the facts. The physician should check that the patient is fully informed of the consequences of the decision and has the capacity to make informed decisions. In the end, the physician must respect a competent, informed patient's right to make decisions about medical care, even if the physician believes a decision is unwise.

Patients Who Lack Decision-Making Capacity

Hospitalized patients may be unable to participate in decision making because of medical illness, psychiatric illness,

medications, delirium, or dementia. In such circumstances, the physician's obligation is to protect the patient from the adverse consequences of uninformed decisions. This can be done by consulting an advance directive or an appropriate surrogate.

Advance Directives

Advance directives are oral or written statements, made by patients when competent, to guide care if they lose decision-making capacity. Advance directives may offer substantive directions regarding care, designate a surrogate decision maker, or do both. Physicians must respect advance directives because they promote the patient's autonomy by extending it into the future. The extra effort and consideration required to complete written advance directives give them more weight than oral statements. Nonetheless, in the absence of a written advance directive, clear oral statements of a patient's preferences are ethically acceptable and should be respected. Because some patients fear that in completing an advance directive they relinquish their decision-making authority, it is important to inform them that advance directives take effect only if they lose decision-making capacity. Among the issues commonly addressed in advance directives are the desire for cardiopulmonary resuscitation (CPR), mechanical ventilation, transfer to the intensive care unit, and artificial hydration and nutrition. If the patient with the advance directive shown in Figure 17.1 was admitted with pneumococcal sepsis and was unable to communicate any preferences, the prior written statement would offer guidelines to her surrogate and physician regarding her preferences for care. In

I, *Carmen Picatta*, hereby appoint:

Name: Robert Picatta
 Address: 123 Main St., San Francisco, CA 94110
 Telephone Number: 415/555-1212

As my agent to make health care decisions for me.

If I become ill and need machines to keep me alive, I am willing to have them if there is hope that I will ultimately be able to live independently without them. I do not want to be kept alive on machines indefinitely.

If my heart stops, I want to be allowed to die peacefully. I do not wish to have CPR under any circumstances.

Witness: *Joe Smith* Signature: *Carmen Picatta*

Witness: *Jane Low*

Figure 17.1 Example of an advance directive.

this case, a trial of mechanical ventilation and a DNR order would be consistent with the patient's wishes and represent the appropriate course of action.

Among the limitations of advance directives are that few people have them, they are usually not available to the hospital physician at the time a decision must be made, and they often fail to address the specific clinical situation at hand (5). When advance directives do provide adequate guidance or designate a surrogate, they must be respected.

Surrogate Decision-Making

If it is feasible, the hospital physician should elicit patient preferences regarding CPR and other aspects of medical care, in addition to the patient's general values, goals, and choice of a surrogate, before this information is actually needed. For example, at the time of admission the physician could say, "There is something I talk about with all the patients I care for in the hospital: Who will help me make decisions about your medical care if you get too sick to tell me directly?" Such a statement serves to normalize the discussion and lessen patient concerns that the physician is raising these issues because of a belief that something bad will happen to the patient. Once the physician

has established the patient's choice of a surrogate, he or she can ask whether the surrogate has been informed of the patient's preferences. The physician can then ask directly about the patient's preferences for CPR. Because patients who have overly optimistic impressions of the outcomes of CPR are less likely to request it after learning of the actual chance of success, physicians should inform patients of the outcomes in addition to the risks and benefits of CPR (6) (Table 17.1). Finally, physicians should remind patients and all members of the health care team that a DNR order itself has no bearing on the provision of any other treatments.

When an advance directive is unavailable and an appropriate surrogate has not been previously designated, it falls to the physician to identify a surrogate for an incompetent patient. In the ideal setting, the surrogate will be someone who knows the patient well, understands the patient's values and goals, has discussed with the patient what he or she would want done in certain circumstances, and is committed to acting in the patient's best interests. The physician needs to probe for statements the patient may have made about values and goals of care, what circumstances the patient had in mind, and whether the patient understood the consequences and alternatives. The goal is to achieve *substituted judgment*, in which decisions are made as

TABLE 17.1
OUTCOMES OF INTERVENTIONS THAT ARE SOMETIMES CALLED "FUTILE"^a

Study	Patients	Intervention	Outcome	Percentage/(n)
Rubinfeld and Crawford, 1996 (17)	Bone marrow transplant recipients with sepsis or renal and hepatic failure, and respiratory failure	Mechanical ventilation	Survival 30 days after extubation and discharge from the hospital	0 (0/53)
Wachter et al., 1991 (8)	AIDS patients with PCP and respiratory failure	Mechanical ventilation	Survival to hospital discharge	0 (14/35)
Bedell et al., 1983 (9)	All hospitalized patients who suffer cardiac arrest	CPR	Survival to hospital discharge	14 (41/294)
	Subset of patients with pneumonia	CPR	Survival to hospital discharge	0 (0/58)
	Subset of patients with creatinine >2.5 mg/dL	CPR	Survival to hospital discharge	5 (3/64)
Taffet et al., 1988 (10) ^b	Hospitalized patients age 70 or greater who suffer cardiac arrest	CPR	Survival after code	31 (24/77)
			Survival at 24 hours	29 (22/77)
			Survival to hospital discharge	0 (0/77)
	Hospitalized patients less than 70 years of age who suffer cardiac arrest	CPR	Survival after code	43 (137/322)
			Survival at 24 hours	39 (124/322)
Subset of patients with cancer	CPR	Survival to hospital discharge	7 (22/322)	
Subset of patients without cancer	CPR	Survival to hospital discharge	0 (0/89)	
			Survival to hospital discharge	9 (21/240)

^aReaders may wish to contrast the outcomes with Schneiderman's "zero out of 100" standard in deciding whether the interventions are in fact "futile" (12).

^bA total of 399 CPR efforts were made for 329 patients. Data for patients over and under age 70 are reported per CPR effort; data for patients with and without cancer are reported per patient.

CPR, cardiopulmonary resuscitation; PCP, *Pneumocystis jirovecii* pneumonia.

patients would make them, not as surrogates want to make them for patients or would want to make them for themselves. Virtually all states allow patients to designate a surrogate or health care proxy. In New York and Missouri, state laws require a high standard of evidence regarding a patient's oral directives and restricts the ability of family members to limit some care in the absence of formal advance directives. Despite such laws, sound clinical and professional ethics advocate respecting a patient's wishes, even if they were orally expressed, and acting in the patient's best interest.

In the absence of a prior designation, it is customary to turn to family. The surrogate hierarchy typically begins with the spouse, then adult children, then other family members, and finally friends. This approach is appropriate because these people are most likely to know the patient's preferences, to the keep the patient's best interests foremost, and to advocate on the patient's behalf. Certain states, such as Illinois, have laws that designate which family members have priority as surrogates. In some cases, it is difficult to determine who the appropriate surrogate should be. For example, an elderly woman who is comatose with end-stage cirrhosis and who gave no advance directive may have two adult children who disagree about her code status. In such circumstances, it is helpful to focus the discussion on what the patient would want in that particular situation. It may require repeated discussions with the patient's children to reach a mutually agreeable decision (12). Other members of the health care team, especially social workers, chaplains, and nurses, may be helpful in talking with the surrogates (Chapter 4).

Realistically, surrogates often do not know what the patient herself would have wanted, and decisions are based on the *best interests* of the patient rather than on substituted judgment. When the physician cannot identify a surrogate for an incompetent patient, it is appropriate for the physician to make decisions based on a perception of the patient's best interests, considering both the quality and duration of life. Quality-of-life considerations must be made with care because of the potential for bias, as physicians and family members tend to underestimate the value that patients place on their quality of life.

DO NOT RESUSCITATE ORDERS AND DECISIONS ABOUT LIFE-SUSTAINING INTERVENTIONS

Decisions about CPR and life-sustaining interventions are very common in the hospital. For example, one study found that decisions to withhold or withdraw life-sustaining interventions accompanied by the writing of DNR orders preceded 90% of deaths in the intensive care units at two teaching hospitals (12). Figure 17.2 provides

an algorithm regarding decisions about life-sustaining interventions.

Although DNR orders are common, problems with them remain. First, although physicians may fear that discussing DNR orders will upset patients, studies confirm that the vast majority of patients want to discuss these issues, expect physicians to initiate the discussion, and may be more satisfied with their care after these discussions (13). Second, there are large variations in how often physicians write DNR orders for patients with different diseases but similar prognoses (14), reflecting a potential inequity in treatment. Finally, many physicians fail to write DNR orders for patients who want them (1). Thus, the hospital physician has a responsibility to initiate discussions about DNR orders, to raise the issue equally with all patients, and to write DNR orders when patients request that they do so.

Most patients who ultimately receive DNR orders are competent at the time of admission but not competent when the DNR order is finally written (1). Therefore, *physicians should routinely discuss code status with patients at the time of admission*. In fact, hospital physicians treating a patient for the first time can turn the disadvantage of not knowing the patient into an advantage in discussing code status by honestly saying, "I haven't met you before, and it's important for me to know you as a person and what's important to you about your medical care." Even if the primary care physician has already discussed code status with the patient, the hospital physician can confirm that the patient has made an informed choice and has not had a change of heart.

In the absence of a written DNR order, CPR is initiated for all patients in the hospital who have a cardiopulmonary arrest. This presumption to use CPR is based on the ethical principle of beneficence and the goal of providing a potentially life-saving intervention to patients. In addition, first responders to a cardiac arrest usually do not know the patient. If CPR is not initiated immediately, its effectiveness is reduced. This approach places a responsibility on physicians to establish a code status for each patient early in the hospitalization so that they can respect the wishes of patients who want to forgo CPR.

Do Not Resuscitate Orders in the Operating Room

Occasionally, patients with DNR orders require surgery or an invasive procedure. Some physicians are reluctant to allow a DNR order to remain in effect in the operating room. They argue that general anesthesia and conscious sedation can precipitate the need for more formal resuscitation, and that it is too difficult to operate or administer anesthesia with limitations placed on resuscitative interventions. Despite these arguments, some patients may wish to have

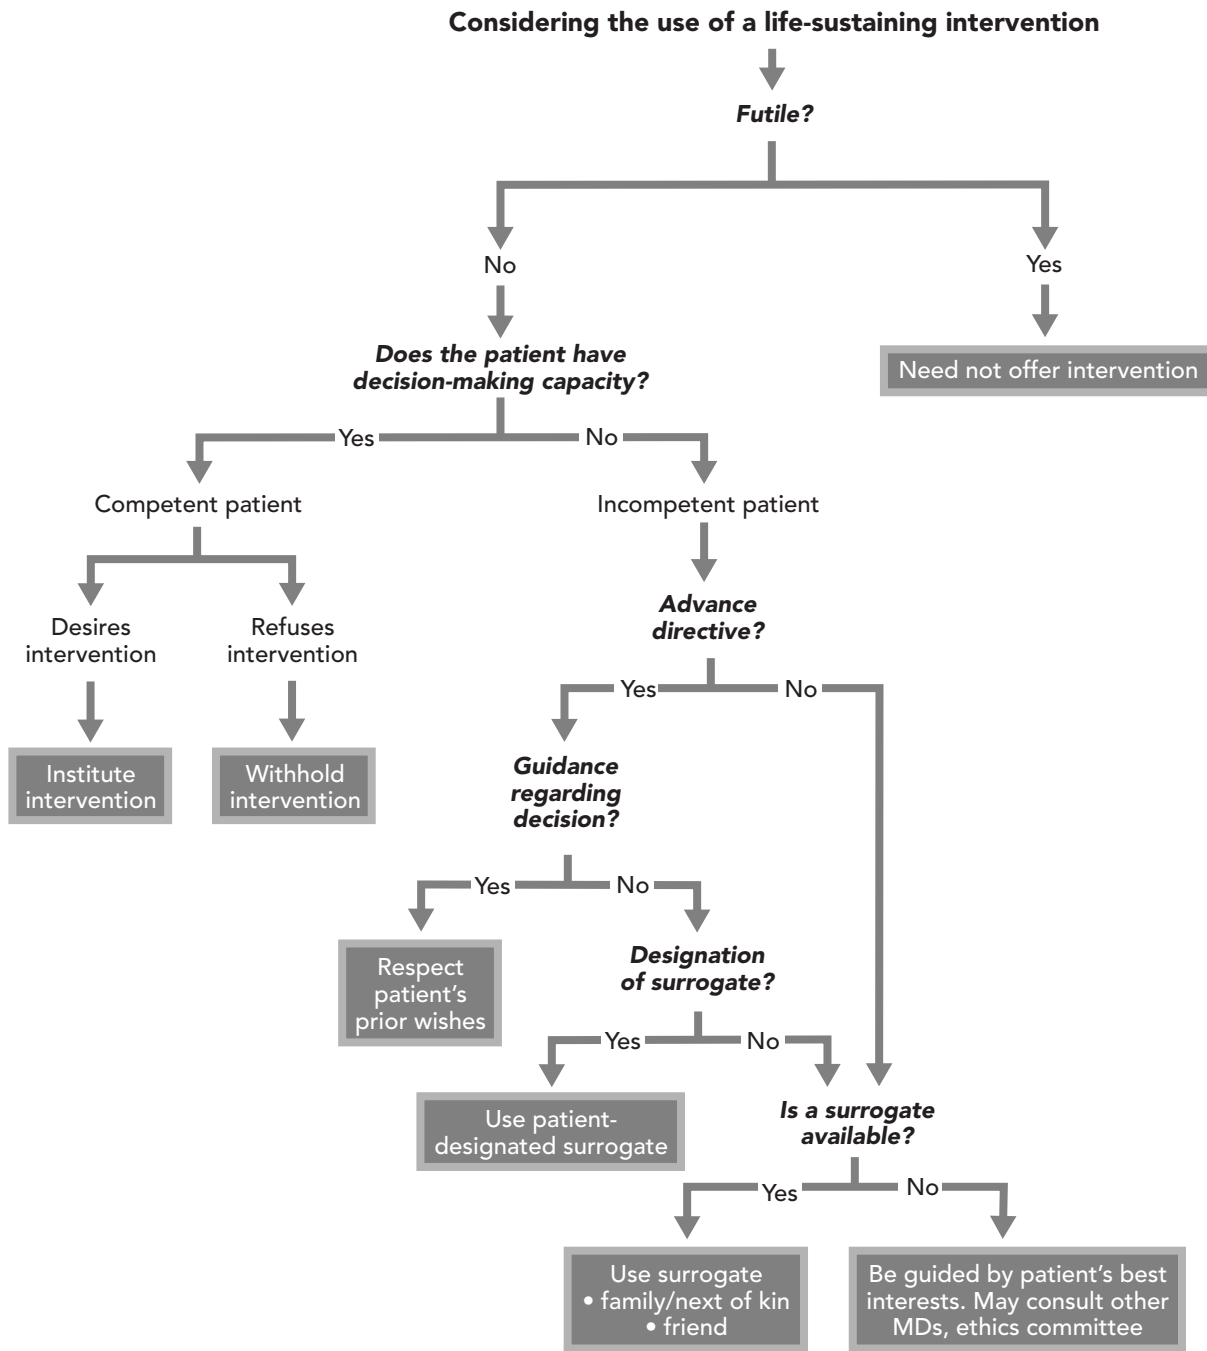

Figure 17.2 Decisions regarding life-sustaining interventions.

surgery to palliate pain or relieve a bowel obstruction yet feel that if they had a cardiopulmonary arrest for any reason in the operating room, they would not want CPR initiated. Physicians should not refuse to perform an operation for a patient simply because the patient insists on forgoing CPR (15). In order to respect patient autonomy, it is best to reconsider code status before surgery and other invasive procedures, to explain how resuscitative efforts work, and to respect the patient's request to keep a DNR order in effect.

Withdrawal and Withholding of Interventions

Withdrawing and withholding life-sustaining interventions are ethically and legally equivalent, although the former is often more emotionally difficult than the latter (16). If interventions could not be withdrawn, patients might be reluctant to attempt them even if potentially beneficial for fear they could not be withdrawn later.

Most often, the physical withdrawal of an intervention falls to nurses or respiratory therapists, not physicians. It is

helpful if the attending physician is present or available when care is withdrawn to lend support, respond to problems, and ensure that the patient's suffering is alleviated. The process of withdrawing ventilation ("terminal weaning") is described in Chapter 23, and additional issues in end-of-life care are described in Chapter 19.

Futile Interventions

Occasionally, patients or their surrogates may demand care that the physician believes does not provide any potential medical benefit. Physicians should discuss these situations with patients and surrogates and strongly recommend against such interventions.

Physicians are not obligated to provide an intervention when:

- The intervention has been tried and failed.
- There is no pathophysiologic rationale for the intervention.
- Maximal therapy is failing.
- The intervention cannot achieve the goals of care.

In these situations, interventions are considered futile. The term *futility* is often used by physicians to justify unilateral decisions to withhold certain interventions requested by the patient or surrogate. Such unilateral decisions override the patient's autonomy and the power of surrogates to make decisions for incompetent patients. Hence, unilateral judgments of futility must be made carefully. Schneiderman and colleagues have proposed a "zero out of 100" standard that restricts the use of the term futility to cases in which no successes have been seen in the last 100 similar circumstances (10). Despite seeming objective, such a standard is arbitrary and is not universally accepted by patients or physicians as defining futile care. Still, by this or any comparable standard, it is clear that true futility is rare (Table 17.1) and that physicians often use the term loosely.

In general, it is best to talk about potentially futile situations with patients and their surrogates because an agreement can be reached in almost all circumstances. Even prolonged discussions are preferable to unilateral decisions by the physician that alienate patients and erode trust in the medical care system (17).

Leaving Against Medical Advice

Physicians may encounter a patient who seeks to leave the hospital "against medical advice." In such a case, the physician should explore the reasons for the patient's decision in the hope of uncovering misunderstandings or concerns that can be addressed. If the patient insists on leaving the hospital despite these discussions, the physician should respect the patient's choice by providing the medications, referrals, instructions, home care, and follow-up necessary to maximize the medical outcome. Some physicians are re-

luctant to arrange for such services because they fear they will be liable for providing substandard care. However, the physician's duty to act in the patient's best interest requires that the physician try to optimize a patient's care even if the patient refuses the level of care recommended by the physician.

When patients decide to leave against medical advice, it is helpful, but not absolutely necessary, to have them sign a form stating that they understand and accept the risks associated with leaving. More important than this signature is that a patient be offered services to aid recovery, and that both the patient's understanding of the risks and the attempts to convince the patient to remain in the hospital are carefully documented in the chart.

Emergency Procedures

Occasionally, physicians confront emergency situations in which immediate treatment is necessary to save life or limb, the patient is incapable of giving consent, and a surrogate cannot be located. There is a widespread misconception that in such situations it is necessary to invoke a "two-physician hold," whereby two physicians verify that the patient requires emergency treatment and is incapable of consenting to it. In fact, a determination by one attending physician is sufficient to initiate emergency treatment. In the absence of a DNR order, the presumption is that people would want such care and would not want care delayed by the lack of consent. After the immediate threat is dealt with, the physician should make every effort to discuss ongoing care with the patient or an appropriate surrogate.

ISSUES IN THE CURRENT HEALTH CARE ENVIRONMENT

Ethical challenges arise as a result of the current emphasis on restraining health care inflation. Although controlling costs is important, the mechanisms used to achieve this goal—financial incentives and utilization review, among others—may create conflicts of interest for physicians (18). Nonetheless, physicians have a responsibility to allocate health care resources justly and are not obligated to order an intervention simply because a patient requests it.

Timing of Hospital Discharge

One common situation that exemplifies this issue involves length of stay and the timing of hospital discharge. If a patient with community-acquired pneumonia is clinically stable and medically ready for discharge but refuses to go home, the physician should try to elicit and address the patient's concerns. A patient who is afebrile, breathing room air, and taking oral antibiotics may still feel too

weak to go home despite being clinically stable for discharge. Attending to details like social support, transportation, in-home services, rehabilitation, and follow-up may allay a patient's fears about leaving the hospital. If the patient still feels uncomfortable about going home and there is no one at home to care for the patient, short-term placement in a skilled-nursing facility may be appropriate. Patients who still refuse discharge should be informed that they may be at financial risk for subsequent hospital days. Although the patient's request to remain in the hospital is an expression of the patient's autonomy, a physician's responsibility to allocate resources justly means that the patient's request may be rightfully refused.

In some situations, the physician believes that the patient is not quite ready for discharge but the insurer or medical group determines that the patient has exceeded the allocated length of stay. Payers may stop or reduce hospital payments at this point. In such situations, the physician has an obligation to advocate on behalf of the patient. The physician should not misrepresent the patient's condition or institute or continue unnecessary interventions to secure payment, but should make necessary phone calls and write letters to secure additional days. Finally, physicians should keep in mind that length of stay and other guidelines are recommendations, not requirements. A compassionate and effective system will allow for outliers and the use of discretion in individual cases.

Confidentiality and Privacy

Patients expect that their medical information will be kept confidential, and it is this knowledge that helps encourage patients to seek medical care and reveal sensitive information to clinicians. Challenges to confidentiality abound and clinicians must be mindful not to discuss private patient information in public places. The federal government issued new federal privacy regulations under the Health Insurance Portability and Accountability Act (HIPAA) that took effect in April 2003 (19). These regulations cover identifiable health information in electronic, paper, or oral form. Under these regulations, providers and health plans must notify patients about privacy, develop organizational policies and procedures regarding privacy, and educate staff about privacy issues. Despite concerns that the regulations might interfere in the care of patients, they are designed not to. They allow for the use or disclosure of personal patient information without consent for clinical care, treatment, payment, and health care operations. The latter category includes quality assurance and quality improvement programs, accreditation and licensing, training programs, and business planning. Similarly, no patient consent is required for use of or disclosure of patient information for public health, abuse,

neglect, or domestic violence reporting, judicial or administrative proceedings, and law enforcement purposes. Under HIPAA, patients must give specific authorization for use of their personal information for marketing and most clinical research. HIPAA also provides patients with the right to review their medical records and request that corrections be made. States and health care organizations may have confidentiality laws or policies that are stricter than the federal regulations.

In caring for patients in the hospital, these regulations reinforce the ethical principle of confidentiality. Hospital physicians should continue to discuss patients with colleagues involved in a patient's care and obtain help with diagnosis, prognosis, or treatment. However, the HIPAA regulations require clinicians to take reasonable precautions to protect confidentiality. For example, bedside charts in the emergency department or on the wards must be covered or situated in such a way that passersby cannot see the information on the chart. Furthermore, although HIPAA does not forbid physicians from discussing patients at nursing stations, in the hallways, or in semiprivate hospital rooms, physicians should keep their voices down to reduce the possibility that conversations will be overheard. Physicians should continue to discuss their patient's care with people who identify themselves as family members, unless the patient forbids them from doing so or they judge that such discussions would be harmful to the patient. Of particular importance, health care providers must resist the temptation to discuss patient information in public places such as elevators and public cafeterias. Breaches of confidentiality erode trust in physicians and may have adverse economic, social, and psychological consequences for patients. Although the presumption should always be that physicians maintain confidentiality, there are specific circumstances when physicians are required by law to override confidentiality, including child or elder abuse, certain infectious diseases such as tuberculosis and syphilis, and injuries caused by deadly weapons. In these circumstances when confidentiality must be breached, physicians should disclose the least amount of information to the fewest people necessary to fulfill reporting requirements.

Role of Ethics Committees

Ethics committees may provide consultation on difficult cases. The committee typically includes physicians from several clinical departments, nurses, social workers, lawyers, a risk manager, and community members. Although the decisions of the ethics committee are meant to offer guidance and are typically not binding on physicians or patients, the ethics committee can help resolve disagreements among members of the team, among members of the patient's family, or between the health care team and the patient or surrogates. In institutions that lack an active

and effective ethics committee, physicians can obtain similar assistance from colleagues.

Ethics and the Hospitalist Model of Care

The traditional relationship between patient and primary care physician provides many ethical protections for patients, including confidentiality, shared decision making, and respect for patient autonomy. Hospitalist models, which introduce a purposeful discontinuity of care, threaten these protections and raise certain ethical concerns (19).

For example, the hospitalist and primary care physician may disagree on the best course of action for an inpatient. In such circumstances, both physicians should be given the opportunity to present the options to the patient clearly and completely to allow the patient to make the final decision. If it can be organized, a joint meeting involving patient, family, and both physicians would provide the patient with the best opportunity to make a truly informed choice.

Ethical issues may also arise during end-of-life decisions. For example, consider a patient with metastatic cancer who prefers to forgo CPR in the event of a cardiac arrest that accompanies a worsening of disease but nevertheless wants CPR for an acute arrest. Or, consider a patient who has a DNR order in the chart but now presents to the emergency department with an anaphylactic reaction that may be easily reversible. Like emergency medicine physicians, the hospitalist is disadvantaged by lacking a prior relationship with a patient who is *in extremis* and unable to communicate the applicability of prior preferences. Hospitalists will need to become expert in discussing advance directives. They will also need to develop systems to involve primary physicians rapidly in these difficult decisions.

As hospitalists assume control of inpatient care, they must also take responsibility for providing ethical protection currently vested in the relationship between the patient and the primary care physician. An approach that keeps the patient's best interests foremost, defines a clear role for the primary physician, and takes advantage of the expertise and availability of hospitalists will best serve both patients and physicians (20).

CONCLUSIONS

In dealing with difficult ethical challenges, physicians need to consult with thoughtful colleagues, be able to tolerate uncertainty, and maintain their own integrity while respecting the opinions of others. By applying basic ethical principles and communicating effectively with patients, surrogates, and other members of the health care team, physicians can resolve nearly all ethical dilemmas that arise in the hospital.

KEY POINTS

- Care should be guided by the ethical principles of autonomy, beneficence, non-maleficence, justice, and confidentiality.
- For patients who lack decision-making capacity and have no advance directive, the physician and surrogate should work together to make decisions to help guide care.
- Hospitalization may be a particularly good time to discuss code status and advance directives.
- The withdrawal and withholding of interventions are ethically and morally equivalent.
- Although physicians need not provide futile interventions, they must be very cautious about using this rationale to deny care because true futility is rare and applying the rationale overrides patient autonomy.
- In emergency situations in which there is an immediate threat to life or limb, the patient lacks decision-making capacity, no surrogate decision maker is available, and there is no indication that the patient would refuse treatment, the presumption is to provide care.
- Ethics committees may provide consultation on difficult cases and can help resolve disagreements.

Pain Management in the Hospitalized

18

Patient

Robert V. Brody

INTRODUCTION

There are few symptoms that engender so much patient concern and disability as pain, and few areas in which there is so great a gap between the capabilities of modern medicine and the actual effectiveness of our practice. For more than 25 years, studies have repeatedly documented our failure to manage pain adequately; the more severe the pain, the worse we do at management.

After decades of relative neglect by the medical profession, there is renewed interest in the management of acute and chronic pain. Some of this energy is fueled by a new understanding of the pathophysiology of different types of pain, some by the recent availability of both new medications and more rational strategies for the use of old ones, and much by the increasingly vocal demands of patients and families. Research performed in hospice units has shown satisfaction with pain control in the range of 80%–90%, which leads other patients, particularly those with chronic pain, to ask, “Why do I have to be dying to have my pain controlled?” Increasingly, hospitals, surveyors, and even state medical boards are regarding pain management as a quality-of-care issue (Chapter 12). Nevertheless, studies continue to show a high prevalence of pain in hospitalized patients and significant dissatisfaction with inpatient pain control (1).

This chapter begins by outlining some basic principles of pain assessment and management. Commonly used drugs and other agents are reviewed, and some guiding principles

of pharmacologic therapy are developed. Then, common challenges in inpatient pain management are considered: treatment of neuropathic pain, treatment of pain in the patient with a history of substance abuse or HIV infection, and treatment of pain in the older hospitalized patient.

GENERAL PRINCIPLES OF PAIN MANAGEMENT

Nature of Pain

According to the International Association for the Study of Pain, pain is an unpleasant sensory and emotional experience, most often associated with actual or potential tissue damage or described in terms of such damage (2, 3). Pain is not just the unpleasant sensation, not just the perception of the sensation, but also the emotional reaction to or experience of the perceived sensation. As such, *pain is always subjective*. The subjectivity creates a dilemma for the clinician. By virtue of the observations and tests available to clinicians, we know more than a patient does about the structure and function of his or her liver, blood, kidneys, heart, bones, nerves, and even brain. However, no test or observation can accurately tell the clinician whether a patient is in pain. The only “test” the clinician has available is to ask the patient and listen to the answer.

Pain has consequences. In addition to enduring unnecessary suffering, patients with unrelieved pain become

Figure 18.1 Examples of visual pain intensity assessment scales. (Reprinted from Acute Pain Management Guideline Panel. Acute pain management: operative or medical procedures and trauma. Clinical practice guideline. AHCPR Publication No. 92-002. Rockville, MD: Agency for Health Care Policy and Research, Public Health Service, U.S. Department of Health and Human Services, February 1992, with permission.)

catabolic, respond less well to curative medical or surgical treatments, have a greater complication rate from these therapies, show a higher rate of emotional disturbance, and in some circumstances die sooner.

Cultural and psychological factors influence the expression of and tolerance for pain. Other factors that decrease the pain threshold (i.e., cause the patient to be in more pain) include insomnia, fatigue, nausea, anxiety, fear, misunderstanding, anger, shame, sadness, depression, introversion, any other discomfort, and the memory of past pain and expectation that pain will recur. Conversely, the threshold for pain may be increased (i.e., the patient will be in less pain) with relief of other symptoms, sleep, rest, sympathy, understanding, and diversion, and with the use of anticipatory and around-the-clock dosing of pain medication.

Clinical Assessment and Goals of Pain Management

The approach to the patient in pain begins with a pain history (4). Commonly used tools of pain assessment are shown in Figure 18.1. The patient should be asked to rate the severity of pain on a scale of 0 to 10, with 0 indicating no pain and 10 the worst imaginable pain. Some patients (e.g., children or those with whom it is difficult to communicate) may find it easier to rate their pain by using a picture-based scale (Figure 18.2). After any therapeutic intervention, the provider needs to learn how much relief

Figure 18.2 An example of a picture-based pain intensity assessment scale.

was achieved; one does so by asking the patient to rate the pain again and recall how long the relief lasted. The dose of the analgesic is adjusted to give the patient adequate pain control; the interval between doses is adjusted so that the analgesic effect is uninterrupted. The goal of pain management is not necessarily “zero” pain; rather, it is the *maximally functional patient*, with the patient ultimately deciding whether the goal has been reached.

Additional questions that should be included in the pain history relate to the following:

- Significant previous or ongoing instances of pain
- Previously used pain control methods and their effect, and the patient’s preferences for pain management
- Attitudes of the patient and family toward the use of opioid, anxiolytic, and other medications, and any history of substance abuse
- Typical coping response of the patient for stress or pain, the presence of any psychiatric disorders, and ways that the patient describes or shows pain. A discussion with current or previous providers of outpatient treatment for pain is often enlightening
- The patient’s functional status and the contribution of pain to any loss of function
- The meaning the patient ascribes to the pain (e.g., brings back memories of trauma, makes it impossible to support a family, or signifies that death is at hand)

The physician’s examination should supplement the history in making as specific a diagnosis of the causes of the pain as possible. Such a diagnosis facilitates treatment of the underlying pathophysiology and allows the symptomatic treatment to be tailored to the specific type of pain. It is common for hospitalized patients to have more than one painful condition. Some patients in significant pain will show evidence of adrenergic stimulation (i.e., sweating, tachycardia), whereas others may be in severe pain and not demonstrate such findings. It cannot be presumed that the patient who dozes off between doses of analgesics is malingering or is being overtreated; such a patient may be making up for a large physiologic sleep deficit, be under the influence of sedatives, or have another cause of altered mental status.

Except when they identify a specific etiology, laboratory tests are unhelpful in the assessment of pain. For example, a bone film or scan may demonstrate a metastatic lesion that would benefit from radiotherapy. An electrocardiogram and measurement of the troponin level may demonstrate that chest or arm pain is caused by myocardial infarction, for which the optimal approach to pain management is rapid reperfusion. However, *there is no blood test or imaging study for pain itself*. Patients in severe pain may have normal white blood cell counts, sedimentation rates, or other markers that have been proposed to help confirm the “reality” of pain. In the end, pain is subjective, and the clinician is left with the patient’s assessment as the only test to assess the presence or severity of pain.

Initial Management

There is a tendency to move rapidly toward pharmacologic management of pain, especially in the hospitalized patient, in whom acute pain (which may be self-limited) is likely. It is worth remembering that many patients will benefit from *physical measures*, such as the application of heat or cold, and that *nonpharmacologic approaches*, such as relaxation, distraction, imagery, transcutaneous electrical nerve stimulation, or physical therapy, may also be useful.

Most hospitalized patients in pain, however, will require a pharmacologic agent to help control the symptom. The World Health Organization Committee on Cancer Pain has popularized the concept of an *analgesic ladder*, classifying conventional analgesics into 3 steps: the higher the step, the stronger the agent and the more likely an adverse reaction.

Step 1 agents include aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and propoxyphene. For noninflammatory painful conditions, acetaminophen is usually as effective as an NSAID and lacks the problematic side effects of gastrointestinal bleeding, platelet dysfunction, renal failure, and occasional confusion. For inflammatory conditions, it is useful to remember that there are no data showing greater analgesic or anti-inflammatory efficacy of one NSAID versus another, including parenterally administered ketorolac (5) or COX-2 inhibitors. The latter may cause less gastrointestinal bleeding but have significant rates of other adverse reactions, including GI symptoms, and are expensive. Moreover, the recent findings of increased cardiovascular risk associated with rofecoxib (Vioxx), which led to the drug's withdrawal from the market, have raised concerns about the entire class of COX-2 inhibitors (6).

Step 2 agents include codeine, hydrocodone, tramadol, meperidine, and mixed agonist-antagonists, such as pentazocine. Dose-response curves for these agents reach a plateau, in contrast with the curves of step 3 agents, which have no upper limit in dosing. Because a metabolite of meperidine accumulates and causes irritability and, occasionally, seizures with repeated dosing, the use of meperidine as an analgesic should be limited. However, it remains the best agent for prevention or treatment of rigors and post-anesthesia shivering. Tramadol, a non-opiate with serotonin reuptake inhibiting properties, binds to the μ -opiate receptor; therefore, it has many of the same properties as opiates and, like opiates, can be abused. In addition, it has the potential to cause seizures. Mixed agonist-antagonists, such as pentazocine, cannot be titrated like step 3 agents because of significant psychotomimetic effects. Because of their antagonist properties, they must be allowed to wear off before a stronger, purely agonist opiate can be used.

Step 3 agents that are frequently used include morphine, hydromorphone, oxycodone, fentanyl, methadone, and levorphanol. See Table 18.1 for approximate dose conversions to use when switching from one agent or route of administration to another. *Morphine* is the standard against

which other analgesics are measured. Most short-acting preparations give relief for 3–6 hours, whereas the effects of long-acting preparations last 8–12 hours. In general, it is easier to titrate analgesia with short-acting preparations. Once the patient's pain syndrome is stable, the physician can calculate the total 24-hour dose, divide by 2, and administer the equivalent long-acting preparation every 12 hours. Do not allow long-acting tablets to be crushed, because this converts the drugs to short-acting forms.

The dose-response curve of *oxycodone* does not plateau, a similar effect to that of morphine. In the past, oxycodone was usually prescribed in combination with aspirin or acetaminophen; such formulations cannot be titrated above a certain threshold because of the potential toxicity of the second drug. Oxycodone can be prescribed alone in a short-acting form or sustained-release preparations, allowing the clinician to take advantage of oxycodone's lack of a dose-response plateau.

The effects of *fentanyl*, an opiate with a duration of action that is very short when given intravenously, can last as long as 3 days when it is administered by transdermal patch. It takes more than 18 hours for fentanyl to produce a maximum effect when administered in this manner. *The fentanyl patch should be used only to treat stable chronic pain.* Use of the patch is associated with a high incidence of contact dermatitis, which can be prevented by pretreating the skin with several puffs from a metered-dose steroid inhaler.

Although *methadone* is best known for its ability to control the opiate abstinence syndrome, it is also an effective analgesic. Although it is usually given once daily for opiate abstinence, it must be given every 6–8 hours for analgesia. Federal law generally prohibits physicians outside federally licensed methadone programs from prescribing methadone once a day for outpatients but does allow more frequent dosing for pain control. These restrictions do not apply to hospitalized patients.

The following general points about pharmacologic pain management can be made:

- The biologic half-life of the agent must be taken into account when adjusting dosage and interval. The maximum effect of a given dose may not be seen until the drug has been administered for 4–5 half-lives. In addition, the duration of analgesia may be shorter than the half-life, and the half-life may be prolonged in cases of renal or hepatic failure. In the latter situations, one should use short-acting agents with dosing at longer intervals.
- Once pain is controlled satisfactorily, the dose of analgesic usually remains stable. An increase in analgesic requirement most often signals disease progression. Tolerance, a poorly understood phenomenon, develops rapidly to the sedative effects of opiates but is much less likely to develop to the analgesic or constipating effects.
- The onset of analgesia depends on the route of administration. In general, the onset is in 5–10 minutes with

TABLE 18.1
EQUI-ANALGESIC DOSING TABLE FOR OPIOIDS^a

Drug	Approximate equi-analgesic oral dose	Approximate equi-analgesic parenteral dose	How supplied (non-parenteral)
Codeine	130 mg q3–4h ^b	75 mg q3–4h ^b (not recommended)	15, 30, 60 mg tablets, as plain codeine or as Tylenol with codeine No. 2, 3, 4, respectively ^c ; solution: 5 mL = 12.5 mg codeine + 120 mg acetaminophen or 30 mg codeine + 160 mg acetaminophen
Hydrocodone in Vicodin, Lortab, other	30 mg q3–4h	not available	2.5, 5, 7.5, and 10 mg tablets with 500 mg ASA or 500–750 mg acetaminophen ^c
Oxycodone Roxicodone, Intenso; also in Percocet, Percodan, Tylox, Roxicet, Roxiprin, Endodan, Endocet SR (q8–12h)	20 mg IR q3–4h	not available in U.S.	5 mg per plain or combination tablet; ^c 1 mg/mL, 20 mg/mL solution 10, 20, 40, 80 mg sustained-release tablet
Meperidine (Pethidine) Demerol	300 mg q2–3h (not recommended)	100 mg q2–3h (not recommended for around-the-clock dosing)	50, 100 mg tablets, 10 mg/mL syrup
Morphine MSIR, OMS, Roxanol; MS Contin, Oramorph SR (q 8–12 h)	30 mg IR q3–4h, around the clock; 60 mg single dose or intermittent dosing	10 mg q3–4h	2 mg/mL, 20 mg/mL, and other oral solutions; 15, 30, 60, 100, 200 mg sustained-release tablet ^d
Hydromorphone Dilaudid	7.5 mg q3–4h	1.5 mg q3–4h	1 mg/mL oral solution; 2, 4, 8 mg tablets; 3 mg rectal suppositories ^d ; 5 mg rectal suppositories
Oxymorphone Numorphone	not available	1 mg q3–4h	
Methadone Dolophine	60 mg q8h	10 mg q8h	10 mg tablets; 1, 2, and 10 mg/mL solution
Levorphanol Levo-Dromoran	4 mg q8h	2 mg q8h	2 mg tablet
Fentanyl Sublimaze; Duragesic transdermal patch (q 72 h)	not available	2.5 mg/h morphine IV = 30 mg q3h morphine PO = 25 mcg/h fentanyl IV infusion or patch	25, 50, 75, 100 mcg transdermal patch

Use this table for determining approximate dose conversions when changing from one route of administration to another or from one drug to another. The reference dose is morphine 10 mg IV or IM q3–4h. Doses in each column should give about the same amount of pain relief. Use a lower than equi-analgesic dose when changing drugs, then retitrate to the desired clinical response in each patient.

^a Recommended dosing schedules do not apply to patients with renal and/or hepatic insufficiency or other conditions affecting drug metabolism and kinetics. These dosing recommendations should also be modified for persons weighing less than 50 kg.

^b Codeine doses more than 120 mg q4h are not useful because of diminishing incremental analgesia but continually increasing constipation and other adverse effects.

^c Dosing of aspirin or acetaminophen must be considered when combination preparations are titrated.

^d Rectal administration of morphine and hydromorphone is possible, with dosing approximately the same as the oral route.

ASA, acetylsalicylic acid; IR, immediate-release; SR, sustained release.

McCaffery M, Beebe A. *Pain: Clinical Manual for Nursing Practice*. St. Louis, MO: Mosby, 1989. World Health Organization. *Cancer Pain Relief*. Geneva, 1966. Agency for Health Care Policy and Research. *Acute Pain Management: Operative or Medical Procedures and Trauma*. Rockville, MD, 1992.

intravenous administration, 20–40 minutes with subcutaneous or intramuscular administration, and 20–60 minutes for oral administration. With rectal and sublingual administration, the onset may be closer to that with subcutaneous or intramuscular administration because these routes avoid first-pass metabolism in the liver. Intramuscular, intravenous, and subcutaneous doses are considered equi-analgesic for most agents.

- When possible, treat pain prophylactically. Give analgesics before procedures (including placement and removal of chest tubes and bone marrow biopsies) and dressing changes. *Never rely solely on as-needed medications (PRN) when you know the patient will have significant pain.* In general, for patients with moderate or severe pain, use a long-acting oral or transdermal preparation or a constant intravenous or subcutaneous infusion, plus a shorter-acting agent that may be used as needed for breakthrough pain.
- Oral administration is preferred over parenteral administration, because it facilitates a more even blood level, is less expensive and less intimidating, does not require special knowledge such as familiarity with infusion pumps, and does not transmit infections the way needles can. Our society needs to relinquish the unscientific expectation that only a “pain shot” can treat severe pain. As soon as patients can take oral liquids, consideration should be given to changing to an oral pain regimen.
- *Patient-controlled analgesia (PCA)*, with doses administered by the patient within professionally established limits, has been shown to lessen postoperative pain, decrease complications, lead to earlier hospital discharge, and lessen the total amount of opiate consumed. Figure 18.3 shows a model PCA order sheet. Although the concept of patient self-administration and control has been applied most frequently to parenteral PCA pumps, it reinforces the desirability of active patient participation in the selection, assessment, and control of analgesic regimens.
- A *constant opiate infusion* may be indicated for patients with severe stable pain who use a patient-controlled pump. On the other hand, a constant basal infusion is not recommended for patients after simple operative procedures, patients with undiagnosed or changing pain, elderly patients, or patients with hepatic or renal insufficiency.
- *Intraspinal (epidural or intrathecal) regimens* can provide analgesia at lower dosages and may reduce systemic side effects. This route may be especially useful in acute postoperative pain, particularly after thoracic, abdominal, or pelvic surgery. The equi-analgesic epidural dose of morphine is about one-tenth the parenteral dose, and the intrathecal dose is about one-tenth the epidural dose. Although the combination of dilute concentrations of intraspinal anesthetics and opiates provides some advantages over opiates alone, the use of this strategy is limited by the invasiveness of the intraspinal route,

expense, requirements for close monitoring, and need to involve an anesthesiologist or pain specialist. Recently, many surgeons have been placing local pumps to deliver infusions of anesthetics directly into the incisional site. Emerging evidence is that such infusions decrease the need for systemic opioids (7).

- Adverse reactions, especially to step 2 and 3 drugs, must be anticipated. *Assume that all patients taking opiates will be constipated.* Stool softeners and propulsant preparations are useful and should be titrated against the consistency of stool and intervals between defecations. Despite the frequency of constipation, prolonged postoperative ileus almost always has a cause other than opiate analgesia. Similarly, when an altered mental status develops in a patient receiving stable opiates, consider other causes before automatically discontinuing the opiate; these include concurrent medications (especially psychoactive medications), sepsis, and stroke. Avoid the use of naloxone (Chapter 121) if at all possible (the patient may wake up screaming) by relying instead on short-term intense observation. Be prepared to use an ambu bag if necessary. If naloxone is used, dilute it (0.4 mg naloxone in 10 mL normal saline solution) and titrate it carefully until the patient’s mental status clears.

PAIN MANAGEMENT IN SPECIAL CIRCUMSTANCES

The general principles outlined above are applicable to most hospitalized patients with pain. The following sections focus on patients with special needs. In addition, pain management in the postoperative patient is covered in Chapter 31 (2), and treatment of the patient with sickle cell pain crisis is discussed in Chapter 97 (8).

Patients with Neuropathic Pain

Neuropathic pain (9) is characterized by burning, tingling, numbness, and electrical or pins-and-needles qualities. It accompanies many medical and surgical conditions (HIV disease, diabetes, alcoholism, shingles, amputations and other trauma, and cerebrovascular events) and often goes undiagnosed. Conventional analgesics are most useful for somatic and visceral pain; neuropathic pain, resulting from pathology directly affecting nerves, may respond better to other agents. As hospitalized patients may have multiple pains, each must be individually assessed, and the following algorithm should be considered even if only one pain has neuropathic qualities.

Tricyclic agents have specific analgesic effects in neuropathic pain separate from their antidepressant effect. Analgesia is achieved at lower doses than is relief of depression (e.g., 10–25 mg of desipramine may relieve pain versus 150–300 mg for relief of depression); it also is achieved in less time (e.g., 1–3 days for analgesia versus 3–6 weeks for

depression). Many clinicians avoid amitriptyline because of excessive sedation and anticholinergic adverse effects, instead relying on desipramine, imipramine, or nortriptyline. Note that antidepressants without the tricyclic structure (e.g., selective serotonin reuptake inhibitors; see Chapter 119) lack an analgesic effect, and that tricyclics are useful

for neuropathic pain, not somatic or visceral pain. The dose of the tricyclic may be increased as often as every 3 days and titrated to the relief of neuropathic pain or the development of adverse events. The effective analgesic dose may be equal to or even higher than the usual antidepressant dose. If the patient partially responds to a tricyclic

agent, it is best to maintain the highest tolerated dose and add an anticonvulsant.

Antiseizure medications (carbamazepine, gabapentin, phenytoin, valproic acid, clonazepam) have been used successfully to treat neuropathic pain. Carbamazepine is generally used at anti-seizure doses. The upper dose limit for gabapentin in the treatment of neuropathic pain has not yet been defined; doses as high as 6 g daily are being used commonly.

Mexiletine, an oral form of lidocaine, has been used to relieve painful diabetic peripheral neuropathy and is effective in other types of neuropathic pain. The usual dose is 150–200 mg 3 times daily, up to a maximum of 1,200 mg daily. All anti-arrhythmics are potentially pro-arrhythmic, so this agent should not be used in patients with known ventricular dysrhythmias or those with a predisposition to dysrhythmias (e.g., severe dilated cardiomyopathy). Up to 20 mg of baclofen 4 times daily may be useful for neuropathic pain as well as for painful muscle spasm. Capsaicin, a topical agent derived from chili peppers, must be applied to painful areas several times per day and may cause burning. Some patients have even responded to analgesic balm. If these modalities, most often used in combination, do not adequately control neuropathic pain, it is reasonable to add opiates to the regimen.

Patients with a History of Substance Abuse

Physical dependence is defined as a condition in which abrupt discontinuation of an agent, after a period of continuous use, causes physical symptoms (withdrawal or abstinence syndrome). It is a common feature of opioid use, as it is also with antihypertensives, benzodiazepines, barbiturates, corticosteroids, and other classes of drugs. It can be easily managed by gradually tapering the medication if it is no longer indicated. Drug abuse is the inappropriate use of a medication for a nonmedical problem (e.g., to escape family, work, and social or financial problems). Taken to extreme, drug abuse becomes drug addiction, a compulsive pattern of drug abuse and socially inappropriate or dangerous behaviors. *The medical use of opioids is not associated with the development of addiction*, with the exception of the patient recovering from opiate addiction, who may be at substantial risk for relapse. Such patients require an open discussion regarding analgesic choices and positive and negative consequences, including the potential relapse of addiction. When opiates are used in these patients, long-acting preparations should be given at scheduled times; needles, an environmental cue for craving, should be avoided (11). Because of physiologic tolerance, regular users of opiates require stronger analgesics and larger doses to achieve the same analgesic effect than do those who are opiate-naïve. It is useful to separate the treatment of addiction from the treatment for pain and establish a dose of methadone sufficient to keep the patient out of withdrawal while using other agents for pain. Buprenor-

phine, a mild opiate agonist that adheres tightly to opiate receptors, is increasingly being used for treatment of addiction; it may have to be discontinued in the hospitalized patient with new significant pain. Consultation with substance abuse experts is often helpful (Chapter 121).

Patients with HIV Disease

Although there are few studies addressing the management of common HIV-related pain syndromes, the approach outlined in this chapter is generally useful in these patients, with several caveats. Neuropathy is very common and causes significant morbidity. It may be caused by antiretroviral therapies, which should be discontinued as soon as this adverse effect is recognized. The algorithm given above for neuropathic pain often must be modified in AIDS patients because of drug interactions; carbamazepine, for example, interacts with many antiretroviral agents; gabapentin appears to be better tolerated. Management of pain in AIDS patients frequently must take into account issues of dementia and substance abuse.

Older Hospitalized Patients

Assessment of pain in the elderly (12) may be complicated by sensory, cognitive, or communication deficits in addition to an attitude among many elders of resignation to pain. Pharmacologic therapy for pain must be administered cautiously in older patients because of several factors. Renal and hepatic function may be compromised, resulting in prolonged effects of usual doses of agents. Marginal brain, bladder, renal, or other organ function may be further compromised by analgesics, including NSAIDs, antineuropathic agents, and opiates; elderly patients are particularly susceptible to medication-induced falls (Chapter 16).

ASSESSING THE RESPONSE TO THERAPY

Successful management of pain in the hospitalized patient requires the active participation of educated nursing and pharmacy staff. Continuous assessment of pain and appropriate titration of pain medication can best be carried out by nurses acting under physician orders that give them a range of options. Nurses can also identify and address common adverse effects of the chosen regimen. Some institutions have advance practice nurses and clinical pharmacists to further the goal of effective pain management. Many have added a pain assessment (0–10) instrument to the vital sign sheet. Pain management is certainly an area in which patients' best interests are served when physicians work closely with nurses and pharmacists, as well as rehabilitation therapists and mental health workers (Chapter 4).

If the patient's pain has not responded to treatment as predicted, several questions should be asked:

- Did the patient in fact receive the ordered medication? "Opiophobia" is so common among patients, family members, and hospital staff that the medication may never have reached the patient.
- Was the patient prescribed PRN dosing when around-the-clock dosing would have been more effective?
- Does the patient have pain that may be relatively resistant to conventional analgesics (e.g., neuropathic pain)?
- Are there additional pathology or complications that have not been diagnosed or fully appreciated? Repeating the history and physical examination along with indicated studies may be revealing. Hospitalized patients often have more than one pain; muscle spasm is common, as is neuropathic pain and flares of gout (the latter often precipitated by surgery, hemorrhage, starvation, or re-feeding). All these entities may respond to specific therapy once diagnosed.

If the patient still has unrelieved pain, consultation with a *pain specialty team* is indicated. Given the high success rates reported in the literature in managing the pain of terminal disease (Chapter 19), and the increasing use of these same techniques in managing nonmalignant, non-terminal pain, patients and providers should expect that pain will be managed. The old notion that the patient "will just have to learn to live with pain" is increasingly unacceptable.

DISCHARGE ISSUES

As the patient progresses toward discharge, the analgesic regimen should be steadily changed toward the least invasive route that still provides adequate control of pain. The analgesics should be switched to the oral route as soon as liquids are tolerated. Ideally, the medication regimen can be stabilized while the patient is in the hospital; this is preferable to discontinuing a parenteral regimen just as the patient is leaving the ward. Careful thought must be given to the patient's need for analgesics at home (including timing of the follow-up visit) so that the patient leaves with enough of the correct medication. Physicians should have no fear of prescribing opiates at discharge if these are indicated by the clinical situation. They should not allow regulatory barriers (e.g., the preprinted prescription forms required for controlled substances in a few states) to distort clinical practice. Regimens should be as simple as possible to promote adherence. Patients who are likely to remain in significant pain after discharge often do best with one long-acting opiate for around-the-clock pain relief plus a short-acting agent for breakthrough pain. Patients with conditions such as sickle cell disease or migraine, which are likely to cause painful flares, should be given the analgesic tools to use at home rather than be required to depend on

drop-in visits for relief. The primary physician can manage most pain satisfactorily if the principles described above are followed. For those with more complicated pain problems, consider referral to a specialty pain clinic.

CONCLUSIONS

The pain of most hospitalized patients can be controlled promptly and safely by taking a careful history, employing rational pharmacologic and nonpharmacologic modalities, and continuously assessing response to initial management and adjusting the approach as needed. The fact that this vision is often unrealized stands as a major flaw in our current practice. It clearly can be improved through clinician education and the use of a multidisciplinary team.

KEY POINTS

- Clinicians cannot determine whether and how much pain is present without asking the patient and listening to the answer.
- Effective pain management depends on initial and ongoing assessment of the type of pain, its severity, and its response to therapy.
- Hospitalized patients often have more than one kind of pain (e.g., both somatic and neuropathic), requiring more than one kind of approach for effective control.
- Anything that influences the patient's emotional state will influence how much pain is experienced, both positively and negatively.
- The goal of pain management is not necessarily the complete absence of pain; rather, it is the maximally functional patient.
- Oral administration is the preferred route for analgesics.
- Knowledge of and comfort with the appropriate use of opiates can overcome our society's "opiophobia."

End-of-Life Care in the Hospital

19

Daniel Fischberg Paolo Manfredi Diane E. Meier

INTRODUCTION

Palliative care is interdisciplinary care aimed at relieving suffering and improving quality of life for patients with advanced illness and their families. Palliative care may be offered simultaneously with appropriate disease-modifying treatments during a chronic illness, or it may become the focus of care near the end of life. Hospitals traditionally have been structured to efficiently treat acute illnesses and exacerbations of chronic illnesses. When prolonging life is no longer the primary goal, hospitals typically fail to provide alternatives, continuing treatment focused on longevity up to the very moment of death (and often beyond that in the form of cardiopulmonary resuscitation). Although the acute-care hospital is usually not the ideal site of death, currently most Americans die in hospitals (1).

Throughout the course of a patient's illness, alleviation of physical and emotional suffering should be the objective of every health care professional. There comes a point in the evolution of many diseases at which the benefits of some or all of the efforts devoted to prolonging life no longer exceed the burden they pose to the patient's quality of life. The timing of this transition varies with the patient's preferences, and it is better thought of as a gradual, iterative process rather than an epiphany. The prompt recognition of the point at which the burden of life-prolonging efforts exceeds their benefit is essential to avoid unnecessary suffering and inappropriate allocation of resources. In this regard, it is important to note that there is never a time at which "there is nothing more that can be done"; every dying patient can benefit from and deserves skilled attention to palliative care issues.

Effective end-of-life care requires consideration of individual preferences (often inferred from the surrogate's perception of the patient's beliefs), integrated with the ability

to prognosticate disease courses and to treat symptoms such as pain (see Chapter 18), dyspnea, nausea, delirium, and depression (see Chapter 119). Finally, knowledge of the available support systems inside and outside of the hospital is essential for developing an optimal plan of care for seriously ill and dying patients.

ADVANCE DIRECTIVES AND HEALTH CARE AGENTS

With the introduction of the Patient Self-Determination Act of 1990 (2), the importance of individual preferences has become more prominent in medical decision making. *Advance directives* are crucial for delivery of health care tailored to an individual's needs and preferences (see also Chapter 17). They provide a means by which capable patients can make known their preferences in the event they become unable to speak for themselves. Advance directives may contain specific examples addressing cardiopulmonary resuscitation, artificial nutrition, and hydration. More important in an advance directive, however, is a statement about what quality of life is unacceptable for the patient. For example, many patients say that they would not want continued life-prolonging measures if they were permanently incapable of recognizing and interacting with their loved ones. All patients should be strongly encouraged to designate a health care decision-making agent. Because of the variety and complexity of clinical scenarios, an individual designated by the patient to serve as his or her health care representative in case of lost capacity is critical for real-time decision making. The practical impact of advance directives on the delivery of care in the hospital is still controversial but is likely to increase as their use becomes more prevalent (3).

PROGNOSTICATION

Prognostication for decision-making purposes is the complex task of guessing the duration of life of an individual patient with one disease or, as is more often the case, multiple diseases. The prognosis then is integrated with an understanding of the functional status (quality-adjusted life span) that the patient is likely to achieve and finally with the patient's overall view of his or her own quality of life. The patient's wishes should guide the physician in determining, at any particular moment, the ratio of risk and burden to benefit for each test or treatment (ranging from a finger stick for blood-sugar testing to open-heart surgery). If the patient is unable to express himself, individuals who can speak on behalf of the patient (known as *surrogates* or *proxies*) should be consulted.

Among conditions that cause death in the hospital, the presence of multiorgan failure in patients with metastatic cancer or coma allows for a more accurate prediction of the clinical course than organ-specific processes such as advanced heart or lung disease. According to one study, the

median prognoses generated by a statistical model varied substantially among diseases: patients with congestive heart failure were estimated to have about a 40% chance of living 6 months on the day before their actual death; patients with lung cancer were estimated to have about a 5% chance (Figure 19.1). The median prognoses, by physician estimation, were equally inaccurate (4). Another study found that physicians overestimate survival by more than a factor of 5 (5). This lack of precision is inherent to prognostication and highlights the need to begin deliberating about benefits, burdens, and goals of care as soon as a potentially fatal condition is diagnosed.

When trying to prognosticate, it is important to remain mindful of the performance status of the patient, not only at the time of the evaluation but also before the event that prompted hospitalization. For example, consider the case of a 90-year-old patient with a history of dementia who is now in the ICU with respiratory failure after developing aspiration pneumonia while recovering from a fractured hip. In evaluating this patient, the information from the nursing home—that the patient had recently begun to require a

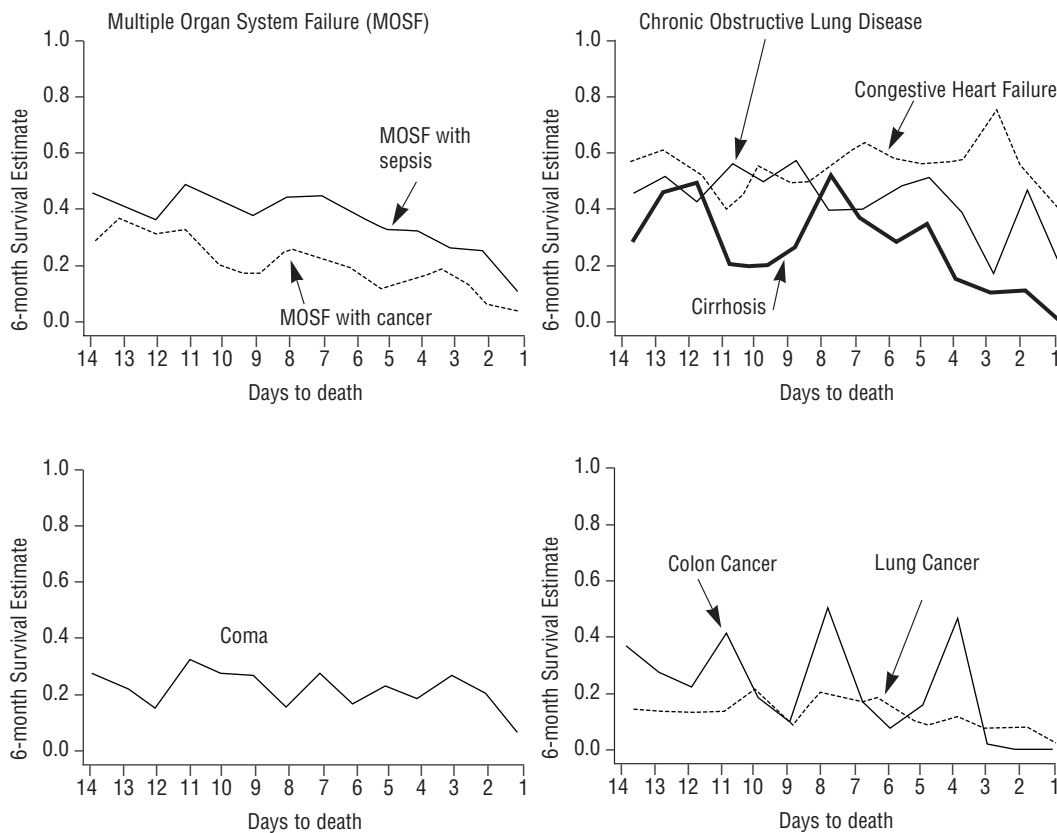

Figure 19.1 Estimates of prognosis in patients near death. Estimates for 6-month survival generated from the model of the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (y axis) by days before actual patient death (x axis) for patients with various diseases. **Top left.** Multiple organ system failure with sepsis (solid line) and with malignancy (dashed line). **Top right.** Chronic obstructive lung disease (solid line), congestive heart failure (dashed line), and cirrhosis (heavy line). **Bottom left.** Coma. **Bottom right.** Colon cancer (solid line) and lung cancer (dashed line).

walker, had frequent falling episodes, and had been losing weight because of refusal to eat—helps the physician determine that, even if weaning from the respirator is possible, at best the patient will be bedridden or chairbound and require a permanent feeding tube.

Another important point, especially for the patient being cared for by an army of specialists, is that there is a general tendency to prognosticate in an organ-specific manner. To continue with the prior example, the surgical wound from the open reduction and internal fixation of the femur appears to be healing, the pneumonia is being treated, the congestive heart failure is mild, the renal function is only moderately compromised, and the nutritional status is fair. Why, then, is the patient still unresponsive and unable to breathe after 10 days of intensive care and ventilatory support? The answer is that the combined impact of multiple insults is more important than the status of single organs and systems.

As often occurs in tertiary-care teaching hospitals, the presence of multiple specialists can be responsible for a fragmentation of care that confuses the clinical picture, especially as the clinical course progressively worsens. This can lead to contradictory and confusing messages about prognosis and goals of care delivered to the patient or the family by different specialists. Regular communication (e.g., through interdisciplinary meetings) with all consultants and family is therefore vital for effective care planning.

INTEGRATION OF PROGNOSIS AND PATIENT'S WISHES

Prognostication is the foundation on which goals of care are established and the plan of care is built. Once it is determined that the elderly woman in our example will not be able to walk or eat even if liberated from the ventilator, the surrogate's knowledge of the patient's wishes under that best-case clinical scenario guides further care. Options at this point include ventilator withdrawal versus continuation of medical care focused on life prolongation, including tracheostomy and gastrostomy for feeding tube placement. From the standpoints of humanitarianism (considering the apparent burden of suffering associated with ongoing aggressive medical care) and economics (in terms of the cost of care and the potential to deploy resources elsewhere) ventilator withdrawal may seem preferable. However, individual (patient or surrogate) preferences continue to strongly influence the goals of care in the United States and often result in the continuation of intensive medical care focused on prolongation of life, regardless of the ultimate quality of the life resulting.

A generation ago, many people separated potentially life-prolonging care into two categories: "heroic" or not. Our more modern understanding has eliminated this false dichotomy, weighing every potential intervention in terms of its benefits and burdens. As such, artificial nutrition

and hydration, antibiotics for infection, diagnostic tests, and rehospitalizations after discharge are all points open for discussion. If the patient is discharged back to the nursing home, it is necessary to clearly communicate the comprehensive plan of care to the receiving institution and medical staff. In discussing goals and options of care with patients and families it is important to emphasize that distressing symptoms (e.g., shortness of breath, pain, fever) can be treated effectively without attempting to reverse or cure the underlying illness, and that withdrawal of artificial nutrition and hydration will not cause suffering (6).

ARTIFICIAL VENTILATION

Artificial ventilation is initiated with the intent to help patients recover from an acute event. Often patients with terminal illnesses or multiorgan failure remain dependent on the ventilator and cannot be weaned. The patient or, if the patient is unable to make his wishes known, the surrogate should be informed about the option of disconnecting the ventilator and the availability of appropriate treatment to prevent and treat dyspnea (see Chapter 23). If, after disconnecting the ventilator, the patient continues to breathe (as may sometimes happen), the most urgent matter is to treat dyspnea (evidenced by tachypnea and use of accessory respiratory muscles) by titrating opioids with or without benzodiazepines or barbiturates until the patient passes away peacefully.

ARTIFICIAL NUTRITION AND HYDRATION

Artificial nutrition and hydration are beneficial for time-limited use while the patient is recovering from an acute event. Their value in treating patients nearing the end of life is controversial (6). Total parenteral nutrition in patients with advanced cancer has not been shown to prolong life.

The provision of nutrients by means of a tube inserted in the gastrointestinal tract or a vein, although clearly a form of medical treatment, carries more emotional weight than other treatments, including artificial ventilation. Even those who wish only comfort measures for their dying relatives often hesitate when asked about withdrawal of artificial nutrition and hydration. It is important to reiterate that artificial feeding is a medical treatment that carries its own burdens, and that dying patients do not suffer if artificial nutrition and hydration are not provided or are discontinued (6). Knowledge of state laws is also important if withdrawal of artificial nutrition and hydration is being considered, especially if the predicted life expectancy of the patient is more than several weeks but the prognosis for any form of functional recovery is dismal (e.g., the patient with advanced dementia).

COMMUNICATING BAD NEWS

Physicians should gather necessary information (e.g., usual prognosis and the pros and cons of treatment alternatives), before meeting with the patient. This may involve team discussions, literature searches, or meetings with consultants. In addition, patients should be asked who they would like to be present during the discussion. Key points are to sit down in a private area, make eye contact, and then start by finding out how much the patient knows—“What is your understanding of the situation at this point?”—and how much he actually wants to know—“Would you like to know all the details of the situation or do you prefer a more general outline? Is there someone else you would like me to speak with?” A substantial minority of patients do not want to be told their diagnoses or prognoses. In this case, the dialogue should continue on more general terms with the patient and on more detailed grounds with a designated health care agent or surrogate. With the majority of patients who *do* want to make informed decisions themselves, the communication of the diagnosis should be followed by a period of silence to allow the patient to register and absorb the information. Subsequently, discuss the treatment alternatives, including palliative care options. It is important to frequently check that the patient is following what the physician is saying, allowing a period of quiet after each question—“Am I making sense? Am I being clear enough?”—and to ask open-ended questions—“How are you doing? Is there anything else that you would like to ask?”

The dialogue then should focus on the available options, including their potential burdens and benefits. Based on the patient’s preferences, the goals of care are established and a specific plan of care is outlined. The meeting should end with a clear statement of the plan for the immediate future and reassurance that the physician will stand by the patient throughout the course of the illness (Table 19.1) (7, 8).

EMOTIONAL AND SPIRITUAL CARE

Supportive counseling should be provided by the treating physicians, nurses, and social workers. Patients and families should be given the time and an appropriate place to voice their concerns and have questions answered. Consistency of recommendations and prognostic information is critical. Such consistency requires frequent and regular communication among providers *before* discussion with patients and their families.

More than 80% of Americans claim to be religious, underlining the importance of spirituality, especially nearing the end of life. Facilitating access to religious support for hospitalized patients and families, therefore, should be a priority (Chapter 4). Access to bereavement support groups also should be made available.

TABLE 19.1

COMMUNICATING BAD NEWS: THE SIX-STEP APPROACH

- Step 1. Start off well.
 Get the physical context right.
 Silence the pager. Sit down. Arrange at least a 30-minute commitment.
 Decide on the best setting.
 Decide who should be there.
- Step 2. Find out how much the patient knows.
 “What have the doctors told you so far?”
- Step 3. Find out how much the patient wants to know.
 “Some of my patients want to know all the details and some prefer a more general outline—which kind of person are you?”
- Step 4. Share the information (aligning and educating).
 “I’m afraid I have some bad news. The biopsy showed that you have lung cancer.” Stop talking and allow some time for silence.
 Proceed with: “We have some decisions to make about what to do next. Would you like to hear about the alternatives?”
 Decide on your agenda (diagnosis, treatment plan, prognosis, support).
 Start from the patient’s starting point (aligning).
 Educate: Give information in small chunks.
 Use English, not “medspeak.”
 Check reception frequently.
 Reinforce and clarify the information frequently.
 Check your communication level (for example, adult-adult).
 Listen for the patient’s agenda.
 Try to blend your agenda with the patient’s.
- Step 5. Respond to the patient’s feelings.
 Identify and acknowledge the patient’s reaction.
- Step 6. Plan and follow through.
 Organize and plan.
 Make a contract and follow through.
 Give the patient a specific day and time to return to see you. Call to check in on them later that evening.

PLAN OF CARE

When the goals of care gradually shift from medical treatment focused on prolongation of life to comfort care, efforts should be made to move patients out of the hospital, unless death is imminent. Although some patients die in the hospital while receiving treatments that could have been successful, a more appropriate site of death probably could have been devised for many of the more than 50% of patients who die in hospitals. The odds of dying in an acute-care hospital are directly related to the number of hospital beds per capita in a given area rather than to personal preferences of patients or family members (3). Improving advance-care planning and the support systems for dying patients available outside of the hospital will allow better compliance with the wishes of patients and families.

Hospice refers to both a philosophy of care and an organization that provides care for patients at the end of their life. Although some hospitals and nursing homes have wings devoted to hospice care, most patients receive hospice care at home. Referral to hospice usually involves leaving familiar systems and providers of care to enter a new system. The patient's physician must certify that the patient's life expectancy is less than 6 months, and in most cases there must be a caregiver in the home; the latter requirement is important because a limited number of hours of custodial home-aid services are provided by most hospices (although this varies by hospice and additional short-term help sometimes is added, as the patient's condition progresses).

Through hospice, a team of experts is available to provide nursing, spiritual, and medical care during the dying process. The Medicare program covers both hospice care and the medications used for the treatment of symptoms related to the primary disease. Counseling, support groups, and religious and bereavement services also are provided by hospice.

Although hospice allows the primary care physician to continue in that role, in most cases responsibility for medical care routinely is relinquished to the hospice physician, often leaving the dying patient with a compounded sense of loss and abandonment just as many other serious losses are occurring. This requirement to refer to a separate system of care and caregivers probably explains why only 20% of adult deaths occur in hospice in the United States (9).

If a patient is expected to die within 24–72 hours, it is probably best to continue care in the hospital, unless he or she has expressed clear wishes to die at home. Many hospitals (more than 800 in 2002) have developed palliative-care teams or units to help provide compassionate end-of-life care to inpatients. In addition to home hospices, discharge options for patients receiving terminal care include a nursing home with hospice care and an inpatient hospice. Home health care also can provide medical assistance at home, although, unlike hospice, certified home health agencies are not typically prepared to focus on the care of dying patients. If home care is directed by a team experienced in end-of-life care, it can provide a useful alternative to home hospice, especially because it provides care that remains linked to the hospital setting and does not require separation from familiar professional caregivers and health systems. Increasingly, hospital-hospice partnerships are forming to better reconcile the goals of expertise, availability, and continuity.

SYMPTOM MANAGEMENT AND THE RULE OF DOUBLE EFFECT

The treatment of symptoms at the end of life is characterized by the appropriate use of medications without inappropriate worries about addiction and with reasonable concerns about respiratory depression. According to the "rule of dou-

ble effect," if a desirable effect (symptom relief) is intended, the risk of a foreseen, but not intended, bad effect (hastening death) is acceptable. If the intended good effect is relief of pain or dyspnea and opioids are titrated carefully, the risk of hastening death is very small; therefore, the rule of double effect only rarely applies. While it is widely believed that the use of sedatives to relieve refractory symptoms leads to hastened death, the best evidence suggests that the opposite is true. In a recent study, patients receiving sedation for refractory symptoms actually lived longer than those who did not require sedation (10). Nonetheless, even if hastened death were a risk, as long as the intended effect is relief of suffering, such use of medications is not only acceptable (by the rule of double effect) but *mandatory* to prevent unnecessary distress and suffering.

Neuroleptics, such as haloperidol, chlorpromazine, risperidone, and olanzapine, are very useful in the treatment of preterminal agitation and delirium. All are also very potent antiemetics.

ORCHESTRATING THE "GOOD DEATH"

When patients are moribund, comfort care is the goal and life-prolonging efforts are no longer appropriate or effective. At that point, key steps include:

- Prompt attention to symptoms
- Effective and compassionate communication with and support of family and involved health care staff
- Removal of unnecessary indwelling tubes, catheters, and drains
- Discontinuation of all procedures and medications that are not providing comfort directly

Religious support should be offered to families. Depending on the availability of inpatient and outpatient support, the site of death should be chosen by the family. If death is imminent, it is best to continue care in the hospital. If death is likely in a matter of days, home, nursing home, or inpatient hospice are all reasonable options. If support is available (e.g., through family or home health aides and specialized nurses), home is often the preferred site of death. Family caregivers should be instructed in advance on how to react to common end-of-life symptoms such as pain, shortness of breath, and agitation with as-needed medications and other measures (e.g., upright positioning and a fan can be very helpful for the relief of dyspnea; reassurance from a familiar voice can improve agitation). Medications that should be readily available to a dying patient include morphine sulfate immediate release liquid (20 mg/cc); lorazepam liquid (2 mg/cc); and chlorpromazine liquid concentrate (100 mg/cc). These medications have rapid onset, can be given sublingually or via the buccal mucosa in case of inability to swallow, and will address a wide range of sources of distress including pain, dyspnea, anxiety, agitation, and nausea. A contact nurse or physician should be available at all times

and should respond promptly to unforeseen crises (e.g., agitation, a pain crisis, or a seizure). Most crises can be dealt with in the patient's home, and resorting to an ambulance is rarely necessary. A do-not-resuscitate form should be kept in the home to avoid the risk of pointless and burdensome efforts. Arrangements with a funeral home should be made in advance, and, when the patient dies, the funeral director should be called first. He will guide the family through the necessary paperwork and logistical steps.

IMPROVING PALLIATIVE CARE

Widespread access to state-of-the-art palliative care requires a collegial effort to overcome attitudinal, educational, economical, and legal barriers (Table 19.2) (11). The prevalent attitude of health professionals, which stems in part from both fear and denial of death as a natural inevitable process, is that prolongation of life, at all costs, is the primary goal of medicine.

Even among physicians there is considerable confusion about the difference between forgoing medical treatments when they are not benefitting the patient and euthanasia. Until very recently, training in palliative care for physicians and nurses was very limited or nonexistent. Educational and clinical programs to improve the care of dying patients are needed urgently, especially at teaching hospitals. The accrediting authorities for U.S. undergraduate and graduate medical education have recognized this need and have mandated training in palliative and end-of-life care. Data consistently show that well delivered palliative care leads to better clinical outcomes, higher patient and family satisfaction, and more appropriate allocation of resources (12). Modification of state regulations that control and limit the prescription of opioids and other controlled substances also is needed to reduce the worries of prescribing physicians who care for patients at the end of life.

KEY POINTS

- Palliative care, designed to relieve suffering and improve quality of life, should be delivered at the same time as all beneficial and effective life-prolonging or curative treatments.
- Prognostication—in terms of both expected longevity and function—is a difficult but important task for the physician. A poor prognosis is not a prerequisite for applicability of palliative care.
- The benefits versus burdens of elements of care, including ventilation, nutrition, antibiotics, venipuncture, and diagnostic testing, are worth discussing with terminally ill patients or their surrogates.
- In communicating bad news, provide sufficient time and silence for the information to sink in, a conducive environment, and offers of regular follow-up as well as physical, practical, emotional, and religious support.

TABLE 19.2
APPROACHES TO IMPROVING PALLIATIVE CARE

Improve professional knowledge and skills

- Continue faculty development in palliative care
- Include palliative care in medical curricula
- Include palliative-care topics on board certification examinations
- Include palliative-care training in residency review requirements
- Include practice guidelines and quality improvement programs in palliative care

Change professional attitudes about care at the end of life

- Make a distinction between decisions to discontinue treatment and active euthanasia
- Make use of terminal sedation as distinct from euthanasia
- Establish standards of futility through consensus by professional organizations
- Educate on the limitations of technology and the desirability of a peaceful death
- Use advance directives as tools to improve physician-patient communication

Reorganize the health care system

- Incorporate the Joint Commission on Accreditation of Health-care Organizations standards for end-of-life care
- Include the International Classification of Diseases, 9th ed., code for terminal care to legitimize hospital palliative care by providing reimbursement
- Make use of hospital-based palliative care units and consultation services
- Make use of quality standards for end-of-life care in managed-care organizations
- Organize formal networks between hospice programs and other health care structures
- Modify state regulations that inhibit prescriptions for opioids
- Include risk management standards that recognize palliative care and respect patient wishes

Patient Safety in the Hospital Setting

20

Kaveh G. Shojania

INTRODUCTION

Long before “medical error” and “patient safety” were commonly used phrases, the medical profession recognized the concept of illness or injury induced by medical care. The term “iatrogenesis” is an ancient word that combines the Greek words *iatros* (healer) and *genesis* (to bring forth) to mean “coming from the healer.” Iatrogenesis is particularly common in the hospital. In fact, Florence Nightingale wrote in 1859: “It may seem a strange principle to enunciate as the very first requirement in a hospital that it should do the sick no harm.”

In 1999, the Institute of Medicine (IOM) published its now widely known report, *To Err Is Human*, (1) and brought these problems, including the rate at which medical care itself contributes to morbidity and mortality among hospitalized patients, to the attention of the medical community, the media, and the public. The often-quoted estimate produced by the IOM—that medical errors result in 44,000 to 98,000 hospital deaths per year—shocked many Americans. While these figures have been debated, (2,3) the widespread public attention given to them has compelled the health care community to seriously attack a problem that has bedeviled medical care since the time of Hippocrates: how to avoid doing harm to patients.

For physicians practicing in the hospital setting, the current interest in patient safety represents an important opportunity to improve both the care of individual patients and the systems in which they work. This chapter reviews the epidemiology of iatrogenic injury in the hospital setting, the psychological principles that have emerged from the study of human error, and the techniques for responding to adverse events and serious errors. The second half of the chapter discusses specific complications of hospital care

and evidence-based practices that reduce their occurrence. Adverse drug events and nosocomial infections, two of the most important categories of hospital-acquired complications, are touched on briefly here and discussed in detail in Chapters 21, 66, 68 and 72.

THE EPIDEMIOLOGY OF ADVERSE EVENTS IN THE HOSPITAL SETTING

Table 20.1 lists studies of iatrogenesis involving general acute hospital care in the United States during the past 40 years. Studies from other countries have produced comparable results, with differences in the rates of adverse events largely due to differences in design and definitions (4).

The two studies that formed the basis of the IOM’s widely quoted estimate of 44,000 to 98,000 annual deaths due to medical error were the Harvard Medical Practice (5) and the Utah-Colorado studies (6) (both included in Table 20.1). These studies screened inpatient records for various potential indicators of adverse events, such as death or other undesirable outcome, transfer from a general ward to intensive care, unexpected return to the operating room, and length of hospital stay above 90th percentile for a given diagnosis. Records that met one or more of these criteria were then reviewed independently by at least two board-certified physicians to identify *adverse events*, which were defined as injuries due to medical management rather than underlying illness. These studies had as their goal an assessment of the relationship between iatrogenic injury and malpractice litigation. Thus, both studies identified a subset of *negligent adverse events*, defined as injuries “caused by the failure to meet standards reasonably expected of the average physician.”

TABLE 20.1**MAJOR EPIDEMIOLOGIC STUDIES OF ADVERSE EVENTS RELATED TO ACUTE HOSPITAL CARE IN THE UNITED STATES^a**

Study	Setting	Principal findings
Schimmel, 1964 (7)	Medical service of a university-affiliated community hospital in New Haven, CT, from 1960–61	20% of patients experienced a <i>complication of medical care unrelated to their underlying illness</i> . 1.6% of hospitalizations involved a <i>complication regarded as causing or contributing to death</i> .
California Medical Insurance Feasibility Study (8)	Screening and reviewing charts from 20,864 stays in California hospitals in 1974	4.6% of hospitalizations involved a <i>potentially compensable event (PCE)</i> , temporary or permanent disability attributable to health care management. 0.6% of hospitalizations involved a <i>PCE</i> that produced death or a major permanent disability.
Steel, 1981 (9)	Two general medical wards, one ICU and one CCU, in a Boston teaching hospital in 1979	36% of patients experienced at least one <i>iatrogenic illness</i> . 2% suffered an <i>iatrogenic illness judged as contributing to death</i> .
Harvard Medical Practice Study, 1991 (5, 10)	30,121 stays at 51 hospitals in New York State in 1984	3.7% of hospitalizations resulted in an <i>adverse event</i> ; i.e., an injury caused by medical management. 1% of hospitalizations involved a <i>negligent adverse event</i> ; i.e., an injury caused by substandard care. 0.6% of hospitalizations resulted in a <i>fatal or permanently disabling adverse event</i> .
ADE Prevention Study Group, 1995 (11)	Admissions to 11 medical and surgical units of 2 Boston teaching hospitals in 1993	6.5% of admissions experienced an <i>adverse drug event (ADE)</i> . 0.06% of hospitalizations involved a <i>fatal ADE</i> . 5.5% of patients experienced a <i>potential ADE</i> (serious medication error that produced no injury).
Classen et al., 1997 (12)	Admissions to a teaching hospital in Utah from 1990–1993	6.5% of hospitalized patients experienced an <i>ADE</i> . 0.2% of hospitalized involved a <i>fatal ADE</i> .
Andrews et al., 1997 (13)	Two intensive care units and one general surgical ward at a Chicago teaching hospital from 1989–1990	17.7% of patients experienced an <i>adverse event</i> that produced at least a temporary disability or more serious injury.
Colorado-Utah Study, 2000 (6, 14)	15,000 discharges from 28 hospitals in Colorado and Utah in 1992	2.9% of hospitalizations resulted in an <i>adverse event</i> ; i.e., an injury caused by medical management. 0.2% of hospitalizations involved an <i>adverse event</i> resulting in death. 30% of all <i>adverse events</i> were judged as negligent.
Hayward & Hofer, 2001 (3)	111 random cases among all deaths occurring at 7 Veterans Affairs hospitals from 1995–1996	6.0% of deaths rated as <i>“definitely or probably preventable.”</i> Reviewers estimated that about 50% of patients would still have died (during this hospitalization). Optimal care for 10,000 patients would result in 1 additional patient living at least 3 additional months in good cognitive health.
Forster et al, 2003 (15)	Consecutive discharges from the medical service of a Boston teaching hospital in 2001	76 patients (19%) experienced <i>adverse events</i> after discharge. <i>Adverse events</i> consisted of symptoms reported by patients (65%), symptoms associated with a temporary disability (30%), serious laboratory abnormalities (3%), and permanent disabilities (3%).

^a Studies included here all reported rates of adverse events and/or errors. Studies without a denominator (e.g., incident reports only) are not included; also excluded from the table are studies with adverse event rates derived primarily from administrative data. The table does not include studies restricted to intensive care units, operating rooms, psychiatric facilities, or nursing homes. Modified from Shojania KG, Wald H, Gross R. Understanding medical error and improving patient safety in the inpatient setting. *Med Clin North Am* 2002;86:847–867, with permission.

One criticism of the IOM's estimate of deaths due to medical error is that the details of the calculations were never provided (16). The relevant inputs to the calculation include the percent of hospitalized patients experiencing an adverse event, the proportion of adverse events associated with death, and the proportion of those cases in which death could have been prevented. Figure 20.1 outlines a reasonable scheme (16) for estimating deaths due to med-

ical error. Interestingly, using the same inputs as the IOM report, no combination of these inputs produces the specific estimates of 44,000 or 98,000 deaths.

While the estimates published in *To Err Is Human* are more speculative than generally acknowledged, it is worth noting that these estimates were restricted to deaths, ignoring the many cases of non-fatal iatrogenesis. Even putting aside the debate over the IOM death rates, it is quite sober-

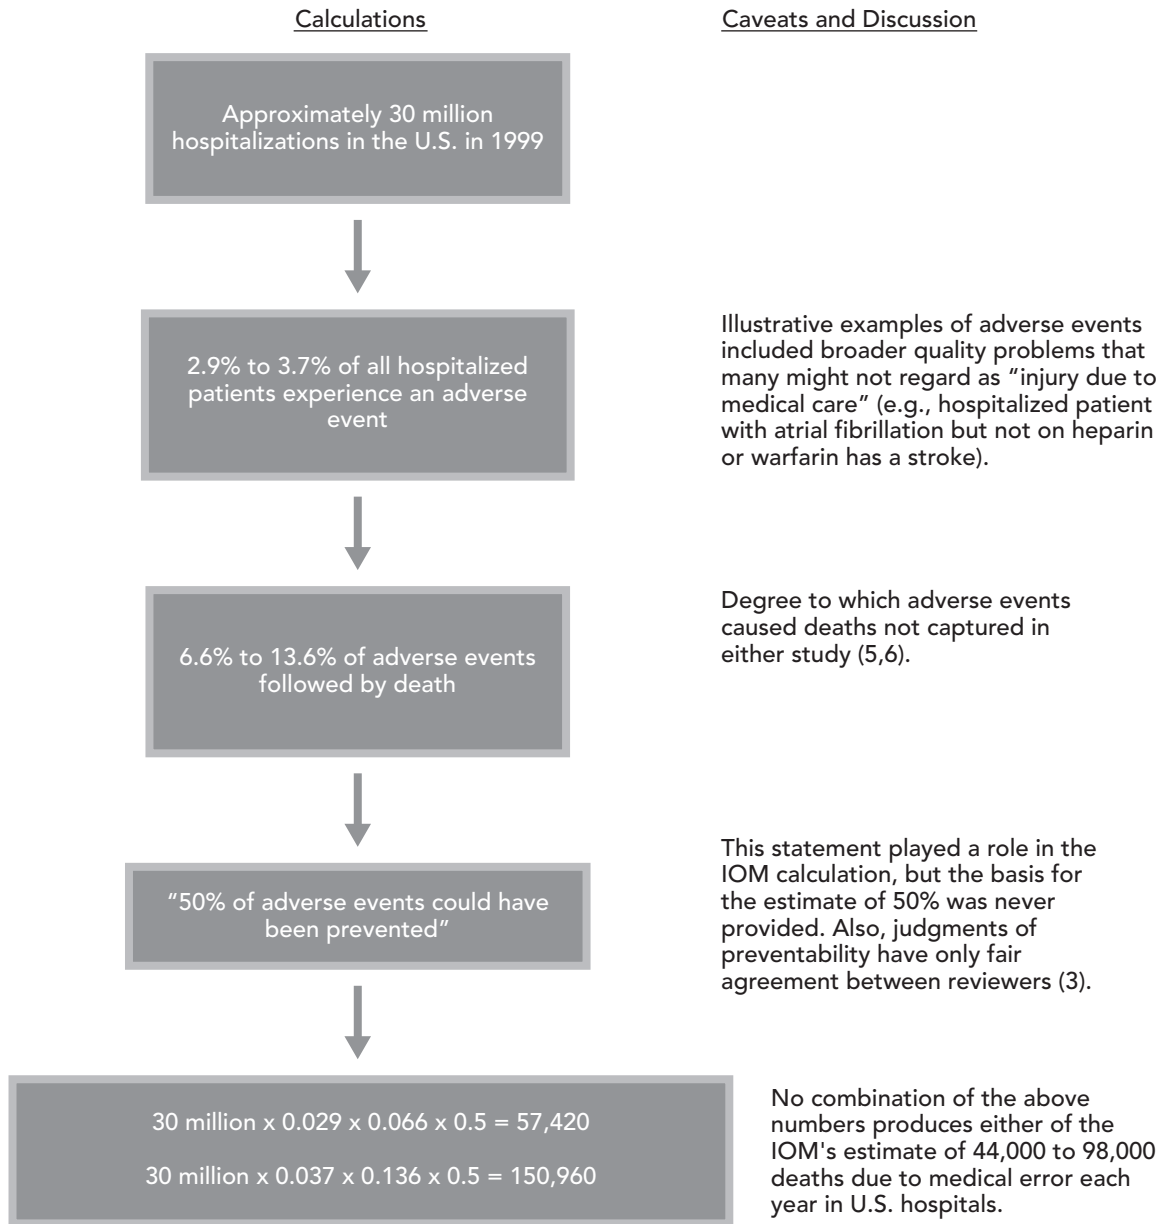

Figure 20.1 Outline of calculation examining Institute of Medicine’s estimate of annual deaths due to medical errors.

ing to compare the adverse event rates in health care with that seen in other hazardous activities and exposures (17, 18). Whereas roughly 1–5 of every hundred hospitalized patients will suffer a major injury from medical care, it takes roughly 8 million enplanements to result in one passenger death. While physicians may balk at the comparison of commercial aviation to the care of complex, acutely ill patients, elective anesthesia in healthy patients probably is a fair comparison. Even in this setting, health care has not achieved a safety record comparable to aviation (19), though anesthesia has been one of the pioneering specialties for patient safety.

Errors vs. Adverse Events

Identifying something as an adverse event does not imply “error” or even poor quality care. It simply implies that an undesirable clinical outcome resulted from some aspect of diagnosis or therapy or even from the mere presence of a patient in the hospital. A large evidence review sponsored by the federal Agency for Healthcare Quality and Research defined a patient safety practice as “any health care structure or process that reduces the probability of adverse events resulting from exposure to the health care system across a range of diseases and procedures” (20, 21).

According to this definition, tracking the rate of falls among hospitalized elders and looking for ways to reduce these rates are patient safety activities, analogous to tracking rates of infection because of resistant nosocomial organisms and developing strategies to reduce these rates. In this broader view of patient safety, errors become the equivalent of intermediate clinical outcomes. Thus, just as we target blood pressure control in order to reduce myocardial infarction and stroke, targeting errors will play a role in preventing many (but not all) adverse events.

Under this view, errors committed by individual health care personnel represent just one element along the causal pathway to adverse events. This perspective serves the immediate purpose of diminishing some of the stigma associated with errors. It also serves the more general constructive purpose of putting individual errors into a broader context of factors contributing to the occurrence of adverse patient outcomes, an approach that has been long used (to great effect) in industries outside of health care.

FRAMEWORK FOR THINKING ABOUT ERRORS

One of the major lessons that health care has had to learn from other safety-conscious industries is that *the pervasive medical culture of individual responsibility and blame stand in the way of efforts to make health care safer*. No amount of individual reprimand will change the fact that all providers will err from time to time. The goal is thus to develop a system that recognizes, and even expects, these occasional human failures and minimizes the chance they will result in patient harm.

The Cognitive Psychology of Errors

The patient safety literature generally defines an error as *an act or omission that leads to an unanticipated, undesirable outcome or to substantial potential for such an outcome* (22, 23). The phrase “act or omission” implies that errors include active behaviors such as prescribing an inappropriate medication dose and passive behaviors such as forgetting to check for allergies prior to prescribing a medication. The term “unanticipated” implies that errors do not include outcomes acknowledged as “acceptable risks” during decision-making processes. For instance, a patient with breast cancer metastatic to brain develops a pulmonary embolism. The treating physicians decide to anticoagulate her after reviewing her most recent head CT scan, which showed no edema, mass effect, or other findings placing the patient at high risk for bleeding. Nonetheless, the patient suffers an intracranial bleed. The decision to administer heparin would not be regarded as an error given that the physicians considered the risk of intracranial hemorrhage from a single metastasis without mass effect and weighed this risk against the expected benefit of anticoagulation for

pulmonary embolism. (On the other hand, this event would still count as an adverse event, since the bleed clearly reflects the impact of medical care and not the patient’s medical condition.)

Types of Error

There are two broad categories of error: *slips* and *mistakes* (17). Slips are inadvertent, unconscious lapses in expected behavior or inappropriate persistence of automaticity. They tend to affect schematic (also called “automatic”) rather than attentional behaviors. For example, you divide your time between a hospital and a skilled nursing facility and, one morning, you absently drive toward the hospital instead of the nursing facility. Unfortunately, the distraction produced by recognizing one slip may lead to another; so, annoyed with yourself (once you realize your error) and flustered because you are now running late, you drive through a red light. Slips are more frequent in the face of competing sensory or emotional distractions, fatigue, and stress. These factors represent the norm in many health care settings.

Mistakes, by contrast, reflect incorrect choices. Rather than lapses in concentration (as with slips), mistakes typically involve insufficient knowledge, failure to correctly interpret available information, or application of the wrong cognitive “heuristic” or rule. Thus, mistakes are often divided into two types of problems—rule-based and knowledge-based (22). For instance, you admit a 60-year-old diabetic with fever, meningismus, and CSF leukocytosis, but order ceftriaxone by itself (i.e., without including empiric coverage for *Listeria* with ampicillin or penicillin-resistant pneumococcus with vancomycin). Whereas stress, fatigue, and distraction contribute to slips, mistakes are attributable to insufficient experience or training.

Responses to the Different Types of Errors

Table 20.2 outlines features that distinguish slips from mistakes. One important point is that, while mistakes invade attentional behavior more frequently than slips invade schematic behavior, schematic behavior is the predominant pattern within a health care setting. Consequently, the absolute number of slips far exceeds that of mistakes.

The practical significance of the distinction between slips and mistakes lies in informing the response to a given error. A *mistake* due to incorrect pattern recognition by an inexperienced physician or nurse likely represents insufficient supervision or oversight by the “system” relative to training. By contrast, when a physician forgets to elicit an allergy history or a nurse forgets to check an allergy history that has been elicited, these represent slips that can be expected to occur from time to time. Remedial education and/or increased supervision will generally not help reduce future occurrences of the same error, whereas redesigning the medication system so that no medication can be administered without an

TABLE 20.2
CATEGORIZATION OF HUMAN BEHAVIOR AND ERROR TYPES FROM A COGNITIVE PSYCHOLOGY PERSPECTIVE

Behavior type	Features	Associated error type	Error-inducing conditions	Examples
Attentional	Involves analysis, planning, oversight Generates sense of mental effort, intellectual satisfaction Quite error-prone	Mistakes <ul style="list-style-type: none"> • Wrong rule applied, pattern recognition failure • Knowledge-based mistakes, wrong judgment 	Inexperience relative to supervision Inadequate training Key information presented in ambiguous or inconsistent ways	Physician misinterprets signs of pulmonary embolus for pulmonary edema; physician prescribes antibiotic for sepsis which fails to cover common resistant bacteria.
Schematic	Automated or scripted Repetitive, may be monotonous, unrewarding Usually requires oversight for best performance	Slips more common than mistakes (inappropriate persistence or lapse in automaticity, unconscious “fumbles”)	Stress, fatigue, distraction, inadequate oversight, system design insensitive or inflexible to changes in context	Telemetry observer fails to notice frequent premature ventricular contractions; nurse receiving numerous intercom calls gives drug to wrong patient.

allergy check probably would. By contrast, after a patient with meningitis due to *Listeria monocytogenes* dies because of inadequate empiric antibiotic therapy, an in-service on empiric antibiotic therapy would be quite reasonable. An algorithmic decision-aid addressing the treatment of suspected meningitis posted in the emergency department would also be a productive quality improvement response to such an event.

In summary, understanding the difference between slips and mistakes will aid in and developing strategies to reduce the recurrence of specific errors in the future. The current literature does not offer direct supporting evidence for using any particular cognitive theory-based plan for error reduction, but the recommendations shown in Table 20.3 are consistent with relevant cognitive theories for planning error-resistant processes (17).

TABLE 20.3
RECOMMENDED RULES OF THUMB FOR “ERROR-PROOFING” HEALTH CARE PROCESSES

Rule of thumb	Discussion and specific recommendations
Focus on schematic behavior over attentional behavior. Design unambiguous schematic systems, but retain flexibility with respect to operator judgment and experience.	Checklists, standardized order sheets, and protocols reduce opportunities for slips. A protocol cannot anticipate all possible clinical scenarios and thus must allow a certain amount of flexibility to avoid endangering patients when unusual situations arise. At the same time, participants should compromise in the interests of reasonable consistency and standardization when necessary.
Enhance attentional behavior through collaboration.	For tasks that must be accomplished with attentional behavior, among the most powerful means for assuring success is collaboration, ranging from informal, “curbside” consultation to formalized team meetings and inclusion of nurses, pharmacists, and various therapists on hospital rounds.
Assume that errors will occur and make their identification and prevention a positive cultural occurrence.	Use the lessons of an error to reduce the likelihood of recurrence. Medical leadership should commend such activities at every opportunity.

Detailed Error Analysis

The above general principles provide a useful framework for thinking about patient safety, but the approach to specific incidents requires detailed analysis of the chronology of events and system factors that contributed to the error or bad outcome. Root cause analysis (RCA) is a retrospective approach to error analysis that was developed to investigate industrial accidents (22) and has more recently been adapted to the investigation of sentinel events in medicine (24). In 1997, the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) mandated the use of RCA in the investigation of sentinel events in accredited hospitals.

The principles and techniques of RCA are described here using a real case and its discussion (25) presented as the first in a series of case-based conferences focusing on patient safety and quality improvement (26). The salient features of the case are summarized below; the names are pseudonyms.

Joan Morris is a 67-year-old female who was admitted to the telemetry unit of a teaching hospital for cerebral angiography. Because of bed limitations, Ms. Morris was transferred to the oncology floor after her successful embolization procedure. She remained in stable condition the next morning. Discharge was intended for later that day.

Meanwhile, Jane Morrison was transferred from an outside institution (also to the telemetry unit) for a cardiac electrophysiology (EP) study. This study had been delayed for two days because of scheduling conflicts, with the result that Ms. Morrison was rescheduled as the first case of the morning on the day of Joan Morris' planned discharge from the hospital.

Through a series of miscommunications and misidentifications involving various nurses, physicians, and support staff, Joan Morris was taken to the EP lab instead of Jane Morrison. One hour into the procedure (programmed stimulation of the heart), it became apparent that the wrong patient was on the table. The procedure was aborted, and the patient was returned to her room.

The RCA occurred in two distinct stages. The first was the assembly of a detailed timeline of the events leading up to the recognition of this error through chart review and interviews with involved personnel. This process established the chronology of events and revealed at least 15 distinct "active failures." *Active failures* refer to the errors and violations that occur at the point of direct contact between the patient-system interface (17, 22). The active errors involved in this case included "unsafe acts" and "rule violations" on the parts of various providers involved with the case, such as the following:

- Only the last name was used when the EP nurse phoned the floor to request the patient be sent down for the procedure.
- The floor nurse sent the patient down for the procedure despite no order in the chart and over the objections of the patient.

- The EP fellow obtained informed consent even though the chart contained no information indicating that this patient needed an EP study.
- The EP nurse checked the patient's wrist identification band against the chart that accompanied her, but not against the list of patients scheduled for EP procedures.

Once a critical incident has occurred, active errors are usually quite apparent; hence traditional error investigations tend to focus on them. The RCA aims to uncover the less apparent failures of system design (*latent errors*) that contributed to these active failures or allowed them to cause harm (17, 27). For example, whereas the active failure in a particular adverse event may have been a mistake in programming an intravenous pump, a latent error might be that the institution uses multiple types of infusion pumps, making programming errors more likely. Thus, latent errors are literally "accidents waiting to happen."

The search for active and latent errors forms the second phase of the RCA and is typically guided by a conceptual framework adapted from British psychologist James Reason (22). In this framework, contributory causal factors are categorized as environmental, organizational, process-related, and so on. These categories are depicted in Figure 20.2 in the form of a "fishbone diagram" (common in error analyses), using errors relevant to the example case in this section.

Limitations and Challenges of RCA

Major challenges in the conduct of RCAs include the problems of hindsight bias, the coloring of the analysis by the prevailing concerns of the day (e.g., staffing ratios, inadequate information technology, discontinuities between the inpatient and outpatient settings), medico-legal fears, and the time they take to conduct.

In addition, RCAs are in essence uncontrolled case studies. They are thus best viewed as hypothesis generating; when possible, these hypotheses should be tested. For example, if several RCAs attribute the use of verbal orders as a root cause, one should look to the literature to see if the impact of verbal orders on error rates has ever been assessed. In fact, the one study that conducted such an assessment found that verbal orders were *less* likely to produce an error than were handwritten ones (28).

In industries outside health care, it is clear why RCAs play such an important role, despite the limitations. Major accidents in aviation, nuclear power, and the petrochemical industries are too uncommon to lend themselves to quantitative analysis. Certain adverse events in health care are also uncommon (e.g., wrong site surgery and infant abduction). Well-designed RCAs are therefore reasonable ways to investigate these events. In health care, however, many adverse events occur with sufficient frequency to permit careful study of prevention strategies. The next section addresses the more common situations in which tra-

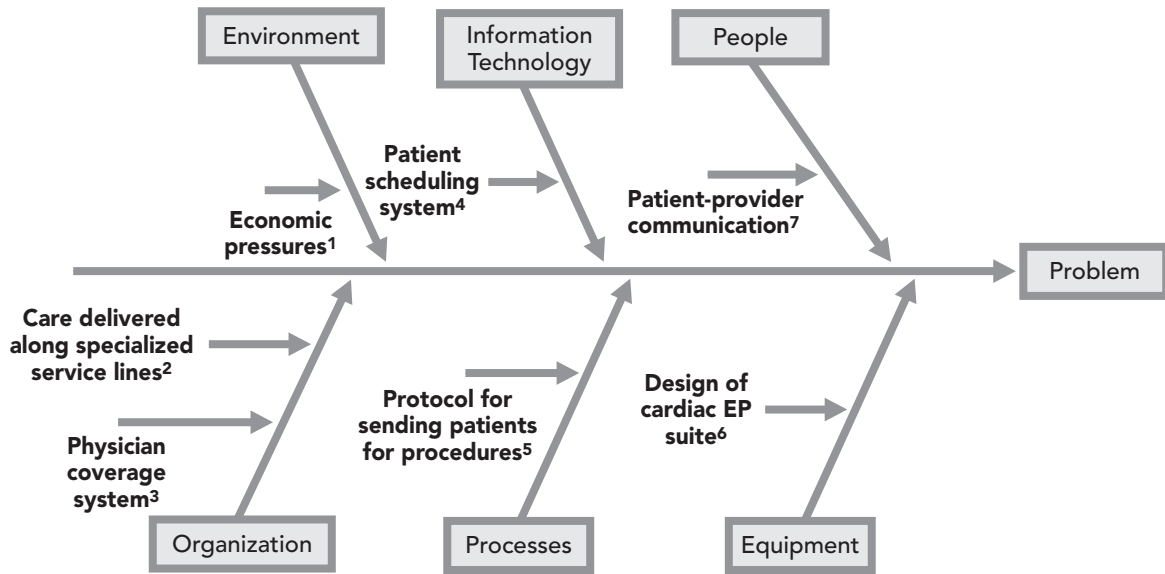

Figure 20.2 Fishbone diagram illustrating categories of latent failures in the “Wrong Patient” case (25).

¹ Economic pressures created some of the organizational strategies (e.g., fragmentation of care along highly specialized “service lines,” boarding of patients on floors unfamiliar with that “service line,” the physician coverage system, and e-mail scheduling system (all discussed below) that contributed to the errors in this case.

² The physicians on the electrophysiology (EP) service at this tertiary referral center had developed a coverage system that allowed them to handle the high volume of consultations from outside hospitals while performing their duties at their own institution. However, this call system meant that the attending and fellow who performed a given EP procedure had often never before met the patient.

³ The development of specialized services (such as the interventional neuroradiology service that admitted one of the patients and the EP service that admitted the other) increases communication problems and the chance that essential information will slip between the cracks.

⁴ The use of an e-mail scheduling system (due to the lack of a systemwide scheduling system) allowed for the occurrence of many minor typographical errors and missing pieces of information (e.g., medical record numbers). Consequently, providers became habituated and indifferent to name discrepancies and did not consistently use patient identification numbers in important communications with other providers.

⁵ The hospital had no requirement that an order be present in the chart in order for a patient to be sent off the floor for a test.

⁶ The design of the EP suite was such that the attending physician (who in this case had met the correct patient briefly the night before) operated a console behind a window in a room adjacent to the suite, so that the physician could not actually see the patient’s face at any time during the procedure.

The patient was taken for the EP procedure despite repeated protests and statements from the patient that she believed there had been a mistake. Physicians and nurses involved in her care assumed she simply did not understand the situation. Routine deficiencies in communication of important issues to patients results in many patients not understanding their medical conditions or plans for their care. As a result, providers expect patients to have misconceptions about tests and procedures, and thus ignore their input, even, as in this case, when the patient is correct.

ditional clinical and epidemiologic research techniques can be applied to improving patient safety.

Evidence-Based Patient Safety Practices

Much of the attention in the literature has focused on large systemwide initiatives, such as acquiring computerized physician order entry or channeling patients to hospitals with high patient volumes. While such initiatives may ultimately prove very powerful quality improvement tools, individual practitioners (or even individual hospitals) will have difficulty implementing sweeping cultural and organizational changes. However, clinicians do have

available to them many evidence-based practices that reduce common complications of hospitalization and do not require major organizational investments (Table 20.4). Other practices related to nosocomial infectious and adverse drug events are discussed in Chapters 21, 66, 68, and 72.

Additional practices and the evidence supporting them are reviewed in *Making Healthcare Safer*, an evidence report sponsored by the federal Agency for Healthcare Quality and Research (20, 21). Readers interested in potential quality improvement activities for their hospital should scan the report’s table of contents or the summary chapters listing all of the practices rated by their evidence. The report

TABLE 20.4**SELECTED EVIDENCE-BASED SAFETY PRACTICES CLINICIANS CAN IMPLEMENT WITHOUT LARGE-SCALE INVESTMENTS OF ORGANIZATIONAL RESOURCES**

Patient safety target	Patient safety practice
Venous thromboembolism	Appropriate prophylaxis (various strategies) (29)
Perioperative cardiac events in patients undergoing noncardiac surgery	Use of perioperative beta-blockers in selected patients (30)
Mechanical complications from insertion of central venous catheters	Use of real-time ultrasound guidance during central line insertion (31)
Adverse events related to discontinuities in care (15)	Better information transfer between inpatient and outpatient providers (32); follow-up telephone calls after hospital discharge (33)
Radiocontrast-induced nephropathy	Acetylcysteine (plus regular hydration protocol) for diabetics and any patient with chronically elevated Cr (34)
Miscommunication and other problems related to poor teamwork (35)	Teamwork training (e.g., for “code blue” responders) (36)
Unsuspected errors in diagnosis	Obtain more autopsies (37)

covers the complete evidence, implementation issues, potential for harm, and other important aspects of each practice in the specific chapter reviews.

CONCLUSIONS

Improving patient safety incorporates two complementary endeavors. The first, inspired by research in cognitive psychology and the lessons of accident investigation in other industries, provides qualitative methods for anticipating errors, documenting critical incidents, and responding to them in a blame-free and structured manner. Using such qualitative methods, physicians can generate meaningful strategies for preventing similar occurrences in the future. Hospital-based physicians have an important role to play in promoting a culture of safety by championing incident reporting initiatives and participating on multidisciplinary teams that analyze adverse events and promote change.

The second approach involves applying the results of quantitative clinical research to reduce the common hazards of hospitalization. Hospitalists also have an important role to play in this arena because many of these safety targets and the associated clinical practices (especially those that cut across organ-based silos) are not on the radar screens of many hospital-based subspecialists.

In both circumstances, physician collaboration with nurses, pharmacists, nutritionists and other health care professionals would likely produce important improvements in patient care. Moreover, physician involvement in these initiatives will demonstrate visible leadership in promoting a culture of patient safety in hospitals and in health care.

KEY POINTS

- The last few years have seen a new appreciation of the risks of hospitalization, and significant efforts to improve patient safety
- Errors can be classified as slips (inadvertent, unconscious lapses in automatic behaviors) or mistakes (wrong choices). Although the latter may be prevented by education, the former is best addressed by system redesign.
- Detailed error analyses (“Root Cause Analysis”) can help identify and help prevent active latent (failures of system design) errors.
- Safety could be markedly improved with widespread implementation of evidence-based safety practices.

Medication Safety in the Hospital

21

David W. Bates

INTRODUCTION

The study that provides the best estimates regarding the risk of hospitalization is the Harvard Medical Practice Study, which evaluated the frequency of iatrogenic injury in patients discharged from hospitals in New York in 1984 (1, 2). Its primary outcome was the “adverse event,” defined as an injury caused by medical management that resulted in disability at discharge or a prolonged length of stay. The study found that adverse events occurred in 3.7% of hospitalizations, and 28% of these were judged negligent. The most frequent cause of injury in this study was the adverse drug event, or injury because of a drug, and these accounted for 19% of adverse events.

CARE OF THE HOSPITALIZED PATIENT

Of the main types of adverse events, adverse drug events (ADEs) have received perhaps the most study. In one study, Bates et al. (3) found 6.5 ADEs per 100 admissions in non-obstetric units in a tertiary care hospital; 28% of these were judged preventable. Of the life-threatening and serious ADEs, 42% were preventable, compared with 18% of significant but non-life-threatening ADEs. Errors resulting in a preventable ADE were more likely to be at the ordering (56%) and administration (34%) stages than at the transcription (6%) or dispensing (4%) stages. A key difference between this and previous studies was that all errors that either resulted in or had the potential to result in an ADE were subjected to a systems analysis by multidisciplinary teams (4). These analyses identified 16 major systems failures as the underlying causes of the errors. Seven of these accounted for 78% of the errors; all could have been im-

proved by *better information systems*. The most common defects were in the systems for disseminating knowledge about drugs, and for making drug and patient information available at the time it was needed.

In fact, many of the current “systems” used in medicine were never consciously designed by anyone and, in effect, just evolved in a haphazard and less than rational manner (3). For example, the “allergy detection system” in many hospitals consists of having several people ask patients about their allergies, including the nurse, the attending physician, one or more residents, and sometimes a medical student or pharmacist, although none of these persons is specifically responsible for this issue. Many of them note the allergies in the hospital chart, but such notations are not necessarily recorded in a central location, and there is often no communication with the outpatient record. The pharmacist may check for allergies by reading the physician’s order and then visually comparing one list (the ordered medications) with another (the allergy list). Not surprisingly, this highly inefficient system allows a number of orders for drugs to which patients have known allergies to slip through (3). However, this system can be redesigned to put all records of drug allergies in one central electronic location, where they can be mapped by drug family and subsequent orders can be checked for problems. Any allergies detected can be displayed to the ordering clinician.

In addition to studies of adverse drug events, many medication studies have focused on medication errors, defined as an error in ordering, dispensing, administering, or monitoring a drug. These errors are common, making them easier to study than adverse drug events. However, most do not result in injury. For example, one study found that 7 in 100 medication errors had the potential to cause an injury and 1 in 100 actually did so (Figure 21.1) (5). Medication

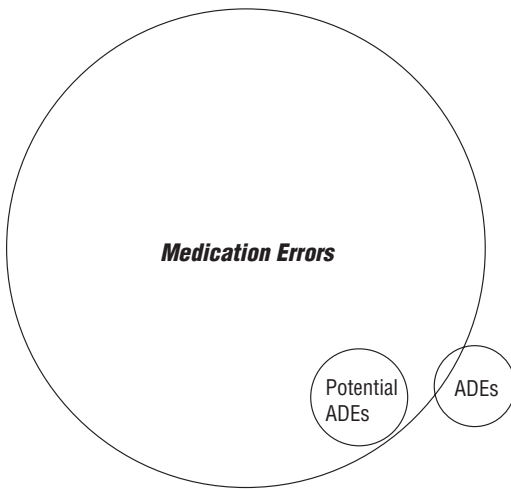

Figure 21.1 Relationships between medication errors, potential adverse drug events (medication errors with the potential to cause injury), and adverse drug events (ADEs). Only a proportion (28% in the Adverse Drug Events Prevention Study) are preventable. (From Bates DW, Boyle DL, Vander Vliet MB, et al. Relationship between medication errors and adverse drug events. *J Gen Intern Med* 1995;10:201, with permission.)

errors almost certainly differ substantially in their propensity to result in injury. For example, a 5-fold overdose may actually be more dangerous than a 100-fold overdose, because it is much more likely to be carried out.

Medication-related risk does not abate when the patient goes home; in fact, the immediate post-discharge period is especially risky. In a recent study, 19% of patients who had just been discharged from a medical service had adverse events, and 66% of these events were adverse drug events (6). Many of these adverse drug events might have been prevented.

MEDICATION SAFETY IMPROVEMENT STRATEGIES

A multidisciplinary panel that included nurses, pharmacists, and physicians made seven key recommendations about actions that organizations could take to reduce the number of ADEs (Table 21.1) (7). Among these, the most powerful is implementation of a systems change: *computerized physician order entry* (CPOE). In two recent studies, such a system prevented 55% to 86% of serious medication errors that otherwise would have reached the patient (8, 9). With CPOE, all orders are legible, and input is structured so that each medication order includes a drug name, dose, route, and frequency. Doses are selected from menus that include only appropriate options, which minimizes the likelihood that too high a dose will be ordered. In addition, orders can be checked for drug allergies, drug-drug interactions, and drug-laboratory interactions. Finally, dosing guidelines for specific drugs, such as aminoglycosides and

heparin, can be displayed, and the computer can calculate doses and recommend monitoring for these agents, which improves outcomes for drugs such as heparin (10) (see also Chapter 10).

When prescriptions are written by hand, the use of abbreviations can cause problems. Although computerization of ordering can minimize many of these issues, most drug orders are still written with the pen. Following the recommendations of the Medication Error and Reporting Program (Table 21.2) (7), which mainly involve avoiding potentially problematic abbreviations, can minimize the likelihood of many such errors.

A variety of additional strategies can improve medication safety. Access to drug knowledge is important, and many applications are now available for handheld devices that can make it easy for physicians to access this information, even if their hospital does not utilize CPOE (11). Bar coding has been used widely in other industries, and, though few published data are available to date regarding its impact in medication dispensing and administration, it is probably beneficial (12, 13). “Smart pumps” are infusion pumps that can be told what medication is being given, and, if too high a dose of medication is entered, the pump can warn the nurse. Importantly, these pumps can also retain a log of what was done, including overrides. Having pharmacists round with the team in the intensive care unit also reduced serious prescribing errors (14). Because a number of these strategies address stages of the medication process other than prescribing, it is likely that to achieve a

TABLE 21.1

TOP-PRIORITY ACTIONS FOR PREVENTING ADVERSE DRUG EVENTS IN HOSPITALS: RECOMMENDATIONS OF AN AMERICAN SOCIETY OF HEALTH SYSTEM PHARMACISTS CONVENED EXPERT PANEL

1. Hospitals should establish processes in which prescribers enter medication orders directly into computer systems.
2. Hospitals should evaluate the use of machine-readable coding (e.g., bar coding) in their medication use processes.
3. Hospitals should develop better systems for monitoring and reporting adverse drug events.
4. Hospitals should use unit dose medication distribution and pharmacy-based intravenous admixture systems.
5. Hospitals should assign pharmacists to work in patient care areas in direct collaboration with prescribers and those administering medications.
6. Hospitals should approach medication errors as systems failures and seek systems solutions for preventing them.
7. Hospitals should ensure that medication orders are routinely reviewed by a pharmacist before first doses and should ensure that prescribers, pharmacists, nurses, and other health workers seek resolution whenever there is any question of safety regarding medication use.

From ASHP guidelines on preventing medication errors in hospitals. *Am J Hosp Pharm* 1993;50:305–314, with permission.

TABLE 21.2**DANGEROUS ABBREVIATIONS AS DEFINED BY THE NATIONAL COORDINATING COUNCIL FOR MEDICATION ERROR REPORTING AND PREVENTION**

Abbreviation	Intended meaning ^a	Common error
U	Units	Mistaken for a zero (0) or a four (4), resulting in overdose; also mistaken for "cc" (cubic centimeters) when poorly written.
μg	Micrograms	Mistaken for "mg" (milligrams) resulting in overdose.
Q.D.	Latin abbreviation for daily	The period after the "Q" has sometimes been mistaken for an "I," for every day, and the drug has been given "QID" (four times daily) rather than daily.
Q.O.D.	Latin abbreviation for every other day	Misinterpreted as "QD" (daily) or "QID" (four times daily). If the "O" is poorly written, it looks like a period or an "I."
SC or SQ	Subcutaneous	Mistaken for "SL" (sublingual) when poorly written.
TIW	Three times a week	Misinterpreted as "three times a day" or "twice a week."
D/C	Discharge; also discontinue	Patient's medications have been prematurely discontinued when D/C (intended to mean "discharge") was misinterpreted as "discontinue" because it was followed by a list of drugs.
HS	Half strength	Misinterpreted as the Latin abbreviation "HS" (hour of sleep).
cc	Cubic centimeters	Mistaken as "U" (units) when poorly written.
AU, AS, AD	Latin abbreviation for both ears; left ear; right ear	Misinterpreted as the Latin abbreviation "OU" (both eyes); "OS" (left eye); "OD" (right eye).

^a In general, these errors can be prevented by spelling out the full word (e.g., "units," "micrograms") instead of using the abbreviation, or by using a computerized order entry.
From U.S. Pharmacopeia. *Drug Information for the Health Care Professional*. Rockville, MD: U.S. Pharmacopeial Convention, 1998, with permission.

large improvement in medication safety it will be important to use many of them simultaneously.

Regarding post-discharge adverse drug events, one study found that a follow-up phone call by a pharmacist involved in the patient's hospitalization was associated with increased patient satisfaction, resolution of medication-related problems, and fewer return visits to the emergency department (15). Scheduling early post-hospital follow-up with the primary care provider or hospitalist is also important.

Monitoring for Adverse Drug Events

Hospitals need to monitor routinely for adverse drug events and use the data to improve quality, without punishing the persons involved unless a repeated pattern of error is identified. Some types of monitoring are required by regulatory agencies, but for adverse drug events, most hospitals rely on spontaneous reporting, an insensitive method that identifies few events (about 1 in 20 ADEs) (16).

A major problem with routine human surveillance is the cost, which is sufficiently high to make it impractical for relatively rare problems like serious adverse drug events. However, computerized searching can be used to look for a variety of events inexpensively by looking for signals, such as use of an antidote (such as Narcan or Flumazenil) or high serum drug levels (17, 18), and it is increasingly avail-

able. Computerized adverse drug event monitoring will likely soon become the main strategy for looking for adverse drug events.

Regardless, it is still important for clinicians to report medication safety issues that they identify to their hospital safety program. These reports can be aggregated to help prioritize safety strategies.

Cost Considerations and Resource Use

Adverse drug events are expensive in addition to being harmful to patients. For example, two studies addressing the cost to a hospital of an ADE reached estimates of approximately \$2,000 per event (19,20), even though these figures exclude the costs of malpractice, admissions resulting from ADEs, and injuries to patients. In one of the studies, the costs of a preventable ADE were higher, at \$4,600 (20). For a 700-bed hospital, the yearly figures are \$5.6 million for all ADEs and \$2.8 million for the preventable events (20). Nationally, ADEs occurring during hospitalization have been estimated to cost \$2 billion per year (17, 21), and admissions caused by ADEs may cost at least as much. Taken together, these data suggest that such events are not only highly undesirable for patients but also extremely costly to the health care system, and they justify investment in strategies for preventing them.

CONCLUSIONS

By judiciously adding the use of technology in the medication process, most hospitals should soon be able to substantially improve medication safety, thereby becoming more rewarding places for physicians to practice. Particularly important prevention strategies include computerized physician order entry, bar coding, "smart" intravenous pumps, and having pharmacists round with care teams.

KEY POINTS

- Adverse drug events are common and costly in both human and economic terms.
- About one-third of adverse drug events are preventable.
- A systems approach that utilizes the theory of error and integrates electronic information tools has the best chance of reducing adverse drug event rates in hospitalized patients.

Critical Care Medicine

Approach to the ICU

22

Patient

Neal H. Cohen

INTRODUCTION

The intensive care unit (ICU) has become one of the major locations for the in-hospital care of both medical and surgical patients. In the United States, approximately 4 million ICU admissions per year cost about \$60 billion per year. (1) Equipping and maintaining the technology required to care for critically ill patients is expensive due to both capital costs and the ongoing requirements to maintain the diverse and skilled group of providers needed to deliver the complex care that is required in the ICU setting.

Over the past decade, new pharmacologic agents, different modes of mechanical ventilation, and other new technologies have led to improved outcomes, but mortality remains between about 8% and 19% (2, 3). The variability in the mortality rate is due to many factors, including different patient populations, the skills of the providers, and the degree to which all the critical skills and resources can be brought together to improve clinical management. This variability in outcomes highlights both the economic and ethical dilemmas that must be addressed each time a patient is admitted, as well as the importance of developing administrative and clinical management strategies to optimize care.

This chapter will describe clinical and administrative approaches to the management of the ICU and the care of critically ill patients. It will address some of the challenges and emphasize how problems can be addressed in a cooperative and collaborative manner with a team of providers who bring a broad base of knowledge and skills to the varying needs of ICU patients.

(RE)DEFINING THE CRITICAL CARE UNIT

ICUs were originally created in the 1960s to centralize nursing staff as well as high-cost monitoring and therapeutic equipment in a single environment within the hospital. Although ICUs were originally designed to care for patients who had respiratory failure and also required mechanical ventilatory support, the clinical capabilities and diversity of patients in ICUs have expanded dramatically. At the same time, the definition of an ICU has become more diffuse, and the differentiation between an ICU and other inpatient settings has become less obvious.

Despite this variability, some specific services are available only in the ICU setting. First, the ICU is designed to provide a therapeutic environment that centralizes clinical resources and nursing staff at a higher provider to patient ratio with immediate availability of highly skilled staff. Second, in most hospitals, specific technologies, such as mechanical ventilation for patients with acute respiratory distress, continuous renal replacement therapy, invasive hemodynamic monitoring, and titration of vasopressor and inotropic agents to support hemodynamics and myocardial function, are available only in the ICU environment. Because of the variability in skills required from one ICU to another, and the variability in the patient population from one hospital to another, the approach to each critically ill patient must be flexible enough to take advantage of an institution's capabilities and the skills and training of the staff. Finally, because of the varying capabilities and clinical needs, a given patient might require ICU care in one hospital, but be adequately cared for in a transitional care unit or telemetry unit in another. In

larger hospitals and those with specialty services that can support service-specific ICUs, special units have been created to focus care on subsets of patients who have specific physiologic problems (cardiac disease, medical vs. surgical ICUs) or have had certain types of surgical procedures (cardiac surgery, transplant, neurosurgery). For many community hospitals, however, multidisciplinary units remain more common.

One of the biggest challenges for the physician who cares for patients with critical illness is to define each patient's clinical needs and understand how and where best to address them. The hospital-based physician must be knowledgeable about the models of care that are available to the patient, the skill set of the providers, and whether there are dedicated intensive care physicians, respiratory therapists or other staff to assist in patient management. In addition, physicians must understand what services can be provided only in an ICU setting and which ones might be available in a less intensive environment, so that patients can be triaged to optimize the utilization of hospital services. For hospitals with telemetry capability in non-ICU settings, for example, most patients who require cardiac monitoring do not require ICU admission.

ORGANIZATION OF INTENSIVE CARE UNITS

The organization model for the ICU varies from one institution to another—and in many cases within a hospital in units that care for different types of patients. Nevertheless, certain principles are fundamental to a successful ICU.

Administrative and Clinical Oversight

Although no single administrative approach is appropriate for every ICU, each unit must have a medical director and a nurse manager. The *medical director* is responsible for setting standards for clinical practice within the ICU and for working with the nurse manager to define staffing patterns, the necessary mix of skills, and the relationships among the physicians, nurses, and other providers. The medical director may be trained in one of many medical specialties, but most commonly the ICU director in medium- and large-size hospitals has specialty training in medicine, pulmonary medicine, cardiology, anesthesiology, or surgery. Critical care medicine, now a recognized subspecialty, crosses multiple medical disciplines. In the United States, critical care medicine training is available as an added qualification after training in internal medicine or its subspecialties, especially pulmonary medicine and cardiology. Formal training in critical care medicine can also follow certification in anesthesiology, surgery, or pediatrics.

Many larger hospitals typically have specialty units whose medical directors are trained in the ICU's area of specialized emphasis. Examples include neurologic ICUs (increasingly prevalent as a result of recent advances in the care of patients with acute stroke and neurovascular disease), and perinatal units for hospitals with large obstetric populations. These proliferating models of care create challenges and opportunities, particularly for the hospitalists who will participate in the care of their patients.

As the pool of physicians trained in critical care has expanded and their value documented, the Leapfrog Group has defined standards for critical care coverage in ICUs (Table 22.1) (3, 4). However, many smaller hospitals cannot support an ICU physician, so the skills needed to optimize patient care must be provided by a group of providers who work together to ensure that the patient receives required care.

In smaller hospitals, the ICU census is typically small, the needs of patients are variable, and physicians certified in critical care are infrequently available (5). To overcome this staffing deficit, many hospitalists have acquired skills to provide these critical care needs. In some cases, the hospitalist communicates with and coordinates care with critical care physicians located elsewhere in the community or within the health care system. In other models, "virtual" ICU care is coordinated by remote physicians who monitor patients electronically, review real time clinical data, perform remote clinical examinations, and visually observe patients by video camera. The critical care physician then communicates with the physician or nurse at the bedside and assists with clinical decision-making. Early studies support the premise that this model can help ensure the availability of critical care support to patients who might not otherwise have access to it (6).

ICU care requires participation by a variety of physicians. Some are unit-based (the intensivists), whereas some participate as primary care providers, hospitalists, or consultants. In general, the ICU physician will facilitate

TABLE 22.1
THE LEAPFROG STANDARDS FOR ICUs^a

ICUs are managed or co-managed by intensivists who:

1. Are present during daytime hours
 2. Provide clinical care exclusively in the ICU
 3. When not in the ICU, can (at least 95% of the time):
 - a. Return ICU pages within 5 minutes, and
 - b. Arrange for a FCCS-certified non-physician effector to reach patients within 5 minutes
- In addition, partial credit is given to ICUs that do not meet 1–3, but in which:
4. Intensivists lead daily, multidisciplinary rounds or make admission and discharge decisions on weekdays
 5. "Teleintensivist" coverage (6) is used

FCCS = Fundamental Critical Care Support course

^a www.leapfroggroup.org. Accessed January 10, 2005.

coordination of care, although in some settings either the hospitalist or the primary provider will serve in that role. This coordinated model of care (i.e., intensivist and hospitalist) can not only improve management in the ICU, but also foster care throughout the hospital stay and facilitate transition of the patient from the ICU to other settings (transitional care, extended care, skilled nursing care).

In addition to physicians, the ICU must have a *nurse manager* who is responsible for staffing and oversight of the nurses and ancillary personnel. The medical director and nurse manager share responsibility for developing policies and procedures and establishing a quality-assurance program to ensure that care is delivered within accepted standards. As requested by regulatory agencies such as the Joint Commission for Accreditation of Healthcare Organizations (JCAHO), the unit should also have *written policies and procedures for all aspects of care*, including admission and discharge criteria and authority, triage procedures, clinical management procedures, and disaster planning. Because the care provided within the ICU is part of a continuum of care, the quality-assurance activities should be integrated with institutional quality-assurance or quality-improvement programs (see also Chapter 12). The ICU staff should define mechanisms to monitor patient care activity, define the standards of care provided to patients within the ICU, and determine if care is below the standard.

Quality improvement initiatives are most easily integrated into ICUs with a uniform patient population that requires common clinical services. By comparison, multidisciplinary critical care units, which provide care to a wider spectrum of patients, require more complex quality-assessment methods to address the needs of varying patient populations and to assure that the staff has the skills necessary to care for these patients. Nonetheless, these activities are essential if care is to be safe and consistent with the current knowledge.

Quality improvement activities must respond to changes in clinical management and institution of new therapeutic approaches. For example, the introduction of continuous renal replacement therapies has significantly influenced fluid and electrolyte management for some critically ill patients. Reengineering efforts designed to reduce the use of laboratory tests, alter the timing for institution of hyperalimentation, or modify other therapeutic interventions must account for these changes in clinical management.

Because of the interdependent nature of ICU care, all physicians and other key providers must participate in quality improvement and reengineering efforts. For example, the institution of clinical protocols that allow the nurse or respiratory therapist to manage patients more directly can be very effective and appropriate (7, 8). However, these protocols change how and when the providers communicate, and modify the roles and responsibilities of the physicians. Similarly, a decision to change the nursing skill mix can be made only after careful consideration of the impact of the change on physicians' expectations and

interactions. Without this interdisciplinary approach to solving problems, attempts to refine practice will fail, and patient care will suffer.

Morbidity and mortality review is also an essential evaluative tool to assess the quality of care and the outcomes associated with ICU care. Traditional morbidity and mortality reviews typically are conducted on a departmental basis, with evaluation of isolated adverse events. For ICU patients, multidisciplinary morbidity and mortality reviews should include the participation of providers from all departments involved in patient care. The goal of the review is twofold: (1) to assess whether the delivered care was appropriate and (2) to determine if the approaches to care should be modified to improve care for future patients.

The "Open" vs. "Closed" Models of Care: An Arbitrary Distinction

In terms of the roles of physicians, an ICU can be "open" or "closed." In an open unit, the patient has a primary admitting physician who will manage and coordinate care in both the ICU and elsewhere in the hospital before and/or after their stay. This physician may be the patient's outpatient physician, a hospitalist, or a surgeon who performed a procedure. A patient's care may also be transferred to a hospitalist at the time of ICU admission, such as when a surgical patient suffers postoperative complications. In either case, in an open ICU, the primary hospital physician continues to coordinate the care of the patient after transfer to the ICU and to serve as the legally responsible physician. In this model, the ICU physicians and other physicians become consultants to the primary provider. The extent of involvement by the ICU physician varies from one unit to another. In most open units, the ICU physician provides emergency and resuscitative care and may be responsible for airway management, ventilatory support, and emergency care. The extent to which the ICU physician provides more comprehensive care will depend on the skills and availability of the primary physician. Although both the primary care and ICU physicians participate in clinical decision-making, primary responsibility stays with the patient's admitting physician rather than with the ICU consultant (see also Chapter 28).

In the "closed" ICU model, the primary responsibility for the patient's ICU care is assumed by the ICU physician. In this model, ICU physicians are immediately available, often because they are continuously present within the ICU. In closed ICU models, neither the patient's outpatient physician nor any other physician involved (such as a hospitalist or surgeon) makes minute-to-minute clinical decisions or writes routine orders.

The differences between the open and closed models are not as obvious as they might seem. Because of the complexity of ICU care and the diverse clinical needs of ICU patients, care *must* be coordinated. All physicians who have knowledge of the patient's clinical condition (both

acute and chronic) should participate in decision-making, even if the ultimate authority for writing orders and making clinical plans rests with one of them, as it must.

Both open and closed models can be successful, but the closed unit has been demonstrated to improve patient care outcomes, and optimize the utilization of resources (3, 9). However, it should be noted that the outcome studies comparing open with closed models were in hospitals in which open models used primary care physicians or traditional (non-hospitalist) ward attendings. To date, there are no studies comparing open model ICUs using hospitalists with closed ICUs, nor studies comparing hybrid models in which intensivists and hospitalists share management responsibilities for patients. Future research in this area will be vitally important (see also Chapter 1).

Whichever model is employed, the key component to providing optimal patient care is ongoing communication among all providers, including critical care physicians, consultants, hospital-based physicians, and the primary care physician. With an ongoing dialogue, all aspects of patient care can be addressed, longstanding relationships with the patient can be maintained, and the transfer of care into and out of the ICU can be achieved without compromising quality.

Key Roles for Non-Physician Staff in the ICU

In addition to physician staffing needs, the ICU requires trained nursing staff, respiratory therapists, and ancillary staff. In some units, only registered nurses are used; in others, the staff includes a combination of registered nurses and licensed vocational nurses. The nurse-to-patient ratio in most ICU settings is either 1:1 or 1:2. Some states mandate ICU nurse-to-patient ratios and the skill mix. In all cases, however, the ratio is dependent on clinical needs and the extent to which ancillary personnel can assume some responsibilities of care.

Staffing patterns have a major impact on the roles and responsibilities of the physicians caring for ICU patients. For example, an experienced ICU nurse often is able to anticipate problems before they occur and notify the physician of subtle changes in the patient's condition. Less skilled personnel may be able to help treat complications when they occur, but be less adept at anticipating them. The relationships among the physicians and the other staff members depend on an understanding of the clinical capabilities and experience of each provider, and a clear delineation of responsibilities.

Other providers are also key to the care of the ICU patient. For example, skilled respiratory therapists can provide a number of diagnostic and therapeutic interventions that can reduce costs, morbidity, and length of ICU stay. Intensive respiratory care, including continuous monitoring of pulmonary function and gas exchange, has allowed early recognition of respiratory failure and rapid institution of interventions (e.g., bronchodilators)

to prevent it. Alternative lung-expansion therapies, including positive expiratory pressure therapy and noninvasive ventilation, also can be provided. In many cases, the expertise of respiratory therapists can prevent the need for tracheal intubation and prolonged mechanical ventilatory support. As ventilator technology has become more sophisticated, the respiratory therapist also often is able to help determine the best mode of ventilation to optimize gas exchange and minimize the complications of positive pressure ventilation.

Emergent airway management is an essential component of ICU care. In most hospitals, tracheal intubation is the responsibility of anesthesiologists, critical care physicians, or emergency-medicine physicians. For hospitals that do not have in-hospital physicians, airway management is usually the responsibility of the respiratory care staff. The physician caring for the ICU patient should understand who is available to provide emergency airway management, their level of skill and experience, and which additional personnel are available to assist if tracheal intubation is difficult or impossible, and if tracheostomy or emergency cricothyroidotomy is necessary.

Physical and rehabilitative therapists, social workers, clinical nurse specialists, pharmacists, and case managers also can significantly improve patient care (see also Chapter 4). For example, the clinical nurse specialist can monitor the quality of care delivered by the nursing staff and teach new skills to improve patient care. Case managers often can help define the appropriate use of clinical resources and facilitate the disposition of the patient when ICU care is no longer required. The physician caring for the ICU patient should interact regularly with these providers and be aware of their skills and experience to maximize the benefit from ICU care and, if appropriate, identify alternatives to the ICU. Most importantly, in all of these examples, the development of clinical protocols that guide management and allow appropriate staff to modify care without waiting for a physician's order will not only minimize delays in care, but also improve care and reduce costs (10).

CARE OF THE CRITICALLY ILL PATIENT

Indications for ICU Admission

New technologies and transitional or intermediate care units have influenced the indications for ICU admission. In some hospitals, services previously restricted to the ICU are now available in other units within the hospital. Furthermore, the indications for ICU admission vary from one institution to another, and often vary from one ICU to another within a hospital. Although the value of the ICU care has traditionally been to optimize nursing care, the need to provide care in an ICU environment is now broader.

With improved understanding of the pathophysiologic mechanisms of critical illness and increased technologic

TABLE 22.2
SOME COMMON INDICATIONS FOR ICU ADMISSION

Acute myocardial infarction	Acute pancreatitis associated with hemodynamic instability
Pericardial tamponade	Liver failure complicated by encephalopathy, renal failure, electrolyte imbalance
Cardiogenic pulmonary edema	Hematologic disorders
Hemodynamic instability	Bleeding disorders necessitating transfusion of large amounts of blood and clotting factors
Hypotension, unresponsive to moderate fluid resuscitation or necessitating vasopressor or inotropic therapy	Acute leukemia complicated by airway compromise, septic shock, respiratory failure
Hypertensive crisis	Infectious disease
Arrhythmias	Sepsis and septic shock associated with hypotension, hemodynamic instability
Supraventricular arrhythmias associated with hemodynamic instability	Endocrine diseases
Ventricular arrhythmias	Diabetic ketoacidosis with hemodynamic instability
Eclampsia, preeclampsia	Hyperosmolar coma
Pulmonary disorders	Thyrotoxicosis associated with hemodynamic instability
Compromised gas exchange with superimposed hemodynamic instability	Severe myxedema
Acute noncompensated respiratory acidosis	Diabetes insipidus associated with severe fluid and electrolyte abnormalities
Hypoxemia, necessitating high flow oxygen therapy	Marked hypothermia
Respiratory failure necessitating mechanical ventilatory support	Drug ingestion, overdose
Noncardiogenic pulmonary edema, acute respiratory distress syndrome	Any overdose or ingestion associated with inability to protect airway
Neurologic disorders	Ingestion of a drug associated with arrhythmias or hemodynamic instability
Acute stroke	Postoperative patients
Neurologic deficit associated with increased intracranial pressure	Hemodynamic instability, excessive bleeding or coagulopathy following major surgical procedure
Intracerebral aneurysm with acute bleed	Postoperative patient requiring mechanical ventilatory support, vasopressor or inotropic therapy
Acute subarachnoid blood	Perioperative myocardial infarction necessitating hemodynamic monitoring or infusion of vasoactive drugs
Severe traumatic brain injury with Glasgow Coma Scale <9	Miscellaneous
Unstable cervical spinal cord injury	Severe hypothermia associated with electrocardiographic changes
Neuromuscular disease with compromised respiratory status	Patients at very high risk for airway compromise, respiratory failure, sepsis
External ventricular drainage system	
Status epilepticus	
Renal dysfunction	
Acute renal failure necessitating continuous renal replacement therapy	
Life-threatening electrolyte abnormalities	
Metabolic disorder with compromised airway	
Gastrointestinal disorders	
Hemorrhage associated with hypotension unresponsive to fluid resuscitation	

capabilities to diagnose and treat complex medical problems, the indications for ICU admission (see Table 22.2) include the need for care by specially trained critical care physicians. Timely observation and assessment for *impending* clinical problems, rather than just treating the problems that have already occurred, has been an increasingly important goal of ICU care.

ICU care is ultimately required for a number of specific clinical indications. For example, patients in need of mechanical ventilatory support for acute respiratory failure require ICU admission. Patients with severe respiratory failure who are not receiving mechanical ventilation also benefit from ICU care, because intensive respiratory care can often prevent progression and avoid the need for tracheal intubation and mechanical ventilation. Respiratory monitoring in the ICU also can more rapidly identify clinical changes that require intervention. In many cases, a care

plan to support the patient with respiratory failure can be initiated in the ICU setting and implemented after transfer from the ICU. Similarly, patients who require invasive hemodynamic monitoring, including arterial lines or pulmonary artery catheters, will generally be managed in an ICU environment capable of providing not only the monitors, but also the staff to interpret the data generated from them and the interventions warranted by that data.

The ICU also remains the preferred location in which to initiate pharmacologic cardiovascular support, including inotropic agents, vasopressors, and intravenous vasodilators. Once a patient is stabilized in an ICU, alternatives to ICU care are available in some hospitals for patients who require continued vasopressor or inotropic therapy but are otherwise stable, without hypotension or arrhythmias. Patients who require invasive therapeutic support, including intraaortic balloon counterpulsation (IABP), a ventric-

ular-assist device (VAD), and extracorporeal membrane oxygenation (ECMO), must be cared for in the ICU. The use of continuous renal replacement therapies (CRRT), such as continuous venovenous hemofiltration, also requires ICU care.

The goal of ICU care, whenever possible, should be to detect potential problems before they occur. In many respects, the most appropriate patients for admission to the ICU are those for whom complications can be avoided by providing greater nursing care or more extensive monitoring. Patients requiring continuous respiratory, cardiovascular, or neurologic monitoring, intensive nursing care, or closer physician observation often can be managed most effectively in an ICU environment. Unfortunately, the justification for ICU admission for these patients is difficult to document, particularly if the ICU care has prevented the clinical problems from occurring. Many payors (and occasionally hospital administrators) cannot understand why ICU care was necessary if no specific intervention was required. As cost-saving strategies mandate a shift of care to less sophisticated environments, outcome studies are needed to demonstrate which patients benefit from ICU care and which clinical services can be provided in alternative sites.

The need for ICU care is also influenced by the availability of transitional or intermediate care units and the capabilities of the other nursing units. In some hospitals, a transitional care unit can provide much of the equipment and clinical capability traditionally delivered in an ICU, especially monitoring to prevent complications or begin to treat them rapidly, if they occur. Using criteria specific to the patient population in the hospital, clinicians can develop strategies for providing graded critical care services that maintain or improve the level of care, while reducing overall costs (11). Some hospitals have increased the nurse-to-patient ratio, added other staff, or modified the skills of the existing staff to expand the clinical capabilities on acute care nursing units so that patients who previously required an ICU can be cared for in a less-intensive environment. For example, cardiac telemetry systems have allowed acute care units to monitor patients at risk for arrhythmias, thereby reducing the need for traditional coronary care unit beds except in the highest risk patients. The use of infusion pumps with fail-safe systems have allowed acute care units to provide safe, continuous infusions of drugs such as dopamine and dobutamine, thereby eliminating the need for transfer to the ICU. Telemetric pulse oximetry and paging devices that notify nursing staff of changes in a patient's condition also allow patients to be "observed" indirectly in traditional acute care nursing units.

Non-ICU facilities also have been developed for patients who are "chronically critically ill" and no longer need the skills and immediate access to critical care providers. For example, the patient who requires long-term ventilatory support can be transferred to a unit or a facility that specializes in the care of ventilator-dependent patients. These settings not only address the specific clinical needs of

the patient, but also generally have better rehabilitative and supportive capabilities to facilitate weaning from mechanical ventilation. Although these more focused clinical facilities are valuable additions, access to them varies considerably from one community to another. Physicians caring for critically ill patients should become familiar with these alternatives as well as with the requirements of payors, many of whom limit their reimbursement when patients transition from one unit to another or enter long-term ventilator care facilities.

Coordinating Clinical Management in the Intensive Care Unit

The management of the critically ill patient mandates a thorough understanding of the clinical problems, management options, and goals of therapy. Critical care management frequently requires rapid evaluation of key issues followed by intervention for life-threatening problems before a complete assessment of all underlying medical problems can be accomplished. For example, the causes of septic shock are numerous (see Chapter 26). The patient who is suspected of having pneumonia as the cause of sepsis may require tracheal intubation and institution of mechanical ventilation to improve oxygenation or maintain ventilation to prevent acidemia. For these patients, cultures should be obtained as soon as possible, and broad-spectrum antibiotics should be administered. Once culture results are available, antibiotic management can be more carefully tailored to the specific organisms. Conversely, if the cause for sepsis appears to be an abscess, a drainage procedure might be required at the same time that antibiotics are administered. In other situations, the cause may be unclear, and treatment may be more empiric while diagnostic efforts progress. The inability to provide appropriate intervention quickly can result in further clinical deterioration and development of multisystem failure that requires greater levels of ICU support and increases the likelihood of poor outcome.

The management of the acutely ill patient also often requires that emergent problems be addressed before the physician understands the underlying medical conditions that might influence long-term decision-making or a patient's pre-specified wishes that might affect management. For example, the patient with a terminal illness who has been receiving palliative care may present in acute distress requiring ventilatory support because of respiratory failure. If no prior information is available about the patient's underlying condition, resuscitative efforts should be initiated. If it subsequently becomes clear that continued ICU care is not appropriate, further care can be withheld or care can be withdrawn after discussion with the patient, the patient's family, surrogate decision-makers, and the physician staff (see Chapter 19).

Although chronic medical conditions often are not addressed directly during the management of life-threatening

problems, management strategies for the acute problem frequently mandate a thorough knowledge of the underlying medical condition. For instance, the patient with underlying chronic obstructive pulmonary disease (COPD) and hypercapnia may present with acute respiratory failure (see Chapter 55). It is essential for the physician to understand the degree of underlying gas-exchange abnormalities and the degree of respiratory reserve (as evidenced by baseline arterial blood-gas measurements and pulmonary function studies) to determine the most appropriate approach to ventilatory management. For example, in some patients with infection or heart failure, noninvasive ventilation provides sufficient support to allow stabilization and treatment of acute respiratory compromise, and permit the patient to avoid tracheal intubation and prolonged ventilatory support. In other cases, ventilatory management may be dictated by the degree of metabolic compensation for respiratory acidosis. If the patient has a significant compensatory metabolic alkalosis, initial ventilator management should provide a relatively lower minute ventilation, adjusted to correct the pH toward normal, not toward normalizing the partial arterial carbon dioxide pressure. Conversely, if the patient presents with a metabolic and respiratory acidosis, ventilatory management should be aimed at normalizing the pH. Hemodynamic support may be required to improve myocardial function, pulmonary perfusion, and oxygen delivery.

To optimize care within the ICU, professional societies have developed practice guidelines to define management strategies and ensure that care is based on evidence about appropriateness and outcome. Protocols for ventilatory management, weaning, sedation, analgesia, insulin infusions, and antibiotics are now commonly used (see Chapter 23). These protocols are most effectively implemented if they have been developed collaboratively with physicians who participate in the care of ICU patients, knowledgeable consultants, nurses, respiratory therapists, and pharmacists. Although some clinicians have expressed concerns that such protocols undermine their clinical judgment and decision-making, protocols can facilitate patient care and optimize the patient-physician relationship. The protocols must undergo regular review and revision, however, so that they are always based on the most current evidence about clinical management (see Chapter 13).

The optimal model for coordinating care depends on the capabilities and experience of the providers and the organization of the ICU. For example, the ICU physician typically is most knowledgeable about the patient's acute needs, including the need for invasive or noninvasive monitoring, airway protection, and mechanical ventilatory support, and is best able to facilitate care by respiratory therapists, case managers, and clinical specialists. Depending on skills, training, and availability, the intensivist or hospitalist may most effectively coordinate the care provided by consultants and evaluate the need for other interventions, such as circulatory-assistance devices, renal

replacement therapies, and so forth. The hospitalist should participate in the decision to admit the patient to the ICU, remain actively involved in clinical decision-making, and manage the transition of care into and out of the ICU. The primary care provider usually has a longstanding relationship with the patient and is knowledgeable about the patient's underlying medical problems, goals for therapy, and important social issues.

The specific roles for the critical care physician and the hospitalist are changing as more critical care services are provided outside of the ICU. The creation of transitional or intermediate care units, expansion of clinical capabilities in other acute care nursing units, and the creation of units to care for chronically critically ill patients have expanded the role for physicians who understand how to treat severely ill patients, prevent deterioration in patients who require monitoring, and help patients transition to less intensive settings. The critical care physician is a valuable resource both for the patient and the hospitalist in defining what care is required throughout the patient's hospitalization, where it can be most effectively provided, and when transfer to or from the ICU is appropriate. For some patients, either the hospitalist or the intensivist may be the most appropriate clinician to coordinate care throughout the patient's hospitalization.

ASSESSING AND ENSURING QUALITY OF CARE IN THE ICU

Evidence-Based Care in the ICU

Clinical medicine has undergone an evolution from primarily experientially based clinical decision-making to evidence-based practice (Chapter 8). Many of the evidence-based practices that are used to optimize perioperative care or medical management of diabetes, hypertension, coronary artery disease, and other conditions, are applicable to the ICU patient and critical care setting. For many patients, the development of evidence-based protocols to facilitate clinical management have been implemented hospital-wide, including in the ICU setting. For example, the use of β -blockers to reduce the incidence of postoperative myocardial ischemia is common in patients requiring postoperative monitoring or ICU care. In some cases, protocols have to be modified or their implementation delayed due to underlying conditions or acute physiologic changes associated with the critical illness. In other cases, the early initiation of evidence-based practices in the ICU setting have been demonstrated to reduce ICU length of stay and improve outcome.

Some examples of evidence-based practices that are now becoming commonly applied in the ICU setting include: respiratory care strategies to reduce ventilator-associated pneumonia, patient positioning and management strategies to reduce the risk of aspiration, prophylaxis of peptic

ulcer disease, anticoagulation and other interventions to minimize the risk of deep vein thrombosis in the bed-ridden patient, transfusion therapy, strategies to expedite weaning from ventilators and reduce days of mechanical ventilation, strategies to reduce the risk of ventilator-associated pulmonary complications, and tight control of blood sugar in diabetic patients. Initiation of early feeding in both medical and surgical patients improves outcome by reducing muscle wasting and shortening rehabilitation. The administration of activated protein C to the patient with early sepsis reduces mortality (see Chapter 26) (12). In many situations, the primary care physician and surgeon may not be aware of the evidence upon which the practices are based; the intensivist and hospitalist have key roles in ensuring the use of practices that have been proven to reduce morbidity and mortality.

As evidence-based practices find their way to the ICU setting, the continuous evaluation of the practices and their applicability to the specific patient must be carefully assessed. The impact of underlying diseases, recent surgery, and other potential complicating factors must be taken into account and may mandate that interventions must sometimes be delayed or modified to maximize their benefit and minimize their risks. For example, if a patient has a coagulopathy in the early postoperative period, the use of anticoagulants might have to be delayed or their dose modified; for the septic patient, administration of activated protein C may have to be delayed for 12 to 24 hours because of the risk of bleeding. The upright positioning of the patient with severe acute respiratory distress syndrome (ARDS) may not be possible due to worsening hypoxemia or dead space ventilation. In these cases, even though the evidence-based practices may be temporarily delayed, the patient should be carefully and continuously assessed so evidence-based protocols can be initiated as soon as possible.

Assessing Outcomes in the ICU: Role for ICU Scoring Systems

A number of scoring systems have been developed to guide management in the ICU, to evaluate resource utilization, and to assess potential outcomes of care. For example, the Glasgow Coma Scale (see Table 117.1) assesses the degree of neurologic injury and is often used to estimate the potential for recovery in patients admitted to the ICU with altered neurologic status. The Ranson criteria (Table 86.3) stratify physiologic abnormalities and prognosis associated with acute pancreatitis. Unfortunately, many of these scoring systems were developed prior to advances in clinical management, so their current prognostic value is less clear.

Resource utilization, as a measure of severity of illness, in the ICU can be measured using the Therapeutic Intervention Scoring System (TISS) (Table 22.3). The TISS also can be used to estimate the need for nursing time and the costs of care.

TABLE 22.3
THERAPEUTIC INTERVENTION SCORING SYSTEM (TISS)

4 points	Pulmonary-artery catheter Intraaortic balloon pump Controlled mechanical ventilation (\pm positive end-expiratory pressure) Vasoactive drug therapy (>1 drug)
3 points	Chest tube Continuous positive airway pressure Intermittent mandatory or assisted ventilation Arterial catheter
2 points	Central venous pressure Two peripheral intravenous catheters Spontaneous ventilation via endotracheal tube or tracheostomy Multiple dressing changes
1 point	Electrocardiographic monitoring One peripheral intravenous catheter Routine dressing changes Urinary catheter

Adapted from Keene AR, Cullen DJ. Therapeutic Intervention Scoring System: Update, 1983. *Crit Care Med* 1983;11:1-3; with permission.

A number of other scoring systems can help compare patients across ICUs or predict outcome of ICU care. Some scoring systems are specific to a single disease or patient population, such as the sequential organ failure assessment (SOFA), whereas others are designed to assess issues such as the level of sedation or pain (13).

The most widely used scoring system is probably the Acute Physiology and Chronic Health Evaluation (APACHE) system (Table 22.4), which considers both the acute physiologic perturbation of critical illness as well as underlying chronic health abnormalities that might influence outcome. The most recent version (APACHE III) has been used to provide benchmarking comparisons among ICUs and to stratify patients for clinical trials. Although less complicated approaches, including the Simplified Acute Physiology Score (SAPS) and the Mortality Probability Model (MPM), have been developed, APACHE remains the most widely-used method for assessing severity and estimating prognosis.

As valuable as these systems may be, it is important to note that none of them can be relied upon to define which individual patient will survive, nor to estimate their quality of life after ICU care.

Transitioning Care

Once a patient has stabilized, the critical illness is controlled, and ICU care is no longer required, an alternative site for care must be identified. Because of the varying

clinical needs, different alternative care sites within each community, waiting lists, and differing payor requirements, discharge planning and identification of disposition options should begin at the time of ICU admission, when goals for ICU care should be clarified and the criteria for transfer outlined. A case manager or social worker should be actively involved in discussions about the patient's continued clinical needs and should provide input into alternatives for further care. Goals should be redefined and shared among members of the care team each day (14). For example, if a patient requires ICU admission for ventilatory support for acute respiratory failure and has a high likelihood to need prolonged mechanical ventilatory support, alternative clinical sites capable of providing

the required care should be identified early in the patient's ICU course. By working closely with the staff of the alternative site, care can be coordinated to ensure that the patient is ready for transfer as soon as clinical needs change. If necessary, a tracheostomy and placement of a permanent feeding-tube can be done early enough in the ICU course to prevent a delay in transfer. It is often valuable to allow families an opportunity to visit the facility and participate in planning for transfer.

Addressing Ethical Dilemmas in Intensive Care Management

The increase in clinical capabilities in the hospital in general and the ICU specifically has created many new challenges for physicians caring for critically ill patients. The nature of critical care medicine is to pursue clinical problems aggressively, to address them rapidly, and to resolve them. Many patients, however, now survive for extended periods of time, requiring extensive and aggressive medical management, often with little or no likelihood of meaningful recovery. The patient may "stabilize" but require such extensive care that transition out of an ICU setting becomes difficult. For other patients, the outcome of ICU care is unacceptable, despite initial interventions that were appropriate and timely. In these situations, ICU care, or sometimes any continued medical care, may no longer be appropriate or desired.

As a result, the providers who participate in the care of the ICU patient will be confronted with questions such as these: Should care be provided to the terminally ill patient? When should care be continued for the patient who has little or no likelihood of meaningful recovery, to what end point, and at what cost? Who is the decision-maker for the patient who cannot express her or his own wishes? If care is to be withdrawn, how should it be done? All providers must understand the needs and goals of the patient and family, clarify the expectations of care, and deal with unanticipated consequences. These issues are addressed in Chapter 17.

If and when a joint decision is made to limit care, the clinicians must clarify how it will be limited and whether some interventions will be withdrawn. From an ethical perspective, there is no distinction between withholding and withdrawing care; for patients and families, however, the former may be easier than the latter. When care is limited or withdrawn, routine clinical needs must still be met, and the comfort of the patient must be assured. Some ICU patients who have been receiving analgesics may require large doses of opiates or other medications.

When a decision is made to limit care, the limitations should be documented in the medical record. The discussion with the patient and family should be recorded, and the specific limitations defined in the orders. All providers should be aware of which services will be provided and which will not. If the clinical situation changes and the plans require modification, the changes should similarly be documented in the medical record.

CONCLUSIONS

As the complexity of inpatient care increases, a large percentage of inpatients now receive care in a critical care, or other monitored, environment sometime during their hospital stay. Regardless of whether the ICU is a specialized or general unit, or whether it is open or closed, the safe and appropriate care of the patient necessitates a multidisciplinary, coordinated, and integrated approach to management. Each provider brings different and often important skills, knowledge, and capabilities to the management of the patient. The hospitalist is an integral member of this team, often leading the team in smaller hospitals (without critical care physicians) and participating in decision-making and the transition of the patient from the ICU to other less intensive clinical environments in all intensive care settings.

KEY POINTS

- Both medical and surgical inpatient care is concentrating in critical care environments, necessitating that all hospital-based providers understand the reasons for ICU admission, the capabilities for care within the ICU, and the most effective ways of managing critically ill patients.
- The administrative and clinical models for the ICU vary among hospitals and within a single hospital based on a number of factors, including availability of critical care physicians, patients' needs, and administrative organizational factors. ICUs can be managed as either open and closed units, but coordination of care among a variety of providers is essential in either model.
- The clinical capabilities and skills of providers vary both within and among hospitals. Decisions about a patient's location must be based on an understanding of the patient's needs and the capabilities of various units in each hospital.
- Because of the complexity and diversity of clinical needs for ICU patients, care is optimized if it is carefully coordinated among the primary care physician, the ICU physician, and consultants. Protocols that define evidence-based practices and ensure standardization of clinical management reduce morbidity and mortality.
- Since the ICU represents only part of the overall hospital course and care for the critically ill patient, disposition planning should be initiated at the time of admission to the ICU to define long-term needs, desired outcomes of care, and plans for transition to less intensive environments.

Ventilator Management

23

Stephen E. Lapinsky *Arthur S. Slutsky*

OBJECTIVES OF MECHANICAL VENTILATION

Mechanical ventilation is a life-saving intervention necessary for the management of respiratory failure complicated by severe hypoxemia or marked hypercapnia. Ventilatory support may result in significant complications, and an important goal should be to minimize or prevent these adverse effects. The first issue to be addressed is whether ventilatory assistance is required and whether intubation is necessary. In many situations in which the patient has severe hypoxemia or cannot protect his or her airway, the decision may be straightforward. However, in some situations the decision requires clinical judgment in which the risks of endotracheal intubation and ventilatory support are weighed against the hazards of not ventilating the patient. Increasing evidence justifies the use of noninvasive ventilation in the cooperative patient.

A major function of ventilatory support is to improve alveolar ventilation. In the patient with hypoventilation, mechanical ventilation corrects hypercapnia and respiratory acidosis. Although the usual goal is to normalize the arterial partial pressure of carbon dioxide ($P_a\text{CO}_2$) and pH, in some situations a $P_a\text{CO}_2$ level higher than normal may be accepted, particularly if high ventilation pressures are required. In the management of severe hypoxemia, ventilation improves oxygenation by the effect of positive pressure on lung volumes and alveolar recruitment, as well as by the ability to deliver a high inspired oxygen fraction. Mechanical ventilation is used to unload the respiratory muscles—an important goal because oxygen consumption by these muscles may account for up to 50% of total oxygen consumption in the patient with acute respiratory failure. This unloading is of particular benefit in the patient with acute myocardial ischemia or reduced oxygen delivery.

BASIC PRINCIPLES

Classification of Ventilators

Ventilation may be achieved by the delivery of either a predetermined volume or pressure to the lungs, on a regular or a demand basis. With *volume-controlled* ventilation, a preset tidal volume is delivered. As a safety feature, a pressure limit is set, which if reached causes pressure to be released and a ventilator alarm to sound. *Pressure-preset* ventilation differs from volume-controlled ventilation in that a level of airway pressure is preset; with this mode, the delivered tidal volume is determined by pulmonary mechanics. For example, a decrease in thoracic compliance results in a proportional decrease in tidal volume. The duration of delivery of the pressure is set as an inspiratory time or as an inspiratory:expiratory ratio and respiratory rate.

Ventilatory Modes

Controlled ventilation, which is the most basic mode of ventilatory support, provides a set tidal volume and rate regardless of the patient's effort or requirements (Table 23.1). A major disadvantage of this mode is the asynchrony that can occur between the patient's spontaneous efforts and the ventilator-generated breaths. *Assisted modes* are triggered by the patient's respiratory efforts and are used to synchronize the patient and the ventilator. In the *assist-control mode*, every patient breath is supported by the ventilator. A minimum rate is set, effectively providing controlled ventilation in the absence of the patient's efforts. This mode is used with volume-preset or pressure-preset ventilation. A disadvantage is that in patients with very high respiratory drives and obstructive airways disease, high minute volumes can produce respiratory alkalosis and/or worsen air trapping.

TABLE 23.1
CLASSIFICATION OF MECHANICAL VENTILATION

Controlled	Assist-control	Synchronized intermittent mandatory ventilation	Support
Pressure or volume preset ^a Use in the paralyzed patient	Pressure or volume preset ^a Use as an initial ventilatory mode	Usually volume preset ^a Use in spontaneously breathing patient	Usually pressure preset ^a Use only in spontaneously breathing patient with adequate respiratory drive
Patient receives mandatory preset ventilator rate All breaths are ventilator-initiated	Patient receives mandatory preset ventilator rate Spontaneous breaths are all ventilator-assisted	Patient receives mandatory preset ventilator rate Spontaneous breaths are not ventilator-assisted	Patient receives no mandatory ventilator rate All spontaneous breaths are ventilator-assisted
No spontaneous breathing possible		Can be used as a weaning mode	Can be used as a weaning mode

^aPressure-preset ventilation: inspiratory pressure level is set on the ventilator, volume is monitored; volume-preset ventilation: tidal volume and flow rate are set on the ventilator, inspiratory pressures are monitored.

Synchronized intermittent mandatory ventilation (SIMV) combines a preset ventilator rate with spontaneous breathing. As in assist-control modes, the ventilator breaths are patient-triggered and therefore synchronized but are mandatory in the absence of patient effort. However, patient breaths in excess of the preset rate do not receive ventilatory assistance (Figure 23.1). Spontaneous breaths in this mode may require significant patient work because of high circuit or demand-valve resistance. This mode, which has the advantage of allowing the patient to perform a variable amount of respiratory work with the security of a backup rate, also can be used for weaning patients from ventilatory support. SIMV may be performed using volume- or pressure-preset ventilation.

Pressure-support ventilation (PSV) is a pressure-preset, flow-cycled mode in which ventilatory support assists all spontaneous efforts. The delivered pressure is triggered by the patient and is maintained until a specific decrease in inspiratory flow occurs. With PSV, the patient determines both respiratory frequency and inspiratory time, with tidal volume being a function of the set level of pressure, patient effort, and pulmonary mechanics. If appropriately set, this mode may reduce asynchrony and optimize patient control over ventilation. In some patients with severe airways obstruction, however, PSV may lead to patient-ventilator asynchrony, especially at high levels of pressure support. The ability to decrease ventilator support from high pressure to near zero also makes this a useful and effective weaning mode. This mode requires spontaneous respiratory efforts and does not guarantee a minimum tidal volume; an apnea backup capability is therefore necessary.

Ventilator Settings

The respiratory rate may be a function of the ventilator setting, spontaneous breathing, or both, depending on the mode. Synchronization of spontaneous breaths with ventilator breaths is achieved by having the ventilator breath

begin when the patient “triggers” the ventilator by generating a small change in airway pressure (e.g., -0.5 to -2 cm H₂O). Insensitive triggering systems may require significant effort from the patient; an oversensitive system may produce spontaneous ventilator cycling. The presence of

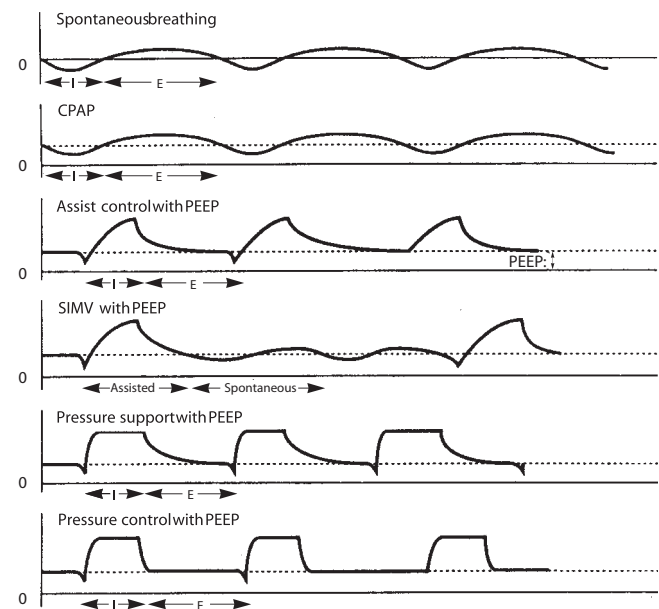

Figure 23.1 Airway pressure tracings during spontaneous respiration and various modes of mechanical ventilation. In the assist-control and pressure-control profiles, the first two breaths are triggered, but the third breath is controlled because no spontaneous effort has occurred. During synchronized intermittent mandatory ventilation (SIMV), spontaneous breathing occurs between ventilator breaths. The pressure-support tracing demonstrates some variation in duration of the inspiratory phase because of flow cycling, compared with the fixed inspiratory period of the time-cycled pressure-control mode. CPAP, continuous positive airway pressure; E, expiratory phase; I, inspiratory phase; PEEP, positive end-expiratory pressure. (Adapted from Lapinsky SE, Slutsky AS. Principles of mechanical ventilation and weaning. In: Dantzker DR, Scharf SM, eds. *Cardiopulmonary Critical Care*, 3rd ed. Philadelphia: W.B. Saunders, 1998;253, with permission.)

residual positive alveolar pressure at the end of expiration (auto-PEEP) may inhibit triggering; the patient must create a negative pressure large enough to overcome this positive alveolar pressure before the ventilator senses a change in airway pressure. Flow triggering, using small changes in airway flow, is available on some ventilators and may be more efficient, but clinical benefits have not been demonstrated.

The inspiratory flow rate and pattern of delivery must be set during volume-controlled ventilation but are determined by patient effort and pulmonary mechanics with pressure-preset modes. In the spontaneously breathing patient, the flow rate setting must match the patient's peak inspiratory demands—usually about 40 to 100 L/min in the adult patient. This inspiratory flow may be delivered in a variety of flow patterns (square-wave, sine-wave, or decelerating flow), but no significant benefit has been demonstrated for one flow pattern over another. A decelerating ramp inspiratory flow has the potential advantage of limiting peak pressure and optimizing mean airway pressure.

Inspiratory flow can be terminated by reaching a preset volume (volume-control), time (pressure-control), or flow rate (pressure-support). Volume cycling delivers the preset tidal volume, but additional patient effort does not produce further volume. Pressure-controlled ventilation utilizes time cycling, in which the set airway pressure (and therefore flow) is maintained for a preset inspiratory time. Additional patient effort during this time allows increased tidal volume. Pressure-support ventilation is a preset pressure mode utilizing flow cycling. Airway pressure is maintained until inspiratory flow falls below a certain level (usually 25% of the peak inspiratory flow). This approach increases patient control over the delivered tidal volume and inspiratory time and may improve patient-ventilator synchrony, but care must be taken in patients with airway obstruction.

Maintaining a *positive end-expiratory pressure* (PEEP) is thought to be useful to minimize ventilator-induced lung injury and to improve oxygenation by increasing mean airway pressure, recruiting lung volume, and redistributing lung water from the interstitial space adjacent to the gas-exchanging regions to the compliant perivascular interstitial space. How to determine the appropriate level of PEEP remains controversial; the most popular methods rely on optimizing some desired physiological end point, be it arterial partial pressure of oxygen (P_aO_2), oxygen delivery, or lung compliance. PEEP can have significant deleterious effects, including a decreased cardiac output and hypotension, particularly in the volume-depleted patient.

The lowest inspired oxygen concentration producing an acceptable P_aO_2 should be selected, in order to avoid lung injury induced by a high concentration. Exposure to an inspired oxygen concentration less than 0.5 is probably not of concern. In patients requiring higher concentrations, P_aO_2 sometimes can be raised by manipulating mean airway pressure (by adjusting PEEP, inspiratory:expiratory ratio, or plateau pressure) or improving mixed venous oxygen saturation (by improving cardiac output).

CARE OF THE HOSPITALIZED PATIENT

Noninvasive Ventilation

Ventilatory support traditionally is performed with an endotracheal tube, but intubation is uncomfortable and is associated with significant risks, such as airway damage and nosocomial pneumonia. There has been increasing interest in the noninvasive application of positive pressure ventilation, which may avoid the potential adverse effects and long-term complications of endotracheal intubation.

Noninvasive ventilation is performed using a tight-fitting nasal or oronasal mask attached to a positive pressure ventilator. Although the nasal mask is usually well tolerated, the face mask is becoming a more commonly used interface and is available in a variety of types and sizes. Conventional ventilators may be used to deliver noninvasive ventilation, usually in a pressure-support mode. Several simpler bi-level pressure-support devices are available to ventilate in a pressure-support mode, with or without a backup rate; they have the advantage of low cost and better compensation for air leaks but do not have the monitoring capabilities of most ICU ventilators.

Noninvasive support can be used in the patient who is able to protect his/her airway and who has adequate spontaneous respiratory efforts, but is failing because of respiratory muscle fatigue or progressive hypoxemia. It may be contraindicated in the patient with a decreased level of consciousness, excessive secretions, recent upper-gastrointestinal anastomoses, or hemodynamic instability. An adequate fit for the mask may not be possible in edentulous patients or those with facial injury or deformity. Noninvasive ventilation is most effective in the management of patients with respiratory failure resulting from chronic obstructive pulmonary disease (COPD) (see Chapter 55), in which a mortality benefit has been demonstrated (1). Cardiogenic pulmonary edema (see Chapter 39) can be effectively treated by noninvasive continuous positive airway pressure. Other potential uses of noninvasive ventilation include patients who refuse intubation and those who require short-term support.

Noninvasive ventilation is initiated by gently applying the mask to the patient's face until it is tolerated; then the mask is secured with head straps. The inspiratory pressure and end-expiratory pressure usually are set initially at 8 cm H_2O and 4 cm H_2O respectively; pressures are adjusted to the patient's comfort and later to arterial blood-gas measurements. The acutely distressed patient may require a rapid increase to higher levels of inspiratory pressure (e.g., 16–20 cm H_2O). Most bi-level ventilatory-support devices deliver room-air gas, and oxygen must be titrated into the circuit according to the patient's oxygen saturation. When using conventional ventilators, the pressure support level can be titrated up until the tidal volume reaches about 7 mL/kg. Inspired oxygen concentration can be set on the ventilator to the desired level.

Noninvasive ventilation is most useful for short-term ventilation, although support for several days to a week is feasible. A significant complication of prolonged use is the development of nasal-bridge ulceration. The mask can be removed intermittently for communication, feeding, or patient comfort. The difficult decisions regarding extubation are avoided by the ease of removal and reapplication of the mask. This mode of ventilation is definitely indicated for patients with COPD, but its exact role in other disease states remains to be determined. The success of noninvasive ventilation often depends on the experience and perseverance of the medical personnel. Patients require close monitoring, and facilities for endotracheal intubation and conventional ventilation should be readily available.

Initiating Mechanical Ventilation

Once the decision is made to institute conventional mechanical ventilation, intubation must be performed in a controlled fashion. All necessary equipment must be available including a laryngoscope, suction, resuscitation bag and mask, and endotracheal tubes of different sizes. Electrocardiographic and oxygen saturation monitoring is essential. The method of intubation depends on individual preferences and level of skill; in the acutely ill patient, however, an awake intubation is safest because it allows spontaneous respiration during the procedure and avoids the desaturation that occurs if a patient is rendered apneic by pharmacotherapy. Most patients with acute respiratory failure have an altered level of consciousness, but the procedure should be explained to them. Topical anesthesia can be used, and small doses of a short-acting benzodiazepine may be beneficial. Anesthetic drugs and neuromuscular blocking agents should be available. The patient must be preoxygenated, and oxygen saturation should be monitored during the intubation. For patients who are not fluid-overloaded, a fluid bolus may be initiated to overcome the hypotensive effect of the sedation and positive intrathoracic pressure.

If the patient is fully sedated following intubation, ventilation is commenced in a controlled or assist-control mode. Pressure support may be chosen in the patient with good spontaneous efforts who does not tolerate assist control (Figure 23.2). Inspired oxygen concentration is set initially at 0.80–1.0 and reduced according to oxygen saturation measurements. A tidal volume of 5–10 mL/kg with a rate of 12–16 per minute is adjusted according to the patient's clinical status and initial arterial blood-gas results. A PEEP of 5 cm H₂O often is provided unless contraindicated by hypotension. It is important not to expect to optimize ventilation until the patient has stabilized and the sedative drugs have taken full effect. Fine tuning, including adjustment of inspiratory flow rate, inspiratory:expiratory ratio, PEEP, and triggering sensitivity, then may be appropriate, along with any other necessary troubleshooting (Table 23.2).

Step 1: Ventilatory mode

AC - Initial mode (particularly if patient sedated, limited efforts)

SIMV - consider if some respiratory effort, dysynchrony

Pressure support - only if good patient effort, more comfortable

Step 2: Oxygenation

FiO₂ - Begin with 80–100%, reduce according to SaO₂

PEEP - Begin with 5 cm H₂O, increase according to SaO₂ and hemodynamic effects

Aim for SaO₂ ≥ 90%, FiO₂ ≤ 60%

Step 3: Ventilation

Tidal volume - begin with 5 to 10 ml/kg

Rate - begin with 12 – 16/min, higher if acidemic

Pressure limit - set at 50 cm H₂O

- aim for ≤ 35 cm H₂O

Step 4: Fine tuning

Triggering - in spontaneous modes, adjust to minimize effort

Inspiratory flow rate of 40–80 L/min: higher if tachypneic, lower if high pressure is alarming

I:E ratio - 1:2, either set or as function of flow rate

Flow pattern - decelerating ramp reduces peak pressure

Step 5: Monitoring

- Clinical - blood pressure, ECG

- Ventilator - tidal volume, minute ventilation, airway pressures

- Arterial blood gases, pulse oximetry

Figure 23.2 Algorithm for initiating mechanical ventilation. AC, assist control; ECG, electrocardiogram; FiO₂, inspired oxygen fraction; I:E, inspiratory:expiratory; PEEP, positive end-expiratory pressure; SaO₂, arterial oxygen saturation; SIMV, synchronized intermittent mandatory ventilation.

Disease-Specific Ventilation

Acute Respiratory Distress Syndrome

Mechanical ventilation with a low tidal volume (6 ml/kg) and plateau pressure less than 30 cm H₂O improves outcome in patients with severe acute respiratory distress syndrome (ARDS) (see Chapter 24) (2). Recognition of the concept of ventilator-induced lung injury has influenced ventilatory strategies. Lung injury in ARDS is not uniform, and the small fraction of uninvolved lung capable of gas exchange should be protected from excessive inflation pressure. In addition to local injury, evidence exists that injurious ventilatory strategies may cause the systemic release of

TABLE 23.2
TROUBLESHOOTING THE VENTILATOR

Problem	Response
Dyssynchrony (“fighting”)	Consider synchronized intermittent mandatory ventilation or pressure control or pressure support Check trigger sensitivity Check inspiratory flow rate Check for auto-PEEP Consider sedation, neuromuscular blockade
Hypoxemia	Inspired oxygen concentration as high as necessary, but aim for <60% Increase PEEP incrementally to 18 cm H ₂ O Consider: Recruitment maneuver Prone position Increasing cardiac output
High-pressure alarm	High peak pressure = airway resistance (e.g., endotracheal tube, bronchospasm) High plateau pressure = lung/chest wall compliance (e.g., pulmonary edema, pneumothorax, “fighting”)
Low-pressure alarm	Patient disconnected from ventilator Inadequate flow rate
Hypotension	Due to volume depletion, sedation, increased intrathoracic pressure Initial treatment: fluid bolus May need to reduce PEEP, minute volume Consider: Pneumothorax Auto-PEEP
Hypercapnea	Accept moderate hypercapnea (50–80 mm Hg) May need bicarbonate for acidosis (controversial)

PEEP, positive end-expiratory pressure.

cytokines (3), potentially resulting in multi-organ failure. For the patient with a noncompliant chest wall (e.g., massive ascites, pleural effusions, pregnancy), higher airway pressures may be accepted. Low tidal volumes may result in alveolar hypoventilation and a rise in $P_a\text{CO}_2$, and this permissive hypercapnia generally is well tolerated (4).

With inadequate PEEP, ARDS may deteriorate because of alveolar damage resulting from repeated opening and closing of alveoli. An adequate level of PEEP is also essential to improve oxygenation and lung compliance. Application of a recruitment maneuver (e.g., 40 cm H₂O continuous positive airway pressure for 40 seconds) may improve oxygenation, particularly in early ARDS (5), but care must be taken to monitor oxygenation and blood pressure during such maneuvers. The utility of these maneuvers in terms of outcome has not been proven. Although the use of the prone position may improve oxygenation by increasing blood flow through well-aerated, previously non-dependent areas and improving pulmonary mechanics, no survival benefit has been noted (6). Nitric oxide may have dramatic effects on oxygenation in a subgroup of patients, but no improvement in any clinically significant end point has been shown in adults.

High frequency oscillation (HFO) is an alternative mode of mechanical ventilation that may be less injurious

than conventional ventilation in ARDS. HFO allows delivery of a higher mean airway pressure (improving alveolar recruitment and oxygenation) without high peak pressures. HFO is carried out at a frequency of 3–8 Hz (180–480/min), with initial settings usually at about 6 Hz, and mean airway pressure at 3–5 cm H₂O higher than the mean airway pressure on conventional ventilation. Frequency is adjusted according to PaCO_2 —lower frequencies produce a higher tidal volume and lower PaCO_2 . Patients usually require deep sedation or even neuromuscular blockade. There are no data demonstrating a clear outcome benefit over conventional ventilation.

Survivors of ARDS regain their lung volume and spirometric values within 6 months, but carbon monoxide diffusion capacity remains reduced at 12 months. Persistent functional disability relates largely to muscle wasting and weakness (7).

Obstructive Airways Disease

The predominant abnormality in patients with obstructive airways disease is incomplete exhalation due to expiratory airflow limitation, which may produce dynamic hyperinflation or *auto-PEEP*, owing to the residual pressure (and volume) in the alveoli at the end of expiration. Auto-PEEP

produces complications such as barotrauma, hemodynamic collapse, and difficulty in triggering the ventilator related to elevated intrathoracic pressure. Auto-PEEP cannot be measured easily in the spontaneously breathing patient, without invasive measurement of pleural or esophageal pressure. The presence of auto-PEEP can be inferred by observing the flow-time tracing—persistent expiratory flow at the onset of the next inspiration suggests that auto-PEEP is present. In the patient on controlled ventilation, auto-PEEP can be estimated by assessing the circuit pressure during brief occlusion of the circuit at the end of expiration. Many modern ventilators perform this measurement automatically. Resistance to inspiratory airflow is increased in asthmatics and results in markedly elevated peak airway pressures (see Chapter 56). A major objective in ventilating patients with obstructive airways disease is to minimize minute ventilation, shorten inspiratory time, and maximize expiratory time, so as to reduce end-expiratory lung volume and auto-PEEP.

Although increasing expiratory time is important, the most important intervention is to reduce minute volume to the lowest acceptable level. In patients with severe airflow limitation, this goal may require controlled hypoventilation with permissive hypercapnia. Heavy sedation or paralysis (see Sedation and Paralysis section on page 179) may be useful to reduce ventilation pressures and to eliminate active expiration in very difficult-to-ventilate patients. The development of hemodynamic compromise resulting from auto-PEEP should be anticipated and managed by a reduction in minute volume and by fluid therapy.

During weaning of the patient with obstructive airways disease, the presence of auto-PEEP may require increased work of breathing to trigger breaths. This problem can be overcome by applying extrinsic PEEP at a level equal to or less than the measured auto-PEEP.

Complications of Mechanical Ventilation

Mechanical ventilation is a life-saving intervention, but it may be associated with significant adverse effects (Table 23.3) related to the endotracheal tube, to ventilator-induced lung injury, to the effects of positive intrathoracic pressure, or to pharmacotherapy necessary to facilitate ventilation.

Endotracheal Intubation

Intubation may produce complications related to local trauma, such as pharyngeal or glottic injury occurring during insertion of the tube, and resulting from prolonged intubation. Cuff inflation pressures greater than 25 cm H₂O may cause ischemic ulceration predisposing to tracheal stenosis. Malpositioning of the endotracheal tube into the right mainstem bronchus produces atelectasis in the other lung and overdistention of the ventilated lung. Inadvertent extubation, a potentially dangerous complication, occurs in the disoriented or uncooperative patient.

TABLE 23.3
COMPLICATIONS OF MECHANICAL VENTILATION

Related to endotracheal intubation
Pharyngeal and laryngeal injury
Malpositioning of the endotracheal tube
Inadvertent extubation
Nosocomial pneumonia
Related to positive pressure or tidal ventilation
Hemodynamic (decreased cardiac output)
Ventilator-induced lung injury:
Barotrauma (pneumothorax, pneumomediastinum)
Volutrauma (pulmonary edema)
Atelectrauma (ventilation at low lung volumes)
Biotrauma (lung injury by inflammation and mediators)
Related to sedation and neuromuscular blockade
Hemodynamic (hypotension, tachycardia)
Skin pressure necrosis
Deep venous thrombosis
Muscle weakness (atrophy, myopathy, polyneuropathy)

Nasotracheal intubation improves comfort in some patients, but there is an increased risk of bleeding during insertion of the tube, and sinusitis may occur as a result of ostial occlusion. Nasal tubes are usually narrower, with increased airways resistance. Tracheostomy may provide some protection from glottic injury, but its major benefits are improving patient comfort and secretion clearance as well as allowing oral feeding. Tracheostomy usually is reserved for patients with an expected duration of ventilation of 2–3 weeks, but the optimal timing of tracheostomy is a matter of some debate.

The presence of an endotracheal tube disrupts normal pulmonary protective mechanisms. Coughing and mucociliary transport are impeded, resulting in the retention of secretions. Although gross aspiration is prevented by a cuffed endotracheal tube, pharyngeal secretions nevertheless may enter the trachea and increase the risk for nosocomial pneumonia. Nosocomial pneumonia occurs in about 30% of patients who are mechanically ventilated, and the risk increases with the duration of ventilation (see Chapter 66).

Positive Pressure

High ventilating pressures and high tidal volumes can produce barotrauma, which is manifested as pneumothorax, pneumomediastinum, or subcutaneous emphysema. The critical pressure that likely correlates best with the propensity to develop barotrauma is the transpulmonary pressure (alveolar minus pleural pressure). This pressure usually is not measured clinically—the most commonly monitored pressures are peak inspiratory pressure and plateau pressure. If these values are relatively low, the transpulmonary

pressure is likely low, but elevated values may result from increased transpulmonary pressure as well as other causes (e.g., increased airway resistance, decreased chest-wall compliance). Preexisting acute and chronic lung disease predisposes the patient to barotrauma. The clinical picture of sudden respiratory distress associated with increased ventilator pressures should suggest the presence of a pneumothorax, particularly if associated with hemodynamic collapse. The radiographic diagnosis of a pneumothorax may be difficult if the chest radiograph is taken in the supine position. Management involves evacuation of the pneumothorax with a percutaneous chest tube. Healing of injured lung may be compromised, and a persistent bronchopleural fistula may develop.

Overdistention of the lung caused by large tidal volumes or high inflation pressures can produce lung injury. This ventilator-induced lung injury may exacerbate the pulmonary injury in patients with ARDS, where only a small portion of the lung remains aerated, and this portion is overdistended by conventional tidal volumes. Some protection against lung injury may be afforded by the use of pressure-limited ventilatory strategies. PEEP may be beneficial by reducing lung injury caused by the shear stresses associated with repeated opening and closing of alveoli.

Positive pressure ventilation may reduce cardiac output and blood pressure by impairing venous return and right-ventricular filling. This problem is aggravated by associated volume depletion and the use of sedative drugs. The effects are most marked in patients with obstructive airways disease and auto-PEEP. Management involves fluid resuscitation and a reduction in the mean airway pressure and minute ventilation.

Asynchrony

Poor interaction between the preset ventilation pattern and the patient's natural breathing rhythm can result in increased work of breathing, hypoventilation, or barotrauma. This patient-ventilator asynchrony manifests as the patient "fighting" the ventilator; it occurs more commonly with controlled ventilatory modes, high triggering thresholds, and flow capacity insufficient to meet patient requirements. The development of auto-PEEP increases the triggering threshold and the work of breathing.

Patient-ventilator asynchrony may occur if the patient begins expiration before delivery of the preset tidal volume has been completed. Slow inspiratory flow rate may be associated with increased work of breathing resulting from active inspiratory effort by the patient. Pressure-preset ventilatory modes have the advantage of allowing the flow rate to be determined by the patient's requirements. However, a rapid breathing rate in pressure-preset modes can result in a significantly reduced tidal volume.

If ventilator adjustments fail to correct patient-ventilator asynchrony, increased sedation or neuromuscular blockade may be a last resort after all physiological reasons

for the asynchrony have been excluded. These interventions eliminate the patient's contribution to ventilation and reduce airway pressures and oxygen consumption.

Sedation and Paralysis

Varying degrees of sedation are necessary during mechanical ventilation to allow for patient comfort. Neuromuscular blockade immobilizes the patient and may be necessary to reduce asynchrony and to facilitate ventilatory strategies such as inverse-ratio ventilation and permissive hypercapnia. Sedative drugs may cause vasodilation and contribute to the hypotension that commonly accompanies positive pressure ventilation. Immobilization puts patients at risk for pressure necrosis of the skin, deep venous thrombosis, retention of secretions, atrophy of the respiratory and peripheral musculature, and atelectasis. If spontaneous respiratory efforts are suppressed, inadvertent disconnection from the ventilator can have disastrous consequences; ventilator alarms require emergent response. Prolonged weakness may occur even after withdrawal of neuromuscular blockade. The depth of paralysis should be limited, and neuromuscular blockade should be withdrawn periodically to assess the neuromuscular status. Daily interruption of sedative drug infusions decreases the duration of mechanical ventilation and the length of ICU stay (8).

Strategies To Reduce Ventilation-Associated Complications

Mechanical ventilation may produce or aggravate lung injury by overdistention of alveoli and by inadequate end-expiratory pressure producing alveolar collapse. Ventilation with low tidal volumes (5–7 mL/kg) to keep plateau airway pressure less than 30 cm H₂O improves outcome, likely by reducing ventilator-induced injury (2). PEEP is protective, reducing the shear stresses associated with repeated opening and closing of alveoli. Similarly, recruitment of previously collapsed lung tissue by periodic sustained inflations (10–40 seconds) at pressures of 30–40 cm H₂O may protect from lung injury as well as improve oxygenation. Pressure-limited ventilation may result in inadequate alveolar ventilation and the development of hypercapnia; this strategy of controlled hypoventilation and permissive hypercapnia is generally well tolerated if the pH is maintained above 7.1. Adequate oxygenation must be ensured, and the patient may require sedation or neuromuscular blockade because of the effects of hypercapnia on respiratory drive.

Standard prophylactic measures often used in the ventilated patient include stress-ulcer prevention with histamine-2 antagonists (see Chapter 80) (9) and low-dosage heparin to reduce the incidence of venous thromboembolism (see Chapter 52). Attention should be paid to providing adequate, preferably enteral, nutrition at the earliest possible time (see Chapter 15).

Weaning and Extubation

Once the underlying cause for acute respiratory failure has resolved, mechanical ventilation can be discontinued. In the patient with a short duration of ventilation and rapidly reversible underlying disease, the ventilator may be disconnected after a trial of spontaneous breathing (see Figure 23.3). After prolonged ventilation, respiratory muscle strength and endurance may be reduced, and a period of progressive withdrawal or “weaning” may be necessary. Different techniques for the gradual withdrawal of ventilatory support have potential advantages and disadvantages. Timing of the removal of the endotracheal tube is important—early extubation may result in respiratory failure and necessitate reintubation, while prolonging unnecessary intubation increases costs and the risk of complications. The most important issue is therefore to have a protocol in which the patient’s ability to sustain spontaneous ventilation is assessed on a regular basis (e.g., every 24 hours).

Screening for Weaning

Before mechanical ventilation can be discontinued, both the underlying respiratory problem that required ventilation and any subsequent complications (such as nosoco-

mial pneumonia or atelectasis) must have largely resolved. The patient should be clinically stable, awake, and responsive. The respiratory neuromuscular system must be able to cope with the ventilatory work load, and oxygenation must be adequate at an inspired oxygen concentration less than 50%. Clinical measures that may be used to assess the likelihood of successful weaning include the tidal volume, respiratory rate, spontaneous minute ventilation, vital capacity, and maximum inspiratory force (Figure 23.3). Although these factors are relatively insensitive and non-specific in predicting weaning success, a low respiratory workload compatible with spontaneous respiration can be indicated by a minute ventilation less than 10 L/min and a respiratory rate of less than 25 per minute. A useful predictor of success is a brief trial of spontaneous breathing while measuring the respiratory rate:tidal volume ratio.

Before removal of the endotracheal tube, the patency of the upper airway and the patient’s ability to clear secretions must be assessed by evaluating the level of consciousness, upper-airway edema, the ability to cough, and the quantity of secretions. A *cuff-leak test* is performed by deflating the endotracheal tube cuff and briefly occluding the tube. If the patient can generate airflow around the tube, significant airway obstruction is unlikely after extubation. The inability to move air does not necessarily preclude extubation,

Step 1: Is the patient ready for weaning/extubation?

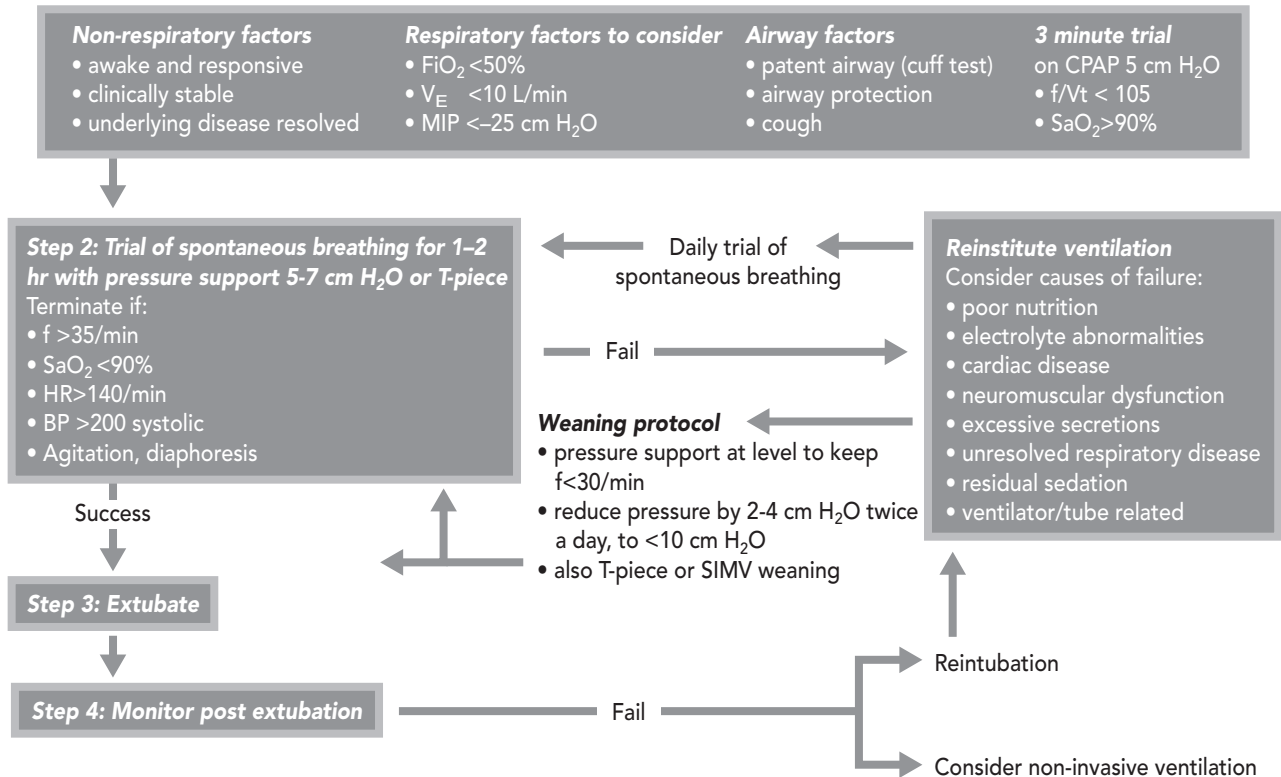

Figure 23.3 Algorithm for weaning and discontinuing mechanical ventilation. *BP*, blood pressure; *CPAP*, continuous positive airway pressure; *f*, respiratory frequency (rate); *FiO₂*, inspired oxygen fraction; *HR*, heart rate; *MIP*, maximal inspiratory pressure; *S_aO₂*, systemic arterial oxygen saturation; *SIMV*, synchronized intermittent mandatory ventilation; *VE*, minute ventilation; *Vt*, tidal volume.

particularly if the endotracheal tube is a large size; however, in such patients, precautions such as preoxygenation and ensuring that personnel and equipment for managing a difficult airway are available must be taken prior to extubation. If mechanical ventilation was initiated to provide an adequate airway because airway patency was compromised, the preexisting airway problem must be alleviated prior to extubation.

For the patient who fails to wean, various factors must be considered. Impaired cardiovascular performance resulting from ischemia or ventricular dysfunction may affect oxygen supply to respiratory muscles or result in pulmonary edema when positive intrathoracic pressure is removed. The presence of electrolyte disturbances (e.g., hypophosphatemia) and poor nutritional status may affect the ability to sustain spontaneous breathing. Residual respiratory disease with excessive secretions and persistent effects of sedation must be considered.

Techniques of Weaning

Following brief ventilation for a reversible condition, ventilatory support may be withdrawn after a trial of spontaneous respiration, which can be performed as a 1- to 2-hour trial on a T-piece or low pressure support (5–10 cm H₂O) while monitoring for signs of fatigue (Figure 23.3). With prolonged ventilation, a period of gradual weaning may be necessary, although daily assessment with a spontaneous breathing trial may suffice. The oxygen concentration often is reduced before weaning from the ventilator is considered; the usual approach is a gradual reduction of the inspired oxygen concentration to a level that can be delivered easily by face mask (e.g., less than 50%). PEEP usually is reduced to a level of about 5 cm H₂O in decrements of 2–3 cm H₂O, while oxygen saturation is monitored. The patient then is weaned gradually from ventilatory support, with monitoring for signs of ventilatory distress or fatigue, such as agitation, tachypnea, diaphoresis, or respiratory acidosis. In recent studies comparing various methods of weaning, weaning failure was less common with a shorter weaning duration using a daily trial of spontaneous breathing than it was with gradual reduction in ventilatory support (10).

As noted above, the critical care unit should have a pre-defined protocol for daily assessment of spontaneous breathing trials, which can guide the decision of whether to extubate or continue ventilation for another 24 hours (10). Trials in which the patient breathes spontaneously with low-pressure ventilatory support (5–10 cm H₂O) have proved as effective as trials of unaided breathing with a T-piece and have the advantage of overcoming the ventilator-induced work of breathing related to circuit and valve resistance.

Weaning using the T-piece involves gradually increasing periods of spontaneous breathing (e.g., 30 minutes, 60 minutes, etc.), ensuring that the patient does not de-

velop fatigue. Adequate rest periods on ventilatory support between trials of spontaneous breathing are essential. There is little evidence in the literature to guide how long the patient should breathe on the T-piece and how long he or she should rest in the intervening period. The aim is to increase respiratory muscle strength and endurance until the patient tolerates spontaneous breathing without assistance. The T-piece provides no support to overcome ventilator circuit resistance.

Pressure-support weaning is performed by gradually reducing the level of pressure delivered to allow the patient to assume an increasing amount of respiratory work. Pressure support is reduced by 2 cm H₂O several times daily, assessing the patient for signs of fatigue. Once the pressure support is reduced to a level that overcomes the ventilator-induced work of breathing (circuit and valve resistance) but provides no additional support, extubation is considered. This level of pressure support, which varies between about 5 and 12 cm H₂O depending on the ventilator and endotracheal tube size, is difficult to determine in the individual patient.

An alternative weaning approach has used SIMV and gradually reduces the ventilator rate, with the patient increasing the amount of respiratory work performed. However, the SIMV approach to weaning has been documented to be less effective than the use of a T-piece or of pressure-support weaning.

Terminal Weaning

An increasingly common occurrence in the intensive care unit is the decision to withdraw life support. If aggressive life-extending measures have failed, the management goal changes to a comfort-oriented approach that includes withdrawing invasive interventions for which the burdens outweigh the comfort benefits (see Chapters 17 and 19). Compassionate withdrawal of ventilatory support, which is an integral part of this approach, is often more difficult to accept than the withdrawal of other support measures. In this regard, a common and acceptable practice is the discontinuation of other therapies, with the expectation that the patient will die on ventilatory support. Although this approach is effective if the patient is dependent on high-dosage inotropic support, it is important that mechanical ventilation not be continued unnecessarily so the dying process is not inappropriately prolonged.

Terminal withdrawal of mechanical ventilation may be performed rapidly by removing the endotracheal tube or by a more gradual weaning process during which the patient may die with the endotracheal tube in place. Each method has potential advantages and disadvantages, as well as strong proponents and opponents. Of paramount importance is that comfort of the patient be ensured and the family be made aware of the process and expected outcome. Often the decision depends on the perceived comfort of the patient and expressed concerns of the family. Extubation

has the advantage of not prolonging the process of withdrawal, but it may be interpreted by some families and staff as being an active intervention with the intent to end the patient's life. Extubation should be preceded by the administration of adequate sedation (usually with benzodiazepines) and opiate analgesics to relieve any sensation of dyspnea. The anticipated outcome should be explained to the family, particularly if demise is expected within minutes, although prediction of the duration of survival is notoriously difficult.

Gradual withdrawal of support may be more comfortable and acceptable but also may prolong the dying process unnecessarily. This approach avoids the very active intervention of extubation. The inspired oxygen saturation may be reduced rapidly to that of room air; ventilatory support (pressure or tidal volume) may be reduced to the minimum; or a T-piece may be used. Adequate sedation and analgesia must be provided to ensure comfort and relief from dyspnea.

CONCLUSIONS

Mechanical ventilation is a necessary intervention to sustain life in the patient with respiratory failure, or to take control of the airway and breathing in the patient with other organ dysfunction. As with any medical intervention, it carries adverse effects, which are related to the presence of an endotracheal tube, the level of pressure delivered, the inspired oxygen concentration, and the duration of ventilatory support. Furthermore, the ventilated patient is at risk for sudden, unexpected catastrophic events such as disconnection from the ventilator or airway obstruction. Close monitoring of even the most stable patient is essential, and the patient should be assessed on a regular basis as to whether continued ventilation is necessary and appropriate.

KEY POINTS

- Correct timing is essential in instituting mechanical ventilation: Too soon or too late exposes the patient to unnecessary hazards.
- Consider noninvasive ventilation in the cooperative patient with an expected short duration of ventilation (e.g., pulmonary edema, exacerbation of chronic obstructive pulmonary disease).

- Prevent ventilator-induced lung injury by avoiding excessive inflation pressures and providing adequate end-expiratory pressure.
- Avoid prolonging ventilation unnecessarily: Assess daily for the ability to wean and discontinue ventilation.

Mark R. Tonelli Leonard D. Hudson

Any discussion of acute respiratory failure as a clinical entity must begin with the recognition that the disorder varies significantly in presentation and has multiple causes (Table 24.1). Decisions regarding appropriate treatments cannot be made without evaluation of both severity and etiology.

Defining acute respiratory failure has been problematic. Physiologically, respiratory failure can be said to occur if either ventilation or oxygenation is inadequate for optimal function of tissue, organs, or the organism. In this sense, the diagnosis of acute respiratory failure relies on arterial blood-gas measurements demonstrating hypercapnia with acidemia or profound hypoxemia. Clinically, however, the diagnosis of respiratory failure generally is suspected prior to obtaining arterial blood-gas measurements. For example, the patient overdosed on heroin with a respiratory rate of 6 per minute or the tight asthmatic with tachypnea both may be presumed to have an acute change in respiratory status. In such situations, respiratory compromise is clearly present, though respiratory failure is not demonstrated until arterial blood gases are analyzed.

The traditional focus on respiratory physiology and mechanistic distinctions based on classes of gas-exchange abnormalities often obscures more clinically relevant aspects of acute respiratory failure. Although an understanding of pulmonary physiology is important in the assessment of respiratory failure, the clinical evaluation generally begins prior to the measurement of arterial blood gases. Respiratory compromise, evident by physical examination, represents the starting point of evaluation and treatment.

Respiratory compromise may result from intrinsic lung disease, but it also accompanies neurologic injury, upper-airway disorders, heart failure, vascular disease, renal failure, metabolic derangement, and systemic infection or inflammation. Respiratory distress may be a presenting complaint or may develop during the course of another ill-

ness. For example, in *acute respiratory distress syndrome* (ARDS), hypoxemic respiratory failure usually develops in patients admitted with another life-threatening illness or injury. However, ARDS sometimes exists on presentation, and virtually any cause of acute respiratory failure can complicate hospitalization. Outcomes research on specific causes of respiratory compromise, such as asthma, chronic obstructive pulmonary disease (COPD), community-acquired pneumonia, pulmonary vascular disease, and heart failure, can guide treatment for those entities.

ACUTE RESPIRATORY COMPROMISE PRESENTING ON ADMISSION

Clinical Presentation

Respiratory compromise should be suspected in any patient presenting complaints of shortness of breath or signs of tachypnea or labored breathing, and it also must be considered in other clinical situations. Neurologic injury or profound central nervous system depression may result in inadequate ventilation as a result of impaired drive or upper-airway compromise without a sensation of dyspnea. Such patients generally are unresponsive and without tachypnea on presentation. Conversely, the patient with inadequate ventilation secondary to other causes may develop neurologic symptoms including agitation, confusion, or depressed level of consciousness.

In the dyspneic and tachypneic patient, other clinical manifestations are dependent on the cause of respiratory compromise. Stridor indicates upper-airway obstruction; audible expiratory wheezing suggests airflow obstruction; and a rapid, shallow breathing pattern often accompanies a restrictive process. The patient with impending respiratory

failure is usually anxious; somnolence or lethargy should alert the clinician to the possibility that assisted ventilation may be required emergently. It is important to remember that normal oxygen saturations may be present in the setting of significantly impaired ventilation, especially if the patient is breathing supplemental oxygen.

The physician's first task is to ensure that the patient's airway is patent and that breathing is adequate to allow for further evaluation. Supplemental oxygen should be provided to ensure adequate oxygen saturation. The resources necessary to perform rapid endotracheal intubation and assisted ventilation should be available readily (see Chapter 23).

Differential Diagnosis and Initial Evaluation

History

Appropriate therapy cannot be administered without an accurate determination of the cause of respiratory compromise. The medical history should focus on both the pertinent aspects of the present illness, including rapidity of onset and associated symptoms, and the past medical history, especially the presence of previous episodes of airflow ob-

struction or heart failure. Acute presentations accompanied by fever, cough, or sputum production suggest infectious etiologies. Sudden onset of dyspnea without systemic symptoms should raise the possibility of airway obstruction, cardiac disease, and pulmonary vascular occlusion. Complaints of chronic and progressive dyspnea with acute worsening most often represent an exacerbation of an underlying pulmonary illness, such as COPD or asthma.

Physical Examination

Initial physical examination should be aimed at both elucidating a cause and assessing the severity of respiratory compromise. Altered mental status without an alternative cause suggests severe respiratory compromise. In patients with airflow obstruction, pulsus paradoxus greater than 20 mm Hg indicates severe obstruction. A respiratory rate greater than 35 per minute in an adult suggests severe respiratory compromise. Estimating the tidal volume by observation and auscultation is an important, but imperfect, measure of severity. Wheezing on auscultation (often both inspiratory and expiratory) usually accompanies severe airflow obstruction, but *wheezing may become inaudible if tidal volume drops low enough*. Rales on examination may accompany heart failure, pneumonia, interstitial lung disease, or diffuse lung injury. Consolidative changes may accompany pneumonia or atelectasis. Normal results of lung examination do not exclude respiratory failure and may accompany some infections (e.g., *Pneumocystis jirovecii* pneumonia), diffuse lung injury, metabolic derangement, and disorders of central respiratory drive.

Laboratory Evaluation

Arterial blood-gas measurement remains the most important laboratory test for determining both the presence and severity of respiratory failure. The hallmark of acute ventilatory failure is the presence of hypercapnia (arterial partial pressure of carbon dioxide [$P_a\text{CO}_2$] >45 mm Hg) along with acidemia (pH <7.35). In acute ventilatory failure, metabolic compensation for hypercapnia has not yet taken place, and the rise in carbon dioxide is directly reflected in a falling pH. In such situations, the base excess remains near zero, and the serum bicarbonate level is close to normal (see Chapter 105). If there has been some time for compensation to occur or if there is an underlying metabolic alkalosis, the bicarbonate level will be high, the base excess will be greater than 2, and the pH will tend toward normal. The presence of a metabolic acidosis (with a base excess of ≤ -2) in the setting of hypercapnia is an ominous sign and should prompt consideration of mechanical ventilation.

Hypoxemia may accompany hypercapnic respiratory failure or may be present if ventilation is adequate. Hypoxemia generally is caused by hypoventilation, by ventilation-perfusion mismatching, or by shunting, often in combination. Low levels (<6 L/min) of supplemental oxygen

usually correct hypoxemia caused by hypoventilation or ventilation–perfusion mismatch, but significant shunting results in much higher oxygen requirements. Shunting occurs if blood flow in the pulmonary circulation does not pass through areas of ventilated lung en route to the left atrium. In virtually any type of lung disease, large areas of alveolar filling or collapse, radiographically evidenced by increased opacification, produce some degree of shunt. The normal physiologic response of hypoxic vasoconstriction acts to minimize shunting. Clinicians should be aware that vasodilators, including nitrates, can overcome this adaptive response and worsen hypoxemia.

Hypoxemia alone is generally not an indication for mechanical ventilation, as 100% oxygen can be delivered effectively to the spontaneously ventilating patient. In some cases of acute lung injury, however, profound hypoxemia cannot be corrected with supplemental oxygen. In such cases, intubation and mechanical ventilation (see Chapter 23) are indicated to provide positive end-expiratory pressure and other ventilator strategies designed to improve oxygenation.

In the setting of acute-on-chronic respiratory failure, the administration of supplemental oxygen often is accompanied by a rise in $P_a\text{CO}_2$. Although generally attributed to a decreased respiratory drive, the pathophysiology of this phenomenon is more complex (see Chapter 55). For the clinician, *fear of a rising $P_a\text{CO}_2$ should never preclude the administration of enough supplemental oxygen to ensure adequate oxygen delivery*. In general, a target range of 88% to 90% oxygen saturation usually allows for adequate oxygen delivery while minimizing the potential increase in $P_a\text{CO}_2$.

Rapid measurement of B-type natriuretic peptide (BNP) appears to be a useful biochemical adjunct to clinical assessment in determining the cause of acute dyspnea in patients presenting emergently (1). An elevated BNP level is seen almost universally in patients with significant left heart failure; however it is important for clinicians to realize that BNP is often chronically elevated in patients with cor pulmonale and can also rise with acute right ventricular failure, such as might accompany pulmonary embolism. Thus, although BNP is a sensitive indicator of heart failure, it is nonspecific. A thorough clinical assessment for alternative or additional causes of respiratory failure must still be undertaken even in the presence of an elevated BNP.

The chest radiograph may be particularly helpful in determining the cause of respiratory failure (Figure 24.1). A chest radiograph without parenchymal infiltrates may accompany respiratory failure secondary to respiratory depression, neuromuscular weakness, upper-airway obstruction, pulmonary vascular disease, and airflow obstruction. Respiratory depression and neuromuscular weakness usually are associated with low lung volumes determined radiographically; airflow obstruction caused by COPD or asthma often presents with signs of hyperinflation, including large lung volumes and hyperlucency. Metabolic disturbances such as profound metabolic acidosis and carbon monoxide poisoning present with a normal chest radio-

graph. Pneumonia, particularly *P. jirovecii* pneumonia, may occasionally be radiographically inapparent early in its course. The chest radiograph is diagnostic in cases of respiratory compromise caused by a large pleural effusion or a tension pneumothorax.

Focal infiltrates seen on the chest radiograph suggest bacterial or fungal pneumonia, aspiration, atelectasis, or pulmonary hemorrhage or infarction. Unusual causes of respiratory failure with focal infiltrates include bronchiolitis obliterans with organizing pneumonia (BOOP), vasculitis such as Wegener's granulomatosis, and alveolar proteinosis. Location and character of the infiltrates may suggest specific causes, but radiographic signs are rarely sensitive or specific.

Heart failure generally presents with a diffuse edema pattern with hilar predominance of infiltrates; however, this pattern is nonspecific and can be seen with ARDS and with bacterial, *P. jirovecii*, or viral pneumonia. Respiratory compromise secondary to collagen vascular disease, drug toxicity, and hypersensitivity pneumonitis also generally presents with diffuse infiltrates. In addition, acute eosinophilic pneumonia, acute interstitial pneumonitis, and the fat emboli syndrome all may cause a radiographic pattern of pulmonary edema and hypoxemic respiratory failure indistinguishable from ARDS (Table 24.2).

INDICATIONS FOR HOSPITAL AND INTENSIVE CARE UNIT ADMISSION

After appropriate diagnostic evaluation, admission should be considered if the cause of respiratory compromise remains unclear or if the patient remains refractory to appropriate treatment. New, persistent hypoxemia is generally an indication for hospital admission. Specific criteria and decision rules for admission with asthma or community-acquired pneumonia have been proposed (see Chapters 56 and 65). The need for mechanical ventilation is obviously an absolute indication for admission to the ICU, and this level of careful monitoring is also appropriate for patients in whom noninvasive ventilation has been instituted (see Chapter 23). ICU admission also should be considered for patients at high risk for requiring mechanical ventilation, especially those with increasing oxygen requirements or those requiring nearly continuous nursing or respiratory care, such as for assistance in clearing pulmonary secretions.

INITIAL THERAPIES

Initial therapy for respiratory compromise must be aimed at the underlying condition. The general question in all cases of respiratory compromise is whether invasive mechanical ventilation is required. The quality of explicit data available to aid clinicians in this judgment is poor. Nonetheless, certain criteria and patterns are helpful in determining whether a patient requires mechanical support.

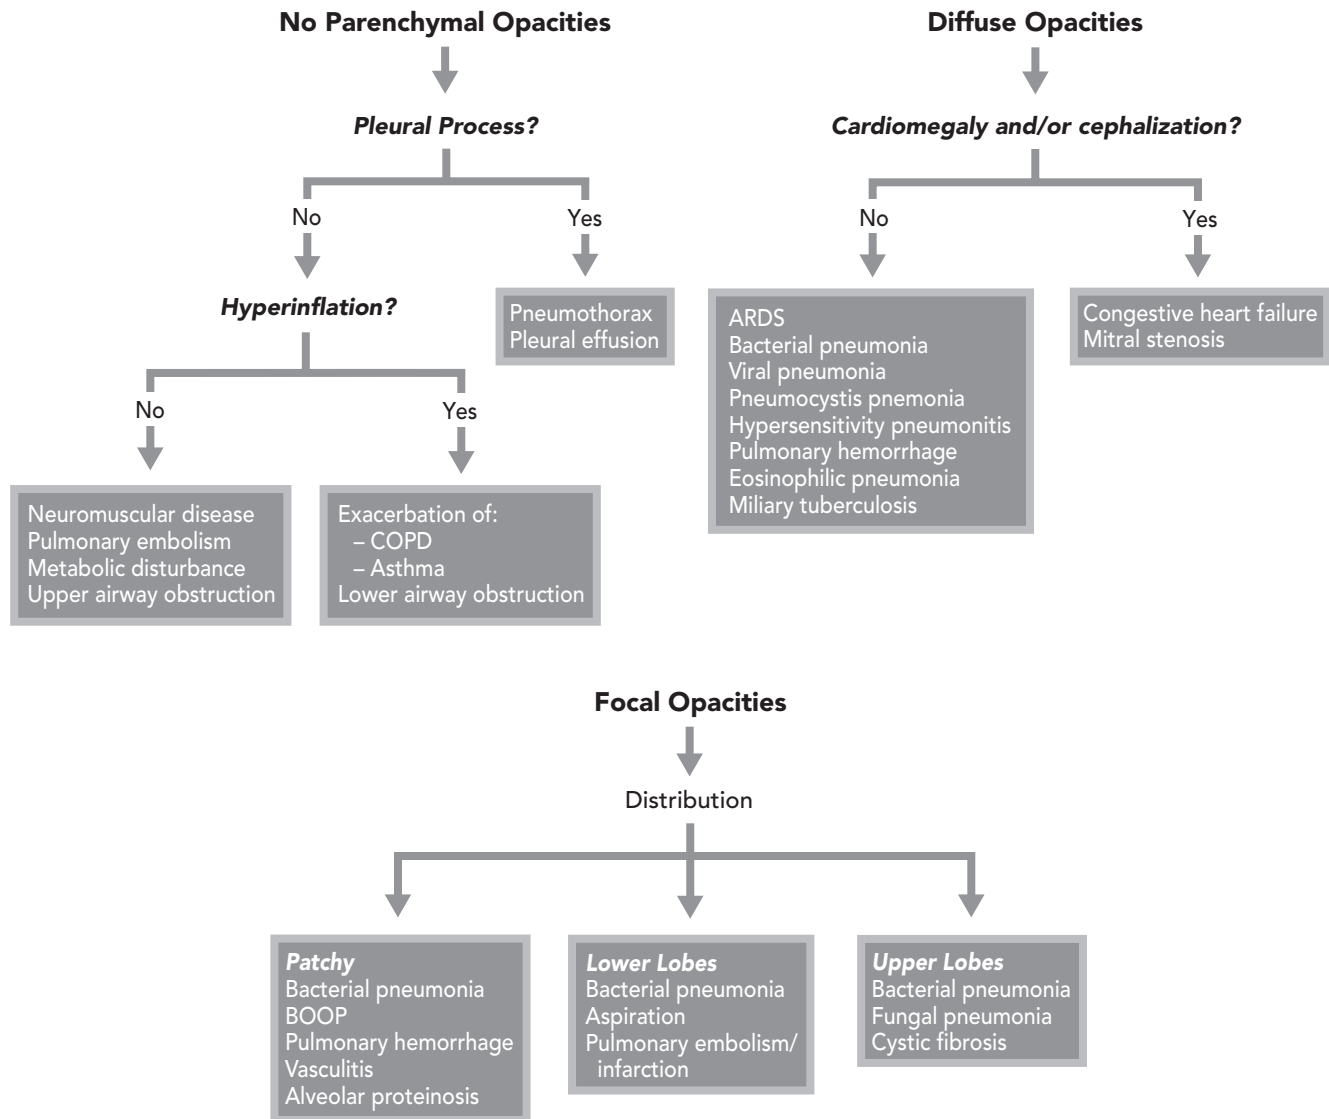

Figure 24.1 Common radiographic manifestations of causes of acute respiratory failure. However, there may be substantial overlap and variation among these patterns. ARDS, acute respiratory distress syndrome; BOOP, bronchiolitis obliterans with organizing pneumonia; COPD, chronic obstructive pulmonary disease.

Indications for endotracheal intubation, with or without mechanical ventilation, include upper-airway injury or inflammation, (e.g., trauma and burns, laryngeal edema, and pharyngeal swelling); and airway compromise, often in the setting of neurologic injury or profound central nervous system depression with loss of protective reflexes, including gag and cough. A patent airway should be guaranteed early, even before the demonstration of attendant hypercapnia. Because intubation is often difficult in patients with anatomic upper-airway obstruction, the assistance of an anesthesiologist or otolaryngologist well trained in airway management is helpful. Intubation over a fiberoptic bronchoscope may also be considered.

Determining whether mechanical ventilation is required in the patient with an exacerbation of airflow obstruction remains problematic. Based on several case series, there is a

concern that mechanical ventilation may worsen outcomes independent of severity of disease, most likely secondary to the hemodynamic consequences of positive pressure ventilation. Hypotension developing after the institution of positive pressure ventilation in the patient with severe airflow obstruction is usually secondary to an intrinsic positive end-expiratory pressure (PEEP) and, if not recognized, may lead to cardiovascular collapse and death (see Chapter 23). Endotracheal intubation also may cause or exacerbate bronchospasm. Generally, it is appropriate to attempt to reverse airflow obstruction aggressively without instituting mechanical ventilation. Because underlying chronic respiratory failure may precede acute decompensation, there is no single level of $P_a\text{CO}_2$ that necessitates mechanical ventilation; the serum pH is generally a better marker of the acute severity of respiratory decompensation. However, se-

rial arterial blood-gas measurements revealing progressive hypercapnia and worsening acidosis are highly predictive of impending respiratory collapse. Physical changes are generally less reliable, as somnolence, decreasing respiratory rate, or a decrease in wheezing may signal either worsening hypercapnia or a positive response to therapy. In the cooperative patient with airflow obstruction, serial measurement of the peak expiratory flow rate is a reasonable noninvasive approach to assessing the effectiveness of therapy (see Chapters 55 and 56).

In the patient with hypoxemia, mechanical ventilation is absolutely required only if 100% inspired oxygen concentration is inadequate to maintain oxygenation (saturation $>85\%$) and there is reason to believe that certain features of positive pressure ventilation, such as PEEP, will improve saturations. For example, abnormal oxygenation in diffuse lung injury is usually responsive to PEEP. If oxygenation is clearly and rapidly worsening in the face of diffuse pulmonary infiltrates, intubation and mechanical ventilation should be considered early in the course, as waiting until saturations are inadequate on 100% oxygen significantly increases the difficulty and risk of intubation. By comparison, large intrapulmonary or intracardiac shunts may result in severe hypoxemia that is minimally responsive to high-flow oxygen but also is unlikely to be improved, and in fact may be worsened, with PEEP.

Given the inherent risks, discomfort, and costs of mechanical ventilation, noninvasive ventilation techniques have become increasingly common over the past decade (see Chapter 23). Noninvasive ventilation may include inspiratory assistance (analogous to pressure-support ventilation), continuous positive airway pressure, or both. Inspiratory assistance is particularly effective if fatigue or neuromuscular weakness is causing or complicating respi-

ratory compromise. Continuous positive airway pressure provides “distending” pressure at end-exhalation, and may both improve ventilation-perfusion matching and increase lung volumes throughout the respiratory cycle, thereby decreasing airway resistance.

There is now good evidence to support the use of noninvasive ventilation for acute exacerbations of COPD, pulmonary edema, and pulmonary contusions (2). Additionally, some reports suggest that this technique may be efficacious in postoperative respiratory insufficiency and acute exacerbations of cystic fibrosis. Weaning mechanically ventilated patients to noninvasive ventilation appears to decrease the incidence of ventilator-associated pneumonia (see Chapter 66) (3). On the other hand, noninvasive mechanical ventilation is not effective in acute hypoxemic respiratory failure (i.e., impending ARDS).

INDICATIONS FOR EARLY CONSULTATION

Because appropriate therapy cannot be provided in the absence of an accurate diagnosis, respiratory failure of unclear cause is an indication for early pulmonary consultation. Respiratory failure associated with diffuse infiltrates seen on chest radiograph without evidence of heart failure has a wide differential diagnosis. Early bronchoscopy may be indicated to exclude viral pneumonitis, *P. jirovecii* pneumonia, pulmonary hemorrhage, hypersensitivity pneumonitis, and acute eosinophilic pneumonia. If bronchoscopy is unrevealing, open lung biopsy is indicated in specific situations (Table 24.3).

In the mechanically ventilated patient, hemodynamic instability may be secondary to ventilator effects, such as intrinsic PEEP and barotrauma. If the treating physician does not have the expertise to detect and deal with these

TABLE 24.3
INDICATIONS FOR BRONCHOSCOPY AND
OPEN LUNG BIOPSY IN PATIENTS WITH
ACUTE RESPIRATORY FAILURE

Mucus plugging/lobar collapse not responsive to chest physiotherapy
Hemoptysis
With diffuse infiltrates and:
Immunocompromise
No risk factor for acute respiratory distress syndrome
Consider open lung biopsy in cases in which fiberoptic bronchoscopy is unrevealing

complications directly, then emergent consultation is indicated. Likewise, persistent hypoxemia on high fractions of inspired oxygen (>80%) or high static pressures (>35 cm H₂O) should precipitate a pulmonary consultation, as advanced ventilator strategies likely are required.

ISSUES DURING THE COURSE OF HOSPITALIZATION

The course of acute respiratory failure depends primarily on the underlying etiology. However, several general observations can be made regarding respiratory failure.

If the patient with respiratory compromise fails to improve as expected, evaluation should focus on the likelihood that the presumptive cause of respiratory collapse is in error. For example, the patient with presumed bacterial pneumonia who fails to respond to antibiotics over 72 hours requires a careful evaluation for other possible causes, both infectious and noninfectious, of hypoxemia and a focal infiltrate. Pulmonary consultation, both for an expanded differential diagnosis and for possible bronchoscopy, is generally indicated.

Respiratory failure may also fail to respond to seemingly appropriate therapy because of the development of an additional cause of respiratory compromise. ARDS, for instance, may occur in a significant percentage of patients with bacterial pneumonia and lead to a protracted course of mechanical ventilation. Likewise, both pulmonary embolism and nosocomial pneumonia may complicate the hospital course of any patient.

The conclusion that a protracted course of respiratory failure represents the inexorable progression of a chronic pulmonary disease (such as COPD or cystic fibrosis) is generally a process of excluding other diagnoses. Knowledge of the natural history and outcomes of mechanical ventilation for specific disease states is imperative. Most patients who require mechanical ventilation for even severe COPD can be weaned successfully (4); however the prognosis of patients who require mechanical ventilation for cystic fibrosis is very poor. Respiratory failure in association with hematologic malignancy, and in particular in the course of bone-marrow transplantation, portends a very poor prognosis. Outcomes for many other causes of respiratory failure are less predictable and mortality estimates are often moving targets.

DISCHARGE ISSUES

Guidelines and disease-management strategies have been proposed for specific causes of respiratory failure, including asthma, COPD, and community-acquired pneumonia. In general, discharge should be considered when ventilatory status has returned to near-baseline. Persistent hypoxemia alone does not preclude discharge, as home oxygen therapy is widely available. An oxygen saturation of less than 88%

or an arterial partial pressure of oxygen less than 55 mm Hg, either at rest, nocturnally, or with exercise, is an indication for outpatient oxygen therapy. For all patients with an acute illness, such as pneumonia, and even those with an exacerbation of an underlying illness, such as emphysema, reassessment of oxygen requirements should take place on a regular basis after discharge. Half the patients who require the initiation of oxygen therapy at the time of hospital discharge after an exacerbation of COPD no longer meet criteria for oxygen therapy 1 month later.

Likewise, the need for chest physiotherapy or noninvasive ventilatory assistance does not preclude discharge to home. Multiple devices and techniques are available to enable patients to mobilize secretions, and collaboration with a pulmonologist, nurse, or respiratory therapist familiar with these techniques can facilitate early and safe discharge. Similarly, a variety of ventilatory assist devices, including noninvasive portable ventilators, may allow the patient with chronic respiratory failure, especially that resulting from neuromuscular weakness, to function well at home.

Discharge for patients with prolonged respiratory failure has changed over the past several years. Previously, most mechanically ventilated patients with ongoing medical problems were relegated to the ICUs of acute care hospitals. Largely because of anomalies in Medicare reimbursement, however, facilities specializing in the care of patients undergoing long-term ventilation and other chronically, critically ill patients have arisen in many parts of the United States. Optimally, these facilities provide respiratory care and nursing services similar to ICUs, with an additional emphasis on rehabilitation and the psychological and social needs of patients and families. Quality remains variable, however, and recent revisions in Medicare reimbursement have put economic strains on these institutions. Still, they remain a viable alternative to lengthy stays in the ICU of an acute care hospital.

ACUTE RESPIRATORY FAILURE PRESENTING DURING HOSPITALIZATION

Respiratory compromise may develop in the hospitalized patient because of any of the factors that lead to an initial outpatient presentation with acute respiratory failure. A few causes, however, account for the majority of such cases (Table 24.4). For example, the immobility that often accompanies illness puts patients at significant risk for pulmonary thromboembolic disease, which should be an initial consideration in any inpatient who develops dyspnea, tachypnea, chest pain, or hypoxemia (see Chapter 53).

Inpatients are also at increased risk for developing aspiration, which may precipitate respiratory failure directly or through the development of ARDS or nosocomial pneumonia. The risk factors for aspiration include impaired consciousness, swallowing disorders, and upper-airway in-

strumentation, including nasogastric and endotracheal tubes. The intubated patient runs a 1%–3% risk per day of developing ventilator-associated pneumonia (see Chapter 66), which is associated with an increased mortality rate and increased hospital costs. Several maneuvers have been suggested to minimize colonization, aspiration, and ventilator-associated pneumonia, including semirecumbent positioning, early enteral feeding, and the use of sucralfate rather than H₂ antagonists for ulcer prophylaxis, but the available studies have been small and not always well controlled. Various devices that provide suctioning of oropharyngeal contents above the cuff of the endotracheal tube show promise but have not been tested rigorously. Interestingly, frequent changing of the ventilator circuits appears to increase the risk of ventilator-associated pneumonia, and respiratory care protocols that require routine changes more often than every 2 weeks should be reexamined.

A number of iatrogenic causes of respiratory compromise must be considered in hospitalized patients. Opiates are profound respiratory depressants, and injudicious use may lead to respiratory arrest. Laryngeal edema is a rare but life-threatening complication of multiple medications, particularly angiotensin-converting enzyme inhibitors. Anaphylaxis also may be caused by many medications (see Chapter 120). Hypersensitivity pneumonitis caused by medications can develop over several days and result in respiratory compromise and diffuse pulmonary infiltrates.

ARDS is a frequent cause of acute respiratory failure in patients admitted with other serious illnesses or injuries. ARDS represents a diffuse and nonspecific lung-injury pattern, usually developing under the conditions that precipitate a systemic inflammatory response (Table 24.5).

ARDS generally develops within 24–72 hours of the onset of the inciting illness or injury. The clinical presentation is increasing respiratory distress with tachypnea and hypoxemia. The chest radiograph reveals diffuse pulmonary infiltrates, consistent with pulmonary edema, so the presumptive diagnosis of ARDS cannot be made in the setting

of volume overload or left heart failure. Measurement of the pulmonary capillary wedge pressure (see Chapter 25) can help distinguish ARDS from volume overload and cardiogenic pulmonary edema. In patients requiring mechanical ventilation, lung compliance is usually low (<30 mL/cm H₂O) and minute ventilation is usually significantly elevated (>15 L) in ARDS, although these findings are not necessary to make the diagnosis.

Preventing ARDS in individuals at risk has proven elusive, and the management of patients with ARDS remains primarily supportive. A large, multi-centered randomized trial comparing mechanical ventilation with low tidal volumes (6 mL/kg of ideal body weight) versus high tidal volumes (12 mL/kg of ideal body weight) demonstrated a significant (approximately 25%) reduction in mortality in ARDS patients with the low tidal volume strategy (5). Specific therapies to aid in lung healing or function, including exogenous surfactant, inhaled nitric oxide, and the early use of systemic corticosteroids, have not been demonstrated to decrease the mortality rate. Nonetheless, the survival rate for patients with ARDS has improved significantly over the past decade and is currently in the range of 60%–65% (6). The vast majority of patients with ARDS who do not survive die either of their presenting illnesses or after developing sepsis or multiorgan failure. The initial severity of hypoxemia does not predict outcome and, somewhat counterintuitively, the longer a patient remains on mechanical ventilation the higher the survival rate. Thus, the care of the patient with ARDS is aimed primarily at avoiding complications, particularly infection and additional organ failure. Barotrauma is a common complication of ARDS, but the development of pneumothorax or other types of air leaks does not appear to affect the mortality rate significantly.

In general, the long-term prognosis for survivors of ARDS is good. Although initial pulmonary-function testing is likely to reveal some evidence of restrictive physiology (a reduced total lung capacity), recovery of pulmonary function is usually complete, or nearly complete, 6 months after hospital

discharge. However, exercise capacity (measured by a 6 minute walk) and health-related quality of life frequently remain diminished for at least 1 year after ICU discharge (7, 8). It has been suggested that the institution of corticosteroids late in the course of severe, persistent ARDS may improve outcome (9) and ameliorate the development of irreversible fibrosis, but this therapy may also increase the likelihood and severity of neuromuscular sequelae, such as critical-illness polyneuropathy and myopathy. We do not presently recommend routine use of corticosteroids in late ARDS.

COST CONSIDERATION AND RESOURCE USE

Although data regarding the costs of acute respiratory failure are limited, several considerations warrant mention. First, the use of noninvasive rather than standard endotracheal mechanical ventilation may not have a profound impact on costs. Because the vast majority of patients on noninvasive positive pressure ventilation (NIPPV) require ICU monitoring, at least initially, physician, nursing, and respiratory care costs are high. Secondly, although patients with persistent respiratory failure (>7 days on mechanical ventilation) represent less than 10% of all ICU patients, they account for one-quarter to one-third of total ICU costs (10). Thus, the prevention of respiratory failure, particularly nosocomial pneumonia and ARDS, will provide significant cost savings.

Considerable interest in weaning from mechanical ventilation also may be driven by cost concerns, although multiple studies suggest that the ventilator mode used during weaning is nearly irrelevant for the vast majority of patients, and that physicians' failure to recognize that patients can be liberated safely from mechanical ventilation is the primary cause of unnecessary days of mechanical ventilation (see Chapter 23). Daily weaning parameters or T-piece trials, undertaken by respiratory therapists according to protocol, on all patients with moderate amounts of supplemental oxygen (<50%), low PEEP \leq 5 cm H₂O, and reasonable minute-ventilation requirements (<12 L) may prove to be cost-effective. Weaning certain ventilator-dependent COPD patients to noninvasive ventilation decreases the incidence of ventilator-associated pneumonia and reduces length of stay in the ICU (3). This technique may be applicable to other causes of respiratory failure as well.

KEY POINTS

- Respiratory compromise has myriad causes, and appropriate therapy depends upon the accurate and timely determination of cause and severity.

- Empiric therapy for the most likely cause of respiratory compromise in an individual patient is generally appropriate, but failure to respond as expected should precipitate an evaluation for alternative or contributory causes.
- The incidence of respiratory failure developing in hospitalized patients can be reduced with specific interventions designed to prevent deep venous thrombosis, aspiration, and ventilator-associated pneumonia.
- The survival rate in ARDS is improving, though care remains largely supportive. Lower tidal volumes improve outcome compared with traditional tidal volumes. The avoidance and prompt treatment of complications, particularly secondary infections and additional organ failure, are of paramount importance.

Hypotension, Shock, and Multiple Organ Failure

Bradley D. Freeman **Charles Natanson**

INTRODUCTION

Hypotension, shock, and multiorgan dysfunction are commonly encountered and potentially lethal clinical problems. This chapter reviews the classification and differential diagnosis of shock, the approach to management of the patient with hemodynamic instability, and recent advances that may decrease morbidity and improve survival in these critically ill patients.

DEFINITION AND CLASSIFICATION OF SHOCK

Though a number of definitions for *shock* are commonly used, the most practical describes an acute syndrome initiated by ineffective perfusion and resulting in severe organ dysfunction. Many conditions can result in shock (Table 25.1). In a given patient, the cause may be apparent (e.g., hypotension in a patient with massive upper-gastrointestinal hemorrhage), unclear (e.g., patients with pulmonary embolism, cardiac tamponade, or adrenal insufficiency), or attributable to multiple factors (e.g., a patient with multiple trauma who develops myocardial ischemia and severe infection). It is useful to classify shock as either *hypovolemic*, *cardiogenic*, *extracardiac obstructive*, or *distributive* (Figure 25.1).

Hypovolemic (or *oligemic*) *shock* can occur by any mechanism that decreases intravascular volume, including hemorrhage or fluid loss from the gastrointestinal tract (diar-

rhea, vomiting), urinary tract (diabetic ketoacidosis, diabetes insipidus, excessive diuretic therapy), or skin (burns, extensive desquamation) or into a “third” space (e.g., peritonitis, pancreatitis, postsurgical fluxes). In early stages, compensatory increases in heart rate, peripheral vascular resistance, and myocardial contractility may preserve cardiac and cerebral perfusion. Ultimately, however, the typical hemodynamic picture of shock develops, and is characterized by decreases in mean arterial pressure, stroke volume, and cardiac output (Table 25.2).

Cardiogenic shock is most commonly a consequence of myocardial ischemia or infarction, though other potential causes include cardiomyopathy, arrhythmia, and valvular heart disease. Cardiogenic shock and hypovolemic shock may appear similar hemodynamically, except that cardiogenic shock is associated with elevated central filling pressures and the typical physical findings of jugular venous distention and pulmonary edema. Right-heart catheterization in the setting of cardiogenic shock typically demonstrates a low cardiac index (≤ 2.0 L/min/m²; normal: 3.0–5.0 L/min/m²) and elevated pulmonary capillary wedge pressure (17–20 cm H₂O; normal: 5–12 cm H₂O).

Extracardiac obstructive shock results from physical impairment of adequate forward circulatory flow involving mechanisms other than primary myocardial or valvular apparatus dysfunction. The result is reduced cardiac filling and low cardiac output. Causes include impaired diastolic ventricular filling (e.g., pericardial tamponade, pneumothorax, constrictive pericarditis, extrinsic compression of mediastinal vessels) and increased pulmonary or systemic

TABLE 25.1
DIFFERENTIAL DIAGNOSIS OF SHOCK

vascular resistance (e.g., massive pulmonary embolism, acute pulmonary hypertension, aortic dissection).

Distributive shock describes a hemodynamic state caused by loss of vasomotor control resulting in arteriolar and venular dilatation. The hemodynamic profile is typified by an elevated cardiac output, normal to low central venous and pulmonary capillary occlusion pressures, de-

creased systemic vascular resistance, and hypotension. This form of shock is most commonly associated with sepsis, though it also describes the hemodynamic changes resulting from adrenal insufficiency, hyperthyroidism, anaphylaxis, hepatic failure, and neurogenic dysfunction (particularly following spinal or epidural anesthesia, or spinal cord injury).

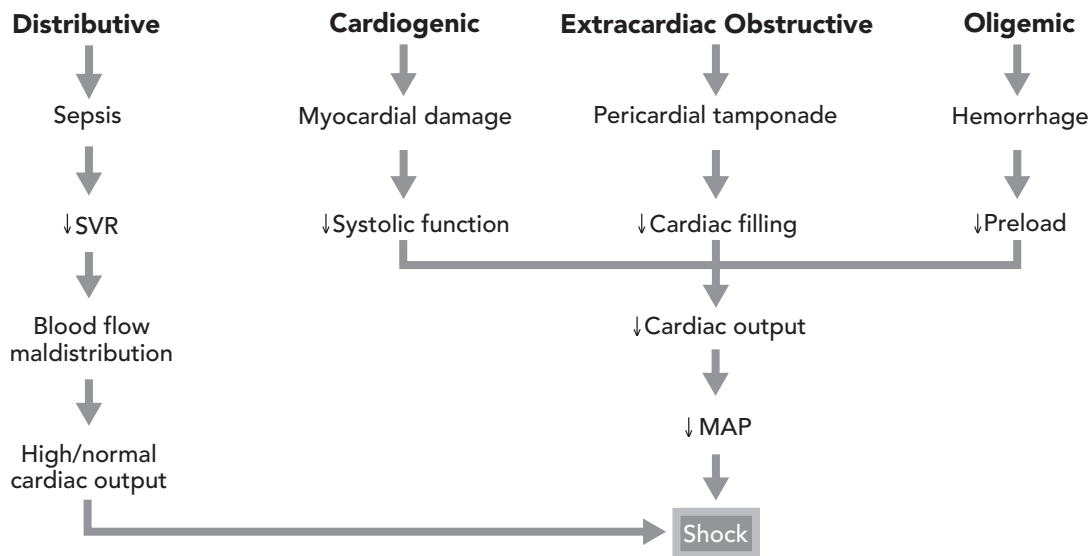

Figure 25.1 The different types of shock. Cardiogenic, extracardiac obstructive, and oligemic shock are characterized by a low cardiac output state causing hypotension. In contrast, in distributive shock, cardiac output usually is preserved or elevated, and hypotension results from a profound decrease in systemic vascular resistance. Myocardial dysfunction is common in sepsis, but cardiac output can be high or normal due to the low SVR. MAP, mean arterial pressure; SVR, systemic vascular resistance. (Adapted from Natanson C, Hoffman WD. Septic shock and other forms of shock. In: Parrillo JE, ed. *Current Therapy in Critical Care Medicine*, 2nd ed. Philadelphia: B.C. Decker, 1991.)

PRINCIPLES OF INITIAL RESUSCITATION

The patient in shock requires a rapid assessment including a pertinent history and physical examination, adequate intravenous access (such as 2 large bore 14g or 16g peripheral catheters), laboratory studies, an electrocardiogram, a chest radiograph, supplemental oxygen therapy, and usually transfer to either an intensive care or intermediate care (“step down”) unit. If substantial hemorrhage is suspected, a blood sample should be obtained for typing and cross-matching of blood for emergent infusion, and the patient’s coagulation status should be assessed and corrected as appropriate. In selected settings, such as profound hemorrhagic shock, fluid resuscitation may be most efficiently achieved with the use of a large bore central venous catheter (such as a Cordis catheter) and rapid fluid infusion devices. Specific documented or suggested causes must be addressed emergently (see Chapters 26, 38, 43, 53, and 78); empiric antibiotics are critical if sepsis may be a factor. Regardless of etiology, some basic concepts concerning initial shock treatment—including fluid resuscitation, and use of vasoactive drugs, and invasive monitoring devices—are generally applicable to all patients.

FLUID RESUSCITATION

The initial treatment of shock centers on optimizing intravascular volume. Except for cardiogenic shock, in which fluid overload may exist at the time of presentation, fluid administration is the most important initial therapy in shock (Table 25.3). Debate persists regarding the optimal type of fluid for resuscitation (e.g., crystalloids, colloids, or hypertonic solutions).

Crystalloids contain sodium as the major osmotically active particle and have the principal advantage of being readily available and inexpensive. Crystalloids distribute uniformly throughout the extracellular fluid compartment, so that only 25% of the total volume infused remains in the intravascular space. Commonly used crystalloids are lactated Ringer’s solution and normal saline (0.9% NaCl). The principal difference is that lactated Ringer’s solution contains potassium chloride and a bicarbonate precursor. Ringer’s and normal saline may be used interchangeably, except that the latter should be used in patients with significant hyperkalemia or severe metabolic alkalosis. *Hypertonic saline solutions* are appealing for patients with shock or burns because, relative to isotonic crystalloids, smaller quantities are required initially for resuscitation, owing to their ability to expand intravascular volume more rapidly. However, the intravascular hypertonic benefit rapidly dissipates as the fluid redistributes between the intravascular and extravascular spaces. Side effects associated with the use of hypertonic solutions include hypernatremia, hyperosmolality, and hyperchloremia. To date, hypertonic agents have not been demonstrated to have any clear survival advantage over standard intravenous solutions (1).

Hypotonic solutions (D5W, 0.45% NaCl) distribute throughout the total body water compartment and expand the intravascular compartment by as little as 10% of the volume infused. Although these solutions are useful for replacing free-water deficits, they should not be used for fluid resuscitation in shock, because of their negligible effect on intravascular volume.

Colloid solutions (albumin, dextran, hydroxyethyl starch) contain high-molecular-weight substances that do not readily migrate across capillary walls. The use of colloids often is considered if crystalloids fail to sustain plasma

TABLE 25.3
COMPOSITION OF COMMONLY USED PARENTERAL FLUIDS

Solutions	Na ⁺	K ⁺	Ca ²⁺	Mg ²⁺	Cl ⁻	HCO ₃ ⁻ (as lactate)	Dextrose (g/L)	mOsm/L

volume, potentially because of the low colloid osmotic pressure of crystalloids.

Although *albumin* preparations ultimately distribute throughout the extravascular space, the initial volume of distribution is the vascular compartment. The result can be more rapid restoration of intravascular volume than seen with crystalloid use. Both 25% albumin (100 mL) and 5% albumin (500 mL) preparations expand the intravascular volume by an equivalent amount (450–500 mL). Albumin preparations may offer less benefit to patients with adequate colloid oncotic pressure (serum albumin >2.5 mg/dL, total protein >5 mg/dL). The cost per unit volume of albumin is substantially greater than the cost of the intravascular volume-equivalent amount of crystalloid solutions. Because of cost considerations, albumin preparations should be used judiciously.

A number of synthetic colloid solutions have been developed. *Dextran* is a synthetic glucose polymer that undergoes predominantly renal elimination. Dextran solutions expand the intravascular volume by an amount equal to the volume infused. Side effects include renal failure, osmotic diuresis, coagulopathy, and laboratory abnormalities (i.e., elevations in blood glucose and protein, interference with blood cross-matching). Dextran 40 and Dextran 70 are used most commonly for acute volume expansion. *Hydroxyethyl starch* (hetastarch) is a glycogen-like synthetic molecule that is available as 6% solution in 0.9% NaCl. Infusion of hetastarch, like 5% albumin, increases the intravascular volume by an amount equal to or greater than the volume infused. Whether colloid solutions provide a clinical benefit over crystalloid solutions for resuscitation remains a vigorously debated question (2–5).

Because of the risk of transmission of blood-borne pathogens as well as the logistic problems associated with acquiring, storing, and screening blood products, *blood substitutes*, such as stroma-free hemoglobin, have been developed. At the time of this writing, however, none of these products have been approved by the U.S. Food and Drug Administration for clinical use.

Suggested Approach to the Initial Fluid Management of the Patient with Shock

Initial resuscitation of the patient in noncardiogenic shock begins with rapid fluid infusion. Frequently, it is necessary to infuse a bolus of 2–3 L of crystalloids to restore blood pressure and peripheral perfusion. This aggressive fluid resuscitation supports the patient's blood pressure, cardiac output, and perfusion in the early stages of shock while the underlying cause is sought and more definitive therapy is instituted. The patient with acute blood loss resuscitated without blood replacement requires a volume of crystalloid equivalent to approximately four times the volume of blood lost. For example, approximately 2,000 mL of crystalloid solution is required to compensate for a 500 milliliter blood loss. In the setting of acute massive blood loss, the administration of non-type-specific blood (e.g., type O) should be considered, if type-specific blood is not immediately available. Although the early use of colloids in the resuscitation regimen may result in the more prompt restoration of tissue perfusion and may lessen the total volume of fluid required for resuscitation, no data support any improvement in outcome compared with crystalloid infusion alone.

Patients who receive large volumes of intravenous fluids may develop coagulopathy, due principally to dilution and hypothermia. Accordingly, coagulation profiles and platelet counts should be monitored and corrected as necessary, particularly in patients who have ongoing blood loss or in whom invasive procedures are planned. Similarly, core temperatures should be monitored, and mild degrees of hypothermia ($T < 36^{\circ}\text{C}$) should be treated by external warming and infusion of warm fluids.

VASOPRESSOR THERAPY

In addition to fluid administration, pharmacologic support of blood pressure with vasopressor agents (Table 25.4) is frequently necessary in both the initial resuscitation and subsequent support of patients with shock.

Norepinephrine is a catecholamine vasopressor with both α - and β -adrenergic effects. At low doses, norepinephrine has a positive inotropic effect. However, with increasing doses, its vasoconstrictive effects outweigh its inotropic effects, and cardiac output may decrease as a consequence of increased afterload. A potential adverse effect of norepinephrine is profound vasoconstriction, resulting in hypoperfusion and ischemia. In practical terms, norepinephrine at moderate dosages (1–4 mcg/min) has the ability to increase systemic pressure while maintaining or increasing cardiac performance; because of its marked ability to increase systemic pressure, norepinephrine is becoming the most frequently used pressor for the initial therapy of shock. It is also commonly used as an adjunct to other va-

sopressors with predominately β -activity, such as dobutamine, in cases of refractory shock. Norepinephrine infusions typically begin at 1 mcg/min and are titrated to the desired effect. The usual dosage range is 2–4 mcg/min, with an upper limit typically of 12 mcg/min.

Dopamine is an endogenous catecholamine and neurotransmitter. When administered intravenously, its cardiovascular effects are dose-dependent and reflect the relative degrees of stimulation of the sympathomimetic (α - and β -) and dopaminergic receptors. At low doses (1–2 mcg/kg/min), dopamine selectively activates dopaminergic receptors in the renal, mesenteric, and cerebral circulations, increasing perfusion to these regions. At intermediate doses (2–10 mcg/kg/min), dopamine stimulates β -receptors in the cardiac and peripheral circulations, producing a modest inotropic effect. At higher doses (>10 mcg/kg/min), dopamine stimulates α -receptors in the systemic circulation, producing vasoconstriction. Dopamine is also commonly used for the initial management of circulatory shock. Of note, clinicians frequently use dopamine at low doses (“renal dose” dopamine, sometimes with other pressors) in an attempt to maintain renal perfusion and promote urine output in patients with (or at risk for) acute tubular necrosis. However, this application has not been prospectively demonstrated to alter renal injury or patient outcome (see Chapter 100).

Dobutamine, a synthetic catecholamine with predominately β_1 (inotropic) but also weak β_2 (vasodilatation) activity, is often used for the management of low cardiac output states caused by inadequate cardiac systolic function (e.g., low ejection fraction). Because dobutamine does

TABLE 25.4
VASOPRESSORS COMMONLY USED IN THE MANAGEMENT OF SHOCK

Drug	Dosing	Adrenergic effects			Dopaminergic	Indications
		α	β			
Norepinephrine	0.5–80 mcg/min	3+	2+	0	Initial emergency treatment of hypotension (any cause, especially sepsis)	
Dopamine	1–2 mcg/kg/min	1+	1+	3+	Oliguria despite normal blood pressure	
	2–10 mcg/kg/min	2+	2+	3+	Initial emergency treatment of hypotension (any cause) and alternative treatment for bradycardia	
	10–30 mcg/kg/min	3+	2+	3+		
Dobutamine	2–30 mcg/kg/min	1+	3+	0	Cardiogenic shock and cardiogenic pulmonary edema with marginal blood pressure	
Epinephrine	0.5–1 mg (1:10,000)	1+	2+	0	Cardiac arrest	
	1–200 mcg/min	2+	3+	0	Severe hypotension and bradycardia	
	0.3–0.5 mg SQ (1:1,000)				Anaphylaxis	
Phenylephrine	20–200 mcg/min	3+	0	0	Distributive shock when no cardiac effect desired	
Isoproterenol	2–10 mcg/min	0	3+	0	Refractory bradycardia	
Amrinone	Load: 0.75 mcg/kg over 3 min; infuse: 2–15 mcg/kg/min	0	0	0	Cardiogenic shock, usually as a synergistic agent with dobutamine	

Modified from Jimenez EJ. Shock. In: Civetta JM, ed. *Critical Care*. Philadelphia: Lippincott-Raven, 1997:363, with permission.

not appreciably increase systolic pressure, it is not indicated as monotherapy for patients with cardiogenic shock. Further, it generally should not be used, even as combination therapy, in patients with cardiac failure secondary to diastolic dysfunction or in patients with hypertrophic obstructive cardiomyopathy, because its β -sympathomimetic effect may exacerbate these conditions. The usual dosage range for dobutamine is 5–15 mcg/kg/min.

Epinephrine is an endogenous catecholamine. Given its potency and potential for untoward effects (myocardial ischemia, tachyarrhythmia, intracranial hemorrhage, etc.), it is not used commonly as initial pharmacologic support for shock in adults. As with dopamine, epinephrine's effects are largely dose-dependent (e.g., primarily a β -agonist at low doses and an α -agonist at higher doses). Epinephrine also inhibits the release of inflammatory mediators from immune cells in response to antigenic challenge, which may partially explain its beneficial effect in the setting of anaphylaxis. Intravenous epinephrine is indicated for the management of cardiac arrest associated with pulseless ventricular tachycardia, ventricular fibrillation, asystole, pulseless electrical activity (initial dose: 1 mg intravenously every 3–5 minutes), and for severe anaphylactic reactions (initial dose: 3–5 mL of 1:10,000 solution [0.1 mg/mL] intravenously) (see also Chapter 120).

Phenylephrine, a catecholamine with pure α -adrenergic activity, is effective in the treatment of distributive shock because it increases systolic blood pressure without producing tachycardia. It should be used with caution in patients with underlying cardiovascular dysfunction, however, because of the risk of precipitating ventricular failure. Typical initial infusion rates are 20–40 mcg/min.

Amrinone is a phosphodiesterase inhibitor that has both vasodilator and inotropic effects. These combined actions produce an increase in cardiac output without an increase in cardiac stroke work, an effect roughly equivalent to dobutamine. Amrinone is indicated as single-agent therapy in the management of low cardiac output states caused by systolic heart failure. It is used most frequently as a second agent that is added to dobutamine in cases of refractory heart failure. Amrinone is given by loading with 0.75–1.5 mg/kg followed by an infusion rate of 5–10 mg/kg/min. Because of excessive vasodilatation, amrinone may cause hypotension, especially in hypovolemic patients.

Vasopressin, which is naturally secreted by the posterior pituitary gland, possesses multiple physiologic effects including vasoconstriction mediated by V1 receptors present in numerous vascular beds. Circulating levels of vasopressin appear to be depressed in shock. When administered exogenously in "physiologic doses" (e.g., 0.01–0.04 units/min), vasopressin is synergistic with exogenous catecholamines, yielding a pressor effect without evidence of organ hypoperfusion. When administered at doses >0.04 units/min, the pressor effect of vaso-

pressin is associated with potentially deleterious renal, mesenteric, and coronary vasoconstriction. Specific recommendations regarding the routine use of this agent for hemodynamic support await more thorough clinical evaluation (6).

Suggested Approach to Initial Vasopressor Therapy

The appropriate use of vasopressors frequently requires accurate assessment of a patient's cardiovascular status by either invasive or noninvasive monitoring. It is not uncommon, however, to institute vasopressor therapy in a patient who remains hypotensive despite rapid fluid infusion and for whom sophisticated monitoring is not immediately available. If hypotension persists (e.g., mean arterial pressure <60 mm Hg) despite aggressive fluid resuscitation, vasopressor therapy may be indicated. The use of an agent with both α - and β -adrenergic activity, such as norepinephrine or dopamine, is an appropriate initial choice: These agents increase systemic pressure via their α -adrenergic effect and augment cardiac output via their β -adrenergic effect. Vasopressors should be started in the therapeutic range and then titrated to the desired hemodynamic effect (e.g., mean arterial pressure ≥ 60 mm Hg). Empiric vasopressor use is continued until a more detailed assessment of the patients' cardiovascular status and the cause of shock can guide targeted therapy.

INVASIVE MONITORING DEVICES

It is estimated that 1.2 million pulmonary artery catheters are inserted annually in the United States, with an associated cost of \$2 billion. Despite this pervasive use, disagreement persists regarding clinical indications for pulmonary artery catheters, the interpretation of data generated by these devices, and the goals of therapy based on these data (7). Randomized trials have shown no benefit for the routine use of pulmonary artery catheters in elderly patients undergoing high-risk surgery (8) or in patients with shock due to sepsis, the acute respiratory distress syndrome, or both (9). In the latter study, only about 5% of patients randomized to initial care without a pulmonary artery catheter later received one for perceived clinical needs. Neither of these studies linked pulmonary artery catheters to specific, protocolized interventions, and earlier randomized trials of goal-oriented hemodynamic therapy in critically ill patients have yielded conflicting results (10). Nevertheless, ongoing trials are evaluating the combination of pulmonary artery catheters with specific therapeutic protocols. Furthermore, no trial has evaluated the utility of pulmonary artery catheterization in shock of unknown cause.

Use of the Echocardiography and/or Pulmonary Artery Catheter to Determine the Type of Shock

If a pulmonary artery catheter and/or echocardiography is needed and used to determine the cause of shock in a patient who otherwise has shock of unknown etiology, it can reveal one of four hemodynamic profiles (Table 25.2).

Oligemic shock is typified by normal cardiac function, a low cardiac output, low pulmonary capillary wedge pressure, and elevated systemic vascular resistance. These findings should prompt the clinician to consider the potential causes of oligemia and to initiate or augment fluid resuscitation.

Cardiogenic shock is indicated by markedly diminished cardiac function and output with elevations in systemic vascular resistance, pulmonary capillary wedge pressure, and central venous pressure. Mixed venous oxygen saturation is typically low. Resuscitation should be directed toward improving cardiac function by optimizing preload and administering potent sympathomimetic agents (e.g., dopamine alone or dopamine and dobutamine in combination). Mechanical cardiac support (e.g., intra-aortic balloon counterpulsation or ventricular-assist device) should be considered in refractory patients. (see Chapter 39).

Extracardiac obstructive shock secondary to cardiac tamponade is evidenced by typical echocardiographic findings, diminished stroke volume with elevation and equalization of cardiac filling pressures (i.e., central venous and pulmonary capillary wedge pressure). Pericardial tamponade requires emergent pericardiocentesis (Chapter 46). Alternatively, extracardiac obstructive shock as a consequence of pulmonary embolism is suggested by diminished cardiac output, elevated central venous and pulmonary artery diastolic pressures, and normal or low pulmonary capillary wedge pressure (Chapter 53). Empiric anticoagulant therapy should be considered pending confirmation by appropriate diagnostic tests.

Distributive shock is suggested by decreased blood pressure and systemic vascular resistance; normal, near-normal, or supra-normal cardiac function, elevations in cardiac output and mixed venous saturation, and normal pulmonary capillary and central venous pressures. Because sepsis is a frequent cause of distributive shock, this hemodynamic profile suggests the need for rapid cultures, broad spectrum antibiotics, and a thorough search for a site of infection (see Chapter 26).

Use of Hemodynamic Endpoints to Guide Fluid Therapy and Vasopressor Use

Patients with normal cardiac function generally should receive intravenous fluids to achieve normal to slightly

elevated central venous and pulmonary capillary wedge pressures (12–18 mm Hg). If hypotension persists despite achieving these resuscitation endpoints, vasopressor therapy should be instituted because persistent infusion of fluids alone to reverse shock may increase intravascular pressure and produce complications of volume overload (e.g., pulmonary edema). For patients with poor cardiac performance and low cardiac output (cardiac index <2.5 L/m²), an agent or agents should be selected to provide both α - and β -adrenergic stimulation (e.g., epinephrine, norepinephrine plus dobutamine, or dopamine plus dobutamine) in an effort to enhance both cardiac contractility and vascular tone. Conversely, for patients with hypotension and preserved cardiac function and output (cardiac index ≥ 2.5 L/m²), agents with predominately α -adrenergic activity (e.g., norepinephrine, phenylephrine) should be used to augment blood pressure. These general recommendations may require modification for patients with specific causes such as myocardial infarction (Chapter 38) or pulmonary embolism (Chapter 53). Because the risk:benefit ratio of the pulmonary artery catheter in guiding ongoing management is unclear and because this device has been associated with long-term complications, it should only be used when other methods are insufficient or the patient is unstable hemodynamically. These indications may broaden if ongoing randomized trials demonstrate the catheter's usefulness in other situations.

OTHER INTERVENTIONS THAT MAY BE USEFUL IN PATIENTS WITH SHOCK OF UNKNOWN CAUSE

If easily treatable causes of shock are not apparent, a limited differential diagnosis of potentially life threatening conditions should be entertained. If either anaphylaxis or acute adrenal insufficiency is a diagnostic consideration, corticosteroids should be administered. These agents should be given on a rapidly tapering schedule as the patient stabilizes or as other causes of hemodynamic compromise become apparent. For anaphylaxis, the recommended dose is hydrocortisone 300–500 mg intravenously every 6 hours or methylprednisolone 60–125 mg intravenously every 6 hours, tapering either agent off in 48–72 hours (see Chapter 120). For adrenal insufficiency, the recommended dose is hydrocortisone 100 mg intravenously every 6 hours (although higher doses sometimes are given), tapered according to the patient's response to illness (see Chapter 109).

Timely administration of antibiotics is essential to the successful treatment of septic shock and should be considered whenever there is any suspicion of systemic infection, such as with fever, hyperdynamic cardiac profile, obvious site of infection, or immunocompromise (see

Chapter 26). Anticoagulation is essential in preventing subsequent thromboemboli in patients with pulmonary thromboembolism. Pending definitive diagnosis or exclusion of pulmonary emboli, heparinization should be considered if there is sufficient suspicion based on the presence of predisposing factors or appropriate hemodynamics (see Chapter 53).

Blood products should be administered early if the hematocrit is reduced and occult hemorrhage possibly underlies hemodynamic compromise. If hemodynamic collapse occurs in patients who have undergone recent percutaneous placement of central venous catheters, the diagnosis of tension pneumothorax should be entertained; needle decompression with a large bore (e.g., 14g) catheter followed by tube thoracostomy placement is indicated. If a patient may have pericardial tamponade, due to either recent trauma, an invasive procedure, or preexisting pericardial disease, echocardiography and rapid diagnosis and therapy are lifesaving (Chapter 46).

ENDPOINTS OF RESUSCITATION: CAN OUTCOME FROM SHOCK BE IMPROVED?

One of the principal goals driving the timely resuscitation of the patient with shock is to restore perfusion and prevent organ injury. However, even with extraordinary efforts, organ failure frequently occurs.

One hypothesis suggests that organ failure during critical illness occurs as a consequence of inadequate oxygen delivery. Accordingly, a number of investigators have proposed that patients should be resuscitated to elevated, or supra-physiologic, hemodynamic endpoints so as to prevent organ failure and improve outcome. Several trials testing this hypothesis in patients following ICU admission failed to demonstrate a benefit. A recent study, however, suggests that therapy directed toward achieving *normal* hemodynamic parameters, if implemented early after the diagnosis of shock and prior to ICU admission, may improve survival (11). In this study, patients with severe sepsis or septic shock were randomized immediately following presentation to the emergency department to either conventional therapy or early goal-directed therapy, which included fluid resuscitation to achieve a CVP of 8–12 mm Hg, vasopressor administration titrated to achieve a mean arterial pressure of 65 mm Hg, and blood transfusion to achieve a central venous O₂ saturation of 70%. Patients assigned to standard therapy received significantly less fluid resuscitation and had significantly higher mortality rates. Whether this approach can be generalized to other disease processes remains unstudied, but the findings of this study support appropriate early and aggressive resuscitation of patients with shock.

KEY POINTS

The hemodynamically unstable patient is a challenging clinical problem. The mechanisms by which hypotension and shock ultimately result in organ failure are not fully known. Although the approach to these patients must be individualized based on specific cause, some basic principles apply to all patients:

- The causes of shock can be categorized based on hemodynamic profiles into hypovolemic, cardiac, extracardiac obstructive, and distributive. This framework is particularly helpful in the patient whose cause of shock is unclear or could be attributed to several potential causes.
- The initial resuscitation of the patient with shock should be directed at rapidly restoring circulating intravascular volume through the use of crystalloids, colloids, or blood products. In septic shock, inadequate early fluid resuscitation appears to have an adverse effect on survival.
- The use of vasopressors is essential for restoring systemic perfusion if the patient does not respond quickly to intravenous fluid therapy or is hemodynamically labile. Although therapy must be individualized, norepinephrine and dopamine, individually or in combination, are reasonable empiric choices. The titration of these agents as well as the addition of other agents is based on response to therapy and the acquisition of additional clinical information.
- Echocardiography and/or pulmonary artery catheters can help determine the cause of shock and direct initial therapy. If pulmonary artery catheters are used, the duration of catheterization should be limited to the minimum required time.
- The appropriate endpoints for resuscitation in the critically ill patient are normal values of oxygen delivery and other hemodynamic variables, in conjunction with other clinical evidence of adequate tissue perfusion (e.g., normal mentation, adequate urine production, clearance of acidosis).

Sepsis Syndrome

26

Todd W. Rice Gordon R. Bernard

INTRODUCTION

Sepsis syndrome, the body's systemic response to such disparate infections as pneumonia, peritonitis, pyelonephritis, and meningitis, is the leading cause of death in non-coronary intensive care units and the tenth leading cause of death overall in the United States. Although recent treatment advances have improved outcomes of patients with sepsis, mortality rates still approach 30%–40%. In addition, the incidence of sepsis has steadily increased over the past two decades due to increasing numbers of elderly and immunocompromised patients, increasing use of immunosuppressive therapies, and increasingly widespread use of invasive therapeutic and monitoring devices. Current reports estimate that almost 700,000 cases of sepsis occur in the United States each year (240 cases per 100,000 population) (1,2).

In general, the term sepsis refers to a *systemic inflammatory response syndrome* (sometimes abbreviated as SIRS) resulting from infection. When sepsis causes end-organ dysfunction (renal, cardiovascular, hematologic, neurologic, etc.), it is called *severe sepsis*; and when it causes arterial hypotension and organ hypoperfusion, it is called *septic shock*. Although the phrase "sepsis syndrome" can encompass many different septic conditions, it is routinely used to describe patients with severe sepsis or septic shock. The systemic inflammatory response syndrome is not specific to sepsis and can result from a variety of other pathophysiologic mechanisms, such as hemorrhage, severe dehydration, heart failure, pericardial tamponade, pancreatitis, or trauma, all of which can cause hypotension, shock, and multiorgan system failure. Sepsis produces generalized endothelial dysfunction with resulting inflammation and altered coagulation (3). It is initiated by infection with bacteria or other microorganisms. Then, it is mediated by the effects of their various endo- and exotoxins, and amplified by endogenous inflammatory and coagulation mediators, including leukocytes, macrophages, cytokines (e.g., tumor necrosis factor and interleukins 1, 2, and 6), throm-

boplastin, and thrombin. These inflammatory and coagulopathic responses, to the extent they serve to eradicate pathogens, are vital. However, these same responses are often nonspecific in their targets and imperfectly regulated, resulting in irreparable damage to normal tissues.

WHEN SEPSIS SYNDROME PRESENTS ON ADMISSION

Issues at the Time of Admission

Clinical Presentation

The spectrum of presenting manifestations of sepsis is extraordinarily broad, ranging from the elderly patient who complains only of weakness and dizziness to the otherwise healthy young adult with overwhelming pneumonia and hypotension. Although signs of a localized infection may be present, patients with sepsis "typically" present with a conglomeration of the signs and symptoms of the systemic inflammatory response syndrome, namely tachycardia, tachypnea, hyperthermia (or hypothermia), and leukocytosis. Tachypnea, which is often the first sign of sepsis, is almost universally present in patients with severe sepsis. Additionally, patients with severe sepsis often demonstrate hypotension, obtundation, oliguria, and a lactic acidosis. Unfortunately, sepsis may present without such typical features, and a high clinical index of suspicion must be maintained whenever a patient (particularly one who is elderly or immunocompromised) presents with nonspecific symptoms.

Initial Evaluation and Differential Diagnosis

The foundation of the initial evaluation is a careful medical history and physical examination. The history should elicit any predisposing factors and possible source of infection to guide the choice of empiric antibiotics. Any immunocom-

promising conditions (e.g., prior use of corticosteroids, asplenia, radiation or chemotherapy, hematologic malignancy, HIV infection, prior transplantation, alcoholism, or diabetes mellitus) should be noted, along with any unusual recent exposures, such as tuberculosis, meningococcus, influenza, or legionella. Any recent history of procedures (including surgeries, endoscopies, dental work, genitourinary manipulation, intravascular catheters or other indwelling devices) or use of vaginal tampons should be considered. Information about cough or sputum production, headache or neck stiffness, chest or abdominal pain, nausea, vomiting, jaundice, diarrhea, flank pain, dysuria, hematuria, urinary frequency, or skin lesions can help direct further investigation.

The initial physical examination should focus on vital signs including, if possible, supine and standing heart rate and blood pressure, respiratory rate and pattern, and temperature. General attention must be paid to the patient's alertness, orientation, skin temperature, perfusion of hands and feet, skin lesions, and any indwelling catheters. The head and neck should be examined for the presence or absence of scleral icterus, meningismus, and sinus tender-

ness, as well as for any abnormalities of the tympanic membranes or oropharynx. The lungs should be examined for altered breath sounds, signs of consolidation, rales, rhonchi, wheezes, or pleural rubs. The cardiovascular examination should assess possible jugular venous distention, edema, murmurs, rubs, gallops, peripheral pulses, splinter hemorrhages, Roth spots, Osler's nodes, and Janeway lesions. The abdomen and pelvis must be assessed for tenderness, guarding, rebound, operative scars, the presence and character of bowel sounds, flank tenderness, blood in the stool, and pelvic tenderness or discharge.

In many cases of sepsis, such as a toxic patient with a lobar pneumonia, the diagnosis is readily apparent. In others, a good deal of detective work is needed, and the diagnosis of sepsis is uncertain until results are obtained from blood tests, radiographs, and other investigations (Table 26.1). Non-infectious conditions such as pancreatitis, trauma, severe hemorrhage, myocardial infarction, drug overdoses, and even heat stroke can mimic sepsis and often must be excluded by a thorough history, physical examination, and laboratory testing before the diagnosis of sepsis syndrome can be established.

TABLE 26.1

INITIAL LABORATORY AND RADIOGRAPHIC EVALUATION OF THE PATIENT PRESENTING WITH SUSPECTED SEPSIS SYNDROME

Tests that should be obtained initially in *all* patients:

- Complete blood count with differential and platelet count
- Sodium, potassium, chloride, bicarbonate, blood-urea nitrogen, creatinine, and glucose measurements
- Bilirubin, alkaline phosphatase, and aminotransferase measurements
- Prothrombin time and partial thromboplastin time
- Two sets of blood cultures—at least one drawn from someplace other than an already established IV
- Pulse oximetry
- Chest radiograph (upright preferred if patient is able)
- Urinalysis and urine culture

Tests that should be obtained in *selected* patients:

- Lumbar puncture (in any patient with even a slight suspicion of meningitis)
- 12-lead electrocardiogram (in any patient with hypotension, abnormal auscultatory findings, pulse irregularities, chest discomfort, or any history of cardiac disease)
- Echocardiogram (in any patient with suspicion of tamponade, acute cor pulmonale, infective endocarditis, acute valvular regurgitation, or severe left ventricular dysfunction)
- Flat and upright abdominal films (in any patient with worrisome abdominal findings)
- Nasogastric aspiration (in any patient who may be having upper-gastrointestinal hemorrhage)
- Amylase and lipase (in patients with signs and symptoms consistent with pancreatitis)
- Abdominal ultrasound (in patients suspected to have biliary disease or postrenal obstruction)
- Abdominal computed tomography scan (in patients suspected of having pancreatitis, abdominal abscess, or retroperitoneal hemorrhage)
- Urine and serum toxicology screens (in any obtunded patient or patient with possible overdose)
- Arterial blood gases (in patients with tachypnea, decreased oxygen saturation, or acidosis)
- Magnesium, phosphate, and calcium measurements (in patients with renal insufficiency, acid-base disturbances, or other indications)
- Thoracentesis or paracentesis (in patients suspected to have empyema, parapneumonic effusion, or spontaneous bacterial peritonitis)

In the patient with shock, resuscitative efforts must be started immediately, accompanied by an abbreviated, carefully focused initial evaluation. The principal aim of the evaluation is to differentiate septic shock from other forms of shock (e.g., cardiogenic shock, hemorrhagic shock, or pericardial tamponade). Once septic shock is diagnosed, early and aggressive goal-directed resuscitation should be instituted. Aggressive volume repletion with crystalloid, correction of severe anemia with transfusions of packed red blood cells, and support of cardiac function with inotropic agents help improve the oxygen saturation of mixed-venous blood (4). If the patient is more stable, a more deliberate initial evaluation can be undertaken.

Indications for Hospitalization

All patients with severe sepsis should be hospitalized. Even the patient who "eyeballs well" after hydration and initial antibiotics in the emergency department is at risk for sudden and severe deterioration. Some patients with sepsis improve rapidly with antibiotic therapy, and such patients may only need a day or two of inpatient therapy. Unfortunately, however, the natural history of sepsis is highly variable, and many patients require protracted hospitalization.

Indications for Initial Intensive Care Unit Admission

Many hospitals have well-equipped, well-staffed general medical units or "stepdown" units capable of managing patients with uncomplicated sepsis syndrome. Unfortunately, a large percentage of patients with sepsis syndrome already have, or are at high risk of developing, severe sepsis with organ failure, complications that mandate ICU admission (Table 26.2).

Initial Therapy

As in any life-threatening illness, the hierarchy of therapeutic priorities in sepsis syndrome begins with assuring that the patient has a patent airway, with adequate oxygenation and ventilation. Patients in shock require aggressive resuscitation with crystalloids (often as much as 5–10 liters), combined with transfusions of packed red blood cells and inotropic support to maintain adequate tissue perfusion (4). Beyond the initial stabilization of airway, breathing, and circulation (the "ABCs"), the next priority whenever sepsis syndrome is being considered (even before the diagnosis has been confirmed) is to obtain appropriate culture specimens and then *immediately to begin broad-spectrum antibiotics* directed against all of the likely pathogens, an intervention known to decrease mortality (5). In addition to antibiotic coverage, outcomes are improved when the source of infection is eradicated. Practically, this means that the search for potential sources should begin as

TABLE 26.2

SEPSIS SYNDROME: INDICATIONS FOR ICU ADMISSION

Hypotension, and consequent need for vasopressors, if volume resuscitation fails to achieve and maintain a systolic blood pressure of 90 mm Hg or a mean arterial pressure of 65 mm Hg
Hypoxemia, if oxygen by face mask fails to achieve and maintain arterial oxygen saturations above 90% or mechanical ventilation is likely to be needed
Marked metabolic abnormalities (e.g., severe acidosis, uremia, jaundice, or severe electrolyte derangements)
Depressed sensorium, with likely need for endotracheal intubation for airway protection
Oliguria or anuria
Sepsis concomitant with underlying cardiac problems (e.g., arrhythmias, coronary disease, heart failure, or pericardial disease)
Sepsis concomitant with underlying pulmonary problems (e.g., chronic obstructive pulmonary disease)
Desire to utilize invasive monitoring (e.g., arterial cannulation or pulmonary artery catheterization)

soon as the hemodynamic and respiratory statuses are stabilized (6). Controlling the source of infection may require percutaneous or surgical drainage of a pocket of pus (e.g., empyema or abscess) (see Chapters 62 and 64), removal of devitalized tissue (e.g., necrotizing fasciitis, necrotic ulcers, or infarcted tissue), or removal of an infected foreign body (intravascular catheter, tampon, or artificial joint). Other elements of initial therapy are tailored to the specific needs of the individual patient (Table 26.3).

ISSUES DURING THE COURSE OF HOSPITALIZATION

Because of the association of sepsis syndrome with multi-organ system dysfunction (see Chapter 25), the problems that arise during its course are legion. As a generalization (and somewhat of an oversimplification), the patient who ultimately succumbs to sepsis has several characteristics. The most important prognostic indicator is the development of organ dysfunction, especially hypotension and acute respiratory distress syndrome (ARDS). Both hypotension, especially septic shock requiring vasopressors for longer than 48 hours, and respiratory failure severe enough to require mechanical ventilation portend a high likelihood of death. Mortality has been estimated to be at least 25% with either, and increases by 15–20% for each additional failing organ (7). In addition, chronic underlying medical co-morbidities and hypothermia further worsen the prognosis (8).

Nonetheless, many septic patients survive despite multi-organ system failure and long, complicated hospital courses. To optimize their chances of survival, with minimal residual

TABLE 26.3
INITIAL THERAPY OF SEPSIS SYNDROME

Assure adequacy of airway patency, oxygenation, and ventilation. Assure adequate arterial pressure to maintain cerebral and coronary perfusion; the usual target is a mean arterial pressure of 65 mm Hg or a systolic of 90 mm Hg.

If hypotensive, start with large-volume intravenous fluids. Fluids may be crystalloid, colloid, or blood products. Unless pulmonary edema is present, volumes of 5–10 L can be administered.

If arterial pressure does not respond adequately to intravenous fluids, start vasopressors. Some studies have shown improved outcomes using norepinephrine compared with dopamine (9). One strategy is to start with norepinephrine at 2 mcg/min, titrate up as needed. If the patient is still hypotensive on 50 mcg/min of norepinephrine, addition of replacement dose vasopressin (0.04 Units/min) can be considered (10). If norepinephrine precipitates tachyarrhythmias, switch to phenylephrine, starting at 30 mcg/min.

As soon as culture specimens are obtained, start broad-spectrum parenteral antibiotics (5). Do not merely write the antibiotic order; *make sure the drug is given immediately*. Once culture and sensitivity data become available, the spectrum of antibiotic coverage can be narrowed correspondingly. Call a surgical or interventional consultation if there is undrained pus (e.g., empyema, abscess, etc.) or devitalized tissue needing removal (e.g., necrotizing fasciitis, necrotic ulcers, infarcted tissue, etc.) (6).

Remove any infected foreign bodies (e.g., intravascular catheters, artificial joints, etc.).

If the patient requires ventilatory support for acute lung injury or acute respiratory distress syndrome (ARDS), use a low tidal volume approach (6 cc/kg of ideal body weight, decreased to 4 cc/kg of ideal body weight if needed to keep plateau pressures below 30 cm H₂O) (11).

Address metabolic and hematologic derangements.

Acidosis usually corrects with adequate ventilation and restoration of perfusion; consider bicarbonate administration in extremes (e.g., pH <7.0). Consider acute hemodialysis for life-threatening hyperkalemia. Treat hyperglycemia or hypoglycemia. Correct hypokalemia, hypocalcemia, hypomagnesemia; be cautious if renal function is questionable. Administer vitamin K and transfuse packed red cells, platelets, or fresh frozen plasma as clinically indicated.

If any question of adrenal impairment, give dexamethasone 10 mg IV. Dexamethasone does not interfere with an interpretable adrenocorticotrophic hormone (ACTH) stimulation test (see Chapter 109). Corticosteroids may improve outcome in patients with adrenal insufficiency (12), but are not helpful and may be harmful when patients with sepsis syndrome do not have adrenal impairment. If febrile, administer acetaminophen and/or ibuprofen. Start parenteral histamine-2 blockers. Patients with hemodynamic instability should have arterial cannulas placed: To facilitate accurate titration of vasopressors. To facilitate frequent blood sampling. Start drotrecogin alfa (activated) in patients with severe sepsis and a high-likelihood of death (e.g., APACHE II ≥ 25 ; vasopressor requirement) unless contraindicated (3). Dobutamine and transfusions of packed red blood cells have been advocated to increase cardiac output and oxygen delivery and may improve outcome if used early to correct low mixed-venous oxygen saturation (4).

morbidity, clinicians should adhere to a number of important precepts (Table 26.4).

Special Considerations in Selected Populations

Patients with Severe Sepsis (i.e. Organ Dysfunction From Sepsis)

Patients who develop at least one dysfunctional organ from sepsis have severe sepsis. Organ dysfunction occurs because of damage resulting from an over-exuberant systemic inflammatory and thrombotic response to the infection. This response causes endothelial dysfunction and subsequent microthrombi. *Activated protein C*, a protein with anti-inflammatory and anti-thrombotic properties, is reduced in many patients with severe sepsis, and these patients have a poorer prognosis. Recombinant human activated protein C (rhAPC), also known as drotrecogin alfa (activated),

decreases morbidity and mortality in patients with severe sepsis and a high-likelihood of dying (e.g., APACHE II score > 25 or need for vasopressors): in a randomized trial, severely septic patients receiving drotrecogin alfa (activated) as a continuous infusion of 24 mcg/kg/min for 96 hours had a 6% absolute reduction and 19% relative reduction in 28-day, all cause mortality (25% mortality in those receiving drotrecogin alfa compared with 31% in those receiving placebo) (3). Overall, one life was saved for every 13 patients receiving drotrecogin alfa treatment, and in the patients with the highest APACHE II scores (i.e. ≥ 25), one life was saved for every 8 patients treated. The most frequent and concerning adverse event of the drug is bleeding, although only 2% of patients experienced a severe bleed while receiving the drug. The infusion should be held for 2 hours before and 30 minutes after any percutaneous procedure and for 2 hours before and 12 hours after any surgical procedure because of its anticoagulant properties. The mortality benefit of drotrecogin alfa (activated) may not outweigh the risk

TABLE 26.4**THE PATIENT WITH LINGERING SEPSIS AND MULTIORGAN SYSTEM FAILURE: 10 PRECEPTS FOR DAY-TO-DAY MANAGEMENT**

1. Examine the patient and listen to the nurses.
2. Review the patient's medications every day, considering dosage adjustments and potential drug interactions.
3. Do not leave hardware in (including central venous catheters, pulmonary artery catheters, bladder catheters, etc.) unless clearly necessary.
4. Obtain and repeat imaging studies whenever substantive questions arise.
5. Ensure the source of infection is controlled (abscess fully drained, all necrotic tissue removed, infected hardware removed, etc.).
6. Prevent complications: ensure acid suppression for ulcer prophylaxis; use heparin (low molecular weight or undifferentiated) or pressure stockings to prevent deep venous thromboses/pulmonary emboli; physical therapy to prevent contractures; good skin care to prevent decubitus ulcers.
7. Prevent secondary infections: insert central lines with sterile technique and maximal barrier protection; wash hands between patients; use gloves and gowns when examining patients with resistant organisms; elevate the head of the bed when giving tube feedings; minimize ventilator tube changes and central venous catheter manipulations; ensure endotracheal and feeding tubes are orally placed.
8. Narrow antibiotic coverage when culture data return; if the patient is not improved after seven days of antibiotics, consider switching or discontinuing them.
9. Individuals vary in their physiologies: If the patient does not mentate or urinate at a mean arterial pressure of 65 mm Hg, push it to 75 mm Hg and see what happens.
10. Be realistic: Experienced clinicians know, with or without help from standardized approaches such as APACHE scores (see Chapter 22), when there is no longer a realistic prospect for survival.

of hemorrhage, specifically intracranial hemorrhage, in patients with severe thrombocytopenia (platelet count <30,000/mL), meningitis, or marked coagulopathy (INR >3), and its use in these patient populations should be undertaken with extreme caution, if at all.

Septic Patients Requiring Mechanical Ventilation

Regardless of the source of the infection, patients with sepsis often develop inflammation in other organs of the body, especially the lungs and kidneys. Acute lung injury, or the acute respiratory distress syndrome (ARDS), occurs in about one of every five patients with sepsis (1), usually resulting in respiratory failure and the need for mechanical ventilation. "Low tidal volumes" (6 mL/kg ideal body weight or less) should be utilized when any patient with ARDS, including those with sepsis, needs mechanical ventilation (11). If plateau pressures exceed 30 cm H₂O when ventilating with tidal volumes of 6 mL/kg ideal body weight (IBW), then the tidal volume should be decreased

(to a minimum of 4 mL/kg IBW) until plateau pressures are below 30 cm H₂O (see Chapter 23).

Persistent Hypotension in Septic Patients

Patients with sepsis typically develop hypotension because of peripheral vasodilation. This hypotension may correct with aggressive fluid resuscitation, but septic patients may require vasopressors to maintain an adequate arterial perfusion pressure. Sometimes, septic patients have refractory hypotension despite the administration of adequate volume and increasing doses or numbers of vasopressors. These patients with refractory hypotension may be either deficient in vasopressin or lack adequate adrenal reserve for their level of illness. Replacement of physiologic doses of vasopressin (i.e., 0.04 units/min) may increase blood pressure and allow weaning of other vasopressors (10). However, the dose of vasopressin should not be escalated as it can result in cardiac and mesenteric ischemia.

Some patients with septic shock have persistent hypotension because of lack of adrenal reserve. A few of these patients meet the traditional criteria for adrenal insufficiency, but more have relative adrenal insufficiency: they possess some adrenal function, but lack the adequate reserve to compensate for their critical illness. These patients have less than a 9 mcg/dL increase over baseline cortisol levels when challenged with a short corticotropin (ACTH) stimulation test and may benefit from glucocorticoid replacement (12). (See also Chapter 109.) However, not all patients with sepsis and persistent hypotension should be treated with exogenous glucocorticoids, since steroids can worsen the outcomes of septic patients with preserved adrenal function.

Discharge Issues

For patients with sepsis syndrome, the principal discharge issue is that of leaving the ICU. It often is difficult to know how to utilize ICUs in the most cost-effective manner, but it clearly is not efficient to discharge patients recovering from sepsis syndrome from the ICU until they have reasonable prospects of not having to be readmitted. In general, this decision implies that patients have been off vasopressors and mechanical ventilation for at least 24 hours and that their renal, hepatic, hematologic, and metabolic parameters are stable or improving. Patients with sepsis syndrome who survive the ICU often experience significant residual weakness and other disability, and many can benefit from a stay in a rehabilitation facility after hospital discharge.

When Sepsis Syndrome Presents During Hospitalization

In most respects, the diagnostic and therapeutic approach to a patient who develops sepsis syndrome during hospitalization is no different than the approach to a patient

who presents to the hospital with sepsis syndrome initially. There are, however, a number of additional considerations.

First, the development of sepsis syndrome during hospitalization is much more likely to be related to such iatrogenic factors as surgery, instrumentation, intravascular catheters, Foley catheters, or immunosuppressive therapy. Second, because these are nosocomial infections, there is a much higher likelihood of microorganisms that are relatively resistant to commonly used antibiotics (see Chapter 64). As such, it is prudent to start empiric broader spectrum antibiotics and to consider infectious-diseases consultation sooner rather than later. Third, before developing sepsis syndrome, these patients already had underlying medical or surgical illnesses sufficiently severe to require hospitalization. Thus, their risk of a poor outcome is greater than that of patients who present with sepsis syndrome *de novo*.

Cost Considerations and Resource Use

ICU care consumes enormous personnel, equipment, pharmacy, and blood-bank resources. It is estimated to account for one-third of the overall budget in an average hospital. While a patient with sepsis syndrome is in the ICU, the physician can economize on unnecessary diagnostic tests and may opt for a less expensive antibiotic regimen. However, some expensive treatments, like drotrecogin alfa (activated), should not be withheld simply for financial concerns. In fact, one recent analysis suggested that this expensive therapy may in fact be cost-effective in certain populations (13).

Ultimately, however, there are two promising avenues for significant savings. First, practice diligent, meticulous medicine, avoiding mistakes, minimizing setbacks, preventing complications and secondary infections (see Table 26.4), and recognizing that good medicine might reduce the length of stay of the average patient who survives but paradoxically might increase total costs by extending the length of stay of the person who does not ultimately survive.

Second, be more circumspect in the use of the ICU by uniformly soliciting advance directives from patients who, by virtue of age, illness, debility, or philosophy, might choose to forego aggressive medical care, and more consistently to limit or withdraw care in patients already in the ICU who no longer have realistic prospects for survival (see Chapters 17, 19, and 22).

KEY POINTS

- Sepsis syndrome is the most common cause of death in non-coronary ICUs in the United States and is the tenth most common cause of death overall.
- Despite advances in therapy, the mortality rate of sepsis syndrome remains approximately 30%.
- Resuscitative measures and initiation of antibiotic therapy must occur simultaneous with rapid initial diagnostic evaluation.

- Foci of infection must be sought and eradicated.
- Patients with severe sepsis and most with sepsis syndrome require hospitalization. Most patients with severe sepsis require ICU management.
- As the pathophysiology of sepsis becomes better understood, new specific treatments (e.g., drotrecogin alfa [activated]) can improve outcomes.
- Many patients recover quickly with appropriate antibiotics and hemodynamic support (aggressive fluid resuscitation, with or without vasopressors).
- Unfortunately, many patients with sepsis syndrome develop multiorgan system failure, require costly technology (e.g., mechanical ventilation and hemodialysis), and have lengthy ICU stays.

Procedures in Hospital Medicine

27

Rachel L. Chin

INTRODUCTION

Physicians who care for hospitalized patients must commonly perform procedures to facilitate diagnosis and therapy. The risks of such procedures are often increased in hospitalized patients because of comorbid illnesses, poor wound healing, anticoagulation (either therapeutic or caused by the patient's disease state), and the frequent need for haste. It is essential, then, that hospital physicians be skilled in the performance of common procedures and recognize those situations in which a procedure can be done more safely if guided by technology (e.g., ultrasound guidance for thoracentesis or central venous catheterization) or a specialist.

This chapter will review the indications, contraindications, equipment required, and technique of some of the most common procedures performed on hospitalized patients.

ARTERIAL PUNCTURE AND CANNULATION

Introduction

Arterial cannulation is often required in the evaluation of a critically ill patient. Several arteries can be used, but the most common is the radial artery.

Indications

- Arterial pressure monitoring
- Arterial blood gas sampling or blood sampling for any purpose

Contraindications

- Insertion of a needle through an area of cutaneous infection
- Aneurysm with or without a palpable bruit
- Bleeding diathesis or on anticoagulants before correction of the clotting deficits
- Decreased collateral blood flow
- Presence of severe atherosclerosis (a relative contraindication)

Equipment

Positioning

- Armboard
- Folded towel
- Adhesive tape

Skin prep

- Sterile gauze
- Povidone-iodine solution (Betadine®) or prepackaged povidone-iodine sticks
- Alcohol prep pads

Sterile field

- Gloves, mask, sterile drape, local anesthetic

Local anesthetic

- Syringe, 1-mL
- Needle, 25-gauge
- Lidocaine, 1%

Arterial cannulation

- Angiocath, 20-gauge

or

- Radial artery catheterization set, 20-gauge (Arrow™), with guidewire

Dressing

- Antibiotic ointment
- Sterile gauze

Pressure monitoring

- Arterial pressure transducer
- Pressure tubing

Procedure

Before cannulating the radial artery, confirm adequate collateral circulation by performing the Allen test (Figure 27.1). Occlude both the radial and ulnar artery and have the patient pump the blood out of the hand by opening and closing the fist. With the hand open, release one of the occluded arteries and note the return of color to the hand within 5 seconds. Repeat with the other artery. If the circulation is inadequate, do not cannulate the artery.

Position

Place the patient and wrist in supine position with the arm abducted and forearm supinated.

Landmarks

Palpate the radial artery, which is radial to the flexor carpi radialis tendon.

Technique

Dorsiflex the wrist over a folded towel between the wrist and the armboard. Tape the hand to the armboard (Figure 27.2).

Put on a protective mask and gloves. Anesthetize the skin over the site with 1% lidocaine. Be careful not to obscure the artery by injecting too much lidocaine. Prepare and drape the wrist in a normal sterile fashion.

Prepare the catheter by sliding it out, then back in to break the seal. Insert the angiocatheter or radial artery catheterization (Arrow) set with guidewire into the artery at a 45-degree angle to the axis of the vessel (Figures 27.3 and 27.4).

If you see blood flash into the catheter, advance the needle 1–2 mm and then cannulate the artery by sliding the cannula over the needle. If using the Arrow set, first advance the guidewire using the Seldinger technique (see the description under “Central Venous Catheterization,” on page 215), and then advance the cannula into the artery over the guidewire (Figure 27.5).

A

B

Figure 27.1 The Allen test to confirm collateral circulation. **A.** The radial and ulnar arteries are both occluded. **B.** The clinician releases the radial artery to test its patency. The test is then repeated for the ulnar artery. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Figure 27.2 Positioning and prepping for arterial cannula insertion. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Remove the needle while leaving the cannula in place. Strong arterial flow indicates proper positioning.

Attach the cannula to the transducer tubing, and apply dressing. Apply antibiotic ointment to the puncture site, and secure it with sterile dressing.

Remove the towel under the wrist and reapply the arm-board securely.

KEY POINTS REGARDING ARTERIAL PUNCTURE AND CANNULATION

- In iodine-allergic patients, pHisoHex® or chlorhexidine gluconate (Hibiclens®) is an acceptable alternative to povidone-iodine (Betadine) solution or prepackaged sticks.
- Avoid tissue necrosis with distal ischemia (typically caused by repeated punctures that result in thrombosis),

especially in patients with poor ulnar arterial flow or patients in shock.

- Apply firm pressure for 5 minutes after puncture and 10 minutes after removal of a peripheral artery catheter, longer if the patient is anticoagulated.
- Retrograde flushing of the cannula can cause retrograde arterial embolism of blood clots.
- The risk of infection increases as the duration of cannulation is prolonged. Arterial catheters should be changed after 4 days if continued monitoring is necessary.
- Avoid catheter embolization by not pulling back the plastic catheter after it has been placed through the needle. The end of the catheter may be sheared off by the sharp needle bevel.

ARTHROCENTESIS

Introduction

Arthrocentesis is both a diagnostic and therapeutic intervention, which commonly is performed at the bedside without complications.

Figure 27.3 Technique for inserting the angiocatheter through the skin. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Figure 27.4 Cannulation of the artery is demonstrated by the flash of blood. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Figure 27.5 Arterial cannulation using the Seldinger technique. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Indications

- Diagnosis of joint effusions, especially when infectious arthritis is a possibility.
- Traumatic joint effusions such as ligamentous or bony injuries may be confirmed by finding blood in the joint.
- Fat globules in the fluid may diagnosis an intra-articular fracture.
- For nontraumatic joint disease, the fluid can be analyzed for a septic joint or crystal-induced arthritis (i.e., gout or pseudogout).
- Arthrocentesis can also provide relief of pain from a tense hemarthrosis or effusion, thereby also enabling the practitioner to examine the joint in question.
- Local instillation of medications such as lidocaine can also provide relief of pain and help in the examination or reduction of a fracture.
- Local instillation of corticosteroids may be appropriate in patients with inflammatory arthritis (such as gout or rheumatoid arthritis) after infection has been excluded.

Contraindications

- Insertion of a needle through an area of infection (cutaneous or osteomyelitis).
- Bleeding diatheses may be a relative contraindication, but arthrocentesis to relieve a tense hemarthrosis in patients with bleeding disorders can be performed if the

bleeding disorder is corrected with appropriate clotting factors prior to the procedure (Chapter 98).

- Arthrocentesis of a prosthetic joint should be performed predominantly to exclude an infection, usually by an orthopedic surgeon or rheumatologist unless the procedure is urgent (Chapter 110).

Equipment

Skin prep

- Sterile gauze
- Povidone-iodine solution (Betadine) or prepackaged povidone-iodine sticks
- Alcohol prep pads

Sterile field

- Gloves, mask, sterile drape

Local anesthetic

- Syringe, 5-ml
- Needles, 25- and 22-gauge
- Lidocaine, 1%, 10 mL

Aspiration or injection equipment

- Syringes: 5-, 10-, and 30-mL
- Needles: 22-, 20-, and 18-gauge
- Sterile specimen tubes
- Injectable saline

- Drugs for instillation (i.e., methylene blue, lidocaine, corticosteroids)

Dressing

- Adhesive bandage

General Techniques

1. Define the joint anatomy.
2. Select an approach.
3. Prep and drape.
4. Use universal precautions.
5. Inject local anesthetic along the needle tract.
6. Perform the arthrocentesis.
7. Apply the dressing.

For further information, see specific arthrocentesis techniques below. Use an 18–22 gauge needle of appropriate length. Avoid injury to articular cartilage with the needle by providing traction on the joint, and avoiding “walking” off the bone to find the joint space. Use the largest needle possible to avoid having the lumen become obstructed with blood clots. Send the synovial fluid for studies as indicated (i.e., cell count, microscopic examination, cultures, Gram stain, etc.).

Specific Procedures

Glenohumeral joint (Figure 27.6)

Position: The patient should be sitting upright, arms at the side and hands on lap.

Landmarks: The coracoid process medially and the proximal humerus laterally are palpated anteriorly.

Anterior technique: Insert needle lateral and inferior to coracoid; direct to anterior rim of glenoid.

Posterior technique: Insert needle 2 cm inferior to posterior angle of acromion, direct to posterior rim of glenoid.

Radiohumeral (elbow) joint (Figure 27.7)

Position: The patient should be sitting upright on a gurney with the elbow flexed at 90 degrees. Pronate the forearm, and place the palm flat on the table.

Landmarks: Palpate the lateral epicondyle of the humerus and the head of the radius. To palpate the radial head, pronate and supinate the forearm in a flexed 90-degree angle.

Technique: Place the needle between the lateral epicondyle of the humerus and the radial head. Direct the needle medially.

Radiocarpal (wrist) joint (Figure 27.8)

Position: Flex the wrist to 30 degrees, and apply traction to the hand.

Landmarks: Palpate the bony landmark, the tubercle of Lister. A depression can be palpated just ulnar to the

Figure 27.6 Approaches to arthrocentesis of the shoulder. **A.** Glenohumeral joint. **B.** Acromioclavicular joint. **C.** Subacromial bursa. **D.** Bicipital tendon. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

course of the extensor pollicis longus tendon distal and ulnar to Lister’s tubercle (Figure 27.9).

Technique: Insert a 22-gauge needle dorsally, distal to tubercle of Lister and medial to extensor pollicis longus tendon.

Interphalangeal and metacarpophalangeal (fingers) joints (Figure 27.10)

Position: Flex the fingers to approximately 15–20 degrees, and apply traction.

Landmarks: On the dorsal surface of the finger, palpate the distal bony prominence of the distal metacarpophalangeal phalanx and proximal end of the proximal phalanx for the metacarpophalangeal joint. For the interphalangeal joints, palpate the distal end of the proximal phalanx and the proximal end of the middle phalanx. The extensor tendon runs down the middle of the digits.

Technique: Insert a 22-gauge needle into the joint space dorsally, medial or lateral to the extensor tendon.

Figure 27.7 Approach to arthrocentesis of the elbow. **A.** Radiohumeral joint. **B.** Lateral epicondyle. **C.** Olecranon bursa. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

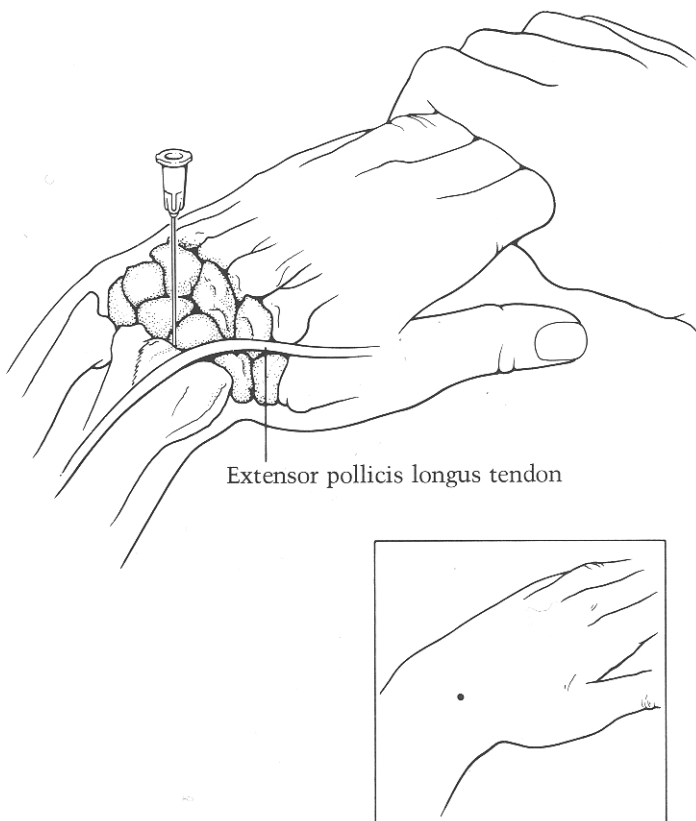

Figure 27.8 The wrist (radiocarpal) joint. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

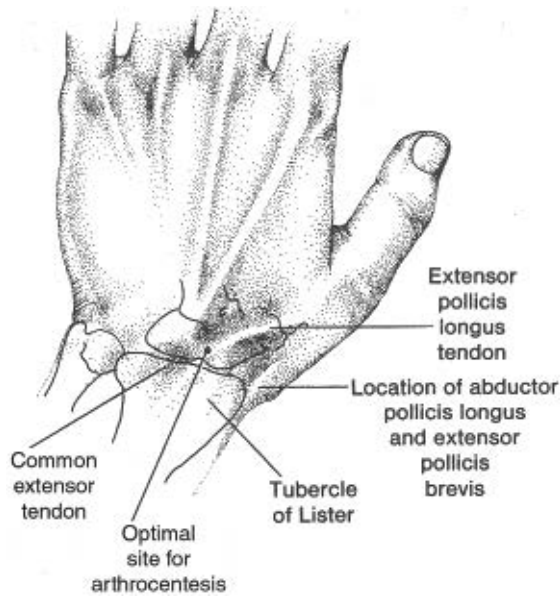

Figure 27.9 The approach to radiocarpal arthrocentesis. The best site of aspiration is through the depression, which can be palpated just ulnar to the course of the extensor pollicis longus tendon, distal and ulnar to Lister’s tubercle. (Reprinted from Simon RR, Brenner BE, eds. *Emergency Procedures and Techniques*. 4th ed. Philadelphia: Lippincott, Williams and Wilkins, 2002, with permission.)

Carpometacarpal (thumb) joint (Figure 27.11)

Position: Oppose the thumb to the little finger, and apply traction to the thumb.
 Landmarks: Palpate the space between the abductor pollicis longus tendon and the base of the metacarpal, lateral (palmar) to the anatomical “snuff box” (which is dorsal to the abductor pollicis longus). Extend the thumb to palpate the abductor pollicis longus tendon.

Technique: Insert a 22-gauge needle proximal to the prominence of the base of the metacarpal, on the palmar side of the abductor pollicis tendon. Avoid the “snuff box” because it contains the radial artery and superficial radial nerve.

Knee joint (Figure 27.12)

Position: Keep the knee extended and have the leg relaxed.
 Landmarks: The medial aspect of the middle/superior portion of the patella.
 Technique: Insert an 18-gauge needle 1 cm medial to the patella, and direct it under the patella and into the intercondylar femoral notch. If the patient tenses the quadriceps, the space will be difficult to enter. Be prepared to aspirate 50–70 mL of fluid if there is a large effusion.

Tibiotalar (ankle) joint (Figure 27.13)

Position: Have the patient lie supine on the gurney, and plantar flex the foot.
 Landmarks: Palpate the space between the tibialis anterior tendon and the medial malleolus. Dorsiflex the foot to palpate the tibialis anterior tendon.
 Technique: Insert a 20-gauge needle 2–3 cm into the space between the tibia and talus. Palpate the anterior tibial tendon, and place the needle medial to it, directed into the hollow at the anterior margin of the medial malleolus.

Interphalangeal and metatarsophalangeal (toe) joints (Figure 27.13)

Position: Have the patient lie supine on the gurney, and flex the toes to 15–20 degrees. Apply traction to the toes.

Figure 27.10 The finger joints. **A.** Metacarpophalangeal. **B.** Interphalangeal. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

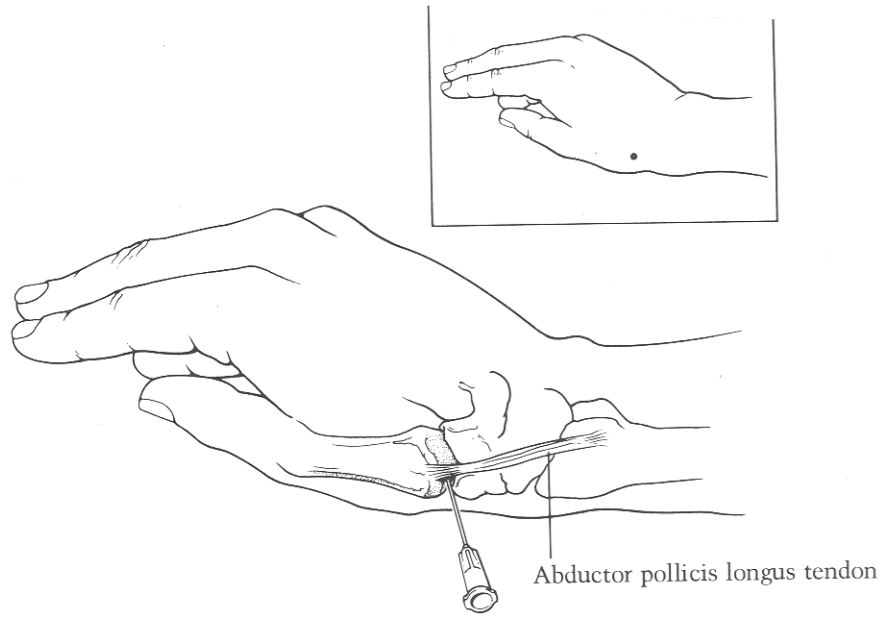

Figure 27.11 The thumb (carpometacarpal) joint. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

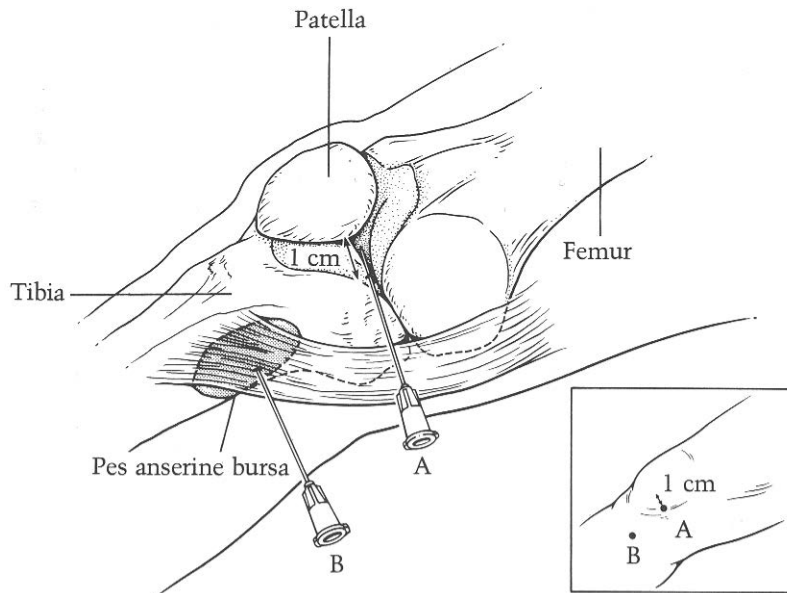

Figure 27.12 The knee. **A.** The knee joint, anteromedial approach. **B.** The pes anserine bursa. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

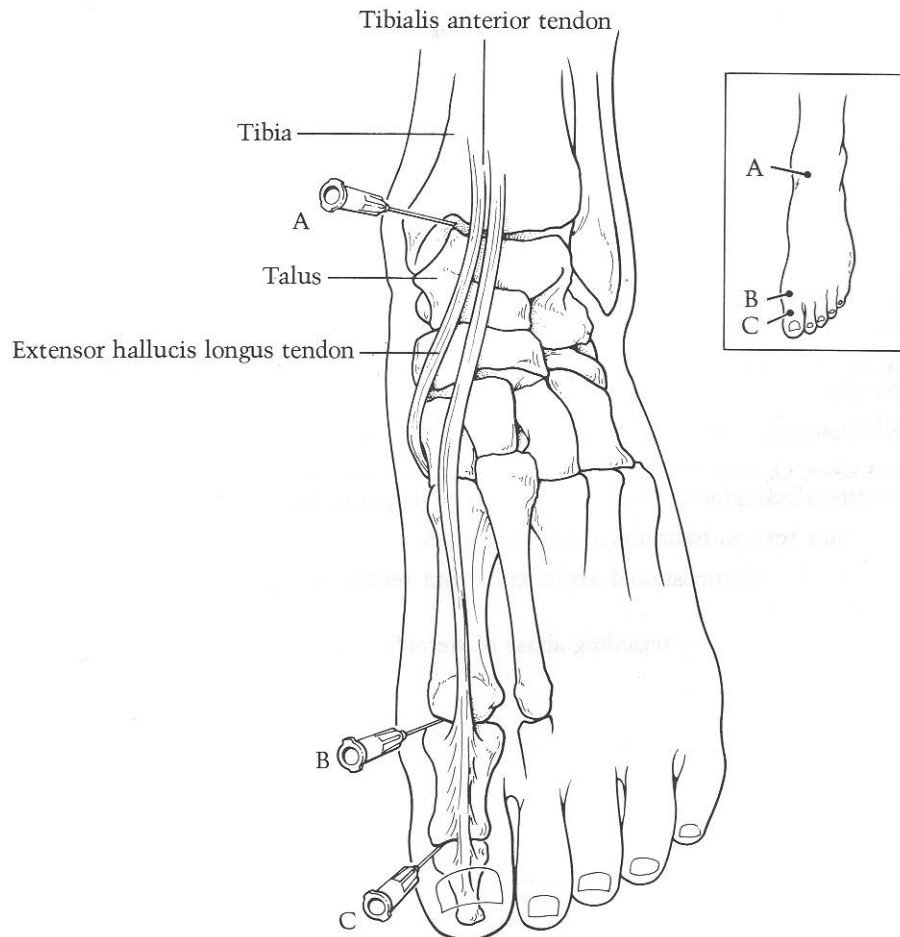

Figure 27.13 The ankle and toe joints. **A.** Tibiotalar (ankle) joint. **B.** Metatarsophalangeal joint. **C.** Interphalangeal joint. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bed-side Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Landmarks: On the dorsal surface of the toes, palpate the distal bony prominence of the distal metatarsophalangeal phalanx and proximal end of the proximal phalanx for the metatarsophalangeal joint. For the interphalangeal joints, palpate the distal end of the proximal phalanx and the proximal end of the middle phalanx. The extensor tendon runs down the middle of the digits.

Technique: Insert a 22-gauge needle into the joint space dorsal, medial or lateral to the extensor tendon.

- Clotting abnormalities should be corrected prior to aspirating a hemarthrosis.
- Have the patient in a sitting or lying position to avoid a postprocedural vasovagal episode.
- If you are culturing for *Neisseria gonorrhoeae*, be sure you have the correct culture medium. Store the specimen in an anaerobic environment.
- Be sure to use adequate local anesthesia to keep the procedure relatively painless.

KEY POINTS REGARDING ARTHROCENTESIS

- In iodine-allergic patients, pHisoHex® or chlorhexidine gluconate (Hibiclens®) is an acceptable alternative to povidone-iodine (Betadine) solution or prepackaged sticks.
- Use meticulous sterile technique to prevent infection, and never pass the needle through infected skin.
- Take a careful allergy history to avoid a hypersensitivity reaction from an allergy to the medication.

CENTRAL VENOUS CATHETERIZATION

Seldinger Technique

This technique, first described by Sven Ivar Seldinger in 1952, is now the standard approach for the insertion of a catheter into a blood vessel or space. Using the Seldinger technique, the clinician places an introducer needle into the desired blood vessel, next inserts a guidewire *through* the introducer needle, and finally slides the catheter *over* the guidewire (Figure 27.14).

Figure 27.14 The Seldinger technique. **Panel A.** 1. Introduce needle on syringe through puncture wound in skin into the vessel (for arterial cannulation, syringe unnecessary; for venous cannulation, aspirate gently). 2. Remove syringe. **Panel B.** 3. Slide soft-tip of J-tip guidewire through needle into vessel. **Panel C.** 4. Remove needle, leaving guidewire in place. **Panel D.** 5. Insert dilator over guidewire into vessel. 6. Remove dilator. **Panel E.** 7. Slide catheter over guidewire into vessel. **Panel F.** 8. Remove guidewire, leaving catheter in place. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Indications

- Need for intravenous access in an emergency
- Central venous pressure monitoring (internal jugular or subclavian vein cannulation)
- Hyperalimentation
- Vasopressor administration
- Transvenous pacemaker insertion
- Hemodialysis
- Cardiac catheterization
- Pulmonary angiography

Contraindications

- Insertion of a needle through an area of cutaneous infection
- Patients with distorted local anatomy or landmarks
- Previous radiation therapy to the clavicular area (for subclavian vein cannulation)
- Patients with significant chest wall deformities (for subclavian vein cannulation)
- Bleeding disorders or anticoagulation therapy
- Vasculitis
- Suspected pre-existing injury to the vessel

Equipment

Skin prep

- Sterile sponges, alcohol, povidone-iodine solution

Sterile field

- Mask, gown, gloves, sterile drape

Local anesthetic

- Plastic syringe, 3-ml, with 22-gauge needle
- Lidocaine 1%, 5ml

Cannulation Equipment

- Multilumen (triple-lumen) central venous catheter set with 7 Fr \times 6" (16 cm) radiopaque catheter *or* single-lumen central venous catheter set
- Saline flush
- Suture material in kit
- Scalpel

Dressing

- Antibiotic ointment
- Sponges
- Transparent adhesive film

Infusion

- Intravenous solution, tubing, and IV stand

Technique

Prepare equipment and obtain necessary consent according to hospital policy. Put on a protective mask and gloves. Prepare the insertion area with swab sticks or sterile gauze soaked with the povidone-iodine solution. Warn the patient that the solution will be cold.

Insert the introducer needle into the desired blood vessel as described in the appropriate subsection below. Advance the introducer needle with its cannula into the blood vessel, aspirating gently until there is a flashback of venous blood, usually at a depth of 3–4 cm. For internal jugular or subclavian vein cannulation, keep the needle and syringe almost parallel to the table, at a 20-degree angle. When there is free flow of blood from the open cannula, prepare to slide the guidewire through the blood vessel.

Pulsatile flow identifies an arterial puncture and mandates immediate withdrawal of the needle (1). A single arterial puncture without laceration rarely causes serious harm.

If there is no blood return, aspirate gently to confirm intravenous location. If blood is still not aspirated, remove the needle and start again. Do not reinsert the needle through the *in situ* cannula because of the risk of shearing of the catheter tip.

When it is time to slide the guidewire, occlude the cannula hub with your thumb to prevent bleeding or air embolus. When using a safety syringe and hollow plunger

with a guidewire opening, there is no need to remove the needle/cannula from the syringe. For internal jugular or subclavian vein cannulation, ask the patient to exhale, hum, or perform a Valsalva maneuver to raise intrathoracic pressure and reduce the possibility of a pneumothorax. Slide the guidewire through the cannula into the blood vessel. For internal jugular or subclavian vein cannulation, turn the patient's head to the ipsilateral side as the guidewire is advanced to prevent the guidewire from going up the internal jugular vein.

Remove the cannula, holding the guidewire in place. Incise the skin about 1.5 cm with a no. 11 blade over the wire. Pass the vessel dilator over the guidewire, and then remove the dilator while holding the wire in place.

For internal jugular or subclavian vein cannulation, judge the approximate distance from the puncture site to the superior vena cava, and then insert the single- or multilumen central venous catheter over the wire. Thread the catheter over the wire until it protrudes from the infusion port. Hold the wire firmly, and while holding the catheter near the entry, use a twisting motion to push the catheter over the guidewire to the predetermined length, if any.

The guidewire should slide out of the distal infusion port while the catheter is held firmly in place. If the wire does not slide easily, *do not force it in*, but pull the catheter back 1–2 cm and try again. If the wire cannot be removed, both the catheter and wire may have to be removed together.

With the central line catheter in place and the wire removed, draw blood and cultures through the distal port with a vacutainer. After collecting blood, connect this port to the intravenous line or attach the cap.

There should be blood throughout the lumen; if not, aspirate until the lumen is filled with blood, and flush with saline solution to avoid air entrapment. This process should be performed on all the ports.

Secure the catheter to the skin by suturing the catheter clamp or by stapling (some kits have manual staples that fit through the clamp holes) (Figure 27.15). Apply a sterile dressing over the puncture site, and tape securely.

After internal jugular or subclavian vein cannulation, obtain a chest radiograph to confirm placement of the catheter in the superior vena cava and to exclude a pneumothorax or hemothorax.

Internal Jugular Vein Cannulation

The internal jugular vein is the most common site for central venous access. Knowledge of neck anatomy is important.

Procedure

Position

Assure adequate lighting and elevate the bed to a comfortable level. Have the patient in a supine position in Trende-

Figure 27.15 Subclavian vein cannulation and the technique of securing the catheter to the skin. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

lenburg 10–20 degrees. Turn the patient’s head away from the internal jugular vein site.

Landmarks

The apex of the triangle formed by the two heads of the sternocleidomastoid muscle and the clavicle serves as a landmark. The internal jugular vein runs deep to the sternocleidomastoid muscle and then through this triangle

before it joins the subclavian vein to become the brachiocephalic vein (Figure 27.16).

Technique

After prepping the neck and clavicular area, infiltrate 1% lidocaine anesthetic into the apex of the triangle formed by the two heads of the sternocleidomastoid muscle and the clavicle.

Place the patient in Trendelenburg position with the head rotated 45 degrees away from the site of cannulation. Place the index and middle finger of the nondominant hand on the carotid artery and insert a 22-gauge finder needle through the skin, immediately lateral to the carotid pulse and slightly superior to the apex of the triangle. The needle is advanced past the apex of the triangle, in the direction of the ipsilateral nipple, at an angle of 20 degrees above the plane of the skin, keeping it almost parallel to the bed. The vein is usually located near the surface of the skin and is often cannulated at a depth of less than 1.3 cm. If the first pass is unsuccessful, the needle should be directed slightly more medially on the next attempt.

With the finder needle in place, insert the 18-gauge introducer needle right alongside it and into the vein. Follow the general Seldinger technique as described in Figure 27.14.

Subclavian Vein Cannulation

Procedure

Position

Assure good lighting and elevate the bed to a comfortable level. Have the patient in a supine position in Trendelenburg 10–20 degrees, with the option of placing a roll under the patient’s shoulders to accentuate the clavicles. Turn the

Figure 27.17 Positioning, prepping, and draping for subclavian vein catheterization. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

patient's head away from the subclavian vein site (Figure 27.17).

Landmarks

The axillary vein, which becomes the subclavian vein as it crosses the first rib, is a 10–20 mm large, valveless vessel. The vein lies posterior to the medial third of the clavicle. It

is separated from the subclavian artery by the anterior scalene muscle, which has a thickness of 10–15 mm. Other important structures related to the course of the vein are the vagus and phrenic nerves, which course medially in front of the subclavian artery. The trachea and esophagus lie medial to the vein. No vital structures are crossed in entering the vein at the medial one-third of the clavicle between the subclavian vein and the skin (Figure 27.18).

Technique

After preparing the neck and anterior chest area, infiltrate 1% lidocaine anesthetic into the middle of the clavicle, and insert the needle 2–3 cm caudal under the clavicle (Figure 27.19). If the patient is on mechanical ventilation, the ventilator must be disconnected while performing this maneuver to avoid a pneumothorax from the positive airway pressure.

The left index finger is placed in the suprasternal notch, and the thumb is positioned at the costoclavicular junction. These landmarks serve as the reference points for the direction of the needle as you aim for the suprasternal notch (Figure 27.20).

A finder needle is generally not long enough to locate the subclavian vein and is therefore not used. Insert the 18-gauge introducer needle attached to the syringe through the same anesthetic puncture site into the subclavian vein. Follow the general Seldinger technique as described above.

The correct position of the catheter is in the superior vena cava, not the right atrium or ventricle. The superior vena cava begins at the level of the manubrial-sternal junction and terminates in the right atrium, approxi-

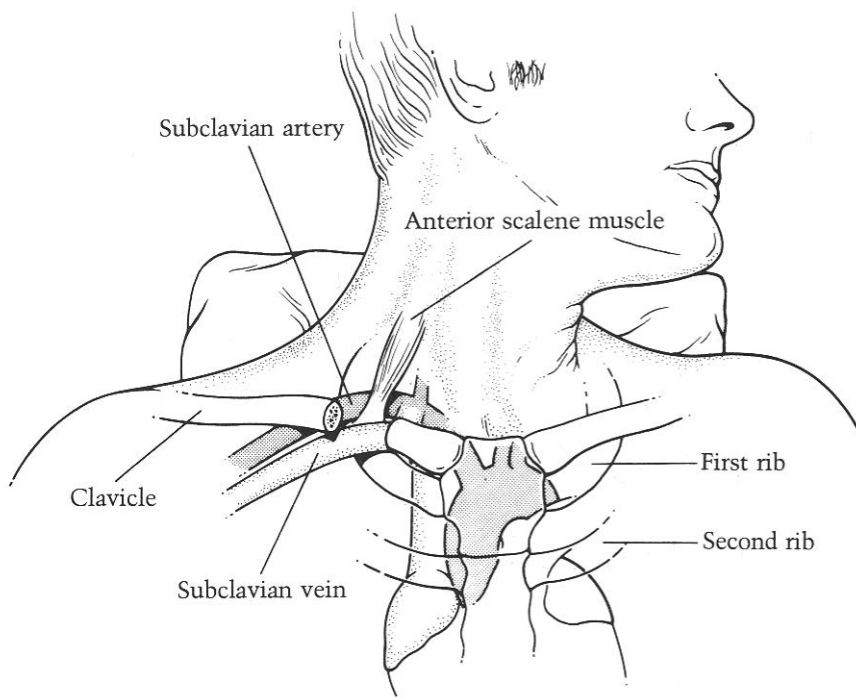

Figure 27.18 Anatomic landmarks for subclavian vein catheterization. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

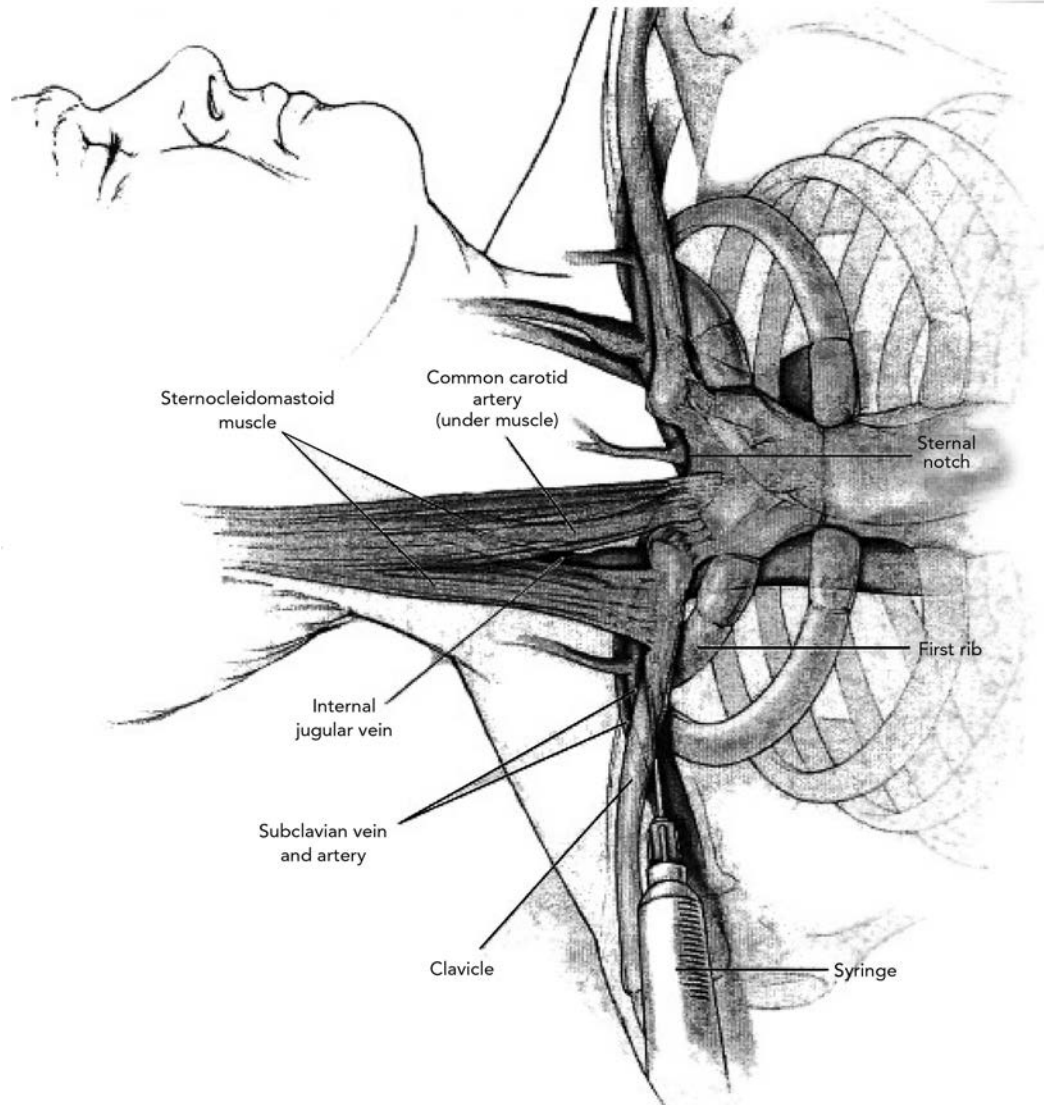

Figure 27.19 Insertion of the catheter into the subclavian vein. (Reprinted from McGee DC, Gould MK. Preventing complications of central venous catheterization. *N Engl J Med* 2003; 348:1123–1133, with permission.)

mately 5 cm lower. Therefore, the catheter should be threaded 2 cm below the manubrial-sternal junction. This distance can be estimated by placing the catheter parallel to the chest wall before insertion. Standard catheters in central line kits are 16 cm long, which is the appropriate length for the average adult. Nevertheless, proper placement is best assessed by a chest radiograph rather than by predetermined measurements.

Femoral Vein Cannulation

The femoral vein is easily located by palpating the femoral artery (the vein is just medial to the artery). Although femoral vein cannulation does not potentially jeopardize critical structures, it carries greater infectious and thrombotic risks than subclavian or internal jugular cannulation. Importantly, complication rates are usually lower when

central lines are placed by experienced physicians (“practice makes perfect”), regardless of the site.

Procedure

Position

Assure good lighting, and elevate the bed to a comfortable level. Have the patient in a supine position. The leg should be slightly abducted and externally rotated to increase exposure of the femoral vein.

Landmarks

Identify the femoral vein by palpating the femoral artery, which is always lateral to the vein in the femoral canal below the inguinal ligament and halfway between the anterior iliac spine and the pubic tubercle. The mnemonic

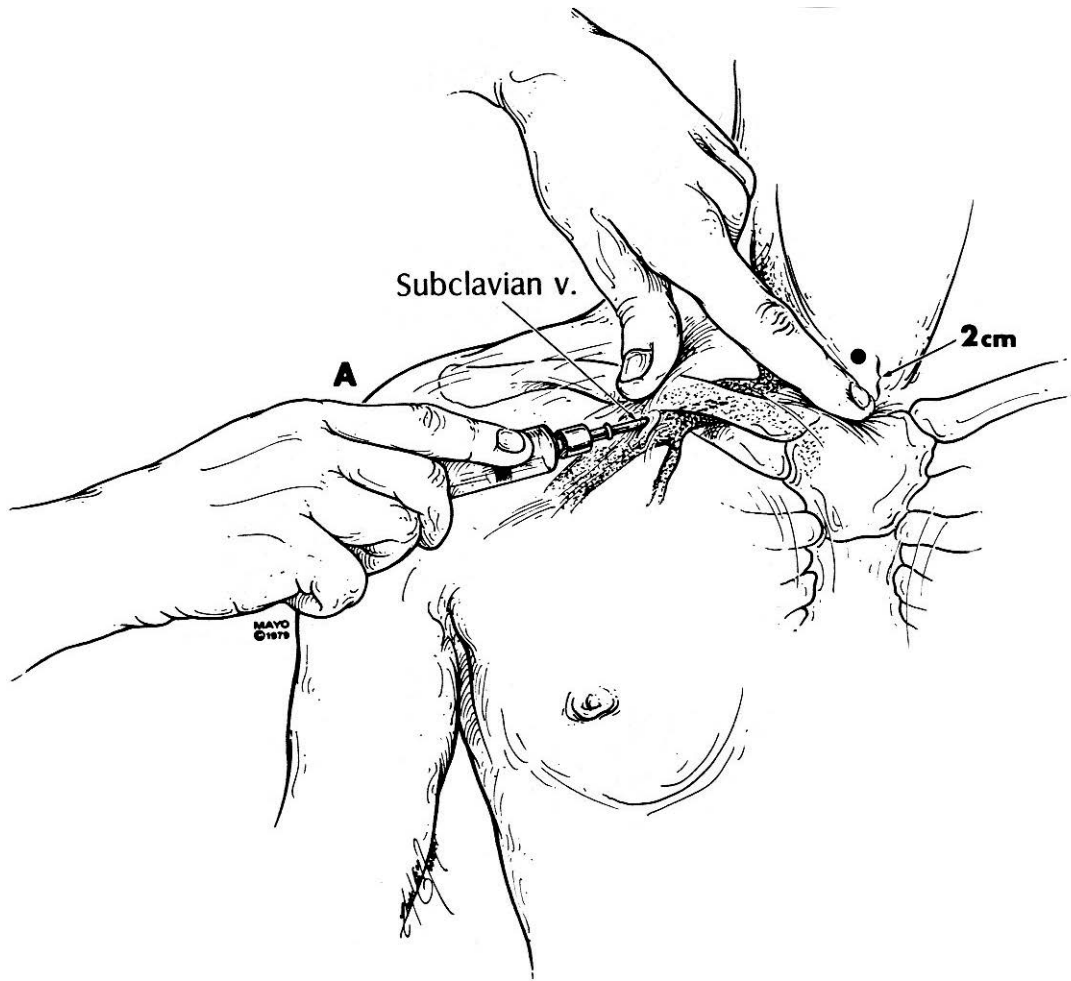

Figure 27.20 Hand positioning during subclavian venipuncture (note that gloves should be worn). (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

NAVEL (from lateral to medial: Nerve, Artery, Vein, Empty space, Lymphatics) is a reminder for where the vein is located in relation to the artery. A right-handed physician usually will find it easier to cannulate the right femoral artery.

Technique

After prepping the groin area, infiltrate 1% lidocaine anesthetic medial to the femoral pulse. Aspirate with each change in needle location to avoid injecting directly into a blood vessel.

Place the index and middle finger of the nondominant hand on the femoral artery, and insert a 22-gauge finder needle with a 5-mL syringe through the skin, immediately medial to the femoral pulse and below the inguinal ligament. The needle is advanced at an angle of 45 degrees above the plane of the skin, at a depth of 1–2 cm. If the first pass is unsuccessful, the needle should be directed slightly more medially on the next attempt.

With the finder needle in place, insert the 18-gauge introducer needle right alongside it and into the vein. Follow the general Seldinger technique as described above. Ensure that the patient will not ambulate with the femoral catheter in place. Patients can sit up, but clinicians should be aware that this position may cause discomfort and kinking of the catheter.

Ultrasound Guidance for Central Venous Catheterization

Catheter placement may be assisted by the use of a portable ultrasound device. Real-time ultrasound can provide visualization of the blood vessels and surrounding structures before and during insertion of the catheter and thereby reduce the incidence of complications, especially when the anatomy is difficult to discern by palpation (Figures 27.21 and 27.22). Studies have demonstrated improvements in accuracy and efficiency when internal jugular catheteriza-

Figure 27.21 Ultrasound guidance for central vein catheterization. Ultrasound image of the right side of the neck. **C.** carotid artery; **RIJ.** right internal jugular vein. (Reprinted from *AHRQ Web M&M*, March 2004: <http://webmm.ahrq.gov/spotlight/cases.aspx?ic=51>, with permission.)

tion was performed with portable ultrasound; the benefits in subclavian catheterization are less certain (2). However, real-time ultrasound guidance is a relatively new technique and requires sufficient training and experience to achieve competency.

KEY POINTS REGARDING CENTRAL VENOUS CATHETERIZATION

- In iodine-allergic patients, pHisoHex or chlorhexidine gluconate (Hibiclens) is an acceptable alternative to povidone-iodine (Betadine) solution or prepackaged sticks.
- Insert the cannula gently to prevent a hematoma from developing where the venous wall would be injured or traversed.
- Never lose hold of the guidewire, especially when placing the final catheter over the wire.
- Be sure to dilate the soft tissue and vessel by making an adequate scalpel incision and placing the entire dilator into the vessel.
- Do not use the subclavian approach in patients who have coagulation disorders or are receiving full anticoagulation because it is impossible to apply direct pressure to an oozing subclavian vein.
- Subclavian venipuncture is not a good route for rapid volume resuscitation unless no other access is available because very large (i.e., 14-gauge) catheters are best placed in the femoral or a peripheral vein. A peripheral 5 cm, 14-gauge catheter can deliver roughly twice as much fluid as a 20 cm, 16-gauge central venous catheter.

Figure 27.22 Portable ultrasound machine for vascular access procedures. (Reprinted by permission of SonoSite, Inc.)

- To avoid a pneumothorax after the cannulation of the internal jugular or subclavian vein, abandon the procedure after two unsuccessful attempts, and keep the syringe on the needle until the needle is in the vein. To avoid air embolism (caused when air enters through the open cannula or needle), maintain the patient in Trendelenburg position, and occlude the open needle hub with a finger. Avoid excessive wire/catheter advancement by premeasuring the length on the patient's chest wall; then confirm the position of the catheter tip on a chest radiograph. After the catheter is placed, raise the head of the bed to reduce venous pressure and thereby prevent a hematoma.
- If a patient with a pre-existing pneumothorax needs central venous access, a vein should be cannulated on the same side as the pneumothorax.
- Remove the catheter as soon as possible to prevent catheter-induced thrombosis.

LUMBAR PUNCTURE

Introduction and Indications

Cerebrospinal fluid (CSF) should be obtained via lumbar puncture in patients with a fever of unknown origin, especially if there is headache, an altered level of consciousness, or suggestion of a stiff neck (Chapter 70). The presence of meningeal signs may not be evident in patients who are old, debilitated, immunosuppressed, or partially treated with antibiotics.

Lumbar puncture should also be performed in patients who are suspected of having subarachnoid hemorrhage despite a normal head CT scan (Chapter 117) because 5%–8% of acute subarachnoid hemorrhages will not be detected by the initial CT scan.

Other uses of the lumbar puncture include injection of anesthetic agents, chemotherapeutic agents, and antibiotics, and drainage of fluids.

Contraindications

- Insertion of a needle through an area of infection (cutaneous or osteomyelitis)
- Bleeding diathesis or anticoagulant therapy
- Papilledema or other signs of increased intracranial pressure
- Focal neurological signs until a space-occupying lesion is excluded

Equipment

Skin prep

- Sterile sponges (usually three swab sticks, or prepackaged povidone-iodine sticks)
- Povidone-iodine (Betadine) solution
- Alcohol prep pads

Sterile field

- Gloves, mask, sterile drape, and towel

Local anesthetic

- Syringe, 3-mL
- Needles, 25- and 22-gauge
- Lidocaine, 1%

Prepackaged lumbar puncture preparation kits, including

- Spinal needle with stylet 20-gauge \times 3 1/2 inch
- Four specimen vials with caps, 10 ml

- Manometer with three-way stopcock

Dressing

- Gauze pads
- Bandage

Procedure

Position

The most important step in this procedure is positioning the patient. The lateral decubitus position, with the patient flexed in fetal position, is the most common approach. The back should be at the edge of the bed, and the knees, hips, back, and neck should be maximally flexed. Shoulders and pelvis should be perpendicular to the floor.

Landmarks

Find the midline of L4-L5 or L5-S1, which is an imaginary measured line drawn from the patient's posterior superior iliac crest to the floor (in the lateral decubitus position) (Figure 27.23). The adjacent interspace above or below may be used, depending on which appears to be most open to palpation. The spinal cord ends at the level of L1-L2 in adults.

An alternative is the *sitting-up approach*, which is used for obese patients and patients with lumbar spondylosis, rheumatoid arthritis, scoliosis, or ankylosing spondylitis. Have the patient sit on the edge of the bed, leaning over two pillows or sheets on a bed stand (Figure 27.24). Find the midline of L4-L5 by palpating the posterior superior iliac crest and the spinal interspace.

Technique

Prepare the equipment and obtain necessary consent according to hospital policy. Put on a protective mask and gloves. Prepare the puncture site with swab sticks in the povidone-iodine solution. Warn the patient that the solution will be cold.

Figure 27.23 Left lateral decubitus position for lumbar puncture. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Figure 27.24 The sitting position. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Drape the patient. Place a sterile towel between the patient's hip and the bed. Infiltrate a skin wheal with 1% lidocaine anesthetic by using the 25-gauge needle, switching to the 22-gauge needle for deeper infiltration.

Hold the needle between both thumbs and index fingers (Figure 27.25). Insert the spinal needle into the subcutaneous tissue. The needle should have the bevel parallel to the axis of the spine. Some have speculated that pointing the bevel laterally may allow the needle to penetrate the transverse fibers of the dura rather than cut through them, thereby reducing spinal fluid leakage after the needle has been withdrawn.

Angle the needle cephalad, toward the umbilicus. Advance slowly until a very subtle "pop" is felt as the needle passes through the ligamentum flavum dura. The "pop" may not be felt with the very sharp needles in the disposable sets. Accordingly, the operator must remove the stylet frequently and check for flow of cerebrospinal fluid to avoid transgressing the subarachnoid space. If there is no flow, advance the needle with the stylet and check for flow at each 2 mm interval (in adults, the needle should be at a depth of approximately 4 cm, depending on the patient's body habitus).

When the needle is in the subarachnoid space, attach the manometer and three-way stopcock. Normal pressures are 70–180 mm CSF. If the readings are elevated, have the patient relax and extend the legs to decrease intra-abdominal pressure. Avoid having the patient breathe deeply because the resulting hypocapnia induces falsely low pressure readings due to cerebral vasoconstriction.

After measuring the pressure, turn the stopcock and collect the fluid. Tube 1 is used for protein and glucose levels and for electrophoretic studies. Tube 2 is used for

microbiologic (Gram stain and cultures) and cytologic studies. Tube 3 is for cell counts and serologic tests for syphilis. In the presence of a traumatic (bloody) spinal tap, cell counts should be performed in tubes 1 and 4—if the source of the blood was tap-related trauma, the red cell count should be markedly lower in tube 4. A traumatic tap is not a particularly dangerous problem, and no specific precautions are needed except that these patients should be observed for signs of cord or spinal nerve compression owing to a hematoma.

Figure 27.25 Hand position during lumbar puncture, showing the insertion of the spinal needle into the subcutaneous tissue. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Remove the needle after collection, and apply a dressing. Instruct the patient to remain flat in bed for 1–3 hours.

KEY POINTS REGARDING LUMBAR PUNCTURE

- In iodine-allergic patients, pHisoHex or chlorhexidine gluconate (Hibiclens) is an acceptable alternative to povidone-iodine (Betadine) solution or prepackaged sticks.
- To prevent transtentorial or tonsillar herniation, never perform a lumbar puncture in the presence of papilledema or focal neurological signs unless a mass is excluded.
- Keep stylet in place with the needle. This method prevents viable epithelial cells from entering the spinal canal, where they can form an intraspinal epidermoid cyst.
- Use sterile technique, and avoid performing lumbar puncture through an area of cellulitis to prevent iatrogenic meningitis, epidural empyema, or subdural empyema.
- Remove small volumes of fluid slowly, and prescribe prolonged bedrest (an extra few hours) in elderly patients. The removal of large volumes may result in the tearing or avulsion of perforating veins.
- Avoid excessively lateral or deep penetration so as to keep from lacerating the anterior or lateral epidural venous plexus.
- Transient headache occurs after 5%–30% of all punctures. Headaches usually persist for 1–2 days, but occasionally last up to 10 days. Headaches are usually suboccipital in location. Keep patients well hydrated and remove only the volume of fluid needed for studies.
- Use adequate anesthesia to prevent backaches.
- Insert the spinal needle with the bevel parallel to the axis of the spine to prevent the spinal needle from puncturing or grazing the nerve root and causing transient radicular pain.
- If the opening pressure is unusually high, have the patient straighten the legs, and recheck the pressure.

PARACENTESIS

Introduction

Abdominal paracentesis to remove up to 100 ml of ascites may be performed safely and easily at the bedside with simple needle aspiration. For patients who have reduced respiratory capacity and difficulty breathing, 3–6 liters may be removed slowly, to avoid hypotension and electrolyte disturbances. Large-volume paracentesis (greater than 6

liters) may have an immediate hemodynamic effect, with precipitous hypotension, tachycardia, and oliguric renal failure.

Complications of paracentesis are usually minor and infrequent if appropriate procedure is followed. Procedure-associated risks include a 1% risk of significant abdominal-wall hematoma, a 0.01% risk of hemoperitoneum, and a 0.01% risk of iatrogenic infection. The only absolute contraindications to paracentesis are disseminated intravascular coagulation or recent thrombolytic therapy. Severe coagulopathy and thrombocytopenia (INR >2 or platelet count <50) may need correction prior to the procedure to minimize the risk of bleeding, although there are no data supporting specific cut-offs.

Indications

- Diagnosis of infection or malignancy
- Therapeutic relief of excess peritoneal fluid

Contraindications

- Insertion of a needle through an area of cutaneous infection
- Pregnancy
- Prolonged prothrombin time and a low platelet count (relative contraindications)

Equipment

Commercially prepared thoracentesis/paracentesis kits have most of the equipment, but if a kit is not available, the following equipment can be assembled.

Skin prep

- Sterile gauze
- Povidone-iodine solution or prepackaged povidone-iodine sticks
- Alcohol prep pads

Sterile field

- Gloves, mask, sterile drape

Local anesthetic

- Syringe, 5-ml
- Needles, 25- and 22-gauge
- Lidocaine 1%, 10 mL

Paracentesis

- 50-mL syringe with three-way stopcock
- 14- or 16-gauge angiocatheters or Caldwell paracentesis needle/catheter
- Curved clamps, two
- Sterile connecting tubing (from stopcock to bottle)
- Specimen tubes
- Plasma vacuum bottles

Procedure

Position

The supine position is the most common approach. An alternative approach is the lateral decubitus position.

Landmarks

There are four standard landmarks for paracentesis (Figure 27.26). Most physicians prefer the lower abdominal sites. Others claim that the specific location is not important if the site is lateral to the rectus sheath so that the inferior epigastric artery is avoided.

Technique

Prepare your equipment and obtain necessary consent according to your hospital's policy. Put on a protective mask and gloves. Prepare and drape your patient using sterile technique. Warn the patient that the solution will be cold.

Infiltrate a skin wheal with 1% lidocaine anesthetic by using the 25-gauge needle and switching to the 22-gauge needle for deeper infiltration. For simple diagnostic paracentesis, a 50-mL syringe with a 20- or 22-gauge needle or angiocatheter is sufficient. For removal of large volumes of fluid, insert an 18- or 20-gauge spinal needle or angiocatheter into the subcutaneous tissue.

Insert the needle at an angle, or use the Z-tract technique (retraction of the abdominal skin caudad before inserting the needle). This technique is often used to help seal the needle tract after paracentesis, thereby preventing persistent ascitic fluid drainage.

Figure 27.26 Standard landmarks for paracentesis, including the four quadrants lateral to the rectus muscle and a few centimeters below the umbilicus in the middle. (Reprinted from Roberts JR, Hedges JR. *Clinical Procedures in Emergency Medicine*. 3rd ed. Philadelphia: WB Saunders, 1998, with permission.)

A minimum of 50 cc ascitic fluid is required for adequate studies (Chapter 83). In patients with tense ascites that causes respiratory distress, the removal of 1–3 liters will be necessary for symptomatic relief.

Suction should be applied while the needle is advanced and until abdominal fluid is obtained. If the initial fluid stops, the needle or catheter can be rotated or angulated. The catheter should never be withdrawn through the needle, as this may cause shearing of the cannula. Turning the patient to a lateral decubitus position may help if the patient is initially supine.

For removal of large volumes of fluid, attach a 50-ml syringe to a three-way stopcock (optional) and intravenous tubing. Once fluid is aspirated from the syringe, attach the IV tubing to the vacuum bottle, and open the stopcock to the bottle. When the procedure is completed, remove the catheter and needle as a unit in one fast, continuous motion, and apply a sterile occlusive dressing to the site. Published literature supports the use of plasma expanders (particularly albumin) to prevent circulatory dysfunction after large-volume (>5 liters) paracentesis (3).

Commercially prepared thoracentesis/paracentesis kits are another alternative. The catheters in these kits are larger than necessary for paracentesis and can cause leakage at the site after removal.

Patients with definite ascites and no prior surgery can undergo bedside paracentesis safely without radiologic localization. If the fluid level is difficult to detect, or if there are surgical scars, portable ultrasound can be used to help locate the fluid and help visualize the surrounding structures to avoid perforations.

KEY POINTS REGARDING PARACENTESIS

- In iodine-allergic patients, pHisoHex or chlorhexidine gluconate (Hibiclens) is an acceptable alternative to povidone-iodine (Betadine) solution or prepackaged sticks.
- Empty the bladder to prevent puncture of a full bladder.
- Do not insert the needle over sites of surgical scars to prevent bowel perforation resulting from possible intra-abdominal adhesions. In patients with prior surgery, consider the use of ultrasonic guidance.
- Correct clotting abnormalities to avoid serious intraperitoneal or abdominal wall hematoma.
- Avoid the rectus muscle, where the superior and inferior epigastric vessels lie.
- Avoid visible collateral venous channels on the abdominal wall.
- Insertion of the needle through the linea alba (relatively avascular midline) lessens the risk of hemorrhage.
- Persistent fluid leakage may be remedied by placing a purse-string suture around the puncture site and by instructing the patient to lie on the side opposite to the puncture site.

THORACENTESIS

Introduction

Thoracentesis is a method for removing pleural air or pleural fluid for diagnostic or therapeutic purposes. If fluid, blood, or air accumulates in the pleural space, respiration may be compromised. If the accumulation is rapid and progressive (e.g., tension pneumothorax), there may be cardiovascular compromise in addition to severe respiratory effects. The underlying etiology of an effusion will also affect the severity of symptoms.

The pleural space, which is a potential space between the visceral and parietal pleura, normally contains a thin physiologic layer of pleural fluid. With normal inspiration, negative pressure develops within the thorax and is transmitted through the pleural space to the pulmonary parenchyma, thereby allowing the influx of air. During normal expiration, the elasticity of the pulmonary parenchyma and chest wall allows exhalation.

Indications

- Diagnosis of pleural effusion
- Therapeutic removal of pleural air or fluid

Contraindications

- Insertion of a needle through an area of infection
- Bleeding diathesis or anticoagulant treatment without correction of the clotting deficits
- Ipsilateral ruptured diaphragm unless performed under ultrasound or fluoroscopic guidance

Equipment

Commercially prepared thoracentesis needle/catheter kits have most of the equipment, but if a kit not available, the following equipment can be assembled.

Skin prep

- Sterile gauze
- Povidone-iodine solution (Betadine) or prepackaged povidone-iodine sticks
- Alcohol prep pads

Sterile field

- Gloves, mask, sterile drape

Local anesthetic

- Syringe, 5-mL
- Needles, 25- and 22-gauge
- Lidocaine 1%

Thoracentesis

- 50-ml syringe with 3-way stopcock
- 14- or 16-gauge angiocatheters, or 16- or 18-gauge pigtail catheter with a guidewire
- Curved clamps, two
- Sterile connecting tubing (from stopcock to bottle)
- Specimen tubes
- Plasma vacuum bottles

Procedure

Position

Positioning of the patient depends on whether the procedure is intended to remove air or fluid. To evacuate a pneumothorax, the patient should be supine with the head of the bed elevated 30 degrees (Figure 27.27). To drain an

Figure 27.27 Thoracentesis. The position for air removal. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Figure 27.28 Thoracentesis. The position for fluid removal. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

effusion, have the patient sit up and lean forward against a table with a pillow (Figure 27.28).

Landmarks

The site for aspiration of *air* should be the second intercostal space in the midclavicular line unless adhesions are present (Figure 27.29).

The site for aspiration of *fluid* is the midscapular line or the posterior axillary line at a level below the top of the fluid (Figure 27.30). This level is appreciated clinically by the height of dullness to percussion and the decrease in tactile fremitus. Ultrasound guidance should be used, either by the treating physician, if he or she is competent, or by a radiologist, to determine the appropriate level. Radiographic localization (with ultrasound, CT, or fluoroscopy) is also appropriate for small or loculated effusions.

Technique

Prepare the equipment and obtain necessary consent according to hospital policy. Prior to the procedure, place the patient on supplemental oxygen. Hypoxemia invariably follows drainage of a pleural effusion or pneumothorax. The drop in PaO₂ ranges from 5–20 mm Hg and is prevented by oxygen supplementation.

Obtain radiographic studies as needed until you are comfortable with the diagnosis, location, and extent of pleural effusion. Have your current erect chest radiograph at the bedside. Confirm fluid level by percussion and/or by ultrasound. Use the first or second interspace below the fluid level, but not lower than the eighth intercostal space (to prevent intra-abdominal puncture).

Put on a protective mask and gloves. Prep and drape your patient using sterile technique. Infiltrate local anesthetic, and aspirate pleural air or fluid. Advance the needle over the superior edge of the rib and “walk” over

Figure 27.29 The optimal site for needle aspiration of pneumothorax: the second intercostal space at the midclavicular line. (Reprinted from O’Connor RE, Feldstein JS, Bouzoukis JK. Thoracentesis in the emergency department. *J Emerg Med* 1985;2:433–442, with permission.)

Figure 27.30 The preferred site for thoracentesis: the sixth intercostal space, just medial to the scapula. (Reprinted from O'Connor RE, Feldstein JS, Bouzoukis JK. Thoracentesis in the emergency department. *J Emerg Med* 1985;2:433–442, with permission.)

the rib. The needle is held perpendicularly to the chest and advanced through the intercostal space while the aspiration-infiltration process is continued until the pleura is entered.

Once the presence of air or fluid is confirmed, clamp the needle at the skin level to mark the depth, and then

withdraw the needle (Figure 27.31). Mark the needle depth with the second clamp to prevent the needle from penetrating too deep and to minimize the possibility of perforating the visceral pleura. Small catheter drainage of pneumothorax has been described but has not gained widespread acceptance. Aspirate to obtain the fluid and confirm placement.

For removal of large volumes of fluid, use a 14-gauge intracath needle on a syringe with a stopcock to the same depth as that marked by the clamp (Figure 27.32). The catheter should never be withdrawn through the needle because shearing of the cannula may result. Once the cannula is in place, remove the clamp, and withdraw the needle stylet as the cannula is advanced. Attach a 50-mL syringe to a three-way stopcock and sterile tubing. After fluid is aspirated from the syringe, attach the tubing to the vacuum bottle, and open the stopcock to the bottle.

Patients may experience severe pleuritic chest pain, dyspnea, or palpitations if large volumes of fluid are removed too rapidly. It is recommended that no more than 1 liter be removed at a time; rarely, removal of large volumes can result in re-expansion pulmonary edema.

Commercially prepared thoracentesis kits are another alternative. Follow the same procedures as above, except use the catheter from the kit (Figure 27.33). Connect the long catheter with a 5-mL syringe and stopcock. Prepare the catheter by sliding it out and then back in to break the seal (Figure 27.34). Insert the needle to the same depth as marked by the clamp. Aspirate to confirm fluid, and advance the catheter into the pleural space. Withdraw the needle from the pleural space while leaving the catheter in the pleural space (Figure 27.35). Attach the tubing in the kit to the vacuum bottle, and remove the effusion.

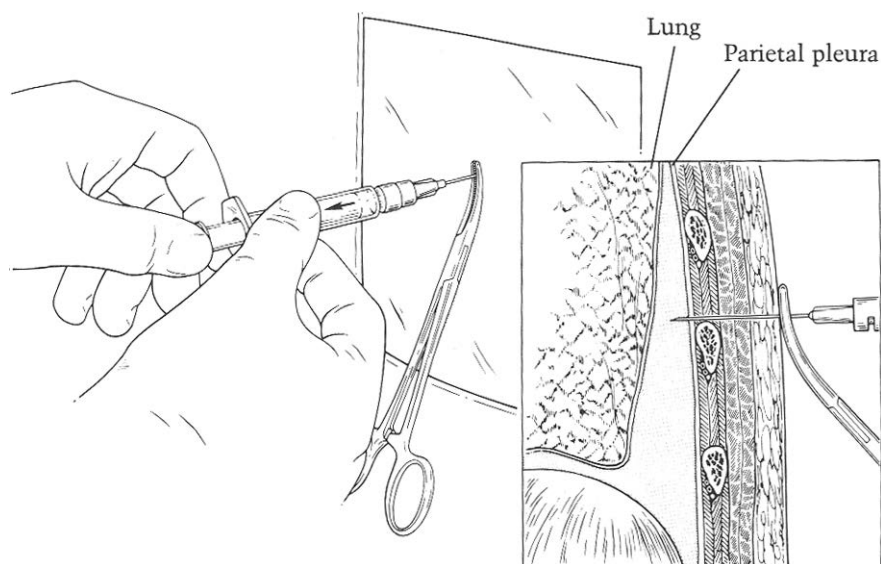

Figure 27.31 The technique of thoracentesis. Infiltration of local anesthesia, then confirming the presence of air or fluid. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Figure 27.32 Inserting the thoracentesis needle (attached to the syringe) to the same depth as that marked by the clamp. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Figure 27.33 An alternative thoracentesis technique, using a catheter with a Y-sidearm. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

Figure 27.34 Breaking the seal between the Y and the tube. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

When the procedure is completed, remove the catheter and needle as a unit in one fast, continuous motion, and apply a sterile occlusive dressing to the site. Repeat a chest radiograph to ascertain the amount of fluid removed and to check for the possibility of a pneumothorax. Send specimens to the laboratory (Chapter 60).

KEY POINTS REGARDING THORACENTESIS

- In iodine-allergic patients, pHisoHex or chlorhexidine gluconate (Hibiclens) is an acceptable alternative to povidone-iodine (Betadine) solution or prepackaged sticks.
- Be extremely careful when performing thoracentesis in mechanically ventilated patients to prevent tension pneumothorax.
- Use extreme caution in patients with pleural adhesions from conditions such as previous tuberculosis, hemo-pneumothorax or empyema, because of the danger of piercing the closely approximated visceral pleural and lung.

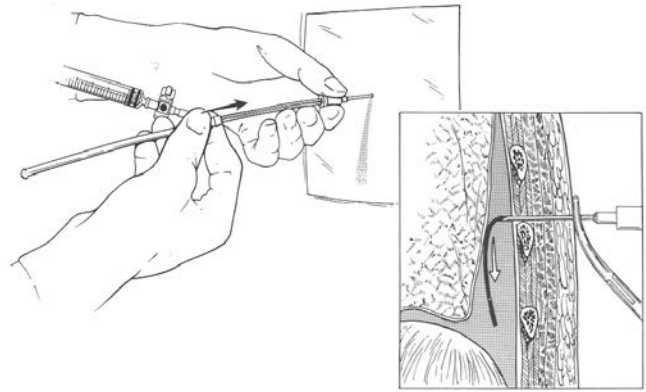

Figure 27.35 Advancing the catheter into the pleural space. (Reprinted from VanderSalm TJ, Cutler BS, Wheeler HB, eds. *Atlas of Bedside Procedures*. Boston/Toronto: Little, Brown and Company, 1988, with permission.)

- Avoid performing thoracentesis lower than the eighth intercostal space posteriorly to avoid a splenic or hepatic puncture.
- Use a short-beveled needle and/or clamp the needle to prevent excessive penetration and to avoid a pneumothorax or organ puncture.
- Insert the needle at the superior margin of the rib to avoid laceration of the intercostal vessels that lie directly under the rib.
- Correct abnormal bleeding prior to procedure.

Medical Consultation

Geno J. Merli Howard H. Weitz

INTRODUCTION

Over the past 30 years, the role and responsibilities of the medical consultant have changed. This evolution has resulted, in part, from the availability of consensus and evidence-based guidelines regarding patient evaluation and care as well as from increased social and financial pressures to minimize the length of hospital stay. Traditionally, preoperative assessment and postoperative follow-up of the surgical patient were the predominant roles of the medical consultant. More recently, the medical consultant's role has expanded to include the assessment and care of patients who are hospitalized with medical problems on nonmedical services such as psychiatry, rehabilitation medicine, and obstetrics and gynecology. The medical consultant must possess a broad fund of knowledge and expertise to address an ever-widening scope of responsibility. This chapter introduces fundamental issues of the art and communication of medical consultation.

ORGANIZATIONAL STRUCTURE OF MEDICAL CONSULTATION SERVICES

The structure of medical consultation services varies among institutions, and a range of organizational structures can meet the goal of providing high-quality consultative medicine. The least centralized structure allows or even encourages each generalist and specialist to perform consultations or provide medical comanagement for his or her own patients or the patients of others consistent with any traditional referral patterns at a particular hospital. This approach is analogous to the prehospitalist stage of inpatient medicine. Recently, however, the availability of hospitalists to care for medical inpatients has been transforming practice patterns in inpatient consultative medicine as well. Hospitalists are readily available and should be appropriately skilled to provide timely consul-

tation and needed inpatient follow-up. As a result, the organization of inpatient consultation may well go through stages similar to those for inpatient medical care.

Innovative medical consultation programs have expanded their scope substantially. Instead of a responsive service that provides prompt and efficient consultation on request, these newer services provide routine comanagement of the medical problems of patients hospitalized on nonmedical services (1). For example, a system may be in place for routine medical consultation whenever a nonmedical attending physician admits a patient with a diagnosis of insulin-dependent diabetes, asthma or chronic obstructive pulmonary disease requiring bronchodilators, prior myocardial infarction, or heart failure (2). An automatic consultation also may be triggered by the development of a number of in-hospital problems, such as transfer to an intensive care unit, a chest radiograph demonstrating pulmonary edema, a positive ventilation-perfusion scan suggesting pulmonary embolism, or positive blood cultures. In some institutions, these consultations are directed to the relevant medical specialist, but in other settings they initially may generate a consultation with a hospitalist, either because of the hospitalist's ready accessibility or because of multiorgan system disease. In addition, the hospitalist's familiarity with posthospital alternatives, such as skilled nursing facilities and home care, that help explain hospitalists' ability to reduce length of stay, may also be relevant to many nonmedical inpatients.

In the comanagement model, the medical consultant becomes responsible for the patient's nonsurgical issues, either preexisting or newly developed. Comanagement is especially useful in situations in which surgical physicians are not routinely available to deal with postoperative problems because of their heavy commitment in the operating room. Medical expertise is also especially useful for complicated medical problems on services that are less accustomed to dealing with multiorgan system disease, such as orthopedic, urologic, and ear, nose, and throat services. Comanag-

ment is also common on services in which particular types of medical problems are prevalent; examples include cardiologic expertise in patients undergoing vascular surgery and pulmonary expertise in patients undergoing lung surgery. Substantial data indicate that medical comanagement of problems such as insulin-dependent diabetes by an experienced physician can improve the efficiency of inpatient care (2). In these models, the consultant commonly takes delegated responsibility for the medical problem, which generally includes ordering indicated diagnostic tests and therapeutic interventions.

In many institutions, medical physicians may participate in a formal system of preoperative evaluation in a preoperative testing center. Commonly, such units are staffed primarily by anesthesiologists who review the patient's potential anesthetic and surgical risks in the context of the medical history. The ready availability of a medical consultant can increase the efficiency of such units and avoid unnecessary delays in surgery.

TEN COMMANDMENTS OF MEDICAL CONSULTATION

To provide direction for the responsibilities of the medical consultant, 10 "commandments" have been proposed to elevate the art of medical consultation (3). These 10 points, which are not only practical but also appropriate in defining the role of the medical consultant, can be as relevant now as when they were first proposed more than 20 years ago (4).

Once a medical consultant receives a request for a consultation, it is his or her responsibility to complete this request in a timely fashion. If circumstances preclude completion of the consultation, the consultant must notify the requesting physician in ample time for another consultant to complete the task promptly.

The consultant should focus on the issues that the requesting physician has indicated. If the request for consultation is not clear, communication with the requesting physician or house staff is important for defining the reason for consultation.

A complete history, physical examination, assessment of pertinent laboratory tests, and review of appropriate medical records must be provided. The consultant is responsible for acquiring all relevant data that pertain to the request for consultation. This responsibility may require contacting other physicians or hospitals about previous laboratory tests, chest radiographs, cardiac catheterization results, or electrocardiograms.

The consultant must identify and summarize all the pertinent medical problems with respect to their current status and therapeutic management. This review should be thorough enough for the consultant to be able

to assume responsibility for the patient's care should the need arise.

The management plan should be concise, and the therapeutic regimen should be clearly delineated. Requesting physicians will not read or follow long-winded plans. The consultant always should provide options or alternatives for management to give the requesting physician latitude for care should he or she not be comfortable with a particular form of therapy.

New problems or diagnoses that the consultant discovers must be brought to the attention of the requesting physician. Only if the findings are truly emergent and require immediate intervention should the consultant act on them without prior discussion with the requesting physician.

The consultant must provide appropriate documentation of his or her plan in the chart for the requesting physician. Verbal communication with the physician or house staff increases the likelihood that the therapeutic regimen or diagnostic assessment will be carried out. Comanagers not only provide the consultation but help effect the identified recommendations with the agreement of the requesting physician.

The follow-up care of patients is dictated by the medical problems identified in the initial evaluation. Issues may include the follow-up of abnormal laboratory results, the adjustment of medications, or the evaluation of specific medical problems that are important to the surgeon or postoperative care provider. When the consultant's role in the care of the patient is completed, the consultant should document the termination of care in the medical record.

The consultant must develop a rapport with the requesting physician to define the patient care responsibilities for each physician. This relationship may define the role as pure consultant or as comanager with its associated order writing, test ordering, and day-to-day care.

Requesting physicians will appreciate a consultant who provides insightful information concerning the management of their patient. This teaching function should be done with tact and without condescension.

The primary physician, the consultant, and the patient have a complex relationship. The consultant has responsibilities both to the patient and to the requesting physician. In general, the preferred way for the consultant to maximize the patient's benefit is by acting through the requesting physician. Skilled consultants can resolve any potential differences with the requesting physician and present a unified, easily understandable plan of action to the patient. Although the consultant has a responsibility to the patient to bypass the requesting physician if it is the only way to avoid harm, in practice the two physicians should privately resolve such conflicts to maximize the quality of care and avoid placing patients in a position of grappling with conflicting advice.

FORMAT

The actual documentation of a medical consultation can have many formats. One format is a written document based on the Health Care Financing Agency guideline (5) for appropriate documentation for level of service to assure compliance with established standards for all third-party insurers and a database from which to develop impressions and plans.

The consultation document consists of two pages (Figure 28.1). The front page has the impression and plan of management clearly delineated based on the reason for the consultation and the pertinent findings. The plan is specific with respect to dosing of medications, management strategies for concomitant diseases, and the ordering of additional testing. In the case of surgical patients, this assessment and plan must include cardiac risk stratification, prophylaxis of deep venous thrombosis and pulmonary embolism, and the care of concomitant medical problems.

The second page of the consultation form documents the reason for the consultation, history of the present illness, medical history, surgical history, family history, social history, review of systems, physical examination, and laboratory testing. This detailed database is primarily for the medical consultant's future reference and management planning.

Compliance with consultants' recommendations is more common if the consultant has direct contact with the requesting physician, makes a limited number of recommendations, clearly identifies high-priority recommendations, continues to see the patient after the original consultation, and offers specific recommendations regarding drug dosage, route, and duration (6).

GENERAL INDICATIONS FOR MEDICAL CONSULTATION

Trying to define the indications for a medical consultation is a difficult task. In the case of the surgical patient, the requesting physicians must assess specific diseases for specific surgical procedures. The most practical approach is to assess risk factors based on organ-specific disease and postoperative outcomes. For nonsurgical consultations, the indications are defined by the requesting physician's need for assessment or comanagement of a medical problem. For example, substantial data exist to guide recommendations for patients with cardiovascular disease who undergo noncardiac surgery (5,6), patients with pulmonary disease undergoing surgery (7), and the risk of deep vein thrombosis or pulmonary embolism in the postoperative period (8).

In the case of nonsurgical consultation requests, the requesting physician dictates indications. For example, for a

psychiatric patient with anemia and elevated liver enzymes, medical consultation would be requested for evaluation and ongoing care. It is currently difficult to provide specific guidelines for this type of consultation.

INFORMAL CONSULTATION

In addition to formal consultation, informal or "curbside" consultations are a remarkably common component of the medical care system (9,10). Hospital-based physicians are likely to receive many such informal requests because of their high visibility in the hospital corridors and their expertise both with inpatient medical problems and with the interface between the hospital and posthospital care. Informal consultations or requests for targeted advice serve critical roles in medical communication and as ideal mechanisms for assessing the priority and necessity of more formal consultation. By providing useful curbside advice, consultants build trust and camaraderie. The ability to provide useful yet pithy assistance in the curbside mode portends well for a consultant's ability to provide helpful and efficient formal consultation if more detailed evaluation is appropriate. Most consultants believe that responsiveness to curbside questions often can solve a focused problem for the patient at hand and also establish the credibility and hence increase the profile (and ultimately the volume) of medical consultations. However, the consultant must be careful not to make definitive recommendations based on inadequate data. If and when more formal consultation is appropriate, the consultant should make this preference clear. If a consultant feels uncomfortable about giving advice without seeing the patient, it is recommended that the requesting physician be asked a question along the line of, "Do you mind if I see the patient myself before I make a recommendation?"

KEY POINTS

- Medical consultation can be organized in a variety of ways. Innovative services often provide comanagement as well as episodic consultations triggered by particular problems rather than being entirely dependent on requests for consultation.
- General guidelines (e.g., the 10 commandments of consultation) can improve the art and efficiency of consultation.
- The consultant has a complicated tripartite relationship with the requesting physician and the patient.
- Informal "curbside" consultations can be a useful part of the medical care system.
- Compliance with consultative recommendations increases if the consultant directly communicates a limited number of specific, high-priority suggestions guided by continued participation in the patient's ongoing care.

Plan (example):

1. The patient is low risk for postoperative cardiac complications.
2. The patient is very high risk for DVT/PE. Recommend:
 - a. Low-molecular-weight heparin (enoxaparin 30 mg SC q12 hrs) beginning 12 to 24 hrs postop for 7 to 10 days.
 - b. Extended prophylaxis with either enoxaparin 40 mg SC QD or warfarin with INR goal of 2 to 3. Please refer patient to anticoagulation clinic for follow-up after discharge.
3. The patient's hypertension has been well controlled with atenolol 50 mg QD. Give 50 mg of atenolol by mouth prior to surgery then resume on postop day 1.
4. Hold glyburide the morning of surgery and then resume at 5 mg PO QD on post op day 1. Fingertstick blood sugar checks the evening of surgery and at 8:00, 16:00, 20:00 on postop day 1.

Thank you.

Key Principles of Anesthesiology

29

Neal Cohen

INTRODUCTION

The care of the surgical patient has changed significantly over the past 10 years. Advances in anesthesia and surgical practices have reduced the morbidity and mortality rates of surgery. At the same time, a better understanding of the influence of a patient's underlying clinical condition on that patient's surgery has enabled the anesthesiologist to address more effectively the needs of both the patient and the surgeon. The goals for anesthetic management include the following:

- Assessment of the patient's preoperative clinical status
- Preoperative management to address preexisting clinical problems relevant to perioperative care and to optimize the patient's condition prior to surgery
- Development and implementation of a plan for anesthetic management that provides optimal surgical conditions and minimizes physiologic alterations
- Definition of a postoperative management strategy that will ensure the safe transition from the operating room, reduce postoperative pain, minimize the likelihood of complications, and shorten the length of stay

Because of advances in surgical care and anesthetic management options, sicker patients are able to undergo more complex procedures safely—with less pain, shorter recovery periods, and reduced need for inpatient care. Moreover, because of cost pressures, today's patients are rarely admitted to the hospital before surgery, no matter how complex the proposed procedure. In addition, many patients now receive anesthesia, either general or regional, for procedures performed in settings other than the operating room, including endoscopy suites, radiology departments, and physicians' offices. As a result of all these changes in practice, the anes-

thesiologist, primary care provider, and hospital physician must work more closely together than ever before to ensure a thorough preoperative assessment, identify and optimize the management of underlying conditions, and develop a plan of care for intraoperative and postoperative management. Each must have an understanding of the patient's clinical condition and enough knowledge about the surgical procedure and approach to anesthetic management to be able to coordinate care in the perioperative period and beyond.

This discussion reviews some of the most important aspects of the preoperative assessment, defines how decisions are made regarding intraoperative anesthetic management, and describes the major concerns in the early postoperative period.

PREOPERATIVE ASSESSMENT

Improved anesthetic techniques, the expansion of minimally invasive (laparoscopic) surgical procedures, and, perhaps most importantly, a better understanding of the impact of underlying diseases on anesthetic and surgical management have allowed more patients to undergo major surgical procedures more safely than ever before. As a result, the morbidity and mortality associated with anesthesia and surgery are now lower than ever. For many patients with severe chronic illness (i.e., diabetes, coronary artery disease, renal failure), the major risk of complications occurs not while the patient is in the operating room, but a number of days after the procedure. Accordingly, the anesthesiologist, surgeon, and hospitalist must share responsibility for understanding the risks, tailoring perioperative management to minimize them, and developing a strategy that addresses both immediate and longer-term needs.

The initial strategy must include a comprehensive and thoughtful assessment of the patient's underlying physiology and risk, including issues that influence the decision to proceed with surgery or that will alter perioperative care. The first step, therefore, is the preoperative assessment, which should include a number of critical components. First, the potential risks associated with the anesthetic management must be carefully assessed. The American Society of Anesthesiologists (ASA) has developed a physical status classification system that has proved to be a valuable tool for risk stratification (Table 29.1). Although it is not a system that specifically defines anesthetic risk, it has provided a consistent method for evaluating outcome and has been useful in comparing patient populations to modify management strategies based on underlying physiology.

The ASA classification is useful, but it provides only an overview of risk, essentially offering a general assessment that can be used to guide management. Therefore, it must be accompanied by a more specific assessment of the patient's underlying clinical condition and potential risk factors. A thorough history and physical examination continue to be essential components of clinical assessment, although the evaluation is often completed by the primary care provider or anesthesiologist days or weeks prior to surgery. As a result, the evaluation of the patient on the day of surgery can be abbreviated but must include specific assessments that might influence the approach taken in the operating room and thereafter.

For the anesthesiologist, the assessment of the airway is one of the critical components of the preoperative evaluation. For some patients, potential airway problems are apparent based on their history or physical findings. Patients with *obstructive or central sleep apnea* pose significant risks, not only because the airway may be difficult to maintain, but also because of the associated clinical problems, including hypoxemia, hypoventilation, and pulmonary hypertension. In addition, preexisting sleep apnea man-

TABLE 29.1
THE ASA CLASSIFICATION SYSTEM

ASA 1	A normal, healthy patient
ASA 2	A patient with mild systemic disease (e.g., mild diabetes mellitus without complications, controlled hypertension, anemia, chronic bronchitis, morbid obesity without other sequelae)
ASA 3	A patient with severe systemic disease that limits activity (e.g., angina pectoris, obstructive pulmonary disease, prior myocardial infarction)
ASA 4	A patient with an incapacitating disease that is a constant threat to life (e.g., congestive heart failure, renal failure)
ASA 5	A moribund patient not expected to survive longer than 24 hours (e.g., ruptured aortic aneurysm, head trauma with increased intracranial pressure)

TABLE 29.2
THE MALLAMPATI AIRWAY CLASSIFICATION SYSTEM

Class II:	Faucial pillars and soft palate are visible
Class III:	Only soft palate is visible
Class IV:	Only the base of the tongue is visible

dates that the anesthesiologist have a plan for ensuring that the patient has the support necessary in the postoperative period to prevent airway obstruction or severe hypoxemia, whether that includes postoperative care in an ICU or requires availability of continuous positive airway pressure (CPAP) or other technologies postoperatively.

Careful assessment of the airway is also essential for every other patient because for most patients, the manifestation of airway problems becomes apparent only after the patient loses normal airway tone and reflexes when fully anesthetized and paralyzed. Nothing is more frightening to the anesthesiologist than to take a perfectly healthy patient to the operating room and have the patient develop serious complications associated with the airway after induction and prior to tracheal intubation.

To minimize the likelihood of airway management problems and to facilitate planning, a number of evaluative methods are used. First, a routine clinical evaluation of the airway is performed. It includes assessment of mouth and jaw mobility, neck mobility, and vocal cord function. In addition, anesthesiologists frequently assess the airway using the technique described by Mallampati (Table 29.2) (1). The classification describes the degree to which, with routine mouth opening, airway structures are visualized.

This classification system, although not perfectly sensitive nor specific, helps alert the anesthesiologist to potential problems during laryngoscopy and tracheal intubation. In doing so, it allows the anesthesiologist to develop contingency plans and consider alternative approaches to the airway, including the use of a laryngeal mask airway, a fiberoptic approach to intubation, or other options. The assessment that airway management may be difficult does not suggest that general anesthesia should be avoided or that regional or local anesthesia should necessarily be considered. In some cases, if airway management is determined to be difficult, elective tracheal intubation becomes even *more* important so that the airway is secured before a problem arises—as can occur even with regional anesthesia (e.g., total spinal anesthesia). For patients known to have a difficult airway or in those situations when tracheal intubation is not straightforward, the ASA has developed a useful algorithm for management of the difficult airway (2).

In addition to airway evaluation, several other critical issues must be clarified before inducing anesthesia. Fluid status and intravascular volume must be optimized prior to induction of anesthesia to minimize the risk of hemodynamic compromise upon administration of anesthetic agents or analgesics or initiation of positive pressure ventilation. The correct evaluation includes assessment of skin turgor, peripheral perfusion, filling pressures, and, indirectly, myocardial function. This assessment is particularly important in patients with congestive heart failure, whether they are receiving diuretics or not, in patients who have had no oral intake for a number of hours prior to induction of anesthesia, in patients who have undergone a bowel prep prior to surgery, and in patients who received intravenous contrast for radiologic studies, particularly because of their risk of renal dysfunction.

Perhaps as important as the usual preoperative evaluation of any patient, additional assessment and often interventions prior to induction of anesthesia are required for patients with underlying conditions. Systemic diseases that compromise cardiac, pulmonary, renal, or hepatic function are of particular concern. Even when the prior medical management has optimized the patient's condition, the anesthesiologist must understand what has been done to improve the patient and how the intraoperative management can maintain that level of support. For example, the patient with severe obstructive pulmonary disease who is receiving bronchodilators and/or steroids may be well controlled preoperatively. The anesthesiologist must understand how acute exacerbations are managed, which drugs most effectively treat the small airway obstruction, and the associated clinical conditions that might influence anesthetic management, such as pulmonary hypertension or hypoxemia associated with gas trapping (Chapters 55 and 59). The same process must be used to assess how best to treat patients with coronary artery disease in the perioperative period, which patients should receive perioperative β -blockers (3), α -blocking agents, or vasodilators, and which patients might benefit from a preoperative coronary angiogram, coronary dilation, or stent (Chapter 30).

For many patients, the management of the underlying disease may not be optimal at the time of presentation for anesthesia and surgery—in some cases because the patient's condition cannot be optimized. One question that is frequently asked of the hospital physician and the anesthesiologist is whether surgery should be postponed and, if so, how the patient's condition can be improved. Although for many of these patients, the intraoperative management may be relatively uncomplicated, the postoperative course will be unstable. For example, the inadequately treated hypertensive patient will have more unstable blood pressure and increased risk of complications in the postoperative period if the blood pressure is not controlled preoperatively. The patient with severe obstructive pulmonary disease may have a complicated perioperative course due to persistent bronchospastic disease in spite of preoperative

treatment because of impaired mucociliary clearance associated with tracheal intubation. As a result, a discussion about the risks and benefits of delaying surgery versus proceeding without better control of underlying medical problems should include the anesthesiologist, primary care provider, and surgeon (Chapter 30).

One of the most difficult clinical problems for which the risk of anesthesia, surgery, and postoperative complications is high is diabetes mellitus. In addition to the problems associated with glucose control, diabetic patients often have a number of complications of their diabetes, including coronary artery disease and renal failure. Each complication makes anesthetic management more challenging. As part of the preoperative evaluation, a thorough assessment for evidence of complications of diabetes is essential so that the patient's physiologic condition can be optimized preoperatively and to provide the information necessary to manage the patient in the perioperative period.

Data now support tight inpatient glucose control to minimize complications of the disease and improve surgical outcomes (4). As a result, the use of insulin infusions preoperatively, intraoperatively, and postoperatively is encouraged (Chapter 107). A glucose-containing intravenous fluid should be started preoperatively at the same time the insulin infusion is started, generally beginning once the patient is not taking anything orally. The infusion will ensure that insulin is administered continuously and that the absorption of the insulin is not compromised by subcutaneous edema or impaired peripheral perfusion. Once the patient begins to take a normal diet, the infusion can be replaced by subcutaneous insulin as needed.

In the operating room, until recently, concerns about hypoglycemia were at least as great as concerns about hyperglycemia. All the usual clinical signs of hypoglycemia are lost in the anesthetized patient, so anesthesiologists were careful not to be too aggressive about glucose control intraoperatively. Recent studies have demonstrated that more rigid control of the blood sugar not only reduces the acute complications of hyperglycemia (including osmotic diuresis that will complicate intraoperative fluid assessment and management), but also improves wound healing. Bedside glucose monitoring devices have made tighter control more feasible.

Many clinicians consider age an independent risk factor for perioperative complications. While elderly patients often have associated clinical problems that affect management and outcome, age alone should not determine whether to proceed with anesthesia and surgery. With improved anesthetic and surgical management, age is no longer an independent predictor of complications for most surgical procedures. In fact, chronologic age is much less important than physiologic abnormalities in predicting outcome after surgery. For the elderly patient, as is true for every other patient, the anesthesiologist and primary care provider or hospitalist must carefully assess the patient to determine what diseases might influence clinical

management and optimize them as much as possible. The evaluation must also address assessment of underlying organ function, which may not be apparent based on laboratory data alone. For example, in the elderly patient with little muscle mass, a “normal” or slightly elevated serum creatinine might actually represent a significantly reduced creatinine clearance. In addition, it is important to remember that elderly patients have less physiologic reserve and are more likely to have prolonged hospital stays should complications occur. These patients also tolerate sedatives and analgesics poorly, often becoming disoriented and agitated, which further complicates their management (Chapter 16).

INTRAOPERATIVE MANAGEMENT

The anesthetic plan is based in large part on the patient’s underlying clinical condition, although surgical considerations also influence the management alternatives. In addition to addressing maintenance of physiologic control over the patient during the procedure, the plan must address the surgical requirements because one of the goals of good anesthetic management is to create conditions that allow the surgeon to complete the procedure safely and efficiently and to transition the patient from the operating room environment to the postanesthesia care unit (PACU).

Both general and regional anesthesia are reasonable alternatives for most surgical procedures. Some selected cases require one or another anesthetic approach based on specific requirements of either the patient or the surgeon. For example, in brain mapping, as might be required for seizure control, the anesthetic management must ensure that the patient is anesthetized during a portion of the procedure but arousable at the appropriate time. For some cases, a combination of techniques is used to provide optimal surgical conditions, guarantee a secure airway and optimal gas exchange, and reduce the total amount of general anesthesia. Regional anesthesia and analgesia (e.g., epidural analgesics) are often added to general anesthesia to reduce the total amount of systemic opiates as well as to facilitate a smooth transition from surgery to the postoperative period and to provide adequate pain control.

Regional anesthesia is contraindicated in some situations. For patients with neurologic disease, spinal or epidural anesthesia is usually avoided. Although neither are likely to worsen the neurologic deficit, any change in the neurologic disease will be difficult to evaluate, and the effects of the instillation of anesthetic agents into the cerebrospinal fluid or epidural space can be difficult to determine. A more common contraindication to regional anesthesia is systemic anticoagulation. *Regional anesthesia should not be administered to any patient who is receiving*

heparin or coumadin. The use of low-molecular-weight heparin contraindicates regional anesthesia even after the drug has been discontinued because the duration of anticoagulation is difficult to monitor (unlike with unfractionated heparin, where a normalization of the partial thromboplastin time indicates the absence of anticoagulant effect).

Anesthetic management has changed significantly over the past decade, in large part due to a broader array of agents, a better understanding of the benefits and physiologic costs associated with them, and, most importantly, a recognition that intraoperative care is only a part of the overall clinical management. Much more attention is now paid to the entire perioperative period, allowing for smoother and safer transition from the operating room to the postoperative period.

Anesthetic induction is usually performed with *intravenous agents* because of their rapidity of onset and ease of administration. Thiopental and propofol are most commonly used. Each produces rapid unconsciousness; for short procedures, propofol is preferred because patients awaken rapidly with little residual effect. For longer cases, the choice of induction agent is less important. Etomidate and ketamine are occasionally used, particularly for patients with unstable blood pressure, because both generally cause less change in hemodynamics.

A variety of *inhalation anesthetic agents* is available. The most commonly used are sevoflurane and desflurane. Both of these agents are well tolerated and have few side effects. Although all inhaled agents affect the cardiovascular system and can alter vascular tone, when used alone or in combination with other agents they can be administered safely with few sequelae and rapid emergence from anesthesia with less nausea, vomiting, or other side effects.

Many patients now receive a combination of agents to provide anesthesia and analgesia, including inhalational anesthetics, intravenous anesthetics, and regional anesthetics and analgesics. The combination of drugs and techniques enables the anesthesiologist to provide effective analgesia, anesthesia, and amnesia to the patient without compromising hemodynamics or gas exchange. The addition of systemic opiates, such as fentanyl, remifentanyl, continuous infusions of propofol, and titration of inhaled anesthetics and nitrous oxide, can provide ideal clinical conditions and facilitate the transition from the operating room to the postanesthesia care unit.

Muscle relaxants are also commonly administered intraoperatively, both to facilitate tracheal intubation and to provide optimal conditions for the surgeon. The selection of the muscle relaxant depends on the patient’s underlying clinical status and the intraoperative needs. Succinylcholine has historically been used for tracheal intubation. It has a rapid onset and short duration for most patients. It is the only commonly used depolarizing muscle relaxant; it causes fasciculations and raises the serum potassium transiently. It is also associated with malignant hyperthermia.

For the hyperkalemic patient or the patient with severe metabolic acidosis, succinylcholine is usually replaced by a nondepolarizing muscle relaxant. The newer nondepolarizing agents are now most commonly used because the complications associated with their administration are minimal and they have a relatively rapid onset (although not as fast as succinylcholine) and a longer duration of action. The pharmacodynamics of each drug varies; some are cleared primarily by the kidney and should, if possible, be avoided in patients with renal failure. Others are eliminated by a process independent of renal or hepatic clearance.

The choice of the muscle relaxant is not as important as understanding the ramifications of the choice. For some patients, the duration of action can be prolonged and the need for continued ventilatory support critical. All the relaxants have a prolonged duration of action in the acidemic patient (particularly the patient with respiratory acidosis) and the hypothermic patient; many agents have prolonged action in patients with impaired renal function. As a result, every patient who has received a muscle relaxant must be carefully monitored until the effects of the drug on respiratory muscles and upper airway muscles are gone.

Maintenance of *oxygenation* is an essential part of anesthetic management. Although pulse oximetry has improved the ability to monitor oxygenation and minimize the frequency and duration of hypoxemic episodes, adequate oxygen saturation does not ensure adequate ventilation or, more importantly, adequate oxygen delivery. For example, a patient who is anemic or hypovolemic or who has a low cardiac output has impaired delivery of oxygen to peripheral tissues despite a "normal" saturation. To assure adequate delivery, therefore, the anesthesiologist must ensure that intravascular volume is adequate and that oxygen-carrying capacity is ensured by maintaining an adequate hemoglobin and optimizing cardiac output (5). Euvolemic anemia is relatively well tolerated in the patient with good cardiac function; hypovolemic anemia is not.

The amount of *fluids* administered to patients in the operating room can sometimes seem excessive to the nonanesthesiologist. Fluid resuscitation requires an understanding of the preoperative fluid status and must include replacement of the deficit for the patient who has taken nothing by mouth, who may have had limited intake prior to surgery, or who has had excessive extravascular fluid losses (6,7). The administration of bowel preps and fluid extravasation into the bowel, subcutaneous tissues, or other body cavities make assessment of deficit difficult. For some patients, central venous pressure monitoring, assessment of systolic pressure variations with positive pressure ventilation, or other methods may be required to evaluate the intravascular volume. For patients with poor myocardial function, transesophageal echocardiography has become a commonly used and valuable tool for evaluating

fluid status, ventricular filling, and myocardial function during surgery (Chapter 36).

In addition to the challenge of evaluating preoperative fluid losses, intraoperative losses are often underestimated. Blood loss is difficult to quantify. Serial hemoglobin and hematocrit levels can provide some guidance as to the adequacy of fluid and blood replacement, although these values may not represent the true blood loss during acute hemorrhage associated with significant fluid shifts. Dilution caused by excessive crystalloid replacement can also affect the accuracy of the hematocrit as a guide to blood requirements. Other sources of fluid loss must also be accounted for and those fluids replaced. Insensible losses can be high in the operating room, particularly when large surfaces are exposed (such as during open exploratory laparotomy). Manipulation of tissues also causes fluid extravasation and necessitates additional fluid administration. It is not unusual for a patient who is undergoing a straightforward but lengthy surgical procedure to require 5–10 liters of fluid in addition to blood products. Such quantities are not necessarily excessive, but their administration requires careful assessment of intravascular volume, urine output, myocardial function, and gas exchange.

Another aspect of intraoperative management that is often underappreciated is the importance of maintaining normal *body temperature*. Patients can lose a great deal of heat when exposed to the cold operating room environment. A number of studies have now confirmed that normothermia is beneficial for several reasons (8). First, normothermia has been demonstrated to reduce the risk of myocardial ischemia. It also appears to improve wound healing and facilitate recovery. Shivering associated with hypothermia is poorly tolerated, not only because it is uncomfortable for the patient, but also because it increases myocardial oxygen consumption. Warming blankets, heated inspired gases, and, for long cases, warming of fluids and blood products will ensure that the patient maintains a normal temperature.

POSTOPERATIVE CARE

The primary goal of the acute recovery period is to manage the transition from surgery with minimal complications. In the first few minutes to hours after surgery, the goals are straightforward. The patient is closely monitored until the effects of the anesthetic, muscle relaxants, and other drugs are no longer present. The patient should be able to maintain a clear airway, have a good cough and gag, and be awake and alert. Hemodynamics are closely monitored to be sure that fluid resuscitation has been adequate, that cardiac function is maintained, and that urine output is satisfactory. In the early postoperative period, the urine output should be at least 0.5 mL/kg/hour. Over the subsequent few days, the urine output should increase as the patient begins to mobilize fluids.

Pain control is also a critical component of postoperative management (9,10). The goal is to provide optimal pain control without compromising the patient's neurologic status, airway protection, or respiratory function. Titration of analgesics is not as straightforward as it might seem. While the patient is being aroused, pain may become a problem, and the patient may legitimately require additional analgesics. However, as soon as the patient is no longer stimulated, the same analgesics may contribute to respiratory failure, carbon dioxide retention, or hemodynamic compromise. The patient who has required large amounts of analgesics or sedatives in the early postoperative period must be carefully monitored to prevent respiratory deterioration and potential arrest, both in the PACU and after transfer to the hospital ward. Pulse oximetry is often used as the monitor of choice in these situations. *Although the pulse oximeter may provide information about oxygen saturation, it is not a monitor of ventilation.* For a patient who is receiving supplemental oxygen, oxygen saturation may be maintained in spite of dramatic increases in the partial carbon dioxide pressure. These patients require ongoing assessment of the respiratory rate and tidal volume as well as regular stimulation. Occasionally, capnography is required to document air movement and adequacy of ventilation because the obstructed patient will have chest wall movement for a short time even when there is no gas exchange—often misleading the clinician regarding airway patency.

A trend has emerged toward providing the patient with greater control over pain management in the postoperative period. The advantages of patient-controlled analgesia include better pain control, fewer analgesics, and improved patient satisfaction (11). Although patient-controlled analgesia administered through an intravenous line is now commonplace, alternative patient-controlled systems are also finding favor with patients and practitioners. For example, patient-controlled epidural analgesia and anesthesia have been found to be highly effective, and patient-controlled continuous infusions of anesthetic agents into catheters located near the brachial plexus and other locations are also being used with some success (12,13). These techniques have advantages, but they do not reduce the need for careful monitoring of the adequacy of the pain relief, appropriate placement of the catheters, and potential complications and side effects (Chapter 18).

Postoperative *nausea and vomiting* also require attention in the PACU. Although many newer anesthetic agents cause less nausea, problems remain. Nausea may occur more commonly in patients undergoing laparoscopic procedures. The incidence of postoperative nausea and vomiting is also higher in patients with preoperative hypovolemia and orthostatic dysfunction. Several agents are effective in treating nausea and vomiting, including droperidol, ondansetron, and dolasetron (14). Other therapies, including adequate fluid resuscitation in the operating room and use of dexamethasone, have been demonstrated to reduce the likelihood and duration of postoperative nausea (15).

CONCLUSIONS

The care of the patient undergoing surgery and anesthesia has improved significantly, allowing surgeons to perform procedures previously unavailable to many patients. The risks of anesthesia and surgery have also decreased. Patients with significant underlying disease are now able to undergo complex procedures with few complications. These advances are the result of improved technology and also (and probably more importantly) a better understanding of the risks and of ways to reduce them. At the same time, changes in the delivery of care are forcing physicians to reevaluate how they provide care, to whom, and where. To continue to provide these services to an aging and, in some cases, sicker patient population, anesthesiologists, surgeons, hospitalists, and other providers must coordinate their efforts to optimize the patient's preoperative status, tailor the intraoperative management to address these issues, and provide postoperative care based on an understanding of the likely risks and complications of the surgical procedure and their impact on the patient's underlying condition. This coordinated effort will allow physicians to minimize the complications of surgery and anesthesia for patients prior to, during, and after hospital discharge.

INTRODUCTION

Each year in the United States, millions of patients undergo surgical procedures using general, spinal, or epidural anesthesia. Most of these surgical procedures are completed without complications. Some 3%–10%, however, are associated with perioperative morbidity. Most perioperative morbidity and death occurs during the postoperative period and is of cardiac, pulmonary, neurologic, or infectious origin. Perioperative complications occur more frequently in older patients and in those with serious medical illnesses, particularly cardiovascular disease. The purpose of the preoperative evaluation is to assess perioperative risk and to guide interventions to reduce risk. The preoperative consultant must define clearly the patient's medical conditions, evaluate the stability and severity of each condition, determine the need for preoperative testing, and recommend therapy that may reduce the risk of complications. Close communication with the surgeon, anesthesiologist, and primary care physician is crucial to ensure that appropriate care is provided.

PREOPERATIVE EVALUATION IN THE INPATIENT SETTING

Over the past 10 years, surgeons have performed an increasing number of surgical procedures in the ambulatory setting. Furthermore, for many elective major surgical procedures, patients are admitted to the hospital on the morning of surgery. These patients generally are not seen by the inpatient preoperative consultant. Most patients seen by the inpatient preoperative consultant fall into one of three categories: patients undergoing urgent or emergent surgery, trauma victims, and patients with severe underlying medical illnesses who are undergoing major surgery. Compared with the ambulatory setting, the inpatient preoperative evaluation often must be done rapidly, and the urgency of the

surgical condition may limit the consultant's ability to obtain desired diagnostic tests. Furthermore, any decision to delay surgery for further testing or to provide preoperative therapy must be weighed carefully against the potential risk of such delays. It is important for the preoperative consultant to understand the surgical procedures being considered as well as the common physiologic effects of anesthesia to facilitate discussions with the anesthesiologist and the surgical team, particularly if the surgical risk and the risk of delaying surgery are substantial. The inpatient preoperative consultant's most important role is to identify the most serious medical problems, provide an overall risk assessment, and recommend preoperative therapy to optimize organ function with little or no delay in surgical treatment.

The cornerstone of the preoperative evaluation is a history and physical examination. Emphasis is on assessing functional status, exercise tolerance, and cardiopulmonary signs and symptoms. In addition, the preoperative consultant must pay particular attention to any suggestion of previously unrecognized illness, particularly cardiac or pulmonary disease. Routine testing of patients whose history and physical examination do not reveal significant medical problems generally should include a 12-lead electrocardiogram in men over 40 years of age and women over 50 years of age to search for evidence of asymptomatic coronary artery disease. In multiple studies of patients undergoing major noncardiac surgery, the presence of minor abnormalities on the preoperative ECG, including axis deviation, ST segment changes, T-wave changes, and atrial or ventricular contractions are of prognostic importance only to the extent to which they are markers of the severity of underlying myocardial ischemia or heart failure; they are not independently associated with an increased risk of perioperative cardiac complications. Therefore, these findings do not, by themselves, justify detailed preoperative cardiac evaluation or perioperative interventions. Using routine laboratory tests and chest radiography in healthy patients has not been shown to add to the history and physical ex-

amination and is not recommended. Laboratory testing and chest radiography should be considered if a specific abnormality is suspected from the history or physical examination.

TYPE OF SURGERY

The perioperative risk for a patient undergoing a particular procedure depends on the characteristics of both the patient and the procedure. Using the technique of probabilistic decision making (Chapters 6 and 7), the risk assessment begins with a baseline risk that is modified by information obtained during the preoperative evaluation. The baseline risk for any patient is the average risk for a particular procedure at a particular institution. Although complication rates vary from institution to institution, certain generalizations can be made regarding the baseline risk of major cardiac complications (Table 30.1). The risk of other major complications likely follows a similar pattern. Note that procedures performed emergently are associated with more complications than those performed electively.

PREOPERATIVE MEDICATIONS

Most long-term medications should be continued during the perioperative period. This approach is particularly important for cardiac, pulmonary, and anticonvulsant medications. In

TABLE 30.1 RISK OF MYOCARDIAL INFARCTION OR CARDIAC DEATH FOR NONCARDIAC PROCEDURES

High risk (often >5%)

Aortic surgery and other major vascular surgery
Peripheral vascular surgery
Emergent major operations, particularly in the elderly
Anticipated prolonged surgical procedures associated with large fluid shifts or blood loss

Intermediate risk (1%–5%)

Intrathoracic and intraperitoneal surgery
Carotid endarterectomy
Head and neck surgery
Orthopedic surgery
Prostate surgery

Low risk (generally <1%)

Endoscopic procedures
Cataract surgery
Superficial procedures and biopsies
Breast surgery

most situations, such medications can be administered up to and including the morning of surgery and then resumed postoperatively once the patient is eating. One important exception is *monoamine oxidase inhibitors*, which have been associated with intraoperative hemodynamic instability. Ideally, they should be discontinued at least two weeks prior to surgery. It is also generally recommended that metformin be discontinued prior to noncardiac surgery to reduce the risk of lactic acidosis. Metformin may be restarted once the patient is considered stable postoperatively.

CARDIAC EVALUATION

The cardiac complications of noncardiac surgery are the most well-studied area of perioperative risk assessment. The most important cardiac complications include nonfatal myocardial infarction, heart failure, and cardiac death. The principal predictors of cardiac complications are *advanced age*, the *presence and severity of coronary artery disease*, and *left-ventricular dysfunction*.

Multifactorial risk indices sum weights of a variety of cardiac and noncardiac conditions to predict an overall risk of cardiac complications after noncardiac surgery. The Revised Cardiac Risk Index was developed during the modern surgical era (1), has been validated on independent sets of patients, and represents the most useful of these tools currently available (Table 30.2). Preoperative consultants should use an index score to modify a baseline risk rather than as an absolute risk of cardiac complications. A low index score denotes a lower-than-baseline risk, a high score indicates a higher-than-baseline risk, and an intermediate score usually indicates an unchanged risk. This index is particularly useful if a preoperative evaluation must be done rapidly. Most of the data needed to use the index are available from a brief history and physical examination and basic laboratory studies. One important caution is that in patients at high risk for severe asymptomatic coronary-artery disease, this index may underestimate risk. This issue is particularly important in patients undergoing vascular surgery, where noncardiac functional limitations often prevent the occurrence of cardiac symptoms. In such patients, multifactorial indices are more useful if combined with a disease-specific assessment of cardiac risks.

CORONARY ARTERY DISEASE

Coronary artery disease accounts for the majority of severe perioperative cardiac complications, including myocardial infarction, unstable angina, and cardiac death. The magnitude of the increased risk associated with coronary artery disease depends on the severity and stability of ischemic symptoms. Patients with an unstable coronary syndrome (Table 30.3; see also Chapter 37) are at particularly high risk. In patients with stable anginal symptoms, consultants can estimate the perioperative risk by using a standardized scale

TABLE 30.2
REVISED CARDIAC RISK INDEX FOR ELECTIVE SURGERY

Factors—1 point each

- High-risk surgery (intraperitoneal, intrathoracic, or suprainguinal vascular)
- Ischemic heart disease (history of MI or positive exercise test; current angina or use of nitrates; or pathologic Q-waves on ECG)
- Heart failure (history of heart failure, pulmonary edema, or paroxysmal nocturnal dyspnea; bilateral rales or S₃ gallop on physical examination; pulmonary vascular redistribution on chest radiograph)
- Cerebrovascular disease (history of transient ischemia attack or stroke)
- Insulin therapy for diabetes
- Preoperative serum creatinine >2.0 mg/dL

Approximate risks of MI, cardiac arrest, or cardiac death with elective surgery^a

0 factors	0.5%	Low risk
1 factor	1.0%	
2 factors	5%	Intermediate risk
≥ 3 factors	10%	High risk

^a Based on 4,315 inpatients undergoing elective major surgery. ECG, electrocardiogram; MI, myocardial infarction. From Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk in major noncardiac surgery. *Circulation* 1999;100:1043–1049.

such as the Canadian Cardiovascular Society angina scale (Table 30.4). Patients with class I or II symptoms are at low risk for cardiac complications (4%–5% risk of myocardial infarction and roughly a 1% mortality rate). Those with class III or IV symptoms are at higher risk (>10% risk of my-

UNSTABLE CORONARY SYNDROMES ASSOCIATED WITH A VERY HIGH RISK OF PERIOPERATIVE CARDIAC COMPLICATIONS

- Myocardial infarction within 1 month with evidence of persistent ischemia
- Unstable angina
- Accelerated angina

ocardial infarction or death). In most patients for whom the stability and severity of anginal symptoms can be reliably determined from the history, further cardiac testing has not been shown to improve the accuracy of the risk assessment. Therefore, it is not recommended for routine use (2).

Noninvasive Ischemia Testing

Improvements in methods for clinical risk assessment and in interventions to reduce risk, particularly the use of perioperative β-adrenergic blocking agents, have combined to narrow the spectrum of patients who may benefit from preoperative noninvasive testing for inducible myocardial ischemia (3). For example, noninvasive ischemia testing does not improve the clinical risk assessment in patients with documented stable class I or II anginal symptoms, and it should not alter recommended perioperative management. In two types of patients, however, noninvasive cardiac testing may be useful (Chapter 36) because of difficulty in assessing the severity of anginal symptoms accurately: unreliable historians, and patients with severe orthopedic or

TABLE 30.4
CANADIAN CARDIOVASCULAR SOCIETY ANGINA SCALE

Class	Definition	Specific activity scale
I	Ordinary physical activity (e.g., walking and climbing stairs) does not cause angina; angina occurs with strenuous, rapid, or prolonged exertion at work or recreation.	Ability to ski, play basketball, light jog (5 mph), or shovel snow without angina
II	Slight limitation of ordinary activity; angina occurs on walking or climbing stairs rapidly; walking uphill; walking or stair climbing after meals, in cold, in wind, or under emotional stress, or only during the few hours after awakening; when walking >two blocks on level ground; or when climbing more than one flight of stairs at a normal pace and in normal conditions.	Ability to garden, rake, roller skate, walk at 4 mph on level ground, and have sexual intercourse without stopping
III	Marked limitation of ordinary physical activity; angina occurs on walking one to two blocks on level ground or climbing one flight of stairs at a normal pace in normal conditions.	Ability to shower or dress without stopping, walk at 2.5 mph, bowl, make a bed, and play golf
IV	Inability to perform any physical activity without discomfort; anginal symptoms may be present at rest.	Inability to perform activities requiring two or fewer metabolic equivalents (METs) without stopping

Adapted from Goldman L, Hashimoto B, Cook EF, Loscalzo A. Comparative reproducibility and validity of systems for assessing cardiovascular functional class: advantages of a new specific activity scale. *Circulation* 1981;64:1227–1234. vascular disease whose specific cardiac functional status is not known. Noninvasive testing may also be useful in clinically high-risk patients who may be candidates for preoperative coronary revascularization. Prior to testing, the physician should always ask whether the results are likely to change perioperative management.

Exercise electrocardiography can accurately stratify risk in patients who are able to exercise and who will undergo vascular or general surgery. Patients who achieve 85% of maximum predicted heart rate without ischemic electrocardiographic changes are at low risk for cardiac complications. Those who cannot achieve at least 75% of maximum predicted heart rate, with or without ischemic changes, are at substantially higher risk.

Dipyridamole-thallium scintigraphy can accurately predict cardiac complications in selected patients undergoing vascular surgery. In studies of consecutive unselected vascular surgery patients, however, thallium scintigraphy did not significantly alter the clinical risk assessment. This discrepancy likely is explained by a higher prevalence of severe coronary artery disease among the patients selected for testing by their physicians compared with unselected patients. In vascular surgery patients with an intermediate risk clinical assessment, a positive test, defined as an area of thallium redistribution after dipyridamole administration, is associated with a high cardiac complication rate, and a negative test is associated with a substantially lower rate. Although data are limited in nonvascular surgery patients, it is likely that thallium scintigraphy again is most useful diagnostically in patients at intermediate risk on clinical assessment.

In the largest study of preoperative dobutamine echocardiography in patients undergoing vascular surgery, a normal test, defined as the absence of any new regional wall motion abnormality with dobutamine administration, was associated with a very low risk of perioperative myocardial infarction or cardiac death (4). This finding was true for all patients in the study, regardless of whether they were at low, intermediate, or high risk by clinical assessment.

Noninvasive preoperative testing is worthwhile only when it will change perioperative management. In the era of β blockade, such testing is recommended primarily in patients with a history of angina or peripheral vascular disease and with poor or indeterminate functional status (Figure 30.1).

Preoperative Angiography and Revascularization

The role of preoperative coronary angiography and revascularization (with coronary artery bypass graft [CABG] surgery or percutaneous transluminal coronary angioplasty [PTCA], with or without stenting) is controversial. Data from the Coronary Artery Surgery Study trial registry indicate that patients who have undergone prior CABG surgery, particularly if within 5 years, are at lower risk for complications after subsequent noncardiac surgery compared with similar patients whose coronary artery disease was treated medically. In a recent trial (5), patients who underwent PTCA without intracoronary stent placement

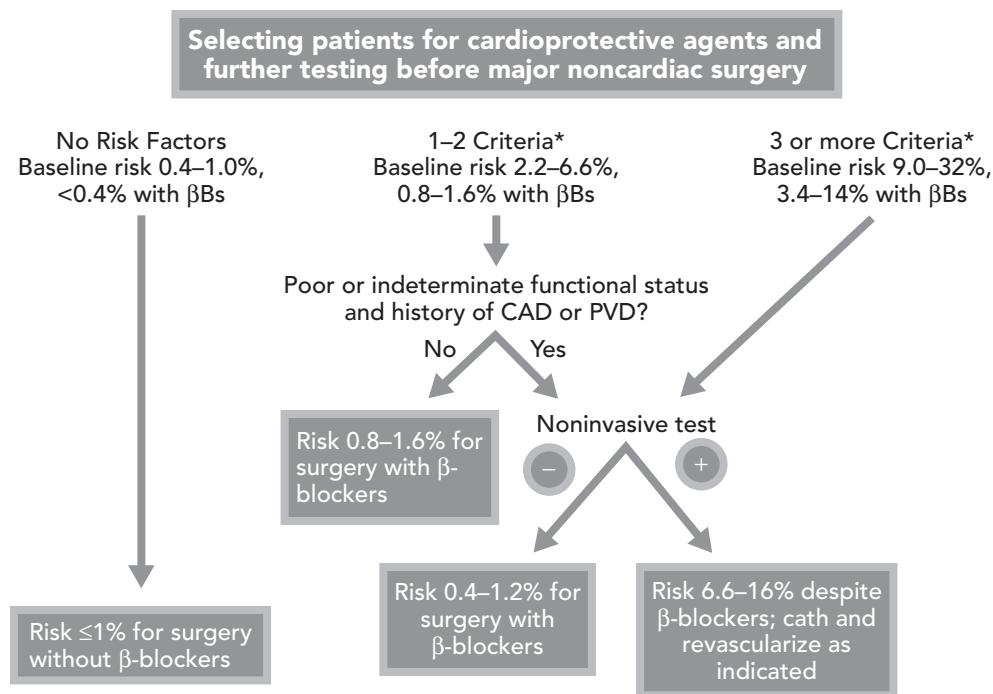

Figure 30.1 Perioperative β -Blockers for elective surgery: patient selection and preoperative risk stratification. *See Table 30.2 for criteria. β B, beta blocker.

had a 1.6% cardiac complication rate with subsequent noncardiac surgery. The rate was 0.8% when PTCA preceded noncardiac surgery by fewer than 4 years but 3.6% if the interval was greater than 4 years. On the other hand, patients who underwent noncardiac surgery within 2 weeks of intracoronary stent placement had a very high morbidity and mortality rate. The rate remained somewhat elevated for another 2–6 weeks and then became very low by about 9 weeks after stenting (5). The very high complication rate is attributable to in-stent restenosis when anticoagulant and antiplatelet therapies are discontinued prematurely. It is prudent, therefore, to delay nonemergent noncardiac surgery for at least 4 weeks, and preferably 9 weeks, after intracoronary stenting.

For low-risk patients, the risk of prophylactic revascularization with either CABG surgery or PTCA (1%–2% mortality in most studies) is likely to be at least as high as that associated with noncardiac surgery without revascularization. Prophylactic revascularization, therefore, is not recommended in low-risk patients. In a recent randomized trial of patients who were undergoing elective vascular surgery at 18 Veterans Affairs medical centers and who had significant, remediable coronary disease, the 258 patients assigned to coronary revascularization (either a percutaneous procedure or bypass surgery depending on the recommendations of their physicians) did no better than the 252 who were managed medically, immediately or over 2.7 years of follow-up (6). Based on these results, preoperative coronary revascularization should be reserved for patients who meet criteria for it independent of the planned surgery (Chapter 37).

Preoperative Medical Therapy

In very high-risk patients with an unstable coronary syndrome, noncardiac surgery should be delayed to allow for stabilization of ischemic symptoms. For high-risk patients undergoing elective surgery who are not candidates for angiography or revascularization, one approach to reduce risk is to delay surgery for several weeks to optimize medical therapy. Although this strategy may reduce risk, it has not been evaluated in clinical trials.

The most effective intervention to reduce risk is *the use of perioperative β -adrenergic blocking agents* (2,3). In the largest study of very high-risk patients (including positive stress echocardiogram results) undergoing vascular surgery, the perioperative cardiac morbidity rate was 3.4% among patients who received perioperative bisoprolol, compared with 34% in the placebo group. It appears that most of the benefit from perioperative β -blockers is mediated through heart rate control. The recommended goal is to achieve a heart rate less than 65 beats per minute throughout the perioperative period. Perioperative β -blockers are recommended for patients with known or suspected coronary artery disease undergoing intermediate-risk or high-risk surgery. Atenolol and bisoprolol have been the most

widely studied agents and are the preferred choices when initiating therapy (Table 30.5). However, patients already taking other β -blockers need not switch to one of these two agents prior to surgery (but they may need their dosage adjusted to achieve the desired heart rate).

In a meta-analysis, α -2 agonists have also been shown to reduce adverse perioperative cardiac complications (7). The largest experience is with mivazerol, which is not currently available for clinical use. Clonidine, an α -2 agonist similar to mivazerol, has been evaluated in a smaller number of patients but is a potential alternative in high-risk patients who cannot take β -blockers.

Intravenous nitroglycerin reduces perioperative ischemia but has not been shown to improve cardiac outcomes. Preliminary data suggest that patients on statins may have fewer postoperative ischemic cardiac events, but the therapy has not been subjected to randomized trials.

Invasive Intraoperative Monitoring

Two commonly used intraoperative monitoring techniques in patients with coronary artery disease are *pulmonary artery catheterization* and *transesophageal echocardiography*. Trials comparing routine versus selective use of intraoperative pulmonary artery catheterization showed no differences in outcomes (8). The limited data available on intraoperative transesophageal echocardiography have not demonstrated an improvement in cardiac outcomes. These monitoring techniques, therefore, should be considered only in high-risk patients, particularly those with unstable coronary syndromes undergoing high-risk procedures. In most situations, the anesthesiologist makes decisions regarding intraoperative monitoring.

The overall approach to patients with known or suspected coronary artery disease is summarized in Figure 30.1.

TABLE 30.5
DOSING SCHEDULE FOR THE ADMINISTRATION OF PROPHYLACTIC β -BLOCKERS

Bisoprolol	5–10 mg ^a given orally once daily, begun before surgery (ideally at least 7 days) and continued for 30 days postoperatively. ^b
Atenolol	5–10 mg ^a given intravenously every 12 hours beginning 1 hour before surgery and continued until the patient is eating; followed by 50–100 mg orally every 12 hours until postoperative day 7.

^a The dose is titrated to achieve a heart rate < 65 bpm.

^b Intravenous atenolol or metoprolol may be used during the time when the patient is not eating.

Adapted from Mangano DT, Layug EL, Wallace AW, Tateo I. Effect of atenolol on mortality and cardiovascular morbidity after noncardiac surgery. *N Engl J Med* 1996;335:1713; and from Poldermans D, Boersma E, Bax JJ, et al. The effect of bisoprolol on perioperative mortality and myocardial infarction in high-risk patients undergoing vascular surgery. *N Engl J Med* 1999;341:1789, with permission.

HEART FAILURE

Patients with poorly controlled heart failure, defined as the presence of jugular venous distention, a third heart sound, or pulmonary edema seen on a chest radiograph, are at substantially increased risk for cardiac complications, including death. In these patients, heart failure should be controlled prior to surgery with diuretics and afterload-reducing agents. This approach probably reduces risk, although it has not been studied in controlled clinical trials. Patients with compensated left-ventricular systolic dysfunction, defined as an ejection fraction less than 50% on echocardiogram or radionuclide ventriculography without overt heart failure on preoperative evaluation, are at moderately increased risk for developing pulmonary edema after vascular surgery but are not at increased risk for other serious cardiac complications.

Any patient with heart failure who has not had an objective assessment of left ventricular function or in whom the cause of heart failure is unknown should undergo echocardiography prior to surgery. The cause and severity of ventricular dysfunction may affect intraoperative and early postoperative management. For example, fluid management will differ in patients with hypertrophic obstructive cardiomyopathy, who need to be well hydrated to avoid obstructive hypotension, and patients with dilated cardiomyopathy, who will need to be kept appropriately fluid restricted. If arranging for such testing requires a substantial delay in surgery, it is justified only in patients with worrisome signs or symptoms that cannot be controlled preoperatively.

VALVULAR HEART DISEASE

Patients with aortic stenosis and a gradient above 20–40 mm Hg have a small increase in perioperative cardiac risk, whereas patients with a gradient above 40 usually have a substantial increase in risk. Symptomatic patients appear to be at higher risk than asymptomatic patients with similar degrees of valvular stenosis. In patients with severe symptomatic aortic stenosis, elective noncardiac surgery should be delayed until valve surgery or balloon valvuloplasty can be performed. Preoperative balloon valvuloplasty may reduce perioperative cardiac complications, though this is an unproven strategy. If noncardiac surgery cannot be delayed, it is crucial that the anesthesiologist be aware of the severity of aortic valvular disease because it has significant implications for intraoperative and postoperative management.

The perioperative cardiac risks associated with other valvular lesions are not as well quantified. Patients with severe mitral stenosis appear to be at increased risk for atrial arrhythmias and heart failure. It is not known to what extent mitral or aortic regurgitation imparts any excess risk independent of that associated with heart failure. In any patient with valvular heart disease, preoperative optimization of cardiac function with medications is recommended

(Chapter 41). If surgical correction of valvular heart disease is indicated, such surgery should precede elective noncardiac surgery. Echocardiography should be considered in patients with a previously undiagnosed heart murmur because it may reveal a lesion that requires antibiotic prophylaxis.

Several surgical procedures are known to produce transient bacteremia with organisms that commonly cause *endocarditis*. Nevertheless, the risk of developing endocarditis after a surgical procedure is low. Certain structural cardiac abnormalities are associated with an increased risk for the development of endocarditis and for increased morbidity once endocarditis develops. Controlled trials have not demonstrated that prophylactic antibiotics reduce the risk of developing postprocedure endocarditis. However, the morbidity associated with endocarditis is high (Chapter 71), and the risks associated with prophylactic antibiotics are low. As a result, if patients with high-risk or moderate-risk structural cardiac abnormalities are undergoing certain surgical procedures (Table 30.6), antibiotic prophylaxis is indicated (Table 30.7).

ARRHYTHMIAS

Most important cardiac arrhythmias are associated with underlying structural heart disease, particularly coronary artery disease and heart failure. It is likely that any association between rhythm disturbances and adverse cardiac outcomes results from the underlying structural heart disease. Cardiac rhythm disturbances in the absence of structural heart disease have not been associated with increased cardiac risk. The finding of an arrhythmia on a preoperative electrocardiogram should prompt an investigation for unsuspected structural heart disease. Preoperative treatment for arrhythmias should be guided by principles independent of surgery. Ventricular rate control should be ensured in patients who have atrial fibrillation. Symptomatic supraventricular (Chapter 42) and ventricular arrhythmias (Chapter 43) should be controlled prior to surgery. Asymptomatic arrhythmias do not require specific therapy. Patients who have an indication for a permanent pacemaker (Chapter 45) should have this placed prior to surgery. If noncardiac surgery is urgent, these patients require temporary transvenous pacing during and after surgery.

HYPERTENSION

Severe hypertension, defined as a systolic blood pressure greater than 200 mm Hg or a diastolic blood pressure greater than 120 mm Hg, during the immediate preoperative period is associated with an increased risk of postoperative myocardial infarction and heart failure. Lesser degrees of hypertension are associated with more frequent

TABLE 30.6**CARDIAC CONDITIONS AND SURGICAL PROCEDURES IN WHICH ENDOCARDITIS PROPHYLAXIS IS RECOMMENDED**

Cardiac conditions	Surgical procedures^a
High risk Prosthetic heart valves Previous bacterial endocarditis Complex cyanotic congenital heart disease Surgically constructed pulmonary shunts or conduits	Respiratory tract Tonsillectomy or adenoidectomy Rigid bronchoscopy Surgical operations involving the respiratory mucosa
Moderate risk Other congenital heart lesions Acquired valvular dysfunction Hypertrophic cardiomyopathy Mitral-valve prolapse with regurgitation or thickened leaflets	Gastrointestinal tract Sclerotherapy Esophageal stricture dilation Endoscopic retrograde cholangiography with biliary obstruction Surgical operations involving the intestinal mucosa Biliary-tract surgery
	Genitourinary tract Prostate surgery Cystoscopy Urethral dilation

^a Dental procedures are not covered in this chapter.

electrocardiographic occurrences of ischemia but not with adverse cardiac outcomes. Severe hypertension should be controlled prior to surgery with rapid-acting agents such as sodium nitroprusside or intravenous β -adrenergic blocking agents (Chapter 48). Moderate preoperative hypertension does not require specific preoperative therapy. Patients with moderate hypertension should be re-evaluated after surgery to determine whether chronic antihypertensive therapy is needed. Generally, a patient's chronic oral antihypertensive medications should be continued throughout the perioperative period.

PULMONARY DISEASE

Postoperative pulmonary complications are common following major surgery. Most of these complications, including atelectasis, bronchitis, and mild bronchospasm, are relatively minor in nature and do not lead to permanent morbidity or a prolongation of the hospital stay. They often require no specific therapy. The most serious postoperative pulmonary complications are pneumonia and prolonged mechanical ventilation, which may occur in up to 19% of patients undergoing cardiothoracic or upper-abdominal surgery. By comparison, serious pulmonary complications occur in less than 3% of patients after lower-abdominal, pelvic, or extremity surgery. Three patient characteristics have been associated with an increased risk of serious pulmonary complications: *obstructive lung disease, tobacco use, and morbid obesity*. Patients with chronic obstructive pulmonary disease (COPD) are at increased risk for both pneumonia and prolonged mechanical ventilation. In studies that have evaluated preoperative pulmonary-function testing in patients with COPD, results have been inconsistent. No single test or combination of tests can reliably predict the risk of pulmonary complications. One exception is that patients who have an $FEV_1 < 500\text{mL}$ appear to be at particularly high risk. Patients with asthma are at risk to develop severe bronchospasm during endotracheal intubation or extubation. If symptoms are well controlled prior to surgery, asthmatic patients do not appear to be at excessive risk for other pulmonary complications.

Patients who weigh more than 250 pounds are about twice as likely to develop postoperative pneumonia as nonobese patients. Current smokers have a twofold to threefold increased risk of developing pneumonia. Smoking cessation for at least 4 weeks prior to surgery reduces the risk of postoperative pulmonary complications, but one week of smoking cessation does not (9). Smoking cessation, nevertheless, should be recommended prior to any surgery as part of routine health care. In a large prospective cohort of U.S. veterans, additional risk factors for pulmonary complications included age over 60 years, dependent functional status, impaired sensorium, and prior stroke (10). A postoperative nasogastric tube is also associated with an increased risk of pneumonia.

Preoperative pulmonary function testing with spirometry or arterial blood-gas measurement is unlikely to change the management of most patients seen by the inpatient preoperative consultant and generally is not required. In patients with severe pulmonary compromise of unknown origin, preoperative testing may be useful to delineate the cause of lung dysfunction because intraoperative ventilator management may be affected by the results. In patients with known COPD who have more severe symptoms than usual at the time of surgery, spirometry may be a useful objective measure of pulmonary function to help identify the need for preoperative therapy.

Preoperative optimization of pulmonary function in patients with COPD or asthma (Chapters 55 and 56) may reduce the risk of postoperative complications. Therapy may include inhaled bronchodilators, theophylline (or aminophylline), or corticosteroids. Antibiotics may be helpful in patients with purulent sputum, especially if sputum can be cleared before surgery. Incentive spirometry and deep breathing exercises with pursed lips, continuous positive airway pressure (CPAP), and intermittent positive pressure breathing (IPPB) can reduce the risk of developing postoperative atelectasis and pneumonia and shorten the length of the hospital stay in patients after upper-abdominal surgery. In most studies, these interventions were equally effective. Incentive spirometry and deep breathing exercises are less expensive and easier to administer than CPAP and IPPB and are the preferred methods in most patients. Incentive spirometry should be used for at least 15 minutes four times daily, and deep breathing should be done hourly. These therapies should begin preoperatively and be continued for 1–2 days postoperatively. For patients undergoing esophageal or gastric resection, CPAP is significantly better than incentive spirometry or deep breathing exercises for reducing the risk of pulmonary complications and is, therefore, the preferred intervention (11).

NEUROLOGIC COMPLICATIONS

The most common serious perioperative neurologic complications are *stroke* and *delirium*. Perioperative stroke occurs in 1%–6% of patients undergoing cardiac, carotid, or peripheral vascular surgery but is rare (less than 1%) after most other surgical procedures. The risk factors for stroke following cardiac surgery include carotid stenosis greater than 50%, a calcified aorta, diabetes mellitus, prior stroke, age over 60 years, peripheral vascular disease, and cigarette smoking (12). In both the cardiac and noncardiac surgical settings, patients with symptomatic carotid stenoses of greater than 50% luminal narrowing are at a substantially increased risk for perioperative stroke. Patients with severe asymptomatic carotid stenoses undergoing noncardiac surgery may be at increased risk, but studies to date are not conclusive. An asymptomatic carotid bruit is not an independent predictor of perioperative stroke. It is

not known whether patients who have undergone carotid endarterectomy are at lower risk for perioperative stroke with subsequent surgery than similar patients who have not undergone endarterectomy. As a result, prophylactic endarterectomy is not recommended prior to necessary noncarotid surgery. However, if carotid endarterectomy is indicated and the noncarotid surgery can be safely delayed, it is preferable to proceed with carotid surgery first.

Postoperative delirium is a common complication, occurring in nearly 10% of patients over the age of 50 after major surgery. Postoperative delirium is associated with significant morbidity, including the development of cardiac and pulmonary complications, prolonged hospital stays, and emotional distress for the patient and family. Several surgical and patient characteristics have been associated with the development of postoperative delirium (Table 30.8). If three or more of these characteristics are present, the risk of developing delirium approaches 50%.

Delirium may occur in 35%–65% of patients after hip fracture repair. In a randomized trial of hip fracture patients, a comprehensive intervention (maintenance of the hematocrit above 30%; minimizing the use of benzodiazepine, anticholinergic, and antihistamine medications; maintenance of regular bowel function; early removal of urinary catheters; and daily visits by a geriatrician) reduced the incidence of postoperative delirium from 50%–32% (13).

Adverse neurologic outcomes are particularly common after CABG surgery. In a large prospective evaluation, the incidence of postoperative stroke was 2.7% and of encephalopathy was 6.9% (12). The risk factors for developing neurologic complications after CABG surgery include age over 70 years, proximal aortic atherosclerosis, or a history of neurologic or pulmonary disease.

Postoperative delirium in patients previously thought not to be demented is associated with a 3.5-fold higher rate of subsequently diagnosed dementia. This dementia is also associated with a significantly higher 5-year mortality rate (14).

HEMATOLOGIC EVALUATION

Several hematologic disorders may have an impact on surgical outcomes. Two common issues faced by the preoperative consultant are the *patient with anemia* and *assessing surgical bleeding risk*.

The most important issue in the anemic patient is to determine the need for preoperative transfusion. If time permits, it is preferable to determine the cause of anemia prior to surgery because certain disorders, particularly hemolytic anemias, may require specific perioperative therapy. Limited studies suggest that surgical outcomes are inversely related to the preoperative hemoglobin level, although these studies did not control for the underlying diseases. Hemoglobin levels below 8 g/dL are associated with the greatest risk. Preoperative transfusion in patients with a hemoglobin level below 8 g/dL may reduce perioperative complications. In patients with coronary artery disease, a preoperative hemoglobin level below 10g/dL has been associated with increased mortality. Thus, preoperative transfusion to a level of at least 10g/dL may be justified in these patients. In an individual patient, the presence of cardiopulmonary disease, the likelihood of surgical blood loss, and the hemoglobin level must be considered to determine the need for preoperative transfusion.

The most important component of the preoperative assessment for the risk of bleeding is a detailed history focused on factors suggestive of a bleeding disorder (see Table 30.9). Patients without evidence of abnormal bleeding on a directed history and physical examination are at extremely low risk for abnormal surgical bleeding (15). Laboratory tests of hemostasis, including the prothrombin time, activated partial thromboplastin time, platelet count, or bleeding time, are not needed. If the bleeding history is incomplete or unreliable, or if abnormal bleeding is suggested, then a formal evaluation of hemostasis is indicated (Chapter 98).

TABLE 30.8

RISK FACTORS FOR THE DEVELOPMENT OF POSTOPERATIVE DELIRIUM

Preoperative factors	Postoperative factors
Age >70 years	Use of meperidine or benzodiazepines
Alcohol abuse	
Poor cognitive status	
Poor physical function status	
Markedly abnormal serum sodium, potassium, or glucose level ^a	
Aortic aneurysm surgery	
Noncardiac thoracic surgery	

^a Defined as follows: sodium <130 mEq/L or >150 mEq/L, potassium <3.0 mEq/L or >6.0 mEq/L, glucose <60 mg/dL or >300 mg/dL.

ENDOCRINE DISORDERS

The perioperative management of patients with diabetes is discussed in Chapter 107.

GLUCOCORTICOID REPLACEMENT

Perioperative hypotension resulting from primary or secondary adrenocortical insufficiency is rare. The administration of high-dose glucocorticoid medications during the perioperative period to prevent complications is controversial. In the only clinical trial comparing high-dose with baseline-dose perioperative glucocorticoid administration in patients with proven secondary adrenocortical suppression, the perioperative complication rates were similar. However, the short-term use of high-dose glucocorticoids during the perioperative period also has not been associated with adverse outcomes. Physicians should consider high-dose glucocorticoid replacement in any patient who has received the equivalent of 20 mg of prednisone daily for 1 week or 7.5 mg of prednisone daily for 1 month within the past year. A commonly used regimen is 100 mg of hydrocortisone administered intravenously every 8 hours for 2 or 3 days. Patients on chronic glucocorticoid medications then should resume their usual dosage. The corticosteroids need not be tapered (also Chapter 109).

HYPOTHYROIDISM

Severe symptomatic hypothyroidism is associated with a variety of perioperative complications, including hypotension, heart failure, and death. If possible, surgery should be delayed in patients with hypothyroidism to allow for adequate thyroid hormone replacement (Chapter 108). For urgent or emergent surgery, it is not known whether one or two doses of thyroid hormone prior to surgery reduces the risk of complications; this strategy is not recommended and should be considered only after consultation with an endocrinologist. Mild or asymptomatic hypothyroidism may be associated with mild intraoperative hypotension

but has not been shown to increase the risk of major perioperative complications. Surgery need not be delayed in such patients to allow for adequate hormone replacement.

KEY POINTS

- Delaying surgery is likely to be justified only if the perioperative risks are substantial, the risks of delaying needed surgery are not substantial, and a delay would lead to a significant reduction in perioperative risk.
- Coronary artery disease accounts for the majority of serious perioperative cardiac complications; patients with unstable coronary syndromes or severe stable angina are at the highest risk.
- Prophylactic β -blockers reduce morbidity and mortality in patients with coronary disease, especially those undergoing major surgery.
- Preoperative noninvasive ischemia testing using dipyridamole thallium scintigraphy or dobutamine stress echocardiography is most useful in patients whose cardiac functional status is unknown and cannot be determined by a standard exercise test.
- Decompensated heart failure is associated with substantial perioperative risk and should be controlled prior to surgery.
- The risk factors for postoperative pulmonary complications include cardiac, thoracic, or upper-abdominal surgery, COPD, morbid obesity, and current tobacco use.
- Maintenance of the hematocrit above 30%, early removal of urinary catheters, maintenance of regular bowel function, and avoidance of benzodiazepines, antihistamines, and anticholinergics may reduce the risk of postoperative delirium in hip fracture patients.
- The most important and reliable tool to assess the risk for abnormal surgical bleeding is a directed bleeding history.

Postoperative Care

31

*Richard H. Savel Jeanine P. Wiener-Kronish
Michael A. Gropper*

INTRODUCTION

Management of patients in the postoperative period has undergone substantial change in the past decade. Improvements in surgical and anesthetic techniques, such as those in laparoscopic surgery, allow sicker and more elderly patients to undergo major surgical procedures safely. An increasing percentage of surgical procedures is performed on an outpatient basis, so the remaining hospitalized patients tend to have more concurrent illnesses and to undergo more invasive surgical procedures. An essential component of caring for the postoperative patient is close communication with the surgeon and anesthesiologist, who can provide information that may have a significant impact on diagnosis and treatment of postoperative problems. Postoperative co-management by a hospitalist may reduce complication rates and, in some circumstances, be preferred by surgeons and nurses (1). This chapter focuses on problems commonly encountered in patients in the immediate postoperative period, both during and after their stay in the post-anesthesia care unit (PACU).

CARE OF THE HOSPITALIZED PATIENT

Initial Assessment

Initial assessment of the postoperative patient should focus on the respiratory and cardiovascular systems. Changes in these systems occur rapidly in the postoperative period and may require admission to the ICU. Patients with any respiratory difficulties (stridor, tachypnea, dyspnea, bradypnea, and hypoxemia) should be transferred to the ICU or kept in the PACU, where physicians skilled in airway management are immediately available. Respiratory status may be rapidly assessed by physical examination, pulse oximetry, and arterial blood gas (ABG) measurement. In general, all patients

should receive supplemental oxygen in the immediate postoperative period because of the high risk of hypoxemia. Patients who have had surgical procedures involving the chest, upper abdomen, neck, and axilla should have chest radiography to exclude pneumothoraces, as should all patients who have had successful or attempted central venous cannulation. Both hypertension and hypotension are common in the immediate postoperative period and require immediate attention. Hypotension and tachycardia may indicate hemorrhage that requires immediate volume resuscitation and surgical re-exploration; hemoglobin concentration should be determined without delay. Volume resuscitation, rather than vasopressors, should be used first in treatment of the hypotensive postoperative patient. Hypertension may indicate pain or significant myocardial ischemia. Mental status should be monitored and documented because changes in mental status may indicate major complications (e.g., carotid artery occlusion or hematoma, subarachnoid hemorrhage). Serum glucose should be assessed and treated as necessary based on recent evidence that tight glucose control and normoglycemia decrease mortality in the postoperative period (2).

Management of Acute Postoperative Pain

Pain associated with surgical procedures is a major determinant of postoperative morbidity and mortality. If pain is not controlled, patients are at increased risk of complications, especially myocardial ischemia and respiratory failure from atelectasis. In addition, fear of postoperative pain is often the single greatest cause of anxiety in surgical patients. The usual approach to postoperative pain has been to use opiates, delivered by intramuscular or intravenous injection and ordered on an "as needed" basis. This approach has been found to be inadequate; intramuscular injection of opiates leads to highly unpredictable levels, resulting in either undertreatment or accumulation of multiple doses,

depending on the dosing frequency, site of injection, and tissue perfusion. *Instead, opiates should be administered on a regular schedule and should be given intravenously* (3). The advent of "patient-controlled analgesia" (PCA) (Figure 31.1) enables the patient to self-administer frequent, small doses of opiates instead of boluses that may result in overtreatment or undertreatment. The PCA's lockout mode prevents overdosing. Studies have shown that postoperative patients prefer PCA over other modes of pain management that produce equipotent analgesia, probably because patients can control their own medication.

As the majority of postsurgical pain is inflammatory in nature, *nonsteroidal anti-inflammatory drugs (NSAIDs)* should be administered in combination with opiates to treat this inflammatory component. When used in this manner, NSAIDs can decrease the total dose of opiates required. NSAIDs should not be used routinely in patients with renal insufficiency or a history of gastric ulceration. In addition, certain postsurgical patients at risk for bleeding, such as those following craniotomy or major vascular surgery, may not be candidates for NSAIDs for the first 24–36 postoperative hours.

Certain patients may benefit from *epidural analgesia*, which can deliver opiates and local anesthetics to the epidural space in small doses with minimal side effects. Although this technique requires placement of an epidural catheter, patients will receive superior analgesia and benefit from sympathectomy if local anesthetics are used.

Ambulation should be with assistance because patients may have partial motor blockade and diminished baroreflexes. A number of studies have demonstrated improved outcomes in patients who have undergone epidural anesthesia for surgery and who continue to receive epidural anesthesia for postoperative pain (4,5). Recent studies have also demonstrated earlier ambulation, earlier return of bowel function, and earlier discharge from the hospital if patients receive epidural anesthesia for postoperative pain after abdominal surgery. Common complications of epidural analgesia include urinary retention, pruritis, and, rarely, significant respiratory depression. Patients who receive epidural anesthesia, either with opiates or in combination with local anesthetics, should have specific postoperative orders to monitor for delayed respiratory depression and to limit the doses of additional opiates. One newer approach to epidural analgesia includes patient-controlled epidural analgesia (PCEA), which allows the patient to control the epidural infusion in much the same way as PCA for intravenous opioid doses.

Delirium

Postoperative delirium is commonly encountered, especially in elderly patients. General anesthesia results in imbalances of central cholinergic systems, which can cause delirium and confusion. The elderly are especially susceptible to this problem. Patients who develop delirium have

Patient Controlled Analgesia

Recommended initial settings:

- 1) **dose** of opiate (See below for equipotent dosing)
- 2) **lockout interval** = 6 minutes
(this is the minimum interval between doses, regardless of the number of patient attempts)
- 2) **basal rate** = 0 (except for chronic pain patients)
- 3) **rescue dose** = usually twice the unit dose in #1 (administered by nurse at patient's request, once/hour)

Opiates: recommended initial unit dose

- morphine: 1 mg/injection
- meperidine*: 10 mg/injection
- hydromorphone: 0.2 mg/injection
- fentanyl: 10 mcg/injection

* Avoid in patients with renal insufficiency.

Figure 31.1 Patient-controlled analgesia. Recommended initial settings for PCA. Usual settings are dilaudid (hydromorphone) 0.2 mg/injection with 6-minute lockout, no basal rate, and a 0.4 mg/hour rescue dose that is administered on demand. Avoid meperidine in large doses and especially in patients with renal failure because of the possibility of seizures induced by the metabolite normeperidine.

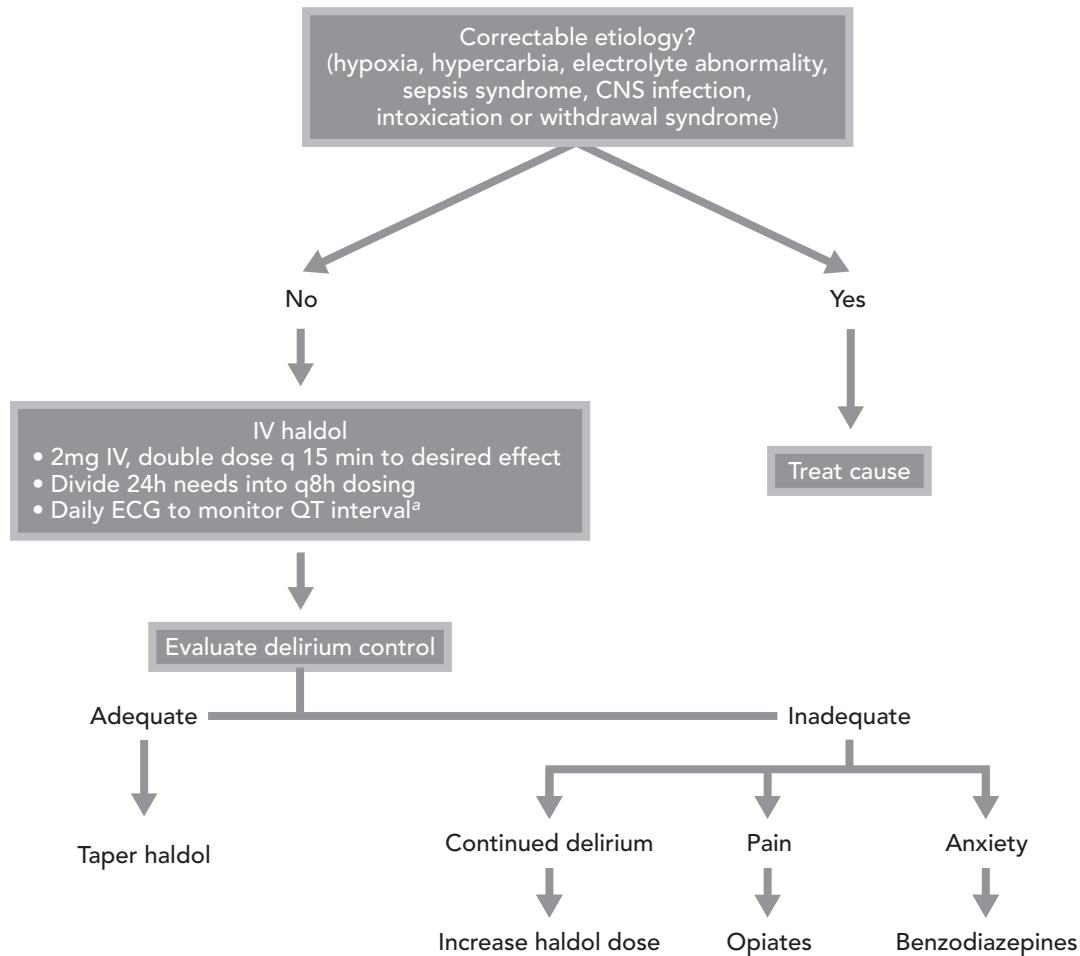

Figure 31.2 Flow Chart for Evaluation and Treatment of Delirium in Postoperative Patients. Correctable etiologies must be ruled out prior to initiation of pharmacologic therapy.^a ECG monitoring must be done prior to therapy and at daily intervals to detect QT prolongation induced by haloperidol. CNS, central nervous system; ECG, electrocardiogram; IV, intravenous.

more complications, longer hospital stays, and an increased need for rehabilitative care. Attention to identifiable risk factors in elderly postoperative patients can reduce the risk of delirium (6) (see also Chapter 16 and Table 30.8).

It is important to identify hypoxemia, pain, and electrolyte disorders, all of which contribute to delirium even in the absence of neuroleptic drugs (Figure 31.2). Benzodiazepines should be used with caution in elderly patients because of the pharmacokinetic and pharmacodynamic changes that occur with aging. For example, the half-life of diazepam increases to nearly 60 hours in 70-year-old patients. In the evaluation and care of the delirious patient, it is often necessary to discontinue all psychoactive medications. In this setting, opiates such as fentanyl may be more predictable and reversible sedatives than are benzodiazepines and other drugs. If sedatives or opiates are used as a continuous infusion, the level of sedation should be assessed several times per day and titrated as needed, with a particular focus on minimizing the duration of mechanical ventilation (7).

Nausea and Vomiting

Postoperative nausea and vomiting are a significant source of preoperative anxiety, and they increase costs because of prolonged lengths of stay in the PACU and hospital. A number of agents used intraoperatively, especially opiates, have been associated with an increased incidence of nausea and vomiting. Laparoscopic, plastic, otolaryngologic, and neurologic surgeries have the highest incidence of postoperative nausea and vomiting. Patient risk factors include female sex, poorly controlled pain, hypotension, and history of motion sickness or previous nausea and vomiting.

A number of antiemetic agents have been evaluated for efficacy, but most studies have been in patients who are receiving cancer chemotherapy. Recently, 5HT₃ receptor antagonists, especially ondansetron and granisetron, have been used for both prophylaxis and treatment of postoperative nausea and vomiting. Other agents to consider include supplemental oxygen, dexamethasone, and lorazepam. Droperidol, which can cause QT prolongation

and torsade de pointes, should be used only after other drug interventions have failed (8).

CARDIAC ISSUES

Prevention of Perioperative Ischemia

Perioperative ischemic events can be significantly decreased in patients at risk for cardiac events by the administration of a β -blocker immediately prior to the operation and throughout the hospitalization (up to 7 days) (Table 30.5, Chapter 30) (9,10). α -2 agonists such as clonidine are unproven but can be considered in patients who cannot tolerate β -blockers.

Perioperative Myocardial Infarction

The most common cause of morbidity and mortality after noncardiac surgery is myocardial infarction. The measurement of serum levels of cardiac troponin I is a sensitive and specific method for diagnosing perioperative infarction. Most postoperative myocardial infarctions occur in the first 5 days after surgery. Ischemic changes in the immediate postoperative electrocardiogram markedly increase the likelihood of a diagnosable myocardial infarction, and so an electrocardiogram is generally recommended soon after surgery. In contrast, serial electrocardiograms or troponin levels are not recommended except in patients with symptoms or new postoperative electrocardiographic changes (11). Remember, however, that *postoperative myocardial infarction may not present with typical pain* because of anesthesia, pain medications, and other postoperative pain. Therefore, nonspecific symptoms such as heart failure, tachycardia, unexplained dyspnea, or relative hypotension should also prompt an electrocardiogram. Elevations of cardiac troponin I or T carry a twofold to threefold increased risk of major myocardial ischemic events in the 6 months after surgery, even in patients without chest pain or diagnosed acute myocardial infarction.

Atrial Tachyarrhythmias

Atrial tachyarrhythmias, which are especially common after cardiac and thoracic surgery, can lead to serious consequences, including stroke, heart failure, myocardial ischemia, and prolonged stays in the intensive care unit and hospital. Atrial arrhythmias occur most frequently in the first 2–3 days after surgery, and they frequently recur. The risk of developing atrial tachyarrhythmias can be reduced by administering β -blockers and/or by not withdrawing β -blockers perioperatively. Atrial arrhythmias are typically precipitated by hypoxia, hyperthermia, electrolyte abnormalities, hypertension, infection, and medications.

Although pulmonary embolism and primary myocardial ischemia are uncommon causes, secondary myocardial ischemia is common. Treatment should focus on reversing the precipitating causes and on rate control (Chapter 42). After 24 hours of atrial fibrillation, anticoagulation therapy should be instituted if not otherwise contraindicated. Because conversion of atrial fibrillation to sinus rhythm does not appear to confer any added survival benefit over rate control alone, cardioversion need be undertaken in the hospital only in patients who cannot tolerate the arrhythmia or the anticoagulation needed for atrial fibrillation (Chapter 42) (12). In many patients, the arrhythmia will resolve as the clinical situation stabilizes, so no long-term therapy will be required.

Postoperative Hypertension

In patients who have postoperative hypertension, pain is the apparent cause in up to 35% of patients, with hypercarbia and sympathetic stimulation during emergence from anesthesia being the other common causes. Treatment should emphasize pain relief, sedation, oxygenation, and diuresis if necessary. When the blood pressure itself needs to be treated, the combined α/β -blocker labetalol is usually the preferred first-line agent. If a continuous infusion is required, options include labetalol, nitroglycerine, fenoldopam, and nitroprusside. Because of its toxicities, prolonged use of nitroprusside should be avoided (13).

INTERPLAY BETWEEN CARDIAC AND NONCARDIAC ISSUES

Patients who have postoperative cardiac complications are 6.4-fold more likely to have a variety of noncardiac complications, including wound infections, confusion, respiratory failure, deep venous thrombosis, and bacterial pneumonia (14). These complications also increase postoperative length of stay and increase 3-month mortality about threefold.

PULMONARY ISSUES

Postoperative Atelectasis and Pneumonia

The most common postoperative pulmonary complication is atelectasis, especially after surgery involving the upper abdomen. The consequences of atelectasis include hypoxemia, which can cause myocardial ischemia or stroke, infection, and delayed ambulation. Results are equivalent whether the atelectasis is treated with positive pressure

treatment (intermittent positive pressure breathing) or negative pressure treatment (incentive spirometry), and incentive spirometry is much more cost-effective, so it should be instituted as soon as the patient is able to cooperate. Preoperative patient training in the use of incentive spirometry (Chapter 30) will improve performance.

Epidural opioid administration reduces atelectasis compared with systemic opioids. The incidence of pulmonary infections and overall pulmonary complications also appear to decrease.

Perioperative Anticoagulation

A variety of perioperative regimens have been advocated for patients taking preoperative anticoagulants (15). For patients whose chronic international normalized ratio (INR) is maintained between 2 and 3, the warfarin can be held 4 days in advance of surgery to reduce the INR to 1.5 on the day of surgery. For patients who have been on anticoagulants for more than 3 months since the last episode of venous thromboembolism, preoperative heparin is not needed. Although low-molecular-weight heparins are superior to unfractionated heparin in most clinical applications, they should be reserved for patients who are not likely to have significant postsurgical bleeding (such as patients undergoing routine surgery on an extremity) because of their longer half-life and inability to be reversed by protamine (Table 31.1; Chapter 98).

Careful attention should be paid to thromboembolism prophylaxis in the postoperative patient. A sample prophylaxis protocol is included (Figure 31.3).

GASTROINTESTINAL COMPLICATIONS

Postoperative Ileus

Residual effects of anesthetics, especially opioids, decrease motility and delay return of normal bowel function. Other causes of ileus include gut manipulation, denervation, pain, and sympathetic outflow. Ileus after abdominal surgery is usually pronounced for 24–48 hours and resolves over the next 2–3 days. Inability to feed orally due to ileus results in delayed hospital discharge, inadequate nutrition, and increased costs. Laparoscopic surgical techniques markedly decrease the incidence of postoperative ileus. In one randomized study of patients undergoing colorectal resections, patients who had laparoscopic procedures had peristalsis first noticed 26 hours after the procedures, compared with 38 hours after the open resections. Furthermore, the first bowel movements occurred 70 hours after laparoscopic surgery versus 91 hours after conventional resection. Finally, oral feedings were tolerated 3.3 days after laparoscopic resections compared with 5 days after open resections (16).

Treatment of ileus should target its underlying cause. If peritonitis has occurred and is caused by a community-acquired infection (i.e., perforated appendix), single agents including ampicillin/sulbactam or ticarcillin/clavulanic acid can be used (17). Postoperative peritoneal infections tend to be caused by more resistant flora, including *Pseudomonas aeruginosa* and methicillin-resistant *Staphylococcus aureus* and *Candida* species. For these nosocomial infections, local nosocomial resistance patterns should dictate empiric treatment, and treatment will need

TABLE 31.1

RECOMMENDATIONS FOR PREOPERATIVE AND POSTOPERATIVE ANTICOAGULATION IN PATIENTS WHO ARE TAKING ORAL ANTICOAGULANTS^a

Indication	Before surgery	After surgery
Acute venous thromboembolism	IV heparin	IV heparin
Month 1	No change	IV heparin
Months 2 and 3	No change	SC heparin ^b
Recurrent venous thromboembolism	IV heparin	SC heparin
Acute arterial embolism (Month 1)	IV heparin	IV heparin
Mechanical heart valve	No change	SC heparin
Nonvalvular atrial fibrillation	No change	SC heparin

^a IV heparin denotes intravenous heparin at therapeutic doses; SC denotes subcutaneous.

^b IV heparin should be used after surgery only if bleeding risk is low.

Consideration should also be given to insertion of an inferior vena caval filter if patient is at high risk for thromboembolism and cannot be anticoagulated. Patients should have daily platelet counts for the first 72 hours after initiation of unfractionated heparin therapy and then every 2–3 days to monitor for heparin-induced thrombocytopenia.

ADH = adjusted dose heparin, subcutaneous UFH to achieve aPTT at high range of normal (35 sec) six hours after dose.

ADDITIONAL CONSIDERATIONS

Renal impairment: Use low molecular weight heparins and fondaparinux with caution in patients with a Scr >2 or CrCL <30 mL/min.

Consider dose adjustments for pharmacologic prophylaxis in patients with a weight of < 50 kg. (Fondaparinux should not be used in patients < 50 kg.)

Obesity: Appropriate dosing for obese patients is not well established. Consider CHAS consult.

4. SELECTION OF THROMBOPROPHYLAXIS: (*√ in box activates order*)

A) NON-PHARMACOLOGIC

Early ambulation: (Low Thromboembolic Risk)

SCD (Knee High): (High Bleed Risk) – Send order to Material Services

Deep Venous Thrombosis Risk Factor Assessment

1. Abbreviations:

- | | | | |
|-------------|---------------------------------|-------------|--|
| VTE | venous thromboembolism | LMWH | low molecular weight heparin |
| LDUH | low dose unfractionated heparin | APLA | antiphospholipid antibody |
| ADH | adjusted dose heparin | CHAS | Comprehensive Hemostasis & Antithrombotic Service
(pager: 719-4023) |
| SCD | sequential compression device | RFS | risk factor score |
| UFH | unfractionated heparin | | |

2. **Thrombophilia** includes:

Factor V Leiden	Prothrombin variant G20210A
APLA or Lupus anticoagulant	Antithrombin III deficiency
Protein C or protein S deficiency	Hyperhomocysteinemia
Heparin induced thrombocytopenia (HIT)	Myeloproliferative disorders (polycythemia vera, essential thrombocytosis (ET))

3. Recommendations for the use of antithrombotic prophylaxis in patients with epidural catheters.

For patients receiving low-dose SC unfractionated heparin (5000units Q12H)

Wait 4-6 hours after a prophylactic dose of UFH before placing or removing a catheter
 Initiate UFH thromboprophylaxis 1-2 hours after placing or removing a catheter
 Concurrent use of epidural or spinal catheter and SC low-dose unfractionated heparin is not contraindicated.

For patients receiving prophylactic-dose LMWH

Wait 24 hours after a prophylactic dose of LMWH before placing a catheter or performing a neuraxial block
 Wait 12-24 hours after a prophylactic dose of LMWH before removing a catheter
 Initiate LMWH thromboprophylaxis 2-4 hours after removal of the catheter
 Initiate LMWH thromboprophylaxis 24 hours after a "single shot" spinal procedure
 Concurrent use of an epidural catheter and LMWH thromboprophylaxis needs to be approved by the pain service

For patients receiving fondaparinux

Extreme caution is warranted given the sustained antithrombotic effect, early postoperative dosing, and "irreversibility".
 Until further clinical experience is available, an alternate method of prophylaxis should be utilized.

4. Dosing recommendations for LMWH and fondaparinux (consider risk factors, caution in patients with renal insufficiency - CrCl < 30 mL/min):

Condition	*Recommended Dose
General Surgery	Enoxaparin 40 mg SQ q24h, 1 st dose 2 h preop
Gynecologic Surgery	Enoxaparin 40 mg SQ q24h
Urologic Surgery	Enoxaparin 30 mg SQ q12h ^c
Major Orthopedic Surgery	Enoxaparin 30 mg SQ q12h, Enoxaparin 40 mg SQ q24h, or Fondaparinux 2.5 mg SQ q 24 h start 6 h post-op
Neurosurgery	Enoxaparin 40 mg SQ q24h If pharmacologic prophylaxis is the chosen intervention.
Trauma and Acute Spinal Cord Injury	Enoxaparin 30 mg SQ q12h If pharmacologic prophylaxis is the chosen intervention.
Medical Conditions (e.g. MI, CHF, malignancy)	Enoxaparin 40 mg SQ q24h

For low-risk procedures, early postoperative mobilization may be the prophylactic approach of choice. ^cHigh-risk patients include those undergoing more extensive, open procedures, including radical prostatectomy, cystectomy, or nephrectomy.

These recommendations are NOT intended to replace an individual clinician's judgment.

P&T Approved June 2002; Revised 1/17/2003

Figure 31.3 (continued)

to be altered on the basis of the results of a thorough microbiologic evaluation of infected fluid (18). Therapies for ileus *per se* are nasogastric intubation and decompression, correction of metabolic abnormalities, and intravenous hydration. Neuraxial blockade with epidural bupivacaine accelerates the return of postoperative gastrointestinal function in patients after colon surgery. Prophylactic nasogastric intubation does not appear to be effective and may result in electrolyte abnormalities and dehydration. Parasympathomimetic agents, such as bethanechol and neostigmine, do not appear to decrease the duration of postoperative ileus. These agents are not recommended because of their side effects. Metoclopramide acts as an antiemetic and prokinetic. Although it may decrease nausea and vomiting, it does not appear to decrease the duration of postoperative ileus.

Stress Ulceration

Routine stress ulcer prophylaxis is not recommended prior to surgical procedures. However, critically ill patients are at increased risk for the development of stress ulcers, and stress ulceration should be considered in patients with abdominal discomfort or distention. Prophylaxis is indicated for patients who have thrombocytopenia, increased serum creatinines, liver failure, respiratory failure, and multisystem organ failure (19).

POSTOPERATIVE RENAL FAILURE

In procedures involving the abdominal aorta, cross-clamping the aorta above the renal arteries results in renal is-

chemia and may lead to acute tubular necrosis. Other patients at risk for postoperative renal insufficiency include those with inadequate intraoperative or postoperative fluid resuscitation, those whose procedures involve large abdominal incisions (insensible fluid losses), or those with massive blood loss. Acute oliguria (urine output of less than 400 mL/day) may be caused by prerenal, renal, and postrenal causes (Table 31.2 and Chapter 100). Acute tubular necrosis from intraoperative renal ischemia may not manifest itself for 24–48 hours. Patients on high doses of opiates may require bladder catheterization to overcome urinary sphincter spasm.

KEY POINTS

- Physicians helping to manage patients postoperatively should maintain close communication with the surgeon and anesthesiologist during the intraoperative and postoperative periods.
- Hypertension and hypotension require immediate attention in postoperative patients because these patients may require urgent re-exploration.
- Aggressive pain management decreases morbidity, cost, and length of hospital stay.
- Patients at risk for perioperative myocardial infarction should be treated with β -blockers throughout the perioperative period.
- Postoperative myocardial infarction often presents without typical chest pain.

Medical Complications of Pregnancy

32

Jeffrey Pickard Linda A. Barbour Raymond O. Powrie

INTRODUCTION

Pregnant women may be hospitalized for medical problems, during which time the hospital physician may be consulted. Before treating a pregnant woman, it is necessary to understand how pregnancy changes the relevant physiology and the way various diseases may present. Diagnosis may be difficult, and treatment may differ from that in the nonpregnant patient. Additionally, diseases specific to pregnancy may complicate evaluation and management.

CARDIAC DISORDERS

In pregnancy, important changes in cardiovascular physiology can alter the normal physical examination and may lead to significant maternal morbidity. By 24–28 weeks' gestation, cardiac output increases by 30%–50%; it then plateaus until delivery. Heart rate may increase slightly but should remain within the normal range. Stroke volume increases with a concomitant decrease in systemic vascular resistance. Blood volume increases by 40%–50%, and red blood cell mass increases by 30%; the result is the "physiologic anemia" of pregnancy. These changes cause the precordial pulse to become stronger and may cause a mild parasternal lift. Both heart sounds are louder and usually split. Up to three-quarters of pregnant women have a third heart sound during the second half of pregnancy. Benign pulmonic or tricuspid flow murmurs are often present, and a venous hum or mammary soufflé may be heard occasionally (1).

Pregnancy may unmask or worsen underlying heart disease, especially late in the second trimester, during labor, and immediately postpartum—the three periods in which

cardiac demand peaks. Regurgitant murmurs usually are well tolerated, whereas mitral and aortic stenosis may lead to pulmonary edema. Moderate to severe pulmonary hypertension of any cause is associated with a significant maternal mortality rate. Patients with Marfan syndrome who have a dilated aortic root are at risk for aortic dissection (1). Ischemic cardiac disease also is tolerated poorly during pregnancy and often leads to myocardial infarction. However, 30%–50% of myocardial infarctions during pregnancy are caused by coronary dissection and occur in women without underlying coronary disease. Virtually any relevant diagnostic or therapeutic procedure, including catheterization, angioplasty, and stenting, may be done during pregnancy.

Palpitations are common during pregnancy but sometimes represent significant tachyarrhythmias. Adenosine, calcium-channel blockers, β -blockers, and digoxin all may be used in the evaluation and treatment of these rhythm disturbances, as may cardioversion if the mother is hemodynamically unstable (2). Of the remaining antiarrhythmics, amiodarone may expose the fetus to unacceptably high iodine levels and therefore should be used only if all others have been ineffective. Cardiopulmonary resuscitation can be performed successfully during pregnancy and is likely to be more successful if the uterus is pulled to the left side to avoid compression of the inferior vena cava.

Pulmonary edema may present in a previously healthy pregnant woman because of marked volume shifts and decreased plasma oncotic pressure, especially in the setting of tocolytics (decreased filling time), preeclampsia (leaky capillaries), or large fluid boluses during epidural anesthesia. Pulmonary edema that does not reverse rapidly with diuretics may indicate that the patient has *peripartum cardiomyopathy*, which may present at any time between the

third trimester and 6 months postpartum. Echocardiography reveals global myocardial hypokinesis. At least one third of patients with peripartum cardiomyopathy go on to suffer progressive heart failure.

RESPIRATORY DISORDERS

Pregnant women increase their minute ventilation because of a progesterone-stimulated increase in tidal volume. The increased minute ventilation lowers the normal arterial partial pressure of carbon dioxide to between 30–35 mm Hg, and a concomitant lowering of the serum bicarbonate results in a compensated respiratory alkalosis. Maternal arterial partial pressure of oxygen should be kept above 60 mm Hg at all times to avoid fetal distress.

Shortness of breath is a common complaint among pregnant women (Table 32.1). Dyspnea of pregnancy is a benign process. The pathophysiology is unclear but is thought to be related to progesterone, which stimulates the increase in tidal volume. It occurs in up to 70% of all pregnant women and resolves spontaneously after delivery if not before.

The treatment of asthma during pregnancy differs little from its treatment outside pregnancy (Chapter 56), and acute asthma exacerbations should be treated as if the woman were not pregnant (3,4). Inhaled β -agonists are used as first-line therapy for mild, intermittent asthma, whereas inhaled steroids are considered first-line therapy for all other types. In general, betamethasone and budesonide are preferred because of their safety record during pregnancy. Experience with fluticasone and flunisolide in pregnancy is limited, but they may be used, if necessary, to control maternal symptoms. Theophylline has an unparalleled safety profile during pregnancy and is an excellent choice as a second-line or third-line agent; serum levels should be kept between 8–12 mg/mL to minimize

effects on the fetus. Leukotriene inhibitors should be avoided at present because there are no safety data regarding their use during pregnancy. Intravenous methylprednisolone and oral prednisone do not cross the placenta to any significant degree and are considered safe for the fetus, although there may be an extremely small risk of cleft palates in infants exposed to prednisone during the first trimester.

HYPERTENSIVE DISORDERS

Hypertension, the most common medical problem seen in pregnancy, is the most important risk factor for the development of *preeclampsia*. Preeclampsia occurs in 5%–10% of all pregnancies and in 20% of women with chronic hypertension regardless of blood pressure control. Blood pressure usually decreases by 10–15 mm Hg during the first two trimesters but returns to prepregnancy levels near term. Pressures above 140/90 in the third trimester suggest either preeclampsia or previously unrecognized chronic hypertension (5).

The main symptoms of preeclampsia are visual disturbances (scintillations or scotomas), headaches, epigastric discomfort, edema (especially in the hands or face), and rapid weight gain. Signs of preeclampsia include hypertension, retinal vasospasm, hepatic tenderness, facial and hand edema, and hyperreflexia. Blood pressure greater than 140/90 or a rise of more than 30 mm Hg systolic or 15 mm Hg diastolic from baseline is considered abnormal and suggests the development of preeclampsia. Laboratory manifestations of preeclampsia include hemoconcentration, thrombocytopenia, proteinuria (>300 mg/dL over 24 hours), elevated creatinine level (>0.8 mg/dL in pregnancy), and hyperuricemia (>5 mg/dL in pregnancy). The *HELLP syndrome* is a severe form of preeclampsia in which hemolysis, elevated liver-enzyme level, and low platelet count occur; urgent delivery is indicated to protect mother and baby.

Women on antihypertensive medication at the time of conception generally can continue their medications during pregnancy (Table 32.2). However, *angiotensin-converting enzyme inhibitors and angiotensin receptor blockers are contraindicated* because they are associated with neonatal renal failure and death, as well as with pulmonary hypoplasia (5). Diuretic therapy may be continued during pregnancy but generally is not initiated once a woman becomes pregnant. Because β -blockers may cause intrauterine growth restriction if used throughout gestation, they are considered third-line or fourth-line agents. Treatment of mild hypertension first noted during pregnancy is controversial because there is no evidence that treatment benefits either the mother or the baby (6). Treatment should be initiated if the diastolic pressure exceeds 100 mm Hg or the systolic pressure exceeds 160 mm Hg. The goal of therapy is a diastolic pressure between 80–90 mm Hg.

TABLE 32.2
ANTIHYPERTENSIVE MEDICATIONS USED DURING PREGNANCY

Drug	Oral dose	Parenteral dose	Comments
Atenolol	50–100 mg/d	—	Intrauterine growth restriction a concern
Clonidine	0.1–0.3 mg b.i.d.	—	Used infrequently
Hydralazine	10–100 mg b.i.d.	5–10 mg intravenous/intramuscular q20–30 min; continuous infusion 0.5–10 mg/h	Safe; useful in hypertensive emergency; second line in chronic hypertension
Labetalol	100–300 mg b.i.d.	20 mg intravenous; then 20–80 mg q20 min; max 300 mg; continuous infusion 1–2 mg/min; at target blood pressure, stop or reduce to 0.5 mg/min	Gaining popularity in both chronic and urgent hypertension during pregnancy
Methyldopa	250–1,500 mg b.i.d. or t.i.d. (max 3,000 mg/d)	—	Safest antihypertensive in pregnancy
Metoprolol	50–200 mg b.i.d.	—	Intrauterine growth restriction a concern
Nifedipine	30–120 mg/d	—	Appears safe; no first-trimester data
Nitroprusside	—	0.5–10 mcg/kg/min continuous infusion	Risk of fetal cyanide toxicity if used longer than 24 h

Physicians other than obstetricians may become acutely involved in the care of a pregnant woman if preeclampsia becomes severe or eclampsia (seizure) supervenes. In contrast to nonpregnant patients, eclamptic seizures are best treated with intravenous magnesium sulfate given as a 6-gram load over 20–30 minutes in a 5% dextrose solution, followed by 2–4 grams per hour continuous infusion. Serum magnesium levels should be assessed (range 4.8–8.4 mg/dL), and calcium gluconate should be administered to reverse any magnesium toxicity (cardiac or respiratory depression) (7).

Blood pressure usually is elevated in severe preeclampsia/eclampsia. Target blood pressure should be around 150/100. However, treatment of the blood pressure has no effect on preeclampsia per se, so patients whose blood pressures are not elevated do not need antihypertensive medication. Aggressive blood-pressure reduction (systolic <140 mm Hg, diastolic <90 mm Hg) should be avoided because of the risk of uteroplacental hypoperfusion. Severe hypotension may occur if calcium-channel blockers are used concurrently with magnesium sulfate. Women with severe preeclampsia are at risk for pulmonary edema because of cardiomyopathy and pulmonary capillary leak. Intravenous fluids should be monitored carefully, and diuretics are required if pulmonary edema develops. Intracerebral hemorrhage may occur, as may oliguric renal failure, even in the absence of severe hypertension. Liver dysfunction of any severity also may complicate severe preeclampsia or eclampsia and should be differentiated from acute fatty liver of pregnancy. Other conditions in the differential diagnosis include systemic lupus erythematosus (Chapter 112) and hemolytic uremic syndrome/thrombotic thrombocytopenic purpura (Chapter 98). Preeclampsia may worsen or arise *de novo* within

the first week postpartum despite the fact that delivery of the baby is the only definitive treatment of this potentially life-threatening disorder.

GASTROINTESTINAL DISORDERS

As pregnancy progresses, changes in gastrointestinal physiology presage the relevant problems seen in pregnant women. Lower esophageal sphincter tone and esophageal peristalsis diminish, increasing the likelihood of gastroesophageal reflux disease (8). Antacids, sucralfate, cimetidine, and ranitidine may be used as necessary during pregnancy. Experience with proton pump inhibitors, especially omeprazole, is growing, and they appear to be safe. Transit time through the gastrointestinal tract is prolonged, and nausea, vomiting, and constipation all are seen more frequently in women who are pregnant. Metoclopramide and prochlorperazine are safe to use. Occasionally nausea and vomiting become severe and prolonged (*hyperemesis gravidarum*) and require hospital admission. Hyperthyroidism, with depressed thyroid stimulating hormone (TSH) and elevated free thyroxine levels, often coexists with hyperemesis gravidarum due to the thyrotropic activity of human chorionic gonadotropin, but it usually is transient and rarely requires treatment.

During pregnancy, gallbladder volume increases, and emptying becomes sluggish; as a result, bile becomes more lithogenic. Biliary “sludge” occurs in up to 30% of pregnancies. Gallstones occur in 2%–4%, but intervention during gestation is required in less than 0.1% of all pregnancies. If intervention becomes necessary, it should be done during the second trimester, if possible, to minimize the likelihood of spontaneous abortion and fetal

malformations (first trimester) and of premature labor and delivery (third trimester). Endoscopic retrograde cholangiopancreatography and cholecystectomy (open and laparoscopic) have been performed safely during pregnancy (Chapter 84).

The diagnosis of abdominal pain during pregnancy may be difficult because the expanding uterus may alter the location and presentation of common causes. In addition, diseases specific to pregnancy may present with abdominal pain (Table 32.3).

Acute fatty liver of pregnancy is an uncommon (1 in 13,000 deliveries) but serious disease characterized by fatty infiltration of the liver, hepatic failure, and encephalopathy developing in the third trimester. The mortality rate is approximately 20%. Acute fatty liver usually occurs after 34 weeks' gestation, and patients present with anorexia, nausea, vomiting, malaise, and right upper quadrant pain; it often is confused with HELLP. Abnormal laboratory values may include anemia with evidence of hemolysis, leukocytosis, increased uric acid, renal insufficiency, elevated liver aminotransferases (aspartate aminotransferase >alanine aminotransferase), prolonged prothrombin time, hyperbilirubinemia, and hypoglycemia (<60 mg/dL). There may be signs of fetal distress. Treatment includes supportive care for the mother (Chapter 82) and prompt delivery of the baby.

Inflammatory bowel disease (Chapter 81) is relatively common during childbearing years. If quiescent at conception, it usually remains so during gestation. Steroids, sulfasalazine, mesalamine, azathioprine, and mercaptopurine all have been used safely during pregnancy. Metronidazole also is considered safe, although some recommend delaying its use until after the first trimester.

Intrahepatic cholestasis of pregnancy (ICP) is a disease characterized by severe pruritis without a skin rash, generally starting in the palms and soles and progressing centripetally (9). It usually occurs during the third trimester.

TABLE 32.3
ABDOMINAL PAIN DURING PREGNANCY

Acute hepatitis from alcohol or toxins
Cholecystitis/cholelithiasis
Ureterolithiasis
Peptic ulcer disease (rare)
Pulmonary embolus
Pneumonia (especially right lower lobe)
Pancreatitis
Pyelonephritis
Appendicitis
Diabetic ketoacidosis
Acute fatty liver of pregnancy
Preeclampsia
HELLP syndrome

Aminotransferases and bilirubin are usually (60%) moderately elevated, but severe hyperbilirubinemia and jaundice are relatively uncommon (25%). Although the maternal course is usually benign, ICP may lead to preterm birth, fetal distress, and fetal demise. Delivery should occur as soon as fetal lungs are mature, usually by 37 weeks (9,10).

DIABETIC KETOACIDOSIS

Pregnant women with diabetes are at increased risk for ketoacidosis throughout gestation, but the risk increases significantly during the latter half of pregnancy. Because of the "accelerated starvation" that characterizes pregnancy and the decreased buffering capacity of maternal serum, diabetic ketoacidosis in a pregnant woman may occur with near-normal glucose levels (11). Therefore, a pregnant woman with diabetes admitted to the hospital because of intractable emesis should be evaluated for diabetic ketoacidosis regardless of her serum glucose. Pregnant women during the second and third trimesters require an additional 100–150 grams of glucose daily to meet the metabolic demands of the fetus and placenta (12). These women may require a 10% glucose infusion to provide adequate carbohydrates until oral intake can be resumed. Otherwise, fat will be burned for fuel, and ketosis will persist (13). Pregnant women with diabetes are also more susceptible to infections, especially of the urinary tract, which also can trigger diabetic ketoacidosis. Pregnancy does not change the recommended treatment of diabetic ketoacidosis (Chapter 107).

THYROTOXICOSIS IN PREGNANCY

Thyroid storm is a life-threatening condition to both mother and fetus. It usually develops in an inadequately treated woman with severe thyrotoxicosis who is subjected to additional physiologic stress such as severe infection, preeclampsia, induction of anesthesia, labor, or surgery (14). The incidence of thyroid storm during pregnancy is estimated at 1%–2% of women with preexisting hyperthyroidism and usually presents with severe symptoms of thyrotoxicosis, fever over 101° F, altered mental status, congestive heart failure, tachyarrhythmias, nausea and vomiting, diarrhea, or abdominal pain. Initial treatment is the same as in the nonpregnant patient. Cold iodide (e.g., Lugol solution, 10 drops every 8 hours, or saturated solution of potassium iodide, three drops every 8 hours) can be administered to the pregnant woman in thyroid storm to diminish the release of thyroid hormone but should be given 1–2 hours after propylthiouracil (15). Iodide can cause fetal goiter, but this is rare if the iodide is given for no more than 3 days. Esmolol (0.25 mg/kg intravenously over 1 minute, then 0.05–0.1 mg/kg/min infusion) and propranolol (20–60 mg orally every 6 hours) can be used

to control maternal heart rate, but blood pressure must be carefully monitored. Hydrocortisone (100 mg every 8 hours) can help maintain maternal blood pressure. It diminishes the peripheral conversion of thyroxine to triiodothyronine (T_4 to T_3) and does not cross the placenta to any appreciable degree (Chapter 108).

THROMBOEMBOLISM

A pregnant woman is 5–10 times more likely to develop venous thromboembolism (VTE) than when she is not pregnant, and pulmonary embolism is a leading cause of maternal death (16,17). This hypercoagulable state exists throughout all three trimesters and persists until 4–6 weeks postpartum. Deep venous thrombosis is most common in the left lower extremity because of the vascular anatomy. It occurs antepartum and postpartum with equal frequency, and antepartum events are evenly distributed throughout gestation. Pulmonary embolism is more likely to occur postpartum, primarily because cesarean section increases the risk of pelvic-vein thrombosis. Other risk factors for thrombosis include previous thrombosis, obesity, venous insufficiency, prolonged bedrest, older age and higher parity, ovarian hyperstimulation, and underlying hypercoagulable states (17). Approximately 50% of pregnant women with thrombosis have a predisposing cause of thrombophilia, the most common being the factor V Leiden mutation or the prothrombin gene mutation (18) (Chapter 98).

It is critical to make the diagnosis of deep venous thrombosis or pulmonary embolism definitively because the diagnosis mandates the use of subcutaneous heparin throughout the remainder of the current and all future pregnancies and usually contraindicates the future use of oral contraceptives. The diagnostic approach should be similar to recommendations in the nonpregnant patient (Chapters 52 and 53); of note is that venography, if necessary, is safe during pregnancy (<0.05 rad) (19). D-dimers increase during pregnancy, and their predictive value for the diagnosis of VTE during pregnancy is unknown. The diagnosis of pulmonary embolism may be missed clinically during pregnancy, in part because the alveolar–arterial oxygen gradient is often normal, perhaps reflecting a younger population with greater pulmonary reserve. Ventilation–perfusion scanning is completely safe during pregnancy (<0.02 rad), but the interpretation is often not definitive. Helical computed tomography exposes the fetus to no more radiation than ventilation–perfusion scanning as long as the fetus can be kept out of the scanning field (20). Pulmonary angiography can be done without significant radiation to the fetus (<0.5 rad) and is recommended if there is any doubt regarding the diagnosis after computed tomography or ventilation–perfusion scanning (21). Magnetic resonance imaging may be used if pelvic vein thrombosis is suspected, but the utility and

safety of other diagnostic modalities have not been adequately established.

The treatment of acute thromboembolism during pregnancy requires intravenous anticoagulation with heparin for 5 days. Subcutaneous heparin then should be given every 8–12 hours for 3–6 months after the acute event, keeping the partial thromboplastin time 1.5 times the control value throughout the dosing interval. After the patient receives at least 3 months of therapeutic anticoagulation, heparin doses of at least 10,000 units twice daily should be continued until term. Heparin requirements increase throughout pregnancy because of increased clearance, expanded plasma volume, increased protein binding, and degradation by the placenta. Upward dosage adjustments are often necessary in the second and third trimesters. Because of the increased levels of fibrinogen and factor VIII during pregnancy, some women will appear to be heparin resistant on the basis of monitoring with the activated partial thromboplastin time (aPTT). Anti-factor Xa levels (0.3–0.6 IU/ml throughout the dosing interval) may be used to guide therapy in these women (22). Heparin-induced thrombocytopenia (HIT) is rare during gestation (23), but women who develop HIT during pregnancy may be treated with danaproid sodium, which does not appear to cross the placenta (24). *Warfarin is relatively contraindicated during pregnancy because of the risk of both fetal bleeding and malformation.* Warfarin is safe to use during breastfeeding and may be used once the baby is delivered; it should be continued for at least 4–6 weeks postpartum because women remain hypercoagulable until then. Low-molecular-weight heparin does not cross the placenta, but dosing requirements during pregnancy have not been determined. If low-molecular-weight heparin is used to treat acute thromboembolism, anti-factor Xa levels should be monitored, and the dose should be adjusted to maintain peak anti-factor Xa levels between 0.5 and 1.2 IU/mL using twice-daily dosing (22). Thrombolytic therapy should be reserved for life-threatening situations because of the significant risk of maternal hemorrhage, preterm delivery, and fetal loss.

RENAL DISORDERS

During pregnancy, the increase in cardiac output and blood volume results in an increase in renal plasma flow; the glomerular filtration rate rises to 150–180 mL/min. Serum creatinine levels typically fall, so a serum creatinine of greater than 0.8 mg/dL is considered abnormal, as is a blood urea nitrogen level of greater than 14 mg/dL. Urinary protein excretion increases to 300 mg/d, and patients with underlying proteinuria may develop nephrotic range proteinuria (>3.5 gm/24 hours) during pregnancy. Renal compensation for the normal hyperventilation of pregnancy results in a serum bicarbonate fall of approximately 4 mEq/L. The influence of progesterone and the mechanical

compression of the ureters and bladder by the gravid uterus result in a normal hydronephrosis of pregnancy, most notably on the right side. Both urinary stasis and reflux may increase as the ureters dilate, and they predispose the pregnant woman to pyelonephritis (mostly right-sided) and stone formation (Chapters 68 and 103) (25).

In addition to the usual nonobstetric causes of acute renal failure, severe preeclampsia, acute fatty liver of pregnancy, and postpartum hemorrhage are causes unique to pregnancy. Idiopathic postpartum renal failure may be pathophysiologically related to hemolytic uremic syndrome and thrombotic thrombocytopenic purpura (8). Renal biopsy should be performed, if necessary, prior to the third trimester. Hemodialysis and peritoneal dialysis can treat renal failure successfully during pregnancy. Dialysis should be performed earlier (blood urea nitrogen level > 60 mg/dL) and more often than in the nonpregnant patient because a blood urea nitrogen level greater than 80 mg/dL is toxic to the fetus. More frequent dialysis also reduces the need to remove large volumes of fluid and the resulting risk of hypotension and uteroplacental hypoperfusion.

Women who have had renal transplants (Chapter 102) usually maintain normal renal function during pregnancy and normally have no evidence of graft rejection. Prednisolone crosses the placenta to only a minimal degree and does not appear to adversely affect the fetus. Azathioprine crosses the placenta, but the fetal liver lacks the activating enzyme, so the fetus is protected from its effects. Cyclosporine does not appear to cause congenital anomalies but may be associated with fetuses that are small for gestational age. Experience with tacrolimus and mycophenolate mofetil is extremely limited during gestation, and these immunosuppressives are generally avoided during pregnancy (26,27).

CEREBROVASCULAR DISORDERS

Cerebrovascular disorders account for 8%–12% of all maternal deaths, and about 35% of all strokes that occur in women of childbearing age occur during pregnancy. Strokes may occur at any time from the second trimester through the first 4–6 weeks postpartum. *Cerebral venous thrombosis*, however, almost always occurs during the first 4 weeks postpartum in association with cesarean section, dehydration, hypercoagulable states, infection, or hyperviscosity.

Over 90% of headaches during pregnancy are migraine or “tension-type.” Approximately two-thirds to three-quarters of women with chronic migraine report that their headaches improve or stay the same during gestation. Nevertheless, cerebral aneurysms and arteriovenous malformations (Chapter 117) may be more likely to bleed during pregnancy or postpartum. Women with new onset of severe headaches during pregnancy, especially with aura or mental-status changes, should be evaluated carefully (Table 32.4). Appropriate imaging studies such as computed tomography

with or without contrast or magnetic resonance imaging or angiography may be done safely during pregnancy and should be used to aid the diagnosis if necessary. Treatment of headaches during pregnancy should start with simple analgesics. Opiates may be used, if necessary, but should be limited to short-term use because they cross the placenta. Benzodiazepines and ergots generally are avoided during pregnancy, as is sumatriptan (although some believe that sumatriptan may be used in selected women [28]). β -blockers may be used if prophylaxis is indicated.

The treatment of epileptic seizures (Chapter 118) during pregnancy is generally the same as in the nonpregnant patient. Seizures that occur for the first time during the third trimester should be considered eclamptic until proven otherwise. If the seizures do not respond to magnesium sulfate, underlying stroke may be causing the epilepsy.

FEVER

Fever in a pregnant woman commonly indicates an infection, with a spectrum of infections similar to that in the nonpregnant woman. However, aspiration pneumonia and acute sinusitis are more common in the pregnant woman. *Listeria* infections can cause significant fetal injury and death unless treated promptly with penicillin or ampicillin (Chapter 70).

Pregnant women also are prone to urinary tract infections and pyelonephritis (Chapter 68), which must be treated aggressively to prevent sepsis. Most of the antibiotics used to treat these infections, including sulfa drugs and aminoglyco-

sides, are safe during pregnancy. Quinolones have been used safely in a limited number of pregnant women despite initial reports that they impair cartilage formation in dogs. *Tetracyclines should be avoided after the first trimester* (29).

Endometritis and septic pelvic thrombophlebitis are important causes of postpartum fever. Endometritis is a polymicrobial infection with genitourinary pathogens such as *Streptococcus*, *Enterobacteriaceae*, and *Bacteroides* species, especially if the infection begins within the first 48 hours postpartum. Women who remain febrile despite what should be appropriate antibiotic therapy are often felt to have septic pelvic thrombophlebitis, even though blood clots usually are not found despite appropriate imaging studies. The recommended treatment for septic pelvic thrombophlebitis is empiric intravenous heparin, but there are no controlled studies to confirm its efficacy.

KEY POINTS

- Pregnancy causes significant cardiac stress that may unmask or worsen underlying heart disease.
- Severe preeclampsia or eclampsia causes significant injury and death and requires aggressive management. Eclamptic seizures are treated differently from epileptic seizures, so the diagnosis of seizures during pregnancy must be accurate.
- Diabetic ketoacidosis during pregnancy may present with glucose levels of less than 200 mg/dL.
- Thromboembolism is five times more common in pregnancy. All relevant imaging studies should be performed to ascertain the diagnosis because the amount of radiation to the fetus is well below that which is still considered safe.
- Most antibiotics, including penicillins, sulfa drugs, and aminoglycosides are safe during pregnancy. Tetracyclines should be avoided after the first trimester.

David F. Gitlin Bernard Vaccaro

INTRODUCTION

Patients with primary or secondary psychiatric disorders commonly present to general hospitals for either psychiatric or medical care. Patients with previously known psychiatric conditions, such as schizophrenia or bipolar disorder, are often a challenge for the nonpsychiatrist with little previous exposure to these illnesses. In fact, these patients may be at greater risk of medical illness than the general population because of decreased self-care, limited access to medical care, and poor compliance with outpatient treatment. Hospital management of these patients should focus on the medical condition. However, additional attention to the comorbid psychiatric illness may be necessary if it complicates or interferes with medical management. Psychiatric medications may require adjustment in the setting of acute renal or hepatic insufficiency or because of potential drug interactions.

Patients without primary mental disorders may demonstrate acute neuropsychiatric symptoms in the hospital. An array of medical illnesses, such as myocardial infarction, stroke, or infections, may disrupt brain function and lead to delirium. Patients may develop acute anxiety or profound depressive mood because of uncertainty about their condition or concern about prognosis. Recognizing and addressing these psychiatric sequelae are essential for the optimal care of all patients.

Finally, some patients may have conditions bordering between medicine and psychiatry. Such patients may present with a variety of somatic complaints, but appropriate evaluation demonstrates no organic etiology. For many patients, a “psychosomatic” condition may exist. Hospital physicians must confront the challenge of understanding such a condition in patients whom they may never have seen before.

DEPRESSION

Depression is perhaps the most common psychiatric condition seen in the general hospital. Appropriate assessment and effective management are the hallmarks of care. Inadequate diagnosis or treatment occurs in over 50% of patients, however, and may result in serious results such as suicide. For a complete discussion of depression, see Chapter 119.

SUICIDE

Suicide, the most common and serious psychiatric emergency, is frequently seen in general hospital EDs and medical services. Suicide is the eighth leading cause of death in the United States, with a rate of 10–13 deaths/100,000 deaths each year. Suicide is the second leading cause of death in teens and young adults ages 15–24. Whites are twice as likely as nonwhites to commit suicide, men are more than four times as likely as women to kill themselves, and the highest suicide rate (41/100,000, or four times the general population) is seen in elderly men (1).

Over 90% of individuals who complete suicide have a psychiatric disorder, most commonly a depressive illness. Higher rates of suicide are also seen with schizophrenia, bipolar disorders, substance abuse disorders, and possibly anxiety and personality disorders. Approximately 20% of completed suicides are accompanied by medical illnesses, and the suicide rate increases with more severe or chronic conditions (1). Fifty percent of individuals who commit suicide saw a physician in the month before the event, but most did not identify their suicidal thoughts directly to the physician. Thus, assessment and management of suicidal risk are critical skills for the hospital physician.

Identification of suicidal potential and the acute management of suicidal behavior are the cornerstones of care for the hospital physician. Some patients will present with primary psychiatric derangements, including agitation, withdrawn behavior, poor self-care, psychosis, and overt suicidal intentions. Patients should be questioned about active suicidal behaviors, and appropriate medical interventions must be taken if overdose or self-inflicted injuries have occurred. The physician must assess suicidal risk and, if it is present, provide a safe and effective treatment environment, which should include the following:

1. *Location* in a secured setting, devoid of objects that the patient might use for self-harm.
2. A *search* of the individual for potentially dangerous objects, such as guns, knives, razor blades, and so on, and for medications that might be used in an overdose attempt. This search should be completed in a timely but, when possible, respectful manner.
3. *Constant observation* by staff.
4. *Physical and/or chemical restraint only as a last resort* in patients whose behavior cannot be adequately controlled with less-restrictive means.

For other patients, the risk of suicide may not be obvious. Patients with new illnesses or diagnoses or with further deterioration of a chronic medical condition may feel overwhelmed and hopeless. Physicians should be alert to signs and symptoms of depression, anxiety, and hopelessness, all of which increase the risk of suicidal ideation. Patients with organic brain disorders, such as delirium, dementia, and traumatic brain injury, may have increased impulsivity and behavioral dysregulation, which may lead to self-injurious behaviors. Asking patients about self-destructive thoughts and intents is the best way to identify patients at risk.

Once a potential risk is identified, it is important to request consultation from the hospital mental health staff, preferably an emergency or consultation-liaison psychiatrist. The psychiatrist will help in the assessment and acute management of underlying psychiatric disorders as well as provide expertise about the potential risk of suicide. The psychiatrist is typically the physician who will determine the appropriate level of care for the patient, including but not limited to psychiatric hospitalization, and help establish proper treatment and follow-up planning. Whenever possible, rapid access to a 24/7 hospital-based psychiatric consultation service is advantageous for effectively managing acutely suicidal individuals.

ANXIETY DISORDERS

Anxiety disorders are frequent in the acute hospital setting. The challenge is determining whether the anxiety is caused by the underlying medical condition, hypoxia, hypercapnea, delirium, alcohol/sedative withdrawal syn-

drome, a reaction to a new medication, or the stress of the medical hospitalization.

Patients with an underlying *panic disorder* may often present to an emergency department with chest pain or acute cardiac syndromes. Anxiety often accompanies cardiac or pulmonary disease as well, such as angina, heart failure, COPD, or asthma. For treatment of acute anxiety, low-dose benzodiazepines (e.g., lorazepam 0.5–2 mg b.i.d. or t.i.d.) are often effective. Longer-acting benzodiazepines such as diazepam or clonazepam are not usually recommended because of their long half-lives and their tendency to accumulate in the geriatric and the medically ill patient. For chronic anxiety, such as panic disorder or generalized anxiety disorder, the use of a selective serotonin reuptake inhibitor (SSRI) may be indicated (2). Serotonin reuptake inhibitors are best started at a low dose and then increased as tolerated (see Chapter 119 for information on selecting and starting SSRIs). Because they are known to suppress respiratory drive, benzodiazepines must be used cautiously in individuals with respiratory conditions such as COPD and sleep apnea.

PSYCHOSIS

Psychosis, by definition, is the presence of perceptual disturbances (hallucinations) and/or thought disturbances (delusions). The patient with psychotic symptoms is often misunderstood on a medical service. Chronic or recurrent psychotic symptoms, which can be present in a number of psychiatric disorders, are the hallmark of schizophrenia but also can occur in bipolar (manic depressive) disorder and major depressions. In the acute hospital setting, the key to assessing psychosis is to determine the course of symptoms. New and acute psychotic symptoms, especially in persons over 50 years of age, are almost always related to an organic brain syndrome, typically delirium or dementia, although occasionally they may represent the index episode of a primary psychiatric disorder. The presence of confusion or a disturbance in the level of consciousness can confirm the diagnosis of delirium. Psychosis associated with dementia typically occurs late in the course of the dementia, and a careful history will often elicit evidence of progressive cognitive impairment (Chapter 115).

When psychotic symptoms are mild and unobtrusive, they can often be managed with gentle reassurance and support. More often than not, however, psychosis is distressing to both patients and staff, and it requires antipsychotic (neuroleptic) medications. In patients with delirium, the psychosis is usually associated with agitation and behavioral disturbance and thus may require rapid response for control. *Haloperidol*, the most commonly used neuroleptic in general hospitals, may be administered intravenously, intramuscularly, or by mouth (Table 33.1). Parenteral haloperidol is often well tolerated, likely has fewer extrapyramidal side effects, and has a long history of use for behavioral dyscontrol caused by delirium (see the

TABLE 33.1
TYPICAL NEUROLEPTIC MEDICATIONS USED IN GENERAL HOSPITALS

Medication	Dosage range for acute psychosis/agitation	Maintenance dosage for psychosis	Available routes of administration
Haloperidol	0.5–5 mg q 30 min p.r.n.	0.5–10 mg	PO/IM/IV
Droperidol	2.5 mg. May repeat in 3 hrs	0.625–5 mg	IM/IV
Chlorpromazine	50–100 mg q 30–60 min p.r.n.	50–500 mg	PO/IM/IV
Risperidone	0.5–2 mg q 1–2 hrs p.r.n.	0.5–6 mg	PO
Olanzapine	2.5–5 mg q 1–2 hrs p.r.n.	2.5–20 mg	PO
Ziprasidone	20 mg q 1–2 hrs p.r.n.	20–160 mg	PO/IM
Quetiapine	25–50 mg q 1–2 hrs p.r.n.	25–400 mg	PO

section about management of delirium that follows). Patients with dementia often require a similar approach, but lower doses are typically used.

Although haloperidol and the other, older neuroleptics are generally safe and effective, the patient must be monitored for side effects that can limit their use (Table 33.2).

The new generation of *atypical antipsychotics* such as olanzapine, risperidone, and quetiapine are beginning to be used in treating acute psychosis and are becoming the mainstay of treatment for primary psychotic disorders (3). They carry a substantially lower risk of inducing of extrapyramidal side effects and other dopamine-blockade effects, such as tardive dyskinesia and the neuroleptic malignant syndrome. However, they carry higher risks of hyperglycemic complications, weight gain, and prolongation of the QT interval.

Patients with chronic psychiatric disorders also develop medical illnesses and are admitted to acute care hospitals. To prevent relapse or decompensation, it is important to maintain the patients on their antipsychotic medications unless otherwise contraindicated. Use of the hospital psychiatric consultant or close coordination with the patient's outpatient psychiatrist can often be helpful.

DELIRIUM

Delirium, or acute confusional states (Chapter 115), are common problems in hospitalized patients. As many as 15%–30% of patients on a general medical service suffer from delirium. The percentage can be as high as 50% in subspecialty populations (such as patients undergoing hip

TABLE 33.2
COMMON SIDE EFFECTS OF NEUROLEPTIC MEDICATIONS

Side effect	Characteristics	Management
Acute dystonic reaction	Sudden onset dystonia, typically of the mouth, jaw, neck, eyes; usually occurs in first few days	Diphenhydramine IM 50 mg b.i.d. or t.i.d.; benztropine 1–2 mg b.i.d., switch to low potency neuroleptic
Secondary Parkinsonism	Cogwheel rigidity, mask facies, pill-rolling tremor, and peri-oral movements; occur more commonly on the higher potency neuroleptics	Diphenhydramine 25–50 mg b.i.d.; benztropine 0.5–2 mg b.i.d., switch to low potency neuroleptic
Akathisia	Internal sensation of restlessness, inability to sit still	Propranolol 10–20 mg t.i.d.; Lorazepam 1–2 mg b.i.d.
Neuroleptic malignant syndrome	Rare but sometimes fatal complication; marked by confusion or mental status changes, lead-pipe rigidity in the limbs, elevated white blood count, elevated CK level, fever, and autonomic dysregulation	Immediately stop neuroleptic; IV hydration, antipyretics; bromocriptine or dantrolene if severe
Cardiac arrhythmias	Rare; QT prolongation leading to torsade de pointes; also seen with atypical neuroleptics	Avoid neuroleptic; close monitoring and correction of potassium, calcium, and magnesium levels; may be less common with olanzapine

Adapted from Norris ER, Cassem, NH. Cardiovascular and other side effects of psychotropic medications. In: Stern TA, Herman, JB, eds. *Massachusetts General Hospital Psychiatry Update & Board Preparation*. New York: McGraw-Hill, 2003;391–398, with permission.

replacement surgery or coronary bypass surgery patients (4)) and up to 83% of ICU patients (5). A multicomponent intervention can help prevent delirium in older patients (6). The presumed underlying mechanism of delirium is an imbalance of dopamine and acetylcholine in the neural synapses. This mechanism may explain why dopamine blockers such as haloperidol have been helpful in controlling the agitation associated with delirium.

The primary management of delirium consists of recognizing the condition and thoroughly searching for underlying medical causes. The causes of delirium are extensive, including metabolic, neurologic, infectious, cardiac, pulmonary, and endocrinologic sources (Table 115.4, Chapter 115). Identifying potentially life-threatening causes is imperative: myocardial infarction, pulmonary embolus, Wernicke's encephalopathy, hypoglycemia, intracerebral bleeding, CNS infections, and stroke. One frequently unrecognized cause of delirium in the medically ill is withdrawal from alcohol or sedative-hypnotic drugs. Patients in withdrawal often develop sudden agitation and confusion 1–3 days into a hospitalization. Interviews with family members or other sources may reveal the drinking history or clarify prior doses of sedative-hypnotic medications. Clonidine can be used as prophylaxis against alcohol withdrawal symptoms (7).

Patients with *organic brain syndromes or psychiatric disorders caused by general medical illnesses* can also present with a myriad of symptoms, from acute confusion and delirium to odd or inappropriate behaviors. Common causes include cerebral hypoxia, stroke, and closed head injuries. Patients may have had falls or trauma in which a closed head injury may have occurred but other injuries were initially more prominent or urgent. Closed head injuries present as confusion, inattentiveness, forgetfulness, apathy, or socially inappropriate and disinhibited behavior. Computed tomography (CT) scans of the head may help identify underlying trauma such as a subdural hematoma or skull fracture, but the scans may be normal in many cases. A magnetic resonance image, which may identify diffuse axonal injury or hypoxic damage, may be diagnostic in cases in which the CT scan is unrevealing despite a strongly suggestive clinical history of head trauma.

Patients can be managed with nonpharmacologic or behavioral interventions as well as with pharmacotherapy. Often, patients who are quietly confused need little or no intervention. The presence of a family member or sitter may help calm the patient. Gentle reassurance and firm limits may be all that are required. If the patient does not respond to these interventions, neuroleptic medication is the treatment of choice. The application of mechanical restraints may also be required when all other appropriate interventions have been unsuccessful.

For mild delirium or delirium in a geriatric patient, initial therapy is haloperidol 0.5–2 mg intravenously, every 30 minutes, until the patient is calm. It is important to allow the 30 minutes for the medication to work before

repeating the dose to avoid oversedation and other complications of neuroleptic use. For a moderately delirious patient, 2–3 mg is given, whereas 5–10 mg is recommended for a severely agitated patient. If the patient is not calmer after the initial dose, the dose may be repeated every 30 minutes until the desired affect is achieved. If a cumulative 10 mg dose of haloperidol is inadequate, 1–2 mg of lorazepam every 30 minutes may act synergistically to help decrease the total amount of haloperidol required. The total required dose of medication needed to calm the patient is then calculated and given in divided doses b.i.d. or t.i.d. Once the patient's symptoms begin to decrease, the medication can be tapered as tolerated.

THE "DIFFICULT" PATIENT

Occasionally, managing a hospitalized patient is challenging because patients may refuse treatments or tests, undermine the staff's efforts to care for them, and react with mistrust and anger. These patients typically have personality traits or disorders that can be disruptive, and they often create strong emotional reactions in the staff who care for them.

A *personality disorder* is defined as a lifelong pattern of maladaptive behavior that does not serve to meet an individual's needs effectively. Signs of a personality disorder include overvaluation of some staff while devaluing others; rapid shifts in mood, especially when given unwanted news; and playing off some staff members against others, called *splitting*. Often these disruptive behaviors arise because the patient feels emotionally out of control, and it is the responsibility of hospital staff to help the patient feel self-contained.

The most important part of treating these patients is recognition of the personality problem itself. This recognition can help staff understand that splitting is occurring rather than personalize the difficult interactions with the patient. Psychiatric consultants can assist the team in understanding the patient's particular personality issues and help tailor the treatment plan to maximize success. Nursing and medical staff should come together to agree on a thoughtful and medically appropriate plan, especially around emotionally charged issues such as pain, anxiety medications, and discharge planning. Difficult patients often need acknowledgment of their suffering and the difficulty of their predicament as well as firm limits. The treatment plan should be communicated to the patient in the presence of the whole team (and documented accordingly) to minimize the opportunity for splitting.

FUNCTIONAL SOMATIC DISORDERS

Emotional distress can trigger physical symptoms, whether it is diaphoresis and tachycardia seen with anxiety or the insomnia, anorexia, and fatigue of depression. Most individ-

uals who have somatic symptoms are able to differentiate whether they are physical or psychic in origin. However, some patients are unaware that their somatic symptoms have an emotional source. Subclinical somatic presentations are common and generally self-limiting.

Functional somatic disorders can present as atypical somatization disorder, hypochondriasis, or a conversion disorder. *Somatization disorder* is a chronic state of persistent and varied somatic symptoms for which there are no discernable organic causes. It typically occurs in young women, many of whom have had traumatic childhood histories. *Hypochondriasis* is manifest by a preoccupation with one's health to the exclusion of all else. Patients with hypochondriasis are convinced they have a serious medical disorder despite repeated evaluations, are difficult to persuade otherwise, and will often present multiple times to multiple health systems. *Conversion disorder* is a demonstrated loss of motor or sensory function not associated with any organic source, presumably as an expression of psychological distress. Common examples include psychogenic seizures, blindness, and paralysis.

Factitious disorders, including the rare variant known as *Munchausen's syndrome*, entail the conscious manufacturing of signs and symptoms by patients. Patients may produce false fevers by surreptitiously heating thermometers, alter laboratory tests with covertly ingested medications, or even inject urine and feces to create false infections. Despite conscious awareness of their behaviors, patients are likely unaware of the psychological process that underlies their actions (8).

Whether or not these patients are consciously aware of their symptom production, the signs and symptoms are caused by psychologic distress too unbearable for the patient to manage. Rather than deal with their psychic anguish, these patients experience their suffering somatically. They may have learned that physical illness can earn them love and attention from caregivers, whereas emotional illness leads to abandonment and criticism.

Hospital physicians may have intense reactions once they realize that a somatic syndrome is not likely caused by an organic etiology. A physician who has invested a great deal of time, concern, and resources may feel especially abused or manipulated or feel that he or she has been made to look foolish. The tendency is to respond angrily by confronting or even abandoning the patient, a response that will not rectify the situation because the patient will soon find another physician and/or health care system in an endless search for care.

Physicians must recognize their essential role in managing these patients. One requirement is to appreciate that the patient is quite ill with either a serious physical disorder or a serious mental disorder. By limiting unnecessary testing and invasive procedures, especially surgeries, the physician helps prevent iatrogenic complications. Although psychiatric consultation is important in understanding the patient's incentive toward illness, patients

with somatic disorders are generally averse to psychiatric intervention or treatment. The psychiatrist typically helps the hospital physician and primary care provider establish a treatment plan that can minimize patients' danger to themselves.

VIOLENT PATIENTS

Violent and aggressive behavior in hospitalized patients is predominantly a manifestation of derangement in brain function: delirium, dementia, head trauma, and drug intoxication/withdrawal states. Aggression can also be seen in patients with psychiatric conditions such as mania, psychosis, severe anxiety, borderline personality disorder, and agitated depression. Occasionally, violent behavior is volitional, representing sociopathy.

Violent behavior in an acute care hospital is relatively rare, but it can be devastating to staff and patients. Hospital physicians must recognize the risk for violence early in the assessment of patients and be sure all staff are warned about a particular patient's potential for aggressiveness. They should then assemble a multidisciplinary team, including nursing, social work, and psychiatry, to address the issue rapidly. Hospital security staff may also play an important role. When behavioral approaches fail, medications or physical restraints may be necessary (9).

INFORMED CONSENT, COMPETENCY, AND THE RIGHT TO REFUSE TREATMENT

A general tenet of good medical practice is to ensure that patients are adequately informed about their condition and understand the risks and benefits of the range of treatments available. Occasionally, patients do not agree with their physician's opinion and/or recommendation regarding evaluation and treatment. Although physicians typically defer to their patients' choices, the physician may at times question whether a patient has the decision-making capacity needed to refuse the treatment. When the risks of refusing treatment are substantial, the physician may request a psychiatric consultation to assess whether the patient is competent to refuse.

Over the past half-century, there has been a movement toward supporting a patient's autonomy for decision making rather than relying on the physician's beneficence (Chapter 17). The courts have adopted the concept of *informed consent*, whereby individual patients should expect their medical providers to inform them adequately but allow them to make the decision free of coercion. *Informed* means that patients are made aware of their condition and that the risks and benefits of treatment (plus all alternatives, including no treatment) are provided in a reasonable manner. The final aspect of the informed consent doctrine

is that a patient's decision making is based upon a presumption of competency to make such a decision, including the following:

1. The ability to make a decision
2. The ability to understand information
3. The ability to appreciate the consequences of one's decision
4. The ability to think rationally (10)

If a physician believes that a patient does not have one or more of these abilities, he or she may conclude that the patient is not competent to make medical decisions. Although the physician may encourage the family (or hospital in lieu of family) to pursue some form of guardianship, the standard of care in most hospitals is to seek the opinion of a psychiatric consultant. The psychiatrist will not only assess the patient's decision-making ability, but also assist the patient, family, and medical team to collaborate effectively on decision making, thereby obviating the need for legal interventions. Occasionally the consultant may identify disruptions in the communications between medical team and patient and, as a result, catalyze increased consensus and agreement.

CIVIL COMMITMENT

Acutely decompensated, mentally ill patients frequently present to emergency departments of general hospitals with psychosis, depression, suicidal ideation or attempts, or potential violence. These patients may present on their own or be brought by police, family, or outside providers. Suicide attempts, including overdoses and self-inflicted injuries, may result in medical hospitalization despite ongoing suicidal risk. A hospitalist may need to decide rapidly whether involuntary psychiatric confinement is preferable to admission to a general hospital.

Most states have statutes that allow for the emergency involuntary hospitalization and confinement of mentally ill individuals who are considered to be an imminent danger to themselves or others. These commitment statutes are typically short-term, lasting anywhere from 2 days–3 weeks. In general, these statutes permit involuntary confinement but not involuntary treatment, which typically requires a separate hearing to assess whether the patient is competent to refuse the actual treatment.

Most jurisdictions permit licensed physicians to hold individuals in the hospital against their will if it is determined that they are a potential danger because of a mental illness. Some states require more than one physician's input, and others require evaluation by designated clinicians or psychiatrists. It is critical that every hospital physician know the local statutes regarding involuntary commitment. However, when the physician is uncertain about the state laws concerning commitment, it is prudent to protect the patient and community by holding the individual until the appropriate

psychiatric evaluation can occur. Hospital lawyers and psychiatrists are useful resources regarding local regulations.

TRANSFER/ADMISSION TO PSYCHIATRIC UNITS

Patients who present with acute psychiatric symptoms may benefit from psychiatric hospitalization. When patients are determined to be a potential danger to themselves or others, hospitalization is typically necessary, whether or not the patient agrees with this recommendation. Most states have two basic processes for psychiatric hospitalization: *voluntary* or *involuntary*.

Voluntary admission, as implied, is when a patient who might benefit from acute treatment in a psychiatric unit agrees to this treatment. For many of these patients, the inpatient treatment provides a more intensive, accelerated approach than can be provided in an outpatient setting. However, restrictions on insurance coverage for inpatient psychiatric care often preclude this option by covering only outpatient counseling or day treatment programs.

Patients who are considered a potential danger to themselves or others must be held in a safe environment until a formal psychiatric evaluation can be performed to determine whether the patient must be hospitalized. Patients who do not agree with this recommendation must be committed involuntarily to the psychiatric unit or hospital. In most states, this requires an evaluation by a qualified psychiatrist or mental health provider.

WHEN TO REQUEST PSYCHIATRIC CONSULTATION

Psychiatric consultation should be considered for patients with any of the following characteristics:

1. Suicidal ideation or behavior
2. Agitated or aggressive behavior
3. Unexplained somatic symptoms
4. Active primary psychiatric disorders
5. Significant emotional dysfunction associated with the primary medical condition
6. Personality traits and disorders that interfere with medical care

In addition, psychiatric consultation should be considered if the physician has serious questions regarding the patient's decision-making capacity.

KEY POINTS

- Patients with chronic psychiatric disorders also develop medical disorders, and careful evaluation is required to detect medical problems and distinguish them from psychiatric symptoms.

- Patients with medical disorders can develop acute psychiatric symptoms, which may represent a manifestation of the medical illness.
- Suicide is typically seen with depression or other mental disorders, and its frequency increases in patients with significant medical disorders.
- Early recognition and management of delirium can decrease morbidity and mortality.
- Antipsychotic medications are essential for the treatment of delirium and psychosis, but side effects of these medications can complicate medical illness.
- Consultation-liaison psychiatrists can assist in assessing and managing functional somatic disorders, difficult-to-manage patients with personality disorders, and potentially dangerous behavior.

INTRODUCTION

Victims of injury are not limited by age, race, gender, or socioeconomic class. Trauma is unbiased in who it afflicts, and it can occur at any time or place. All clinicians must be prepared to treat injured patients, who can present challenging diagnostic and management decisions.

Death from trauma can occur at three separate phases of injury. Those who die at the scene usually have unsalvageable major vascular disruption, high spinal cord injury, or massive head trauma. A second group of patients may lose their lives because of ongoing hemorrhage or evolving injuries. Trauma systems aim to treat these patients within minutes-to-hours following injury. A third group of patients succumb to infection and multiple organ system failure days-to-weeks following trauma.

EPIDEMIOLOGY

Accidents represent the fifth leading cause of death among all age groups, and the leading cause of death in people ages 1–34 (1). About 40,000 Americans are killed in motor vehicle collisions each year, and another 3.5 million suffer nonfatal injuries (2, 3). Another 30,000 deaths occur annually from firearm violence in the United States (4). Among the age groups 15–19, 20–24, and 25–34, accidents, homicides, and suicides cause more than 75%, 72%, and 51% of deaths, respectively (5).

Mechanisms

Injuries are divided into two broad classes. Penetrating trauma is caused by firearms, knives, and other sharp objects that can become impaled. Blunt trauma most commonly arises from motor vehicle or motorcycle collisions, pedestrians struck by vehicles, or falls. However, any significant force sustained by the human body can result in major injury. Sports injuries and industrial accidents are commonly seen. Some types of injuries can result in a combination of both blunt and penetrating damage.

Initial Evaluation

The basic philosophy in caring for a trauma patient is to assume that major injury exists until proven otherwise. The onus is on the health care team to rule out life-threatening injuries definitively and constantly to protect against destabilization of existing injuries. The American College of Surgeons Committee on Trauma has outlined a highly protocolized way of evaluating the trauma patient (6): The primary survey (composed of “A = airway, B = breathing, C = circulation, D = disability, E = exposure”); rapid diagnostic studies; and the secondary survey, which includes a complete history and physical examination of the patient and the performance of secondary diagnostic procedures.

Primary Survey

The primary survey consists of a sequence of systematic evaluations; each component must be addressed before

proceeding. These steps must be constantly reevaluated throughout the workup of the injured patient.

- The first priority is the *evaluation and treatment of airway compromise*. The airway may be secured with simple positioning, insertion of oral or nasal airways, endotracheal or nasotracheal intubation, or surgical access (cricothyroidotomy). Care must always be taken to maintain cervical spine stability; this goal is accomplished with “in-line” traction techniques.
- The second priority is *adequate ventilation and oxygenation*. The physical examination should assess the presence of equal bilateral breath sounds and equal, symmetric rise of the chest. The chest wall should be palpated for crepitus or fractures. Adequate oxygenation can be confirmed with pulse-oximetry. All trauma patients should be administered supplemental oxygen.
- The third priority is *rapid evaluation of the circulation*. Vital signs are obtained, and large-bore IV access is secured. Control of hemorrhage is performed here, most commonly with direct pressure.
- The fourth priority is a *rapid assessment of the patient's neurologic status*. This task includes assessment of the Glasgow Coma Scale (GCS) (Table 117.1) and presence (and level) of focal neurologic deficits.
- The next priority is to *expose the patient completely*, for a comprehensive external examination.

Rapid Diagnostic Studies

During the primary survey, a decision must be made as to the patient's overall stability. Patients who are unstable, as evidenced by shock or severe neurologic disability, should enter into a treatment algorithm that allows for rapid identification and treatment of life-threatening injuries. A chest and pelvic radiograph (at minimum) are required to make decisions about the next intervention. The FAST (*focused assessment with sonography for trauma*) exam is often used in hemodynamically unstable patients to determine whether the source of hemorrhagic shock is injured abdominal viscera that require immediate surgical intervention. In the case of an equivocal FAST, diagnostic peritoneal lavage can be utilized to identify the peritoneal cavity as the source of bleeding. In the technique, a catheter is inserted into the peritoneal cavity, and saline is instilled. Once the saline is removed, it can be examined for presence of blood or enteric contents to establish the diagnosis of visceral injury. It is crucial to conduct the secondary survey to identify all injuries soon after the patient is stabilized.

Secondary Survey

For patients deemed to be “stable,” the secondary survey, which must be performed immediately, includes a history and physical examination to identify all injuries and prior-

itize treatment. An electrocardiogram (ECG), if needed, and blood samples should be obtained, and blood should be sent for type and crossmatch. The clinician must remember to reevaluate the ABCDEs and be prepared to change diagnostic and therapeutic priorities rapidly.

In the hemodynamically stable patient, the FAST is also performed as part of the secondary survey to identify free fluid in the pericardium and specific areas of the abdominal cavity. The test has a reported sensitivity and specificity as high as 90% and 99%, respectively, in the hands of experienced operators (7). The FAST examination can also identify fluid or air in the hemithoraces.

Diagnostic Studies

Most centers will perform chest, pelvic, and lateral cervical spine radiographs in the initial series. Additional views of the cervical spine may be obtained at this time to definitively exclude a cervical spine injury. Thoracic and lumbar spine radiographs are also obtained as clinically indicated.

Head CT scan should be performed in all patients with witnessed or suspected loss of consciousness or altered level of consciousness (GCS <15). If all 7 cervical vertebrae are not visualized on plain radiograph, a CT scan of the cervical spine with sagittal and coronal reconstructions should be performed. CT scans of the chest to evaluate the aorta are indicated for all patients with an abnormal mediastinum on chest radiograph (Figure 34.1). Abdominal and pelvic CT scans should be performed in any patient with an abnormal FAST, abdominal pain or tenderness, or injuries that suggest that a significant force was sustained. Clinical judgment must guide what CT scans or additional studies should be performed.

MANAGEMENT OF SPECIFIC INJURIES

Head Trauma

Blunt head injuries are generally divided initially into minor (GCS = 15–14), moderate (GCS = 13–9), and severe (GCS = 8–3). The CT scan and evolution of the clinical examination guide subsequent management. For patients with a normal CT scan and mild deficit, simple observation is all that is generally required. A patient with a normal CT scan and neurologic exam rarely deteriorates. Such patients can generally be sent home with a responsible observer, although they may still suffer from long-term memory or cognitive deficits. Patients who are intoxicated should be observed until their level of consciousness is normal.

Any patient with an abnormality on CT scan, GCS <12 (or motor component <5), or focal neurologic deficit should be evaluated by a neurosurgeon. Abnormal findings on CT scan include depressed skull fractures, epidu-

Figure 34.1 A: Chest radiograph demonstrating widened mediastinum suspicious for aortic injury. B: CT scan of the chest showing traumatic aortic injury (arrow). Also note mediastinal blood. C: Sagittal reconstructions of chest CT demonstrating aortic injury.

ral hematomas, subdural hematomas (Figure 34.2), subarachnoid blood, parenchymal contusions, and intraventricular blood. Patients with normal CT scans but an abnormal neurologic exam often have diffuse axonal injury. Immediate surgical intervention is indicated in patients who have extra-axial collections of blood with midline shift or worsening mental status. Seizure prophylaxis is often recommended (Table 34.1; see also Chapter 118) (8).

At the discretion of the neurosurgeon, intracranial pressure monitors may be placed. Strategies for management of elevated intracranial pressure include (9), but are not limited to, mild hyperventilation, sedation, paralytics, osmotic diuretics (generally mannitol, 1 gm/kg), hyperosmo-

lar therapy, placement of intraventricular drainage devices, barbiturates, and decompressive craniotomy. The aim of therapy is to maintain a low intracranial pressure while maintaining an adequate cerebral perfusion pressure (>60 – 70 mm/Hg) (cerebral perfusion pressure = mean arterial pressure–intracranial pressure). Intervention must prevent hypoxia and hypotension, both of which worsen long-term outcome (10). Patients with severe head injuries are at risk for coagulopathies and shock, even in the absence of other injuries. Transtentorial herniation, which is often heralded by the “blown” pupil and a Cushing reflex (bradycardia and hypertension), is treated with acute hyperventilation, osmotic diuretics, and immediate neurosurgical evaluation (see also Chapter 117).

Figure 34.2 CT scan of brain with acute subdural hematoma with 1.45 cm midline shift.

Spinal Cord and Spine Fractures

Cervical, thoracic, and lumbar spine fractures are classified as stable vs. unstable injuries. Stable injuries do not pose risk to the spinal cord and are treated with methods ranging from simple pain control to immobilization with collars and braces. Unstable fractures, by definition, pose a risk to the spinal cord, and consultation with a spine surgeon is required for stabilization.

Spinal cord injuries, most of which occur in the cervical cord, are a major cause of short- and long-term morbidity in trauma patients. All patients with a significant mechanism of injury should be assumed to have a spinal cord injury or spine fracture until proven otherwise. Cervical collars and strict logroll precautions should be utilized. A

Evidence of seizure activity

careful neurologic examination for sensory and motor deficits is essential. All patients with spinal cord injury should be evaluated by a spine surgeon. In blunt spinal cord injury, the use of high dose methylprednisolone as a bolus (30 mg/kg), followed by a 23-hour infusion (5.4 mg/kg/hr), currently represents the standard of care, although it is not without controversy (11). It must be started within 8 hours of injury to be beneficial. Further intervention in these patients includes early operative decompression and the avoidance of hypotension, to prevent spinal cord ischemia. Mean arterial blood pressure should be maintained at 85–90 mm Hg for 7 days following injury (12), despite the hypotension that may accompany the loss of sympathetic innervation.

Neck

Blunt and penetrating trauma can result in life-threatening injuries in the neck. Penetrating injuries to the neck can cause exsanguinating hemorrhage, major neurologic morbidity, tracheal disruption, or esophageal/oropharyngeal disruption. Carotid injuries should be evaluated by angiography and treated in consultation with a trauma surgeon or neurosurgeon. All penetrating injuries that violate the platysma muscle also necessitate consultation with a surgeon.

Thoracic

Penetrating injuries to the chest can range from simple soft tissue injury to major vascular disruption. The diagnostic and therapeutic approach must be guided by the patient's stability and the assumed trajectory of the offending object. Simple pneumothorax or hemothorax is treated with tube thoracostomy. Massive hemothorax (initial drainage >1200 mL or >200 mL/hr for 2–3 hours) often requires surgical intervention. Precordial or transmediastinal injuries necessitate evaluation of mediastinal structures by a combination of echocardiography, pericardiocentesis, bronchoscopy, esophagoscopy, contrast studies, and CT scanning (Figure 34.1). All patients with penetrating injuries (other than simple hemothorax or pneumothorax) should be evaluated by a surgeon and all unstable patients require emergent surgical intervention.

Blunt thoracic trauma can also be a major source of morbidity and mortality. Simple rib fractures can lead to splinting and pneumonia if pain control is not adequate. Epidural analgesia by an experienced pain specialist can be extremely helpful. Simple pneumothoraces and hemothoraces are treated with tube thoracostomy. Pulmonary contusions, which can range from mild to severe, may require mechanical ventilation. All patients with po-

tential myocardial injury, ranging from mild sinus tachycardia to major cardiac dysfunction, require an ECG. Hemodynamically stable patients should be treated supportively with telemetry monitoring (13). Major catastrophic injuries such as aortic rupture, severe disruptions of the tracheobronchial tree, esophageal injuries, and myocardial rupture mandate emergent evaluation by an experienced surgeon.

Abdominal

Penetrating abdominal and flank injuries must be evaluated to determine the risk of underlying injury. Any patient with hemodynamic instability, pneumoperitoneum, evisceration, or peritonitis on exam requires laparotomy. For patients without indications for surgical intervention, a variety of diagnostic modalities exist, including observation and serial physical examinations, peritoneal lavage, FAST, triple contrast CT scan (14), local wound exploration, diagnostic laparoscopy, and diagnostic laparotomy. As a general rule, peritoneal or retroperitoneal violation necessitates laparotomy.

The evaluation of blunt abdominal injuries is generally accomplished with a combination of abdominal exam, FAST, and CT scan. Any evidence of peritonitis, pneumoperitoneum, or hemodynamic instability attributable to abdominal injury should be evaluated by laparotomy. Although a detailed discussion of the management of these injuries is beyond the scope of this chapter, observation and angiography are cornerstones of the treatment of splenic and hepatic injuries (15) (Figure 34.3).

Pelvic Fractures

Pelvic fractures are a major source of morbidity and mortality in the trauma patient. Exsanguinating hemorrhage, from either arterial and/or venous disruption, can occur without outward signs of hemorrhage, particularly where there is major injury to the posterior elements of the pelvis. Patients with hemodynamic instability in the setting of a significant pelvic fracture are treated with a combination of fracture stabilization with abdominal binders, or external fixation and angiographic control of bleeding. MAST trousers can be used in the field or during initial presentation to control bleeding, but a simple bedsheet tied securely around the pelvis can be extremely effective in allowing temporary reduction of the pelvic elements. An exhaustive search for associated injuries, such as those of the rectum, vagina, bladder, and urethra, is mandatory. Long-term morbidity can also be caused by prolonged immobilization, which can lead to life-threatening deep venous thrombosis.

Extremity Trauma

Fractures should be stabilized and reduced by simple splinting. Early (within 48 hours) definitive stabilization and fixation is advocated for both isolated injuries and those occurring in the context of a polytrauma (16).

For open fractures or those associated with significant soft tissue trauma, operative irrigation and closure of the defect are necessary to avoid osteomyelitis. Tetanus and prophylactic antibiotics should be administered in all such cases. Major crush injuries may lead to rhabdomyolysis due

Figure 34.3 A. CT scan of abdomen demonstrating splenic “blush” consistent with active bleeding (arrow). B. CT scan of abdomen of the same patient after proximal coil embolization (arrow).

to muscle destruction, which should be treated aggressively to prevent renal failure (Chapter 100).

The fractured or injured extremity must always be evaluated for possible ischemia. Angiography may be required to determine the level and degree of injury and to plan vascular repair. The patient's clinical examination (changes in edema, warmth, and pulses) should be closely monitored for signs of compartment syndrome. This entity can be confirmed by exact pressure measurements done at appropriate intervals by an orthopedist.

SPECIAL CONSIDERATIONS AND COMPLICATIONS

The trauma patient is at unique risk for many complications.

Previous Medical Comorbidities

Information about past medical history is crucial to providing adequate treatment to the trauma patient. Significant cardiac, pulmonary, liver, and renal disease may impact the care of the trauma patient. A dialogue between the trauma team and the patient's primary or hospital physician can be of vital importance in assuring appropriate care.

Pregnancy

The pregnant trauma patient raises issues for the injured mother and the fetus. The general rule is that the mother's welfare takes priority. All diagnostic tests needed to identify the mother's injuries adequately should be performed in a timely fashion, minimizing radiation exposure when possible. Volume resuscitation should be liberal, due to the relative hypovolemia of pregnancy; the mothers of fetuses over 20 weeks of gestation should be placed on their left sides to decrease the pressure of the fetus on the vena cava. Early obstetrical consultation should be obtained and fetal monitoring performed for all patients more than 22 weeks and at the discretion of the obstetrician. The Kleihauer-Betke test can detect fetal blood in the maternal circulation. This test, performed in the lab, makes use of the relative resistance of fetal hemoglobin to acid denaturation. If the test is positive, Rhogam should be administered to all Rh- mothers.

Domestic Violence

Although domestic violence disproportionately affects women, all patients should be screened for it. Early in-

volvement of social workers and specially trained clinicians is imperative. Because patients often deny the true cause of their injury, the index of suspicion must remain high to assure the safety of the patient in the hospital and after discharge.

Nutrition

Patients with major injuries are, by definition, catabolic, with extreme caloric and protein requirements. When possible, enteral nutrition should be provided by a nasogastric or naso-jejunal feeding tube (17). Post-pyloric tubes and promotility agents can aid the delivery of adequate nutrition. Parenteral nutrition is recommended only for patients who are unable to tolerate enteral feeds or where gastrointestinal trauma precludes enteral nutrition (see also Chapter 15).

Infectious Disease

Infections are a leading complication in the trauma patient. Prophylactic antibiotics are efficacious in limited circumstances related to trauma, especially penetrating abdominal wounds and open fractures. First generation cephalosporins are generally used in patients with open fractures for a duration of 48 hours (cefazolin 1 gm IV q8h). Patients with penetrating abdominal injury should receive 1 gram of cefotetan prior to surgery. If a hollow viscus is found to be violated, cefotetan (1 gm IV q 12 hrs) should be continued for 24–48 hours. Patients with open facial fractures should receive antibiotics targeting the anaerobes of the mouth, as well as *Staphylococcus aureus* (clindamycin or ampicillin/sulbactam) for 48 hours. Patients with other injuries are generally not given prophylactic antibiotics.

Prophylaxis for Deep Venous Thrombosis (DVT)

Prolonged immobilization, long bone fractures, pelvic fractures, closed head injuries, and, most importantly, spinal cord injuries put the trauma patient at extremely high risk for the development of DVT and subsequent pulmonary embolism (18). Some centers advocate placement of vena caval filters for all patients with spinal cord injuries. Surveillance duplex ultrasonography is recommended for patients with spinal cord injuries, closed head injuries, or prolonged immobilization (19). The approach to prophylactic anticoagulation is outlined in Chapter 52.

Prophylaxis for Gastrointestinal Stress Ulcers

Injured patients, particularly those with head trauma, are at risk for the development of stress ulcers, especially if they

require long term (>48 hours) mechanical ventilation. All trauma patients should be treated with H₂ blockers or proton pump inhibitors. Early enteral feeding is also extremely effective at reducing the risk of stress ulcerations. Additional information on prophylaxis is found in Chapter 80.

Alcohol and Drug Abuse

Alcohol is often associated with motor vehicle collisions, and both drugs and alcohol are associated with crime and traumatic injury. Toxicology screening should be performed in suspected cases, and a positive toxicology screen should lead to an evaluation for substance abuse.

The management of hospitalized patients with drug or alcohol abuse or withdrawal is described in Chapters 121 and 122, respectively.

Multiple Organ Dysfunction Syndrome

Patients with multiple injuries and those who have significant shock states are at risk for the development of the systemic inflammatory response syndrome and subsequent organ dysfunction. Head trauma, multiple orthopedic injuries, massive blood transfusions, and pulmonary contusions place the trauma patient at an increased risk for the development of acute respiratory distress syndrome (ARDS) (Chapter 24). Cardiac dysfunction can result from direct myocardial injury or loss of sympathetic innervation to the heart. Renal failure may be precipitated by rhabdomyolysis from crush injuries or ischemia secondary to hypoperfusion (Chapter 100). Liver dysfunction and subsequent coagulopathies can similarly result from direct injury or secondary hypoperfusion states (Chapter 82). Any organ can become profoundly dysfunctional from the direct effects of trauma or the subsequent inflammatory response. The treatment for organ dysfunction in this population is primarily supportive.

KEY POINTS

- The initial evaluation of the trauma patient must be performed in an orderly, step-wise fashion designed to identify and treat the most imminently life-threatening problems first. Always remember the ABCDEs: airway, breathing, circulation, disability, exposure.
- Hemodynamically unstable patients require aggressive resuscitation and identification of the cause of shock. Temporary stabilization and transfer to a definitive care center is indicated if specialized personnel are not available.
- The secondary survey identifies specific injuries and prioritizes treatment. Adjunctive studies are utilized as deemed necessary by the health care team.

- Neurologic injuries can be devastating. Maintaining adequate blood pressure and oxygenation is critical. The spinal cord must be stabilized until injury is definitively excluded.
- Penetrating injuries can range from mild to fatal. All hemodynamically unstable patients with possible penetrating injury should have emergent surgical consultation and likely will require operative intervention.
- Specific concerns in the hospitalized trauma patient include malnutrition, infectious complications, deep venous thrombosis, stress ulcers, and the sequelae of alcohol and substance abuse.
- The multiple injury or hypotensive patient may develop systemic inflammation and subsequent multiple organ system dysfunction. Prevention and rapid treatment of shock can reduce morbidity and mortality.

INTRODUCTION

The tempo of cardiovascular disease requires the clinician to diagnose rapidly and treat sometimes before the diagnosis is certain. This time pressure often creates a conflict between the need to be careful, conservative, and correct on the one hand, and the equally pressing need to institute effective interventions rapidly in the acutely ill patient on the other.

This chapter covers common symptoms, signs, and laboratory abnormalities elicited from cardiovascular patients at the time of their initial evaluation for hospitalization.

The evolution of these problems during the course of an inpatient stay is also considered. Symptoms to be reviewed include chest pain, palpitations, and lightheadedness, which all have causes that range from the extremely dangerous to the annoyingly benign; dyspnea (Chapter 54) and syncope (Chapter 44) are covered elsewhere. Common physical findings include the jugular venous pattern, pulse abnormalities, heart sounds, and cardiac murmurs; edema (Chapter 99) is discussed elsewhere. Finally, the electrocardiogram (ECG), chest radiograph, and common biochemical and hematologic test results are discussed.

CARDIAC SYMPTOMS

Chest Pain

History

Because most adults have experienced chest pain of some type in their past, the history of the current episode can be made more valuable by an assessment of its similarity to previous episodes. It is also extremely important to assess the clinical setting in which the chest pain presents itself: a 22-year-old athletic medical student who presents with

substernal chest pain for the first time after hearing a lecture on cardiovascular pathology is much less likely to have active cardiovascular disease, no matter what the quality of the chest pain, than is a 63-year-old hypertensive, hypercholesterolemic man, all of whose progenitors died of coronary disease by age 55 (Chapter 6).

Chest pain can be associated with a number of cardiovascular, pulmonary, and gastrointestinal conditions (Table 35.1). In an individual patient, however, it may be frustratingly difficult to ascribe chest pain to a specific pathologic process. In general, the chest pain history is more useful than the physical examination. Important aspects of the history include the quality, location, radiation, frequency, and duration of the pain; precipitating or relieving factors; and associated symptoms (1–3).

The differential diagnosis of chest pain includes acute coronary syndrome (spectrum from unstable angina to ST elevation myocardial infarction [MI]), angina pectoris, myocardial ischemia resulting from valvular heart disease or cardiomyopathy, aortic dissection, pericarditis, pulmonary hypertension, pulmonary embolism, esophageal spasm/acid-peptic disease, gallbladder/pancreatic disease, pulmonary disease, and musculoskeletal pain. The critical importance of differentiating these entities (Table 35.2) revolves around both the need to intervene as early as possible in some clinical scenarios (i.e., acute MI, aortic dissection) and the fact that the beneficial therapy for a patient with one possible diagnosis (i.e., antiplatelet therapy, anticoagulation, and/or thrombolytic therapy for acute MI) might mean disaster for the patient with another (aortic dissection).

For both *acute MI* (Chapter 38) and *angina pectoris* (Chapter 37), the quality of chest discomfort is classically described as pressure, heaviness, squeezing, tightness, or constriction. However, some patients complain of burning, indigestion, fullness, or “gas”. When a patient complains of

sharp or stabbing chest discomfort that is reproduced by changes in position or palpation, it is much less likely to represent ischemic heart disease. The typical location of the chest discomfort of ischemic heart disease is substernal, but the discomfort may also be principally in the left precordial area. Common sites of radiation include the left shoulder, the base of the neck, and the left more often than the right arm. Less commonly, the pain may radiate to the jaw, teeth, or back. Pain that radiates to the abdomen or legs is unlikely to be related to ischemic heart disease.

Both MI and angina may be associated with shortness of breath and fatigue caused by ischemic myocardial dysfunction, ischemic mitral valve dysfunction, or both. MI is suggested if the pain lasts more than 20–30 minutes, especially if it occurred without obvious provocation. By contrast, anginal pain usually persists for less than 15 minutes and is more likely to be provoked by recognizable physiologic stress. Unstable angina is distinguished from stable angina by its occurrence at rest or with minimal exercise and by its change from any previous stable anginal pattern (Chapter 37). Complete response of chest pain to nitroglycerin within 5 minutes is most consistent with transient myocardial ischemia, although it can also be seen in esophageal spasm.

The presenting symptoms for acute MI may also be different for women and men. In women, shortness of breath is at least as common as acute chest pain, and prodromal symptoms of unusual fatigue are also more common in women, perhaps because their MIs tend to occur at a later age.

True myocardial ischemia may also be found in the absence of demonstrable coronary disease on angiography. For example, some patients may have angina related to episodic coronary artery spasm without underlying severe coronary stenoses, and some patients have true ischemia

TABLE 35.1
DIFFERENTIAL DIAGNOSIS OF CHEST DISCOMFORT

Cardiac disorders	Noncardiac disorders
Coronary artery disease	Gastrointestinal disorders
Stable angina	Esophageal disorders (spasm, reflux)
Unstable angina	Acid (peptic ulcer, gastritis)
Acute myocardial infarction	Cholecystitis/pancreatitis
Valvular disease	Pulmonary
Aortic valve disease (stenosis > insufficiency)	Pneumonia
Myocardial disease	Pleuritis
Hypertrophic cardiomyopathy	Pneumothorax
Other	Musculoskeletal
Aortic dissection	Chest wall pain
Pericarditis	Costochondritis (Tietze’s syndrome)
Pulmonary hypertension (severe)	Thoracic outlet syndrome
Pulmonary embolism	Other

despite the absence of any demonstrable abnormalities in their epicardial coronary arteries (Syndrome X). A newly recognized syndrome has symptoms and ECG changes that clinically mimic acute infero-apical MI in the absence of obstructive coronary disease; it is generally seen in older women in the setting of hypertension and intense physical and/or psychological stress or somatic pain. Labeled the “Tako-Tsubo” syndrome (5) because the left ventricular apex balloons in a pattern likened to the Japanese pot used to catch octopus, it may be caused by microvascular spasm or regional myocarditis. Its transient ECG changes are similar to the acute cardiac findings in the setting of neurologic injuries. Myocardial ischemia can also be found in patients with aortic valvular disease, especially aortic stenosis, or hypertrophic cardiomyopathy because of an imbalance between myocardial oxygen demand and supply (Figure 38.1).

Anemia, thyrotoxicosis, fever, and other high-output states can exacerbate underlying causes of myocardial ischemia but do not usually cause myocardial ischemia themselves in the absence of other underlying abnormalities. The chest discomfort caused by myocardial ischemia resulting from these various conditions usually is clinically indistinguishable from that of angina pectoris.

Recent exposure to recreational drugs, pharmaceuticals, or diet supplements (e.g., cocaine, amphetamines, β -agonist inhalers, ephedrine) can cause coronary spasm or transient increases in myocardial oxygen demand secondary to sympathetic nervous system mediated increases in contractility or peripheral arterial tone. At least in the case of cocaine exposure, patients with significant ECG changes or elevations of cardiac biomarkers are at low risk of death or myocardial infarction (6).

Aortic dissection (Chapter 49) is a less common condition, usually associated with underlying hypertension or an abnormality such as Marfan syndrome that causes the aortic abnormalities. The pain is typically described as tearing or ripping, is excruciating in severity, and has a sudden onset (unlike that of acute MI, which tends to build in intensity over several minutes). The pain often indicates the location of the dissection, with ascending aortic dissections causing pain in the chest and upper back, and descending dissections causing pain in the upper back and mid to lower back and abdomen. The pain is not typically precipitated by exertion, although any stimulus that increases blood pressure or heart rate can exacerbate the dissection. An aortic dissection can compromise a coronary artery, primarily the right coronary artery, and cause acute inferior wall MI. Dissection retrograde into the pericardium can cause acute pericardial tamponade. If the dissection compresses the branch of any major artery, signs and symptoms of arterial insufficiency will be noted, with diminished or delayed pulses and end-organ dysfunction. When aortic dissection is clinically suspected, the physical examination should search carefully for evidence of delayed pulses or vascular insufficiency. The

chest radiograph may confirm an enlarged aorta. Transesophageal echocardiography is an excellent screening test, and computed tomography (CT) or magnetic resonance imaging (MRI) can confirm the diagnosis (7) (Chapter 36).

Pericarditis (Chapter 46) may present with dull or aching chest discomfort similar to that of an acute MI, or with pleuritic discomfort similar to that of pulmonary embolism, pneumonia, or other pleural disease. Pericarditis can also accompany acute MI, usually occurring a day or more after an acute Q-wave MI, and pericardial tamponade can occur with proximal aortic dissection back into the pericardium. The discomfort of pericarditis is often exacerbated by inspiration or coughing. Unless accompanied by acute MI or aortic dissection, the pain is unlikely to be associated with diaphoresis, nausea, or vomiting, and it seldom radiates to the arms. The pain is usually not related to exertion, and it tends to persist for hours or days. A key physical finding is a pericardial rub. In patients with evidence of tamponade or constriction, additional findings of hemodynamic compromise should be sought.

Although heart failure is not commonly associated with chest discomfort, a sense of pressure or fullness may be caused by pulmonary hypertension (Chapter 59) or the excessive stimulation or distention of the J-receptors in the lung parenchyma. Shortness of breath and orthopnea will almost always accompany any chest discomfort associated with heart failure, and the patient may also have jugular venous distention or peripheral edema consistent with secondary right-sided heart failure. Because heart failure may also be a manifestation of other serious causes of chest discomfort (e.g., acute MI, severe myocardial ischemia, aortic dissection, pericarditis, pulmonary embolism), these other possible precipitants of heart failure must be considered in the initial evaluation.

Cardiac arrhythmias commonly cause a sensation of palpitations (see below) rather than true chest discomfort. However, some arrhythmias may precipitate myocardial ischemia and its associated chest discomfort.

The chest discomfort of *pulmonary embolus* (8) or pulmonary infarction can be similar to that of coronary insufficiency when acute right ventricular (RV) strain and ischemia associated with the pulmonary hypertension are present. However, the pain of these conditions is more commonly described as pleuritic in nature and is usually peripheral rather than central in the chest.

The *gastrointestinal* causes of chest discomfort include esophageal motility disorders such as spasm and reflux, acid-peptic diseases such as ulcer and gastritis, and cholecystitis or pancreatitis. Esophageal spasm may mimic myocardial ischemia in terms of its quality and location; even more vexing, it may have a similar response to nitroglycerin. The diagnosis can often be made based on the relation of the pain to meals, exacerbation by recumbent position, and lack of relation to exercise. Esophageal

reflux and spasm commonly respond to antacid therapy. However, a therapeutic trial of antacids in the emergency setting is notoriously inaccurate for making a diagnosis of esophageal or acid-peptic causes of chest discomfort because the resolution of pain caused by ischemic heart disease during the same time frame may be inappropriately attributed to this unrelated therapeutic trial. Gastrointestinal causes of chest discomfort are often associated with abnormalities on the abdominal examination, and, except for esophageal spasm, are unlikely to cause pain that radiates to the shoulder, neck, or arms. Gastrointestinal causes of pain also tend to have a reproducible relationship to eating, to be unrelated to exercise, and to persist for hours.

Pulmonary causes of chest discomfort include pneumonia, pleuritis, and pneumothorax, and tend to be exaggerated by breathing and sometimes by changes in position. The pain is commonly described as sharp and stabbing. The episodes range from fleeting pain associated with a particular precipitant to prolonged and constant discomfort; neither of these characteristics is typical of myocardial ischemia.

Musculoskeletal chest discomfort may be related to a variety of abnormalities of the muscles, bones, and nerves of the chest wall and shoulder. These causes of pain are commonly exacerbated by movement or local palpation, are not otherwise affected by exertion, and do not respond to nitroglycerin. It should be remembered that patients with substantial chest wall trauma may also have cardiac trauma, including myocardial contusion, valvular damage, or damage to the great vessels.

Although traditional cardiac risk factors, such as hypertension, hyperlipidemia, smoking, and diabetes mellitus, increase the likelihood that chest discomfort may be related to ischemic heart disease (and are present in up to 90% of patients with atherosclerotic coronary artery disease [9]), these long-term risk factors are not particularly helpful in the evaluation of the patient with acute chest pain. Rather, the evaluation must focus on attempts to establish a specific diagnosis; patients without a specific diagnosis will commonly require additional evaluation and observation until the most serious causes can be effectively excluded.

Physical Examination

For patients with chest discomfort, the focus of the physical examination should include evaluation of the pulse and blood pressure. If aortic dissection is seriously considered, blood pressure should be measured in both arms, and pulses should be checked in the legs to exclude pulse delay. Evaluation of jugular venous pressure is important to exclude right-sided heart failure or evidence of pericardial constriction and tamponade. The carotid pulse may be diminished in amplitude and its peak delayed in patients with aortic stenosis (Chapter 41), delayed or absent in

patients with aortic dissection, or associated with a bruit in patients with generalized atherosclerosis. Pulmonary evaluation may reveal a pleuritic rub suggestive of pleuritis, pulmonary infarction, or pneumonia; evidence of consolidation suggesting pneumonia; rales or wheezes of heart failure; or findings consistent with pneumothorax. Palpation of the chest wall and related areas may reveal a musculoskeletal cause of pain. On cardiac auscultation, a prominent second component of the second heart sound may suggest pulmonary hypertension, which may reflect pulmonary embolism. A pericardial rub or knock is found in acute pericarditis or pericardial constriction, respectively. Patients with ischemic heart disease may have transient third or fourth heart sounds or a murmur of mitral regurgitation caused by transient papillary muscle dysfunction. The murmur of aortic stenosis (Chapter 41) should be readily apparent, as should the murmur of hypertrophic obstructive cardiomyopathy (see later in this chapter). The murmur of aortic insufficiency may suggest a diagnosis of acute aortic dissection. A careful abdominal examination is critical to evaluate possible gastrointestinal diagnoses, such as cholecystitis or pancreatitis.

Electrocardiogram

The ECG is the most important single piece of information for the evaluation of the cause of acute chest pain. The ECG alone is probably as important as all other pieces of information combined. About 45% of patients with acute MI will have diagnostic findings (new ST-segment elevation or Q waves) on initial ECG. An additional 35% or so of patients will have ST-segment depression or T-wave inversions consistent with ischemia. In patients presenting to an emergency department with acute chest pain but who lack such ECG findings, the probability of acute MI is less than 10%; however, identification of these MI patients, who account for about 20% of all infarcts, is critical. It must be remembered that the ECG is relatively insensitive for detecting infarction of the posterior, lateral, and apical walls of the left ventricle (10), and its specificity is limited by individual variations in coronary anatomy and pre-existing coronary disease.

In interpreting the ECG, several important points must be kept in mind. First, at the time the ECG is performed, notations should be made regarding whether the patient is having active chest pain. Changes with acute coronary insufficiency or arrhythmia can be dynamic and resolve completely when the symptom abates. Second, every effort must be made to obtain previous ECGs so that abnormalities can be compared with those on the old tracing. *Any ECG finding that cannot be proved to be old must be assumed to be new.* The physician must have a low threshold for repeating an ECG while the patient is under observation, especially if the symptoms change in quality, appear or disappear, or persist for more than 10–20 minutes.

Chest Radiograph

The chest radiograph will rarely be diagnostic for the cause of acute chest pain. However, it may establish a diagnosis of pneumonia or pneumothorax, reveal an increased cardiac silhouette consistent with pericardial effusion, indicate pulmonary hypertension, or demonstrate an abnormal aorta suggestive of aortic dissection. It may also show overt skeletal abnormalities or trauma consistent with musculoskeletal causes of pain. Once again, comparison with previous films is critical; in the absence of old films, any changes must be assumed to be new until proved otherwise.

Integrating Clinical Data

Based on the history, physical examination, and ECG, it is possible to arrive at an approximate probability that the patient is having an acute MI (3, 11) (Figure 35.1). These data, derived from patients presenting to emergency departments, may or may not be directly applicable to patients in whom chest pain develops while they are in the hospital.

Initial triage decisions for patients who present to emergency departments with acute chest pain are driven by the probability of acute MI in addition to the probability of complications requiring intensive care (Figure 37.2). The

Figure 35.1 Flow diagram for estimating the risk for acute myocardial infarction in emergency department patients with acute chest pain. For each clinical subset, the numerator is the number of patients with the set of presenting characteristics in whom a myocardial infarction developed, whereas the denominator represents the total number of patients presenting with that characteristic or set of characteristics.^a In frequency, severity, duration, or failure to respond to usual measures. (Adapted from Pearson SD, Goldman L, Garcia TB, et al. Physician response to a prediction rule for the triage of emergency department patients with chest pain. *J Gen Intern Med* 1994;9:241–247, with permission.)

hospital physician may participate in the initial triage decision and in the management of patients in the emergency department. Currently, many chest pain evaluation units (12, 13) are part of the emergency department itself, and hence the hospital physician may not directly participate in initial decision making. In some hospitals, however, the hospital physician may directly supervise the chest pain evaluation unit. In these situations, this physician will be involved in initial triage and management decisions. Patients should generally have telemetry monitoring, serial biomarker determinations and ECGs, and other tests as needed to exclude myocardial ischemia or other important causes of chest pain.

Chest pain evaluation units or observation units may be established in the emergency department itself or in other locations in the hospital. Such units provide continuous ECG telemetry monitoring with ward-level nursing intensity. These units usually have strict entry criteria and prohibit intravenous medications or major ECG changes; many insist that the patients have a low probability for MI by validated methods (Figure 35.1). These units also have strict transfer criteria, so that patients with recurrent angina, MI, or evidence of hemodynamic or arrhythmic instability must be transferred. Similarly, patients who have evidence of other important causes of chest pain, such as pulmonary embolism, aortic dissection, or pericarditis, must be moved to an appropriately intensive location. Chest pain units typically also have a maximum length of stay, usually no more than 12 hours (Chapters 37 and 38). These units may be established by admitting patients to observation status in otherwise empty beds in an ICU or step-down unit, by transforming an existing observation unit into a cardiac monitoring unit, or by using an area in the emergency department itself. Numerous studies have shown that when patients at low risk for MI are admitted to such units, they can receive appropriate care at markedly reduced expense compared with admission to traditional step-down units or ICUs. In most studies, only about 2% of patients admitted to these units are shown eventually to have MI, and only 10%–20% of such patients are admitted from such units (the others are sent home after appropriate observation and pre-discharge noninvasive testing).

Echocardiography can demonstrate wall motion abnormalities or other evidence of ischemia but is not generally recommended for establishing the diagnosis of acute coronary ischemia. Echocardiograms are critical for patients with suspected valvular abnormalities, cardiomyopathy, or pericarditis; transesophageal echocardiography is one of the most sensitive ways to diagnose aortic dissection. In patients with pulmonary embolism or other causes of pulmonary hypertension, the echocardiogram may reveal sufficient tricuspid or pulmonic regurgitation to allow estimation of pulmonary artery pressures, as well as assessment of right ventricular function, an important prognostic variable when deciding on the clinical utility of

thrombolytic therapy in the case of suspected pulmonary embolus.

Perfusion scintigraphy with sestamibi or thallium will commonly reveal abnormalities in patients with acute ischemia. However, it is not clear whether integrating such tests into routine practice will improve decision making in patients with acute chest discomfort (Chapter 36).

Coronary angiography remains the gold standard for diagnosing ischemic heart disease, despite the fact that some patients have ischemia with normal epicardial coronary arteries and other patients with coronary stenoses may have chest pain unrelated to the angiographic findings (Chapter 37). Catheterization may also be critical to diagnose pericardial tamponade or constriction (Chapter 46), localize the site of aortic dissection (Chapter 49), or perform pulmonary angiography to diagnose pulmonary embolism (Chapter 53).

A substantial number of patients with otherwise undiagnosed causes of chest pain may have underlying esophageal pathology. Strong consideration should be given to studies of esophageal motility and acid reflux in patients with recurrent chest pain of uncertain etiology.

When Chest Pain Presents after Admission

The evaluation of chest pain in the hospitalized patient is very similar to that in a patient who presents to the emergency department. The principal difference is that in-hospital chest pain is more likely to be precipitated by fever, anemia, hypoxia, pain, or the wide variety of stresses that are found in sick inpatients. In the hospitalized patient, attention to these precipitating causes may be critical to the evaluation and management of the chest pain itself. For example, the resolution of pain resulting from myocardial ischemia may depend critically on the control of postoperative fever and blood loss. Because patients who are already sick in the hospital typically have less physiologic reserve, attention to the underlying precipitating causes and prompt evaluation and treatment of the precise etiology of chest pain are of key importance.

Palpitations

Palpitations, like chest pain, can be a warning of severe underlying cardiac pathology but can also be completely benign (14). Patients complaining of palpitations may be experiencing bursts of ventricular tachycardia (VT) (Chapter 43), runs of supraventricular tachycardia (Chapter 42), or single premature atrial contractions (PACs), or they may just be keenly aware of a physiologic sinus tachycardia. The physician evaluating the patient must, through careful history and physical examination, select the appropriate diagnostic studies to ensure that the patient is not at risk for sudden death or any other significant adverse cardiovascular event (Table 35.3).

History

A careful history can be extremely helpful in determining the likely etiology of “palpitations” and the likelihood that they stem from serious underlying cardiac disease. The clinical context is crucial. A 65-year-old man with a recent history of MI and decreased left ventricular (LV) function is at higher risk for malignant arrhythmia than is a young person with no other evidence of structural or coronary heart disease.

One critical aspect of the history is the patient’s precise definition of what is being experienced as palpitations. Asking patients to “tap out” what they feel, or tapping out some possibilities for them, can help distinguish a solitary premature contraction from atrial fibrillation or a sustained regular tachyarrhythmia.

Symptoms that accompany the palpitations can help diagnose the arrhythmia and define high- and low-risk patients. Palpitations accompanied by near-syncope (transient loss of consciousness) imply compromised cerebral blood flow. As a general rule, supraventricular tachycardias are less likely to cause presyncopal events than is VT. A notable exception is the case of a patient with reduced LV function, whose cardiac output may fall with any increase in heart rate. Chest pain associated with palpitations should raise concern for concomitant myocardial ischemia.

The next important aspect of the history is the description of precipitating factors. Certain arrhythmias are more likely to be encountered at times of high sympathetic tone, others at times of high vagal tone. Atrioventricular nodal reentrant tachycardia (AVNRT), an arrhythmia that is precipitated by a PAC, occurs more frequently at times of slow heart rates, especially at rest or in bed. Atrial fibrillation may occur at times of high vagal tone, during sleep, or immediately after exercise, but it can also occur in high catecholamine states, such as postoperatively or during exer-

cise (this distinction can be helpful in the choice of therapy). Ventricular tachyarrhythmias are most commonly associated with high catecholamine states. The hereditary long-QT syndrome is characterized by polymorphic VT at times of emotional stress.

Some patients are keenly aware of the maneuvers they can perform to terminate palpitations. AVNRT is often easily terminated by vagal maneuvers, and some patients may note that their palpitations stop when they cough. Ventricular premature beats (VPBs) associated with low heart rates may cease with exercise.

Another important factor is the list of medications, both prescribed and over-the-counter. Patients on diuretics may experience VPBs or VT associated with hypokalemia or hypomagnesemia. Patients on antiarrhythmic medications, psychotropic medications, or some antihistamines are at risk for VPBs and polymorphous VT because of prolongation of the QT interval (Table 35.4). Theophylline derivatives can cause supraventricular tachycardia or VT. Substance abuse can also be an aggravating factor; cocaine, amphetamines, alcohol (e.g., “holiday heart”), and excess caffeine can precipitate palpitations and arrhythmia.

The period of time during which a patient has experienced symptoms is also helpful in determining their etiology. Bypass tract-mediated tachycardias often present in childhood, whereas atrial fibrillation and most VTs start in adulthood.

In the patient who is already in the hospital, the diagnosis of the arrhythmia is often evident (the patient is on monitor), and the physician should focus on the cause of the

TABLE 35.4
CAUSES OF LONG QT INTERVAL

Congenital
Electrolyte abnormalities
Hypocalcemia
Hypokalemia (long QT secondary to fusion of ST segment with “U” wave)
Ischemia
Medications
Antiarrhythmic drugs
Type IA: disopyramide, procainamide, quinidine
Type IC: encainide, flecainide, propafenone
Type III: amiodarone, sotalol
Psychotropic medications
Phenothiazines, butyrophenones (haloperidol), tricyclics
Macrolide antibiotics: erythromycin, clarithromycin, troleandomycin
Seldane
Cisapride
Pentamidine
Ketoconazole
CNS disease: subarachnoid bleed
Hypothyroidism
Myocarditis
Hypothermia

arrhythmia. VPBs and VT are seen in critically ill patients with electrolyte disturbances, hypoxemia, sepsis, myocardial ischemia, and drug side effects. Atrial fibrillation is seen in similar situations; it is also seen with lung processes (e.g., pneumonia, chronic obstructive pulmonary disease), hyperthyroidism, valvular heart disease, and postoperatively.

Physical Examination

The physical examination is critical in the evaluation of a patient with palpitations. Unfortunately, most patients do not have symptoms at the time of examination, but evidence of any underlying heart disease can be helpful in determining the likelihood of a serious etiology of the palpitations.

The pulse can indicate evidence of VPBs or PACs or the irregularly irregular rhythm of atrial fibrillation. Pronounced bradycardia, although normal in the trained athlete, may be a marker of abnormal conduction or need for an “escape mechanism” (e.g., atrial fibrillation in the brady-tachy syndrome). Apical-to-peripheral pulse discrepancies can be found in many arrhythmias. Hypertensive heart disease is a prominent predisposing factor for atrial fibrillation.

Examination of the jugular venous pulse may give a clue to the etiology of the palpitations. For example, flutter or fibrillatory waves may be seen in the jugular venous pressure contour, and cannon *a* waves are often seen in AV dissociation.

The cardiac examination can also yield helpful clues. A laterally displaced point of maximal impulse, dyskinetic impulses or heaves, or palpable extra heart sounds denote the substrate for ventricular arrhythmias. A midsystolic click can diagnose the mitral valve prolapse syndrome, which is accompanied by both supraventricular and ventricular tachyarrhythmias. Significant murmurs may indicate underlying structural heart disease, especially aortic stenosis, mitral regurgitation, and hypertrophic obstructive cardiomyopathy, all of which predispose patients to arrhythmia.

Proptosis, lid lag, and tremors are markers for hyperthyroidism, which predisposes to atrial fibrillation. Tarnished nail enamel and knuckle scarring accompany bulimia nervosa, which leads to electrolyte imbalances that can cause ectopic beats.

Risk Stratification

After a careful history and physical examination, many patients can be stratified into high- or low-risk categories in terms of the likely morbidity associated with their palpitations. At low risk are young patients with isolated premature beats, no evidence of structural or ischemic heart disease on the basis of history and physical examination, no sustained arrhythmia, and no syncopal symptoms. Some patients will have evidence suggesting panic attacks. At high risk are older patients with known coronary artery disease, LV dysfunction,

heart failure, evidence of structural or valvular heart disease on physical examination, or symptoms such as dizziness, syncope, chest discomfort, or dyspnea with the palpitations.

Diagnostic Tests

The easiest and least expensive diagnostic test for palpitations is the 12-lead ECG, which may show PACs, VPBs, a short PR interval, delta waves, Q waves, atrial abnormalities, a long QT interval, or LV or RV hypertrophy. PACs either may be the source of the sensation of palpitations or may trigger AVNRT (Chapter 42). VPBs may be the source of the palpitations or the marker of a more serious abnormality that might predispose to malignant arrhythmia. A short PR interval or a delta wave suggests a preexcitation syndrome such as Wolff-Parkinson-White syndrome. Q waves may indicate previous MI as the substrate for VT. LV hypertrophy may be a marker for hypertrophic cardiomyopathy in a young patient with a predisposition for atrial fibrillation and VT. Fascicular blocks, bundle branch blocks, and AV block are all markers for conduction system disease that may indicate bradyarrhythmia.

An echocardiogram is warranted if signs or symptoms suggestive of any structural heart disease are present (Chapter 44). The echocardiogram can reveal the substrate for malignant ventricular arrhythmias: wall motion abnormalities (suggestive of coronary artery disease or cardiomyopathy), hypertrophic cardiomyopathy, or valvular heart disease. Atrial enlargement, reduced LV function, or mitral annular calcification indicate a higher likelihood of atrial fibrillation. In a young patient with syncope, a cardiac MRI can occasionally be helpful to evaluate for RV dysplasia, an important cause of VT.

In a patient with very frequent symptoms, a 24-hour Holter monitor can diagnose the arrhythmia. For those patients whose arrhythmia is less frequent, an event monitor may be preferable in that the patient can keep the device for a month at a time and trigger it to record only when symptoms occur. Diaries are crucial to correlate arrhythmias with any symptoms.

Treadmill exercise testing can be helpful in a patient whose symptoms are precipitated by exercise. The exercise test can induce the arrhythmia and provide evidence of ischemic heart disease. A person with excellent functional capacity is less likely to have significant underlying pathology.

In a patient with alarming symptoms (e.g., syncope), symptoms refractory to medical management, or a documented substrate for malignant arrhythmia, an electrophysiology study may be warranted. These studies can document and treat bypass tract-mediated arrhythmias, AVNRT, atrial flutter, and ectopic atrial tachycardias (Chapter 42). Electrophysiologic studies can also diagnose and occasionally treat ventricular arrhythmias. These studies are the “gold standard” for the evaluation of palpitations, but

they are invasive and should be reserved for those patients in whom they are necessary.

In the hospitalized patient, the approach to palpitations is similar with the exception that a variety of acute perturbations may precipitate arrhythmias. In hospitalized patients, fever, blood loss, hypotension, hypoxia, pain, and medications are common causes of arrhythmia. Attention to these precipitating causes may be at least as important as specific anti-arrhythmic treatment.

Lightheadedness

Like chest pain and palpitations, lightheadedness can also represent a spectrum of risk, from the completely benign to potentially catastrophic. It can be a difficult symptom for the patient to describe, and alternative terms include "dizzy," "woozy," "weak," "unsteady," and "faint".

Lightheadedness from a cardiovascular cause stems from decreased blood flow to the brain; if prolonged or more profound, syncope will occur (Chapter 44). However, cardiac symptoms must be distinguished from vertigo, decreased proprioception, and impaired visual acuity. Is the room spinning around? Is the sensation worse with poor lighting? Does the patient feel faint? An answer of "yes" to the first question implies vertigo; to the second, decreased proprioceptive or coordination abilities; and to the third, cardiovascular-related "lightheadedness."

The precipitants of the sensation of lightheadedness can also suggest its etiology. Does the patient feel lightheaded on rising from a sitting or lying position? If so, orthostasis is a likely mechanism. Does it occur when the patient is standing for some time? If so, orthostasis or a vasovagal cause is likely. Does it occur with exercise? If so, an arrhythmia, aortic stenosis, or hypertrophic obstructive cardiomyopathy are a possible etiologies. Does it occur when the patient is anxious? If so, hyperventilation should be suggested. Is it related to micturition, cough, or straining to defecate? If so, a vagally mediated response is likely.

Accompanying symptoms can also be helpful in determining the etiology of lightheadedness. Palpitations suggest an arrhythmia that decreases cardiac output. Chest pain suggests myocardial ischemia. Additional neurologic deficits suggest a primary central nervous system condition, such as a transient ischemic attack (Chapter 116) or intracranial mass (Chapter 117).

A thorough review of the patient's medication list is critical in determining both the cause and the severity of the condition. For example, with most antihypertensive medications and many psychotropic medications, lightheadedness can be caused by orthostasis.

The patient's problem list may also be very helpful in determining both the cause and the severity of the condition. Heart failure, coronary disease, and vascular disease all predispose to potentially serious causes of lightheadedness.

Anemia (if severe) or significant recent blood loss can be contributing or causative factors to the symptom. Parkinson's disease, as well as other primary neurologic disorders, may predispose to the Shy-Drager syndrome. Diabetes and alcohol abuse cause neuropathies that can lead to lightheadedness. Anxiety can lead to hyperventilation, which also causes this symptom.

Physical Examination

A slow pulse might indicate heart block or symptomatic bradycardia. A comparison of supine and standing blood pressures and heart rate, especially if it elicits symptoms, can be diagnostic.

Skin turgor, mucous membranes, and jugular venous pressure can be excellent indicators of volume status. Additionally, skin pallor can raise the question of anemia and blood loss.

The cardiac examination should be directed toward consideration of conditions that decrease cardiac output (e.g., aortic stenosis, hypertrophic obstructive cardiomyopathy, or enlarged and dysfunctional ventricles) or predispose to arrhythmias. A loud P₂ sound or right ventricular heave suggest pulmonary hypertension. Auscultatory evaluation for carotid bruits is critical in screening for cerebral vascular disease.

The neurologic examination may reveal evidence of previous central nervous system damage or diseases that would put the patient at increased risk for autonomic dysfunction (Shy-Drager syndrome). Abnormalities in visual acuity or evidence of inner ear pathology may provide non-cardiovascular explanations for the lightheadedness.

Risk Stratification

Risk stratification and further evaluation of the patient with lightheadedness follow the same approach as the evaluation of palpitations, with all efforts focused on identifying underlying or occult structural or ischemic cardiac disease and electrophysiologic pathology.

CARDIOVASCULAR SIGNS

Jugular Venous Pressure

Before recent technologic advances became available (i.e., echocardiography and cardiac catheterization), correct assessments of abnormal jugular venous pressure were essential in certain diagnostic dilemmas, such as the differentiation of constrictive pericardial disease from cirrhosis and other noncardiac sources of peripheral edema and ascites. However, the subjectivity and difficulty of the examination have limited its current applicability. The key parameters are the height of jugular veins (easily assessed via the external jugular veins) and the jugular wave

forms (best assessed in the internal jugular veins, which do not have valves to distort retrograde flow) (Table 35.5).

Perhaps the most reliable way of describing jugular venous distention is as elevated or not. Somewhat more precise estimates can be made by assuming that the “angle of Louis” at the clavicle is 5 cm above the center of the right atrium, and thus the jugular venous pressure is the number of centimeters above this angle added to 5 cm. Unfortunately, this assumption of 5 cm is quite variable, and the true value ranges between 2–8 cm. If the neck veins are obstructed from view, an alternative is to raise the hand and look for the height above the heart at which there is a loss of venous distention. The key wave forms are the *a* wave, which is retrograde flow during right atrial contraction, and the *v* wave, which corresponds to ventricular contraction and is exaggerated in the presence of tricuspid regurgitation.

The jugular veins are a very useful way of assessing a patient’s intravascular volume status and right atrial pressure. Although not a direct measurement of left atrial or pulmonary capillary wedge pressure, the jugular venous pressure can indirectly reflect elevations in these pressures if there is no other cause of elevated right atrial pressure. In contrast, *Kussmaul’s sign*, which is seen in constrictive pericarditis, is an exaggerated distention of the neck veins during inspiration, in contrast to the normal obliteration of venous distention during inspiration.

Hepatojugular reflux can be assessed with the patient at a 45-degree angle and approximately 30–40 mm Hg of pressure placed at the xiphosternal epigastric area and held for approximately 15–30 seconds. This sign is positive if jugular venous distention is sustained for that period of time and immediately falls on removal of pressure. In general,

hepatojugular reflux is an indicator of right-sided heart failure (15), which in most cases is a consequence of long-standing left atrial pressure elevation.

The *cannon a wave* is an indicator of AV dissociation or any second- or third-degree AV block in which the right atrium contracts against a closed tricuspid valve. Intermittent AV dissociation may lead to irregular cannon *a* waves, which are more easily recognized than the regular cannon *a* waves of a junctional rhythm or VT.

Giant v waves are often seen in patients with tricuspid insufficiency as a result of regurgitant blood being transmitted to the right atrium and subsequently to the jugular veins. Tricuspid insufficiency is often present in patients with right-sided heart failure resulting from either left-sided heart failure or pulmonary hypertension of any etiology, but can also represent primary tricuspid valve pathology as in the congenital Ebstein’s anomaly or trauma caused by right ventricular endomyocardial biopsy. This latter procedure is a regular part of the surveillance of heart transplant recipients.

Arterial Pulses

Examination of the arterial pulses is an invaluable component of the cardiovascular examination (Table 35.6). It is the primary modality used to diagnose atherosclerotic peripheral vascular disease, and the presence of abnormalities in the peripheral pulses often suggest similar coronary pathology. Additionally, careful examination of the peripheral arteries facilitates the diagnosis of valvular heart lesions, pericardial tamponade, heart failure, and arrhythmias. However, the examination of peripheral arteries is complicated by its subjectivity and its ill-defined grading system.

Important qualities to note on the physical examination of the peripheral arteries include rhythm, contour, amplitude, and symmetry. Usually, the carotid artery is best suited for examination because of its close proximity to the heart. Examination of the carotid pulse requires a certain degree of caution, in that undue pressure on a carotid body may result in asystole or cerebral embolism. The amplitude of the carotid arterial pulse increases with age, owing to stiffening of the arterial wall. As the amplitude of the pulse is generally proportional to stroke volume, a low-amplitude pulse suggests reduced stroke volume, and increased amplitude suggests an increased stroke volume. Hypotension, aortic stenosis, and mitral regurgitation cause low-amplitude pulses. In contrast, hypertension, hyperthyroidism, high catecholamine states, and aortic insufficiency lead to high-amplitude pulses. In the peripheral vascular bed, low-amplitude pulses imply poor blood flow, either from reduced cardiac output or from peripheral vascular disease.

The contour of the arterial pulse represents the rise and fall of the arterial blood flow. The rise and fall of the pulse is a marker of the rapidity of the ejection of the stroke

TABLE 35.5
JUGULAR VENOUS PRESSURE FINDINGS

Normal

<7–10 cm H₂O (i.e., not elevated)

Elevated

Intracardiac causes of high RA pressures (e.g., RV failure/LV failure, RV infarct)

Other causes

Pericardial tamponade or constriction
Any cause of pulmonary hypertension
Superior vena caval obstruction

Key abnormalities to assess

Giant *v* wave—tricuspid regurgitation
Hepatojugular reflux (abdominojugular reflux)
RV dysfunction and elevated pulmonary capillary wedge pressure
≥15 mm Hg
Cannon *a* wave—AV dissociation
Kussmaul’s sign—constrictive pericarditis

LV, left ventricular; RV, right ventricular; RA, right atrial; AV, atrioventricular.

TABLE 35.6
EXAMINATION OF ARTERIAL PULSE
(PALPATION, AUSCULTATION)

Palpation

1. Amplitude (indirect measure of stroke volume)
 - a. Weak, thready in hypotensive and/or hypovolemic states
 - b. Reduced in aortic stenosis (*parvus*) and mitral regurgitation
 - c. Increased in hyperdynamic states, aortic insufficiency, arteriovenous fistulae
 - d. Pulsus paradoxus—inspiratory fall in systolic pressure >10 mm Hg seen in pericardial tamponade and exaggerated breathing in asthma or COPD
 - e. Pulsus alternans—alternating weaker or stronger pulse in marked LV systolic dysfunction
2. Contour (rapidity of rise and fall of pulse)
 - a. Delayed (*tardus*) in aortic stenosis
 - b. Bisferiens pulse—double impulse classically seen with aortic insufficiency and often in hypertrophic obstructive cardiomyopathy
 - c. Corrigan/Waterhammer (rapid, strong) pulse seen in aortic insufficiency
 - d. Carotid shudder/thrill seen in aortic stenosis
3. Cadence
 - a. Irregularly irregular—atrial fibrillation, frequent multifocal VPBs, PACs
 - b. Regularly irregular—usually PACs, VPBs in a pattern
4. Symmetry
 - a. Symmetric—normal
 - b. Asymmetric—seen in aortic dissection or vascular obstruction

Auscultation

1. Bruits—sign of atherosclerotic vascular disease over that particular artery
2. Transmitted murmur—aortic stenosis (if palpable, called a thrill)
3. Systolic and diastolic bruits imply
 - a. severe vascular obstruction
 - b. aortic insufficiency
4. Arteriovenous fistula

Visual inspection

1. Subungual capillary pulsations (Quincke's pulsations)—seen in hyperdynamic states, aortic insufficiency, anemia
2. Retinal vessels—hypertensive and diabetic changes

COPD, chronic obstructive pulmonary disease; LV, left ventricular;

volume. In aortic insufficiency, for example, rapid high-volume/amplitude pulses are noted, whereas in mitral regurgitation, rapid low-volume pulses are palpated. In aortic stenosis, the slow ejection time translates to a *parvus et tardus* (“weak and delayed”) pulse. Other special pulses include a bisferiens pulse (two impulses in each systole), found in aortic insufficiency and hypertrophic cardiomyopathy, and pulsus alternans, found in heart failure. The former represents the exaggerated dicrotic notch. Pulsus alternans is a manifestation of marked LV systolic dysfunction, in which one weak ejection is followed by a strong one. *Pulsus paradoxus*, which may be seen in cardiac tamponade (and also in severe obstructive lung disease with

exaggerated inspiratory effort), refers to a decline in blood pressure of more than 10 mm Hg during inspiration in comparison with expiration.

The arterial pulses may cue the examiner to the presence of an arrhythmia. Although normally the phrase “irregularly irregular” is used to describe the pulse of atrial fibrillation, frequent extrasystoles may also have this cadence. A “regularly irregular” cadence may correspond to extrasystoles in a fixed pattern with sinus beats.

The symmetry of peripheral pulses may be important in diagnosing vascular obstruction. In the setting of acute chest pain, asymmetric pulses may indicate aortic dissection. Sudden loss of pulses in one limb, accompanied by pain, can be a result of an embolic phenomenon or progressive vascular disease (Chapter 51).

Palpation of pulses is not limited to the periphery. Important information about the abdominal aorta can be gained by examination of its pulse. An enlarged pulsatile mass in the abdomen suggests aneurysmal dilatation (Chapter 50).

A comprehensive examination of the arterial tree includes auscultation in addition to palpation. Bruits are indicative of stenosis and can be heard in the carotid, femoral, renal, and abdominal aortic vessels. A to-and-fro bruit indicates severe obstruction or the presence of aortic insufficiency.

Direct inspection of the arterial tree is possible in a few locations in the body—namely, the eye grounds and the nail bed. Abnormalities of the retinal vessels are found in hypertension, and neovascularization is seen in diabetes mellitus. In the nail bed, dilated capillary loops may be seen with the ophthalmoscope in several collagen vascular diseases, and Quincke's pulses (subungual capillary pulsations) of aortic insufficiency may also be seen.

Heart Sounds

The stethoscope and the auscultatory skills necessary for its effective clinical use symbolize the diagnostic skill that has been lost in the more technologically oriented present-day practice of medicine. Combining clinical clues derived from the auscultatory examination with verification or reinterpretation by an imaging modality offers the best of both worlds. With the advent of high-quality echocardiographic and Doppler interrogation of the structure and function of the heart and valves, the role of the auscultatory examination is often to serve as a screening test to determine the need for further evaluation.

Abnormalities in heart sounds may reflect circulatory status, valvular abnormalities, or other cardiac abnormalities. The normal first heart sound, which represents closure of the mitral and tricuspid valves, is accentuated in rheumatic mitral or tricuspid valvular stenosis, provided that the valve is mobile enough to close completely. The first heart sound tends to be softer in patients with

incomplete mitral or tricuspid valve closure (as in valvular insufficiency) or in patients in whom ventricular systolic pressures are insufficient to close these valves crisply before the beginning of systole. The second heart sound commonly includes discernible aortic closure followed by pulmonic closure. At expiration, the two valves close virtually simultaneously, but with inspiration and increased RV filling and ejection time, the pulmonic valve closes slightly later. The aortic second sound is generally increased in hypertension and decreased in calcific aortic stenosis. The pulmonic second sound is increased in intensity by any process that causes pulmonary hypertension, which delays RV outflow and may also widen the split of the second sound. With an atrial septal defect, the splitting of the second sound tends to be wide and fixed in both inspiration and expiration because increased RV filling and outflow occur regardless of the respiratory cycle.

An S_4 gallop (fourth heart sound) precedes the first heart sound and represents relatively poor distensibility of the ventricle during late diastole at the time of atrial contraction. A fourth heart sound is common in patients with hypertension, coronary disease, or any other condition that leads to ventricular stiffness and impaired compliance. A third heart sound (S_3 gallop) (16) corresponds to the phase of rapid ventricular filling in early diastole; although sometimes found in healthy young adults or pregnant women, it is often a sign of advanced ventricular failure. In patients with rapid rates, diastole may be sufficiently shortened that the third and fourth heart sounds become superimposed and form a summation gallop.

A pericardial knock, which is caused by impaired filling in early diastole in patients with constrictive pericarditis, occurs at about the same time as a third heart sound but is usually louder and more distinctive. The “tumor plop” associated with an atrial myxoma that is prolapsing into the ventricle also occurs at about the same time, but it is usually louder and distinctive from a third heart sound.

A pericardial rub, which is found with pericarditis, is a high-pitched, scratchy sound. It may have one, two, or three components corresponding to ventricular systole, rapid ventricular filling, and atrial contraction.

Common Cardiac Murmurs

The assessment of any cardiac murmur should include the following considerations: timing (systole, diastole), intensity (grades I through VI), frequency (high-diaphragm or low-bell), configuration (crescendo, decrescendo, plateau), quality (harsh, coarse, blowing, cooing, musical, rumble), duration (e.g., pansystolic), radiation (e.g., carotid, axilla, back), and dynamic changes [e.g., effect of ectopic beats or response to breathing, expiration against a closed glottis (Valsalva maneuver), handgrip, standing, or squatting].

Grading the intensity of the murmur is particularly important in ill patients, as alterations from previous baseline

evaluations or ongoing changes may explain the dynamic physiologic status of a patient. The standard grading for murmurs is as follows: I, faint, heard with concentration in a quiet setting; II, heard immediately on auscultation; III, moderate intensity; IV, loud murmur with palpable thrill; V, loud murmur heard with the stethoscope partly on the chest; VI, loud, heard with the stethoscope off the chest. All heart murmurs should also be classified as either systolic, diastolic, or continuous (Table 35.7).

The auscultatory examination can usually differentiate a nonpathologic or functional systolic murmur from a pathologic murmur and further differentiate among the various pathologic murmurs (17). The “flow,” “functional,” or “innocent” murmurs include the ejection murmur related to increased cardiac output (or increased volume or velocity of ejection) and the systolic murmur appreciated only because of the thinness of the chest wall or the unusually quiet surroundings of the examining room. The clinical settings most often responsible for nonpathologic systolic murmurs include fever, anemia, thyrotoxicosis, and vigorous exercise. Innocent murmurs tend to occur in early systole and be grade I to II; have a high frequency, a crescendo-decrescendo configuration, a vibratory or humming quality, and a short duration; and be most prominent at the left sternal border without radiation.

Unfortunately, the very conditions that create the “innocent” murmur (fever, sepsis, or anemia) are often present in sick patients in whom pathologic murmurs would have potentially serious implications. In these sick or unstable patients, there should be a very low threshold for obtaining an echocardiogram (Chapter 36) to evaluate the systolic murmur. Three specific clinical scenarios should also prompt a more aggressive evaluation of the possible “innocent” murmur: (a) the early (3–7 days) post-MI patient with evidence of new hemodynamic deterioration, in whom ischemic mitral regurgitation or a new ventricular septal defect should not be missed (Chapter 38); (b) the septic patient at risk for endocarditis (Chapter 71); and (c) the elderly patient with cardiac symptoms, in whom aortic stenosis must be considered (Chapter 41).

Pathologic murmurs commonly indicate valvular or congenital heart disease and often have characteristic auscultatory findings (Table 35.8). Once an organic murmur is appreciated or suspected, confidence in the auscultatory diagnosis can sometimes be increased with the addition of physiologic maneuvers (Table 35.9). These possible pathologic diagnoses should be confirmed by echocardiography.

Occasionally, neither the cardiac examination nor the echocardiographic evaluation can adequately confirm or exclude one of the previously described etiologies of an auscultatory cardiac abnormality. In some cases, such as the patient with severe chronic obstructive pulmonary disease, an excessively expanded lung parenchyma diminishes the quality of the transthoracic echocardiographic signal.

TABLE 35.7
CLASSIFICATION OF HEART MURMURS

- A. Organic systolic murmurs
 - 1. Midsystolic (ejection)
 - a. Aortic
 - (1) Obstructive
 - (a) Supravalvular—supraortic stenosis, coarctation of the aorta
 - (b) Valvular—AS and sclerosis
 - (c) Infravalvular—HOCM
 - (2) Increased flow, hyperkinetic states, AR, complete heart block
 - (3) Dilatation of ascending aorta, atheroma, aortitis, aneurysm of aorta
 - b. Pulmonary
 - (1) Obstructive
 - (a) Supravalvular—pulmonary arterial stenosis
 - (b) Valvular—pulmonic valve stenosis
 - (c) Infravalvular—infundibular stenosis
 - (2) Increased flow, hyperkinetic states, left-to-right shunt (e.g., ASD, VSD)
 - (3) Dilatation of pulmonary artery
 - 2. Pansystolic (regurgitant)
 - a. Atrioventricular valve regurgitation (MR, TR)
 - b. Left-to-right shunt at ventricular level
- B. Early diastolic murmurs
 - 1. AR
 - a. Valvular: rheumatic deformity, perforation postendocarditis, posttraumatic, postvalvulotomy
 - b. Dilatation of valve ring: aortic dissection, annuloectasia, cystic medial necrosis, hypertension
 - c. Widening of commissures: syphilis
 - d. Congenital: bicuspid valve, with VSD
 - 2. Pulmonic regurgitation
 - a. Valvular: postvalvulotomy, endocarditis, rheumatic fever, carcinoid
 - b. Dilatation of valve ring: pulmonary hypertension, Marfan syndrome
 - c. Congenital: isolated or associated with tetralogy of Fallot, VSD, pulmonic stenosis
- C. Mid-diastolic murmurs
 - 1. MS
 - 2. Carey-Coombs murmur (mid-diastolic apical murmur in acute rheumatic fever)
 - 3. Increased flow across nonstenotic mitral valve (e.g., MR, VSD, PDA, high-output states, and complete heart block)
 - 4. Tricuspid stenosis
 - 5. Increased flow across nonstenotic tricuspid valve (e.g., TR, ASD, and anomalous pulmonary venous return)
 - 6. Left and right atrial tumors
- D. Continuous murmurs
 - 1. PDA
 - 2. Coronary AV fistula
 - 3. Ruptured aneurysm of sinus of Valsalva
 - 4. Aortic-pulmonary window
 - 5. Cervical venous hum
 - 6. Anomalous left coronary artery
 - 7. Proximal coronary artery stenosis
 - 8. Mammary soufflé
 - 9. Pulmonary artery branch stenosis
 - 10. Bronchial collateral circulation
 - 11. Small (restrictive) ASD with MS
 - 12. Intercostal AV fistula

AR, aortic regurgitation; AS, aortic stenosis; ASD, atrial septal defect; AV, arteriovenous; HOCM, hypertrophic obstructive cardiomyopathy; MR, mitral regurgitation; MS, mitral stenosis; PDA, patent ductus arteriosus; TR, tricuspid regurgitation; VSD, ventricular septal defect.

TABLE 35.8**AUSCULTATORY CHARACTERISTICS OF SOME COMMON CARDIAC MURMURS**

Mitral valve prolapse	Soft A ₂ and narrow splitting S ₂
S ₁ normal	S ₃ common
S ₂ normal splitting	Diastolic decrescendo murmur
Midsystolic click	Early peaking systolic ejection murmur common
Earlier—standing, Valsalva	owing to increased systolic flow
Later—squatting, handgrip	Pulmonary stenosis
Midsystolic to late systolic murmur	S ₁ normal
Longer—standing, Valsalva	S ₂ wide splitting
Shorter—squatting, handgrip	Tricuspid regurgitation
Hypertrophic obstructive cardiomyopathy	S ₁ normal
A ₂ normal	Holosystolic murmur
Paradoxical splitting S ₂	↑ with inspiration, squatting
S ₄ usually present	↓ with expiration, standing
Systolic ejection murmur	Atrial septal defect
↑ Valsalva, standing, post-PVC	S ₂ wide fixed splitting
↓ handgrip, squatting	Pulmonic systolic ejection murmur
Bisferiens pulse	Tricuspid mid-diastolic filling murmur if large flow
Mitral regurgitation	Mitral stenosis
Diminished S ₁	Loud S ₁
Wide splitting S ₂	Narrow splitting S ₂
S ₃ (with moderate to severe regurgitation)	Loud P ₂
High-frequency holosystolic murmur	Opening snap
Occasional diastolic filling rumble	Narrow A ₂ -OS interval (severe)
Brisk and low-amplitude carotid pulse	Diastolic rumble with presystolic accentuation
Aortic stenosis	(longer murmur with more severe stenosis)
Ejection sound (noncalcified valve)	Ventricular septal defect
Diminished A ₂ (immobile valve)	S ₁ normal
Paradoxical splitting S ₂	S ₂ wide splitting
S ₃ and S ₄ (if severe)	P ₂ loud
Late peaking systolic ejection murmur	S ₃ often present
Delayed and low-amplitude carotid pulse	Holosystolic murmur
Aortic regurgitation	Mitral filling rumble if large flow
S ₁ diminished	

OS, opening snap; PVC, premature ventricular contraction.

TABLE 35.9**EFFECT OF PHYSIOLOGIC MANEUVERS ON SOME COMMON CARDIAC MURMURS**

Maneuver	Physiologic change	Accentuates	Diminishes
Valsalva (phase II)	↓↓ VR ↓↓ AL ↓ CO	HOCM, MVP	MR, AS, AR
Inspiration	↑ VR	TR, TS, PS, PR	MR
Squat	↑ VR ↑ AL ↑↑ CO	MR, PS, TS, TR, AR	HOCM, MVP
Standing	↓ VR ↓↓ CO	HOCM, MVP	TR, PFM
Handgrip	↑↑ AL	MR, VSD, AR	HOCM, AS
Post-PVC (Long RR interval)	↑↑ C	HOCM, AS	No change in MR

AL, afterload (systemic vascular resistance); AR, aortic regurgitation; AS, aortic stenosis; C, contractility; CO, output; HOCM, hypertrophic obstructive cardiomyopathy; MR, mitral regurgitation; MVP, mitral valve prolapse; PFM, pulmonary flow murmur; PR, pulmonic regurgitation; PS, pulmonic stenosis; PVR, pulmonary venous return; TR, tricuspid regurgitation; TS, tricuspid stenosis; VR, systemic venous return; VSD, ventricular septal defect.

In other patients, mechanical prosthetic valves may cause enough acoustic artifact to hinder accurate diagnoses. In both of these examples, transesophageal echocardiography or magnetic resonance imaging may be necessary to make a correct diagnosis.

LABORATORY ABNORMALITIES

Key laboratory abnormalities that are found in patients with heart disease include abnormalities of the ECG, chest radiograph, and common blood tests. These abnormalities may be found in patients with known heart disease or may be the first suggestion of previously undiagnosed heart disease.

Electrocardiogram

In addition to being useful in diagnosing MI and abnormalities of heart rhythm or AV conduction, the ECG provides evidence regarding ventricular hypertrophy, interventricular conduction, ischemia, and electrolyte abnormalities. The normal QRS axis ranges from -30 degrees to $+90$ degrees. An axis more negative than 30 degrees (left axis deviation) indicates left anterior hemiblock, which is often associated with ischemic heart disease. An axis more positive than 90 degrees (right axis deviation) may be consistent with left posterior hemiblock, again suggestive of ischemic heart disease, or RV hypertrophy. Patients with right axis deviation should be carefully assessed for lung disease or other causes of pulmonary hypertension, such as pulmonary vascular disease or congenital heart disease. Evidence for RV hypertrophy is highly suggestive of pulmonary hypertension or pulmonic valve disease. Evidence of LV hypertrophy should raise questions regarding prior hypertension or left-sided valvular heart disease.

Bundle branch blocks may represent intrinsic conduction system disease or damage from prior MI. Bundle branch blocks may be constant or may be rate-related if the bundle branch is able to conduct normally at lower heart rates but not at more rapid rates. In the hospitalized patient, the new appearance of a bundle branch block, especially of the left bundle, should raise suspicion of acute myocardial ischemia.

ST-segment depression greater than 1 mm is highly suggestive of myocardial ischemia. T-wave inversion may also suggest myocardial ischemia. New ST-T-wave changes arising in the hospital will often require formal evaluation to exclude unstable angina (Chapter 37) or acute MI (Chapter 38). ST-T-wave changes can also be caused by medications (e.g., digoxin) or electrolyte abnormalities (especially hypokalemia).

Chest Radiograph

The finding of previously unsuspected cardiomegaly on a chest radiograph should raise the question of ventricular

dilatation (and heart failure) or pericardial fluid. Echocardiography is indicated to clarify otherwise unexplained cardiomegaly.

An enlarged or tortuous aorta often signifies atherosclerotic disease. However, in a patient with chest discomfort, the possibility of aortic dissection must be considered and appropriate tests obtained (Chapter 49).

The chest radiograph may provide the first evidence of heart failure by showing unsuspected increases in pulmonary vasculature. Heart failure typically leads to increased pulmonary vascular markings in the upper lung fields, whereas a left-to-right shunt typically increases vascular markings in the lower lung fields. A previously unsuspected unilateral right pleural effusion or bilateral pleural effusions may indicate heart failure.

Common Blood Tests

Elevation of the blood urea nitrogen (BUN) may indicate intrinsic renal disease but, especially if out of proportion to the serum creatinine level, often indicates decreased renal perfusion resulting from heart failure. In patients with right-sided heart failure, aminotransferase, alkaline phosphatase, and bilirubin levels may be minimally or even markedly elevated. Some patients will have evidence of poor synthetic function resulting from marked hepatic congestion, with elevated prothrombin time and reduced albumin levels. Patients with right-to-left shunts and hypoxia typically have compensatory erythrocytosis with abnormally elevated hemoglobin and hematocrit levels, while anemia is now recognized as a common finding in late stage heart failure.

KEY POINTS

- In the differential diagnosis of chest pain, the evaluation must focus on the most serious possible causes (e.g., acute myocardial infarction, unstable angina, aortic dissection, pulmonary embolism, and pericarditis).
- The electrocardiogram is the single best predictor of acute ischemic heart disease in patients with chest pain.
- In patients in whom the cause of chest pain is uncertain, a chest pain evaluation unit may provide a rapid and efficient approach to diagnosis.
- Palpitations are very common, and their evaluation is guided in large part by whether there is evidence of concomitant symptoms or underlying structural heart disease.
- Lightheadedness has many cardiovascular and noncardiovascular causes; as with palpitations, further evaluation is guided by the history and physical examination.
- Abnormal jugular venous pressure may be indicative of heart failure, pericardial disease, tricuspid regurgitation, or arrhythmias.

- Arterial pulse examination is critical for diagnosing peripheral vascular disease and aortic dissection. It is also useful in the assessment of valvular heart disease.
- Careful cardiac auscultation of heart sounds and heart murmurs is critical for the cardiovascular assessment; auscultation serves as the key screen to determine whether noninvasive diagnostic testing is appropriate.
- Electrocardiographic changes may point to previously unsuspected ventricular hypertrophy, myocardial ischemia, or electrolyte abnormalities.
- In hospitalized patients, abnormalities on the chest radiograph (e.g., cardiomegaly, pulmonary vascular congestion) may be the first clues of underlying heart disease.
- Abnormalities of renal function, hepatic function, or the hematocrit may be clues to previously unsuspected heart disease.

Diagnostic Tests in Cardiology

36

Karen P. Alexander Eric D. Peterson

INTRODUCTION

The past two decades have witnessed a phenomenal expansion in diagnostic technologies for patients with cardiovascular disease. New stress imaging protocols have improved the detection of coronary artery disease (CAD), and the widespread availability of echocardiography and cardiac catheterization have enabled the accurate measurement of ventricular and valvular function. Although these diagnostic innovations have enhanced patient care, their associated costs have substantially added to health care expenditures. This chapter outlines the general issues regarding test selection and interpretation. It also reviews the major cardiovascular tests for the diagnosis of ischemia (stress electrocardiography, nuclear perfusion imaging, and stress echocardiography) and the assessment of heart structure and function (transthoracic and transesophageal echocardiography, nuclear ventriculography, cardiac magnetic resonance imaging [MRI] and cardiac catheterization). The arrival of several newer diagnostic modalities and electron-beam computerized tomography (CT) are also discussed. The basic electrocardiogram (ECG) and tests for syncope (Chapter 44) and arrhythmias (Chapters 42 and 43) are covered elsewhere.

TEST SELECTION

In the hospital setting, cardiovascular tests are typically ordered for one of four indications. First, they can assist the clinician in identifying a cardiac cause for presenting symptoms such as chest tightness, dyspnea, or syncope. Second, they may be ordered to evaluate physical examination or laboratory findings suggestive of cardiac pathology, such as

a new murmur or an enlarged cardiac silhouette on the chest radiograph. Third, cardiac studies can define changes in the severity of known cardiac conditions (e.g., progression of ventricular or valvular dysfunction). Finally, cardiovascular tests can identify patients who are at high risk for subsequent cardiac events (e.g., preoperatively or following infarction).

To select the most appropriate diagnostic test from the available technologies, the clinician should begin by reviewing what is already known about the patient. The likelihood of coronary disease, and the prognosis, can be estimated based on the patient's presenting symptoms, clinical risk factors, and ECG. *The potential incremental value of the diagnostic study is determined by this "pretest" clinical assessment in addition to the intrinsic sensitivity and specificity of the proposed test* (see discussion of Bayes' theorem, Chapter 6). In general, a diagnostic test provides the most new information in a patient whose pretest likelihood is in the intermediate range. For example, a positive stress study result in a patient with a high pretest probability of disease (such as a 60-year-old male patient with typical angina) merely confirms the diagnosis, whereas a negative study result leaves a posttest likelihood of disease of greater than 20%.

In addition, clinicians should strive to use all the information provided by a given test. For example, exercise ECG testing provides important information concerning hemodynamic responses to exercise and overall cardiovascular fitness in addition to demonstrating ECG signs of ischemia.

Local clinical expertise can also affect test accuracy. Therefore, the diagnostic accuracy of technologies at leading centers described in published reports may differ from that found in local practice. A final consideration is that tests should be reserved for situations in which these results are likely to influence subsequent treatment decisions.

TESTS FOR ISCHEMIA

Stress Induction

Stress testing measures the response of the cardiovascular system to graded increases in workload and oxygen demand. Whereas treadmill and bicycle protocols result in similar maximal heart rates, treadmill testing induces a 6% to 25% higher maximal oxygen uptake and is a more familiar form of exercise for most patients in the United States. However, it is estimated that up to 50% of patients presenting for stress testing are either unable to exercise at all or exercise submaximally because of musculoskeletal, neurologic, or other limitations. In these patients, pharmacologic stress with inotropes (e.g., dobutamine or arbutamine) or vasodilators (e.g., dipyridamole or adenosine) are alternative methods for inducing stress.

Detection of Patterns of Ischemia and Perfusion

Regardless of how the stress is induced, the goal of stress testing is to diagnose obstructive coronary disease, either by inducing functional ischemia or by altering myocardial perfusion patterns. Some patients may experience symptoms such as angina or dyspnea. Ischemia alters normal ventricular repolarization and causes ST-segment depression during ECG stress testing. The ischemia can also cause systolic dysfunction that can be detected as wall motion abnormalities on stress echocardiography. Scintigraphic defects in perfusion with agents such as thallium or technetium (Tc) 99m sestamibi represent areas of myocardium that receive relatively less blood flow than neighboring tissue transiently during stress only (*"reversible" deficits*) or both at rest and during stress (*"fixed" deficits*).

Safety

When performed in a monitored setting, stress ECG testing is remarkably safe, with fewer than 1 death and 5 myocardial infarctions (MIs) occurring per 10,000 tests, and the complication rate may even be as low as 0.8/10,000 tests (1) in patients without contraindications (Table 36.1). Dipyridamole and adenosine pharmacologic stress testing is relatively contraindicated in patients with reactive airway disease because of the potential for bronchoconstriction, and adenosine may induce transient heart block in patients with underlying conduction system disease. Theophylline-containing drugs and caffeine interfere with the action of dipyridamole and adenosine and should be discontinued 24 hours before testing with these agents. Dobutamine is relatively contraindicated in patients with hypertrophic cardiomyopathy, severe hypertension, aortic aneurysms, or a history of serious ventricular arrhythmia.

TABLE 36.1

CONTRAINDICATIONS TO EXERCISE STRESS TESTING

Absolute contraindications

- Acute MI (within 2 days)
- High-risk unstable angina pectoris
- Uncompensated heart failure
- Uncontrolled cardiac dysrhythmia
- Acute endocarditis, pericarditis, or myocarditis
- Symptomatic severe aortic stenosis
- Acute pulmonary embolus
- Acute aortic dissection

Relative contraindications

- Left main coronary artery stenosis
- Symptomatic heart failure
- Severe arterial hypertension
- Significant pulmonary hypertension
- Hypertrophic cardiomyopathy
- Moderate valvular or myocardial heart disease
- Fixed-rate artificial pacemaker
- Psychiatric disorder causing an inability to cooperate with testing
- Advanced atrioventricular block (may use stress imaging)
- Drug- or electrolyte-induced ECG abnormalities (may use stress imaging)

MI, myocardial infarction; ECG, electrocardiogram.

Stress Electrocardiogram

Stress ECG testing is the most widely used and least expensive coronary disease screening modality. It is continued until the patient becomes fatigued or achieves 85% of the maximum predicted heart rate (approximately 220 minus the patient's age). Tests may be terminated earlier if signs or symptoms of severe ischemia (angina, ST-segment elevation, ST-segment depression >0.3 mV, or a fall in blood pressure of 10 mm Hg), arrhythmias, or heart block develop (2).

Test Information

ST-segment depression is considered "significant" if 1 mV or more of flat or downsloping depression is measured 60 msec past the J-point in three consecutive complexes (Figure 36.1A). If ST-segment depression is present on the baseline ECG, twice the resting ST-segment depression is usually required for a positive result (e.g., patients having a baseline depression of 1 mV would require an additional 2mV of ST-segment depression with exercise). In general, the likelihood of multivessel disease is proportional to the degree, distribution, and duration of ST-segment depression. ST-segment depression that is upsloping, however, is normally seen with rapid heart rates during exercise and does not constitute a positive test result (Figure 36.1B).

Figure 36.1 Exercise electrocardiographic (ECG) tracings at peak exertion on standard Bruce protocol. **A.** Downsloping ST-segment depression of 3 mm at peak exercise in ECG leads II and V5 in a patient who stopped exercising at 5 minutes (stage 2) because of severe chest pain at a heart rate of 115 beats/min (a “significant” test for ischemia). **B.** Upsloping ST-segment depression at peak exercise in ECG leads II and V5 in a different patient, who exercised for more than 10 minutes (stage 4) without chest pain and achieved a heart rate of 165 beats/min. This does not constitute a positive test result.

Exercise-induced ST-segment elevation in leads with diagnostic Q waves usually indicates preexisting regional wall motion abnormalities. However, ST-segment elevation seen in leads without existing Q waves can represent coronary artery spasm or even exercise-induced acute myocardial injury.

Exercise-induced premature ventricular contractions and nonsustained ventricular tachycardia occur in up to one-third of patients and are more common in those with CAD. Frequent ventricular ectopy in the recovery phase of testing correlates with an increased risk of death during 5-year follow-up (3), but other arrhythmias are not specific markers for coronary disease unless accompanied by other evidence of ischemia. Finally, exercise-induced supraventricular tachycardias occur rarely and are not generally related to underlying coronary disease.

Patients who can exercise longer than 9 minutes on a standard Bruce protocol or achieve 13 times the metabolic equivalents required at rest (METs) have a very good prognosis regardless of ischemic ECG changes. Chronotropic incompetence (failure to reach age-appropriate heart rate response), abnormal heart rate recovery (a decline in the heart rate of <10 beats per minute in first minute of recovery), and abnormal blood pressure responses (decline in systolic blood pressure with exercise) are important signs of severe coronary disease and poor prognosis (Table 36.2).

Scoring systems such as the Duke Treadmill Score and the VA Treadmill Score have been developed to integrate information provided by the exercise test.

Patient Selection and Indications

The clinical uses for stress ECG testing are broad (Table 36.3). It is most commonly used for the diagnosis of chest

TABLE 36.2

STRESS ELECTROCARDIOGRAPHIC INDICATORS OF SEVERE CORONARY DISEASE^a OR POOR PROGNOSIS

Downsloping ST-segment depression ≥ 3 mV
 Involvement of five or more leads with ST-segment depression
 Early ST-segment depression (<5 METs)
 Prolonged ST-segment depression late into recovery
 Failure to complete stage II of Bruce protocol
 Failure to obtain HR >120/min (off negative chronotropic drugs)
 Exertional hypotension

^a Severe coronary disease is >75% stenosis of three vessels or >50% stenosis of the left main coronary artery.
 HR, heart rate; METs, metabolic equivalents.

TABLE 36.3
INDICATIONS FOR EXERCISE TESTING

Diagnosis

- Patients with interpretable electrocardiogram and an intermediate pretest probability of CAD, based on gender, age, and symptoms
- Before and after revascularization
 - Demonstration of ischemia before revascularization
 - Evaluation of patients with recurrent symptoms suggesting ischemia after revascularization

Risk assessment/prognosis

- Patients undergoing initial evaluation with suspected or known CAD
- Patients with suspected or known CAD with significant change in clinical status
- Post-myocardial infarction
 - Before discharge for prognostic assessment, activity prescription, or evaluation of medical therapy (submaximal at about 2 to 7 days)
 - Early after discharge for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation if the pre-discharge exercise test was not done (symptom-limited at about 14 to 21 days)
 - Late after discharge for prognostic assessment, activity prescription, evaluation of medical therapy, and cardiac rehabilitation if the early exercise test was submaximal (symptom-limited at about 3 to 6 weeks)

Other

- Selection of appropriate settings in patients with rate-adaptive pacemakers
- Evaluation of exercise capacity and response to therapy in patients with heart failure who are being considered for heart transplantation
- Assistance in differentiating cardiac from pulmonary limitations as a cause of exercise-induced dyspnea or impaired exercise capacity when the cause is uncertain.

CAD, coronary artery disease.

Reprinted with permission from Gibbons RJ, Balady GJ, Beasley JW, et al. ACC/AHA guidelines for exercise testing: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, Committee on Exercise Testing. *J Am Coll Cardiol* 1997;30:260–315.

pain in patients who are able to exercise and who have an interpretable baseline ECG (Figure 36.2).

Test Interpretation and Accuracy

A meta-analysis of 58 consecutive published studies of stress ECG reported a sensitivity and specificity of 67% and 72%, respectively, for the diagnosis of coronary disease, although these figures varied considerably across studies depending on the population examined and the study design. For detecting multivessel disease, the sensitivity of stress ECG increases to 81% (1). Estimates of diagnostic accuracy are affected by “workup bias,” which occurs when disease status is not known on all patients tested. When workup bias is

minimized, the sensitivity of ECG changes declines to about 45%, but specificity rises to near 90% (4). Diagnostic accuracy of stress ECG is lower in patients who have abnormal baseline ECGs (hypertrophy and repolarization changes) or who are taking medications (digoxin) that alter the ECG or heart rate. Diagnostic accuracy is also lower in the elderly, who are less likely to reach maximal heart rate targets, and in women, who are more likely to have false-positive ST-segment depression.

Treadmill testing provides important prognostic information. Patients with a normal ECG tracing at stage 3 of a Bruce protocol have an excellent short-term prognosis (1-year mortality <1%). Stress ECG testing following MI effectively identifies a low-risk population (negative predictive value of 90%), although its positive predictive value is more limited (16% to 20%) (5).

Nuclear Perfusion Imaging

Stress myocardial perfusion imaging can be performed with exercise or pharmacologic stress. A radioactive tracer agent is injected approximately 60 seconds before maximal stress or exertion; on completion of the stress, either planar or tomographic (single-photon emission computed tomography, or SPECT) images are obtained. For comparison, resting images are obtained either immediately before or several hours after stress imaging.

Nuclear perfusion imaging commonly uses either thallium (Tl) 201 or ^{99m}Tc-sestamibi. Dual-isotope scanning techniques (e.g., resting ²⁰¹Tl and stress ^{99m}Tc-sestamibi) can decrease the overall rest-stress imaging time to just 90 minutes.

Test Information

Stress perfusion imaging can demonstrate both “reversible defects” and “fixed defects,” which have been equated with territories of ischemia and prior infarction, respectively (Figure 36.3). The size, severity, and distribution of these defects carry important diagnostic and prognostic significance, and their location can be correlated with areas of coronary circulation. Nuclear perfusion imaging can also be used to determine myocardial viability; for example, perfusion deficits that redistribute on delayed repeated imaging (6 to 24 hours following stress) or following administration of a second tracer bolus correlate with areas of “hibernating” myocardium, which is myocardium that does not contract normally because of chronic ischemia but will recover function if and when perfusion is restored. Tracer uptake by the lungs indicates exercise-induced increases in pulmonary pressures suggestive of left ventricular (LV) dysfunction and multivessel coronary disease. Nuclear studies also can provide information on ventricular function with stress (first-pass studies or radionuclide angiography). Typically, LV function is

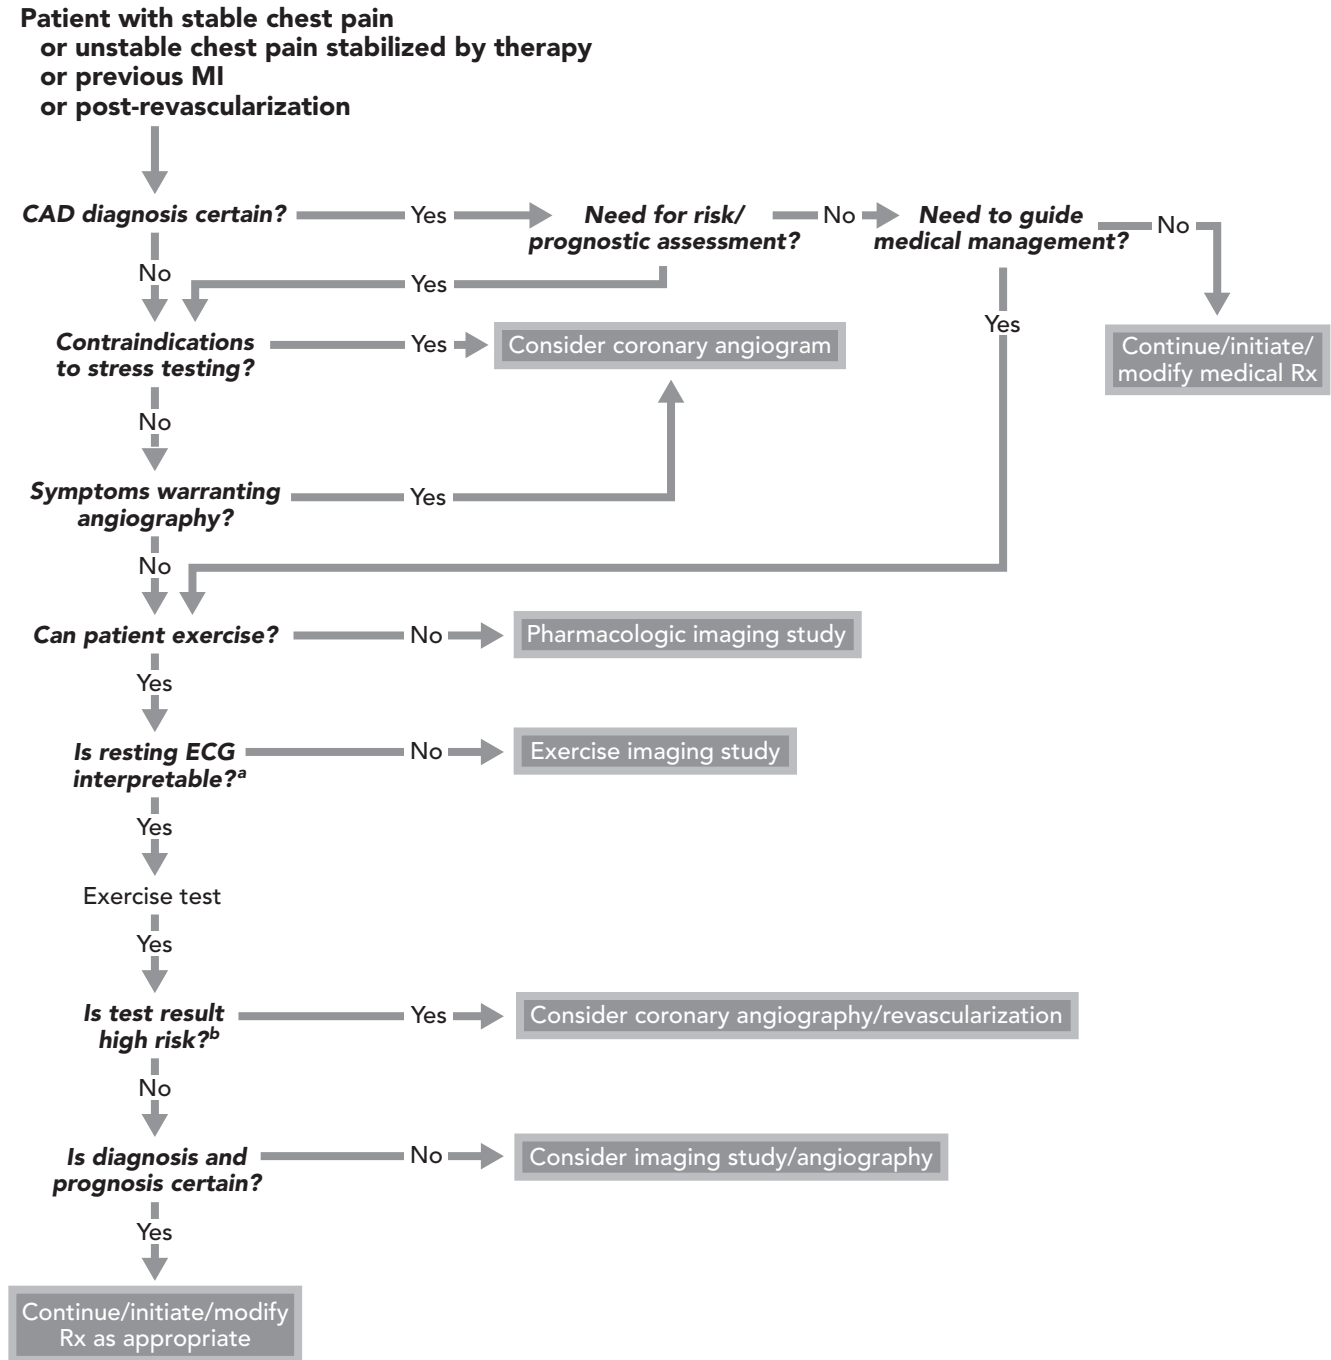

Figure 36.2 Exercise testing for the evaluation of patients with suspected ischemic heart disease.
^aElectrocardiogram is interpretable unless preexcitation, electronically paced rhythm, left bundle branch block, or resting ST-segment depression >1 mm is present.
^bFor example, high-risk if Duke treadmill score predicts average annual cardiovascular mortality >3%.
 MI, myocardial infarction; CAD, coronary artery disease; ECG, electrocardiogram.

Figure 36.3 Single-photon emission computed tomography (SPECT) nuclear perfusion imaging with ^{99m}Tc -sestamibi. SPECT cardiac images displayed at stress (rows 1, 3, 5) and rest (rows 2, 4, 6) in the horizontal long axis (HLA) from anterior to inferior (left to right), vertical long axis (VLA) septal to lateral (left to right), and short axis (SA) from apex to base (left to right). Normal perfusion is seen in rest images, but decreased perfusion to the antero-septal and antero-apical walls occurs at peak stress. Courtesy of Dr. Salvadore Borges-Neto, Department of Radiology, Duke University Medical Center, Durham, NC.

augmented by 5% to 15% with exercise; a blunted increase (<5%) can signal the presence of multivessel disease and poor prognosis, particularly in men.

Patient Selection and Indications

Given its higher cost, perfusion imaging should be reserved for the diagnosis of coronary disease in patients for whom stress ECG is not indicated or when localization of ischemia is important for management decisions (6) (Figure 36.2).

Test Interpretation and Accuracy

Nuclear perfusion imaging is significantly more accurate for the diagnosis of coronary disease than is stress ECG. The reported overall sensitivity and specificity for stress myocardial perfusion imaging range from 80% to 90% in most clinical series and in two meta-analyses (6). SPECT imaging appears to have slightly superior diagnostic accuracy relative to planar imaging, although overall diagnostic accuracy does not seem to vary significantly by type of stress, radioisotope, or type of analysis (quantitative vs. qualitative). False-negative nuclear perfusion studies can occur when collateral circulation masks single-vessel disease or “balanced” hypoperfusion disguises multivessel disease. False-positive studies, in contrast, occur because of tissue attenuation (diaphragmatic attenuation of the inferior wall, breast attenuation of the anterior wall) or left bundle branch block (septal perfusion defects).

Myocardial perfusion imaging can also provide important prognostic information. In a recent large series of patients with suspected or known CAD, the annual rate of cardiac death or MI was 0.8% for patients with a normal test result but 3.9% in those with severely abnormal test findings (7). High-risk test results include large areas of ischemia, multiple territory involvement, LV dilatation, and increased lung uptake. Following MI, the positive predictive value of an abnormal study result for death or recurrent MI was 17%, and the negative predictive value was 95% (5).

Stress Echocardiography

Stress echocardiography is a sensitive way to examine exercise-induced changes in LV wall function. For exercise stress, bicycle protocols have the advantage over treadmill protocols because they allow imaging during exertion. Dobutamine echocardiography and dipyridamole echocardiography are alternatives for those unable to exercise.

Test Information

The contractile force of each segment of the LV is quantitatively assessed at rest and after stress. New or worsening wall motion abnormalities indicate ischemia (Figure 36.4). Flow must be decreased by at least 50% in 5% of the myocardium to cause ischemia sufficient to induce wall motion abnormalities under stress. Conversely, resting wall

Figure 36.4 Stress echocardiography with stress induced regional wall motion abnormality. **A:** Apical four chamber 2-D image of left ventricle at rest. **B:** Anteroseptal wall becomes dyskinetic with peak stress. Solid arrowhead shows the anteroseptal wall bulging away from the left ventricular cavity with systole, and the open arrowhead shows the hinge point between normal and abnormal myocardial contraction.

motion abnormalities do not always indicate prior infarction. Improvement of abnormal resting wall motion with low doses of dobutamine (5 mcg/kg per minute) suggests hibernating but viable myocardium.

Patient Selection and Indications

For the diagnosis of coronary disease, stress echocardiography is particularly advantageous in situations in which ECG tracings are less accurate (women, patients with LV hypertrophy or resting ECG abnormalities) (8). Choice between stress echocardiography and nuclear imaging modalities may be determined by patient factors (e.g., tissue attenuation, imaging windows) or by local experience, availability, and cost. Stress echocardiography may be less helpful in patients with chronic lung disease, because of poor image quality, and in those with baseline wall motion abnormalities.

Test Interpretation and Accuracy

Inducible wall motion abnormalities under stress have a sensitivity of 80% to 90% and a specificity of 85% for detecting CAD (8). The level of stress at onset and the degree of induced wall motion abnormality are predictive of the extent of disease. Failure to achieve maximal stress, delayed post-stress imaging, or poor image quality may all adversely affect test accuracy. Although roughly equivalent to exercise SPECT nuclear perfusion imaging, exercise stress echocardiography generally has a lower sensitivity and higher specificity for detecting CAD. Stress echocardiography is less sensitive for single-vessel disease but more sensitive for multivessel disease because “balanced ischemia” may be unappreciated during nuclear testing.

Dobutamine stress echocardiography has the ability to predict functional improvement in viable myocardium after revascularization, with a sensitivity of 80% and specificity

of 90% (8). After MI, stress echocardiography has a positive predictive value of 48% and a negative predictive value of 86% for subsequent MI and death (5).

ASSESSMENT OF CARDIAC STRUCTURE AND FUNCTION

The assessment of cardiac structure and function has assumed a central role in the evaluation of cardiac patients. Echocardiography, radionuclear angiography, and cardiac catheterization can each provide aspects of this important diagnostic and prognostic information.

Echocardiography

Test Information

The major advantage of transthoracic echocardiography is the ease and speed with which a study can be performed. Its major limitation is obtaining adequate images through the patient’s chest wall. *Transesophageal echocardiography* (TEE) is not limited by imaging through air or rib spaces and is particularly suited for the assessment of cardiac valves, atria, and aortic arch because of their posterior location and proximity to the probe. Major clinical applications of TEE include evaluation of valves for endocarditis, prosthetic valve function, intracardiac masses (including thrombi in the left atrial appendage), and aortic arch pathology (dissection, coarctation).

Although TEE is generally quite safe, it carries minor risks of conscious sedation, hypoxia, aspiration, or damage to the hypopharynx, esophagus, or laryngeal nerves. Relative contraindications to TEE include esophageal pathology, active upper gastrointestinal bleeding, and severe cervical arthritis.

Patient Selection and Indications

Major indications for the use of echocardiography include the evaluation of murmurs found during cardiac auscultation and the evaluation of symptoms such as dyspnea, fatigue, and edema (8) (Table 36.4). In addition, echocardiography can assess ejection fraction and resting wall motion abnormalities in patients with chest pain or with known CAD, especially after MI. Echocardiograms are also indicated to evaluate valvular heart disease, LV hypertrophy, suspected aortic dissection, pericardial disease, as well as cardiac sources of emboli in stroke patients, and for serial assessments of ventricular size and function in patients with known heart failure or valvular disease, especially in the setting of worsening symptoms.

Test Interpretation and Accuracy

Systolic function can be qualitatively estimated as an overall ejection fraction and by the contractile function of each regional wall. Wall motion is described as either normal, hyperkinetic, hypokinetic, akinetic, or dyskinetic (aneurysmal). Left atrial (LA) and LV chamber dimensions and ventricular hypertrophy are measured in standard views.

Intraatrial cavitory defects (as in atrial myxoma or atrial thrombus) may be visualized particularly well with TEE. Intraventricular masses (tumor or LV thrombus) can also be diagnosed. Finally, amyloid cardiomyopathy can be suspected on the basis of thickening and a “ground glass” appearance of the myocardium.

Valvular Regurgitation

The structure, motion, and morphology of the cardiac valves can be clearly seen with two-dimensional (2-D) imaging. Prolapse of mitral leaflets, chordal rupture, widening of the annular ring with decreased coaptation, and valvular degeneration give clues to the presence of regurgitation. Color Doppler is very sensitive in detecting turbulence and regurgitation of flow through valves (Figure 36.5). The width of the origin and the volume of the regurgitant jet on color flow images provide a semi-quantitative estimate of the severity of mitral and aortic regurgitation.

Spectral Doppler can be used to measure the velocity of the regurgitant jet directly. These measurements have several clinical applications, as the velocity (V) of flow through the valve is related to the pressure gradient (DP) across the valve by the modified Bernoulli equation ($DP = 4V^2$). For example, when tricuspid valve regurgitation is present, this relationship between velocity and pressure gradients is useful in estimating pressures in the right side of the heart. Specifically, right ventricular (RV) systolic pressure can be estimated by adding the assumed RA pressure (5 to 10 mm Hg in normal patients) to the tricuspid regurgitation pressure gradient (DP).

Valvular Stenosis

Stenosis is suggested by diminished valve mobility, thickening, or calcifications on 2-D echocardiographic images, and by turbulent flow through the valve on color Doppler images (Figure 36.6). The diagnosis is confirmed by using spectral Doppler to detect elevated velocities as blood travels through the narrowed valve orifice. Velocities can be converted to peak and mean pressure gradients across the aortic valve by using the modified Bernoulli equation ($DP = 4V^2$).

The severity of mitral stenosis is typically assessed from the pressure gradient half-time equation (the time required for the peak pressure gradient between the LA and LV to decline to half of its value). Planimetry, which is direct measurement of the mitral valve orifice on a freeze-frame image, can also be used to assess mitral valve area.

Pericardial Disease

Two-dimensional images enable the identification and assessment of pericardial effusions. An effusion is seen as an “echo-free space” surrounding the heart and can be focal or circumferential. The effusions are visually estimated to be small (<100 cc), moderate (100 to 500 cc), or large (>500 cc). Findings that suggest compromise to RV filling and impending tamponade include early diastolic collapse of the RV, invagination of the right atrial (RA) wall, and respiratory variation in Doppler flow across the mitral and tricuspid valves (Chapter 46).

Septal Defects

Atrial or ventricular septal defects are often associated with abnormal motion of the septum on 2-D images. Color Doppler can occasionally detect septal defects if the direction of flow is parallel to the Doppler signal; otherwise, the diagnosis must be made by observing the flow of agitated saline contrast. The appearance of agitated saline contrast injected through a peripheral intravenous line into the LV establishes the existence of an abnormal connection between structures in the right and left sides of the heart, such as an atrial or ventricular septal defect or a patent foramen ovale.

Radionuclide Angiography

Radionuclide angiography techniques provide the most reproducible and accurate studies for assessing ventricular function under most conditions. These studies are most useful for serial evaluation of ejection fraction in patients with heart failure or those receiving cardiotoxic agents (e.g., doxorubicin). Although they provide highly accurate assessments of ventricular ejection fraction, radionuclide angiography studies are nearly as expensive as Doppler echocardiography and do not provide detailed information regarding cardiac structure or valves.

TABLE 36.4**MAJOR AHA/ACC CLASS I INDICATIONS FOR ECHOCARDIOGRAPHY^a****Evaluation of valvular disease**

- Murmur in a patient with cardiorespiratory symptoms
- Changing symptoms in patient with known valvular disease or with a prosthetic valve
- Asymptomatic patients with severe valvular disease
- Assessment of severity and leaflet morphology in mitral valve prolapse
- Bacteremia without known source
- Documentation of severity in valvular stenosis or regurgitation (e.g., left ventricular and right ventricular size, function, and hemodynamics)
- Timing of surgical valvular repair or selection of alternative therapies
- Identification of valvular lesions and associated abnormalities (e.g., abscesses) in infective endocarditis

Diagnosis and prognosis in myocardial ischemic syndromes

- Identification of cardiac disease in patients with chest pain or severe hemodynamic instability
- Assessment of baseline LV function and infarct size
- Assessment for possible RV infarction or mechanical complications in patients with hemodynamic instability

Patients with dyspnea, edema, or cardiomyopathy

- Assessment of LV size and function in patients with cardiomyopathy or heart failure
- Dyspnea, unexplained hypotension, or edema with clinical signs of elevated central venous pressure or other signs of heart disease
- Changing symptoms in patients with cardiomyopathy

Pericardial disease

- Suspected pericardial disease (e.g., effusion, constriction, or effusive-constrictive process)
- Pericardial friction rub developing in acute myocardial infarction
- Suspected bleeding in the pericardial space (e.g., trauma, perforation)

Cardiac masses and tumors

- Evaluation of patients with clinical syndromes suggesting an underlying cardiac mass
- Surveillance studies after removal of masses known to have a high likelihood of recurrence (e.g., myxoma)
- Surveillance for cardiac involvement and staging in patients with known primary malignancies

Diseases of the great vessels

- Evaluation for aortic dissection, aneurysm, or rupture
- Degenerative or traumatic aortic disease with clinical atheroembolism
- Evaluation for aortic root dilatation in patients or their first-degree relatives with Marfan syndrome or connective tissue diseases

Pulmonary disease

- Suspected or known pulmonary hypertension (e.g., pulmonary artery pressures)
- Pulmonary emboli and suspected clots in the right atrium or ventricle or main pulmonary artery branches
- Lung disease with clinical suspicion of cardiac involvement (suspected cor pulmonale)

Hypertension

- Detection and assessment of functional significance of concomitant coronary artery disease and resting LV function, hypertrophy, or concentric remodeling
- Follow-up assessment of LV size and function in patients with LV dysfunction when there has been a documented change in clinical status or to guide medical therapy

Suspected cardioembolic events

- Patients of any age with abrupt occlusion of a major peripheral or visceral artery
- Younger patients (age <45 y) with cerebrovascular events
- Older patients (age >45 y) with neurologic events but no evidence of cerebrovascular disease or other obvious cause

Arrhythmias, palpitations, and syncope

- Arrhythmias with clinical suspicion of structural heart disease or a family history of a genetically transmitted cardiac lesion associated with arrhythmia
- Before cardioversion in patients in whom extended anticoagulation before cardioversion is not desirable
- Peri-exertional syncope or any syncope in a patient with clinically suspected heart disease

^a Transesophageal echocardiography (TEE) is preferred over transthoracic echocardiography (TTE) for the evaluation of the great vessels (e.g., possible aortic dissection), intracardiac masses (e.g., tumors, clots, vegetations), and prosthetic valves. LV, left ventricle; RV, right ventricle.

Figure 36.5 Parasternal long-axis echocardiographic images showing mitral regurgitation. The panel on the left (**A**) is a two-dimensional image in the parasternal long axis without mitral regurgitation. The panel on the right (**B**) is the same view showing regurgitant flow by Doppler (see arrow), which would be depicted in a color Doppler image as a mosaic of colors, through the mitral valve into the left atrium during peak systole. Color Doppler provides information on the direction of flow by coding signals as moving toward (red/yellow) or away from (blue) the transducer. Turbulent flow is depicted as a mosaic of colors.

Figure 36.6 2-D and Doppler images of severe aortic valve stenosis. **A.** Parasternal short axis view of a calcified aortic valve (AV). **B.** Doppler gradient through the aortic valve. Peak velocity of blood through the valve is 4.8 m/sec, corresponding to a peak transvalvular gradient of 92 mm Hg.

Cardiac Catheterization

Cardiac catheterization generally describes a number of percutaneous catheter-based procedures (e.g., coronary and bypass graft angiography, ventriculography, and aortic angiography) for imaging the heart and its major vessels. In addition, catheterization of the left and right sides of the heart is used to record intracardiac pressures.

Percutaneous peripheral vascular access is obtained in the femoral (Judkins technique), brachial (Sones technique), or radial arteries for catheterization of the left side of the heart, and the femoral or jugular veins for catheterization of the right side. Patients on full systemic anticoagulation or intravenous anti-platelet agents can undergo diagnostic catheterization without difficulty, but for outpatient procedures, low-dose heparin is all that is required (9).

Coronary Angiography

Coronary angiography is the standard for defining coronary anatomy and assessing coronary artery obstructive disease. Coronary arteries are assessed for extent of distribution, flow pattern, collaterals, and luminal irregularities. Stenoses are characterized as concentric or eccentric, discrete or tubular; the presence of luminal filling defects, calcium, or dissections is also noted. Coronary bypass grafts are injected at their site of origin from the aorta or, in the case of the internal mammary arteries, at their origin from the subclavian artery.

Visual interpretation of the degree of stenosis can vary significantly between interpreters and is subject to several types of error. Stenoses may be overestimated or underestimated if the lesion is not concentric or if the reference segment of the vessel is also diseased. In general, qualitative (visual) estimates of stenoses tend to overestimate severity in comparison with quantitative measurements (in which calipers or computer algorithms are used). These limitations of coronary angiography can be improved by the use of *intravascular ultrasound*, which can display a 3-D ultrasonic view of the plaque mass.

Ventriculography

Ventriculography provides information on regional wall motion and overall ventricular function (qualitatively, or quantitatively measured as the ejection fraction or end-systolic LV volume divided by end-diastolic LV volume). Pressure tracings are also obtained in the aorta and LV (which can be used to diagnose aortic stenosis or subvalvular outflow tract obstruction). The mean LV end-diastolic pressure is useful for assessing LV function, and the contour of the waveform is helpful in diagnosing abnormal filling and relaxation patterns.

Aortic Angiography

The aortic root is imaged by injecting a volume of contrast above the level of the aortic valve (aortic arch angiography) or into the abdominal aorta (usually at the level of the diaphragm). Aortic arch angiography opacifies the coronary arteries sufficiently to locate their origins if these are anomalous and demonstrates the size and contour of the ascending aorta. It also can be used to assess the severity of aortic regurgitation. Abdominal aortic angiography opacifies the descending aorta and its branch vessels in the leg and is helpful in identifying aortic aneurysms, renal artery stenosis, or peripheral vascular disease.

Catheterization of the Right Side of the Heart

Catheterization of the right side of the heart provides hemodynamic measurements and waveform recordings from the RA, RV, pulmonary artery, and pulmonary capillary wedge position, in addition to measuring cardiac output. Although it is not a routine part of cardiac catheterization for patients with CAD, it is often performed in those with associated LV dysfunction, cardiomyopathy, shunts, or valvular disease. Characteristic waveforms are present in valvular regurgitation (large *c-v* waves on RA pressure tracing for tricuspid regurgitation, or on pulmonary wedge tracing for mitral regurgitation), and abnormal filling patterns can provide clues to constrictive or restrictive physiology. In mitral valvular stenosis, the gradient between the pulmonary capillary wedge pressure and LV end-diastolic pressure can be used to calculate peak and mean gradients.

Cardiac output is usually determined by the Fick method, which calculates oxygen consumption. Combining cardiac output with pressure gradients across vascular beds can determine the pulmonary and systemic resistance. If intracardiac shunts are suspected, blood gases are drawn from various sites in the right side of the heart to look for an unexpected step-up in oxygenation. For example, if oxygenation increases by more than 5% between the RA and pulmonary artery, a left-to-right intracardiac shunt between these sites probably exists.

Patient Selection and Indications

The most frequent indication for cardiac catheterization is the evaluation of patients with suspected obstructive coronary artery disease (9). For patients with an acute coronary syndrome, early cardiac catheterization followed by any indicated revascularization procedure is of proven benefit (10). Catheterization is indicated for stable angina when it is unresponsive to medical therapy or associated with evidence of LV dysfunction, or with high-risk features on stress testing. Patients with high-risk occupations (e.g., airline pilot) may proceed directly to catheterization for definitive

evaluation of any symptoms consistent with potential myocardial ischemia.

When performed safely, cardiac catheterization has a very low rate of complications, but it can result in serious vascular injury, MI, bleeding, neurologic events (transient ischemic attack, stroke), contrast reaction, and mortality (9) (Table 36.5). Other complications include vasovagal events, worsening renal insufficiency, and hematomas at the puncture site. Overall, the risk to life should be less than 0.2%, and the risk for other serious adverse events should be less than 0.5%. Relative contraindications include recent stroke (within 1 month), progressive renal insufficiency, fever or active infection, severe anemia, thrombocytopenia, electrolyte imbalance, uncontrolled hypertension, or allergy to angiographic contrast media. Patients at highest risk for mortality include the very old and those with New York Heart Association class III or IV symptoms, severe LV or valvular dysfunction, acute or unstable ischemic syndromes, and high-risk noninvasive test results. Patients at highest risk for vascular complications include women, those who are very old or obese, and those with a history of peripheral vascular disease. Hydration and administration of N-acetylcysteine (Mucomyst) prior to cardiac catheterization may reduce the nephrotoxicity associated with the contrast agents.

The indications for and risks of pulmonary artery (right side of the heart) catheterization in severely ill patients are described in Chapter 25.

NEW AND EMERGING DIAGNOSTIC TESTS

Cardiac Magnetic Resonance Imaging (MRI)

MRI is a rapidly evolving technology that produces high-resolution images of cardiac structure and function without interference from surrounding bone or air, biological

hazards, or the need for nephrotoxic contrast agents. MRI is useful when evaluating patients for pericardial abnormalities (e.g., constrictive pericarditis or pericardial hematoma) or certain myocardial diseases (e.g., cardiac amyloid or RV dysplasia). Intracardiac masses (e.g., myxoma or thrombus) can also be imaged in detail. MRI can be combined with pharmacologic stress testing to determine both viability and perfusion of ischemia myocardium. Proximal coronary arteries can often be visualized, but MRI is not currently a substitute for coronary arteriography (11).

Electron-beam Computed Tomography (EBCT)

EBCT uses a single focused electron beam and one stationary detector to measure the calcium content of coronary arteries rapidly. The magnitude of coronary artery calcification (coronary calcium score) predicts the presence of coronary stenoses and the future occurrence of cardiac events with a sensitivity above 90%, but a specificity of only 20% to 50%. Despite this good sensitivity, some plaques lack calcium yet can become unstable and produce symptoms and cardiac events. EBCT may add incremental information for high-risk primary patients who have no symptoms or have atypical chest pain, but a randomized trial showed no benefit from EBCT in terms of the effectiveness of subsequent interventions to improve cardiac risk factors (12). As a result, its routine use as a screening test cannot be recommended.

COST AND RESOURCE USE

Clearly, it is important for physicians to have information about the economic aspects of cardiovascular diagnostic testing (Table 36.6). The full economic implications of a diagnostic test also go well beyond its initial cost and include indirect costs associated with each testing strategy. For example, if a screening study provides a false-positive result, it may prompt further evaluation and increased resource use. Alternatively, a false-negative test result may lead to the high costs (both financial and clinical) associated with a delayed or missed diagnosis. In addition to cost, the efficiency of a testing strategy must be considered. For example, to assess ventricular function and diagnose coronary disease, the physician may order an echocardiogram and stress myocardial perfusion imaging, a rest and exercise echocardiogram or radionuclide ventriculogram, or a cardiac catheterization.

KEY POINTS

- Clinicians should consider a patient's diagnostic and prognostic estimates based on clinical factors before ordering additional diagnostic studies. Diagnostic testing

TABLE 36.5
RISK OF COMPLICATIONS DURING
DIAGNOSTIC CATHETERIZATION^a

Mortality	0.11%
Myocardial infarction	0.05%
Cerebrovascular accident	0.07%
Arrhythmia	0.38%
Vascular complications	0.43%
Contrast reaction	0.37%
Hemodynamic complications	0.26%
Perforation of heart chamber	0.03%
Other complications	0.28%
Total complications	1.7%

TABLE 36.6
MEDICARE CHARGES FOR VARIOUS TESTING MODALITIES (2003, IN U.S. DOLLARS)

Tests for ischemia	Medicare allowable charges (\$)		
	Facility	Professional	Total
Exercise electrocardiogram	56	50	106
Exercise perfusion imaging ^a	463	122	585
Exercise ventriculography	289	72	361
Exercise echocardiography	118	123	241
Tests for left ventricular function			
Radionuclide ventriculography	183	44	227
Echocardiography (2-D/Doppler)	302	65	367
Left-sided heart catheterization	1,869	337	2,206
Cardiac MRI	393	86	479

^a Excluding cost of isotope. All charges are for participating Medicare providers. Electron beam computed tomography (cost, about \$600) is not approved for Medicare reimbursement.

usually provides the most new information in patients with intermediate pretest estimates.

- Most tests provide multiple forms of information, and all information should be considered.
- Stress electrocardiographic testing is an inexpensive strategy for the diagnosis of coronary disease in symptomatic ambulatory patients with interpretable baseline electrocardiograms.
- Exercise stress enables a correlation between symptoms and physical workload and provides information on exercise capacity in addition to ischemia. Pharmacologic stress is an alternative for those unable to exercise.
- Nuclear perfusion imaging and stress echocardiography similarly improve the sensitivity and specificity of stress electrocardiographic testing in the diagnosis of coronary disease.
- Compared with stress echocardiography, nuclear perfusion imaging has slightly superior sensitivity for detecting single-vessel disease but slightly lower specificity and higher costs.
- Decisions regarding which stress test to order should be individualized according to the patient's clinical characteristics and local availability, expertise, and cost.
- Echocardiography has become the standard means for noninvasive assessment of cardiac structure and function.
- For patients with a high clinical likelihood of coronary disease before testing, cardiac catheterization may be the best initial diagnostic test.
- EBCT provides information about coronary calcification (calcium score) and is being evaluated to assess its proper role as an adjunct to risk factor assessment in primary prevention strategies. It is not recommended as a routine screening test or as a diagnostic test in patients with known coronary disease.

- Cardiac MRI provides detailed structural images of the heart and pericardium, but accurate noninvasive coronary artery imaging is not yet a reality.

Angina

Daniel B. Mark

INTRODUCTION

Although clinicians commonly refer interchangeably to angina pectoris, myocardial ischemia, and coronary artery disease, these three terms are not equivalent. *Angina pectoris*, first described in detail by William Heberden in 1772, is a syndrome of characteristic symptoms centering on reproducible exercise or stress-induced precordial chest discomfort that is promptly relieved by rest or nitroglycerin. There is no gold standard for this clinical diagnosis. *Unstable angina* is a progression of the symptom pattern, often with prolonged episodes of angina at rest. Unstable angina portends an increased risk for adverse cardiac events.

Myocardial ischemia is a pathophysiologic disorder caused by reduced perfusion of myocytes. Myocardial ischemia results from an imbalance between myocardial oxygen supply (perfusion) and demand (cellular consumption). Disordered myocyte metabolism results in impaired contraction of the affected heart muscle. Severe, prolonged ischemia may produce irreversible cellular damage and myocardial infarction (MI). Although many clinical tests are thought to assess myocardial ischemia, no diagnostic gold standard exists. Of the diagnostic technologies currently available, positron emission tomography (PET) comes the closest to allowing repeated assessment of the metabolic state of the myocardium.

Coronary artery disease (CAD) typically refers to an anatomic disorder of the epicardial segments of the coronary arteries. It is most commonly caused by focal accumulations of atherosclerotic material in the intima of these arteries. Pathologic examination is the best way to diagnose CAD. The coronary angiogram serves as a more convenient, if imperfect, surrogate standard.

Although these distinctions may appear semantic, confusing these concepts leads to errors in diagnosis and management. The presence of classic anginal symptoms is not pathognomonic for either myocardial ischemia or CAD, and the diagnosis of angina pectoris is not disproved by the absence of CAD on diagnostic testing. Furthermore, myocardial ischemia frequently occurs silently, without angina, and the pathway from myocardial ischemia to anginal symptoms is much more complex than has been previously appreciated. It is possible for anginal symptoms to be produced experimentally without myocardial ischemia, and vice versa. Finally, many people have coronary atherosclerotic disease but have neither angina nor myocardial ischemia. Unfortunately, such preclinical atherosclerotic disease is not always benign; it may progress without warning to either acute MI or sudden cardiac death. Thus, when evaluating these patients, the clinician must be aware of the imperfect relationships among symptoms (angina), the metabolic state of the myocardium (ischemia), and anatomic CAD.

This chapter briefly reviews the relevant epidemiology and pathophysiology of angina and unstable angina and then focuses on the identification and hospital management of symptomatic angina patients. In the current era of cost containment and managed care, it is uncommon for a patient with stable angina to require admission for evaluation or therapy. Clinicians admit patients with anginal symptoms to the hospital because they deem it either unsafe or of uncertain safety to continue outpatient evaluation and management. Most of these inpatients will have either unstable angina pectoris or acute MI. The patient's presenting symptoms need to be integrated with early test data to formulate an initial assessment of prognosis and an initial management strategy (see Issues at the Time of

Admission). As the patient progresses through the hospital course, the clinician must reevaluate the diagnosis and management strategy and make appropriate modifications (see Issues During the Course of Hospitalization). Finally, the clinician must decide when it is safe to discharge the patient from the hospital (see Issues at the Time of Hospital Discharge).

EPIDEMIOLOGY

CAD is the leading cause of death in the United States (about 500,000 deaths each year). The prevalence of angina pectoris approximates 7 million cases, with an annual incidence of 350,000. Unstable angina is the principal diagnosis in about 700,000 hospitalizations annually. Almost 60% of unstable angina patients are over age 65 and nearly half are women. Another 1.5 million Americans have an acute MI each year. Thus, the acute coronary syndromes (acute MI, unstable angina) collectively comprise the most frequent cause of hospitalization for adults in the United States. Hospitalization for unstable angina has increased during the last decade, whereas hospitalization for MI has declined. Whether these trends are a consequence of risk factor reduction, improvements in pharmacotherapy, or changes in discharge coding practices remains unsettled. However, the routine measurement of troponin during the last 4 years has resulted in many patients who would have been diagnosed with unstable angina now being classified as non-ST elevation myocardial infarction, so these trends will likely reverse after 2000 (1).

PATHOPHYSIOLOGY

Determinants of Myocardial Ischemia

In normal subjects, it is nearly impossible to create ischemia by voluntarily increasing myocardial demand (Figure 37.1). Thus, for ischemia to develop, there must be an abnormal reduction in coronary blood flow, an abnormal increase in myocardial oxygen demand, or both.

The heart differs from most other organs in that maximal oxygen extraction already occurs in the resting state. When myocardial oxygen demand increases, the heart muscle is obligated to increase coronary blood flow. Coronary blood flow occurs predominantly during diastole and has three principal determinants: aortic diastolic perfusion pressure, coronary vascular resistance, and the length of the diastolic phase of the cardiac cycle. Factors that reduce coronary blood flow include lower aortic diastolic pressure, obstructive coronary lesions, and tachycardia. In some patients in whom severe obstructive CAD develops, coronary collaterals may mitigate the effects of reduced antegrade coronary flow.

Myocardial oxygen demand is primarily determined by how much work the heart is doing. Higher heart rates (as occur with exercise or tachyarrhythmias) and increased contractility (from increased circulating catecholamines) will increase myocardial oxygen demand. Factors that increase left ventricular (LV) wall tension, including higher systolic blood pressure, ventricular chamber enlargement, and LV hypertrophy, also increase oxygen demand.

Atherosclerotic Plaque Events

Atherosclerosis is a progressive disorder that often begins in childhood, with significant lesions evident at autopsy by the third decade of life. This pathophysiologic process is characterized by the formation of atherosclerotic plaques comprised of smooth-muscle cells, inflammatory cells, cellular debris, lipid, and other material within the intima of medium-size and large arteries. Complex recurrent cycles of endothelial injury, inflammation, and healing produce these lesions. Endothelial injury, believed to be the initiating event, has been linked to hypercholesterolemia, hypertension, cigarette smoking, diabetes, viruses, chlamydia infection, and homocysteine.

Atherosclerotic plaques vary in their composition, consistency, and vulnerability to rupture. Mature plaques contain a soft, lipid-rich, atheromatous gruel center supported by outer, collagen-rich, sclerotic components. Plaques may contain varying amounts of hard and soft components. A

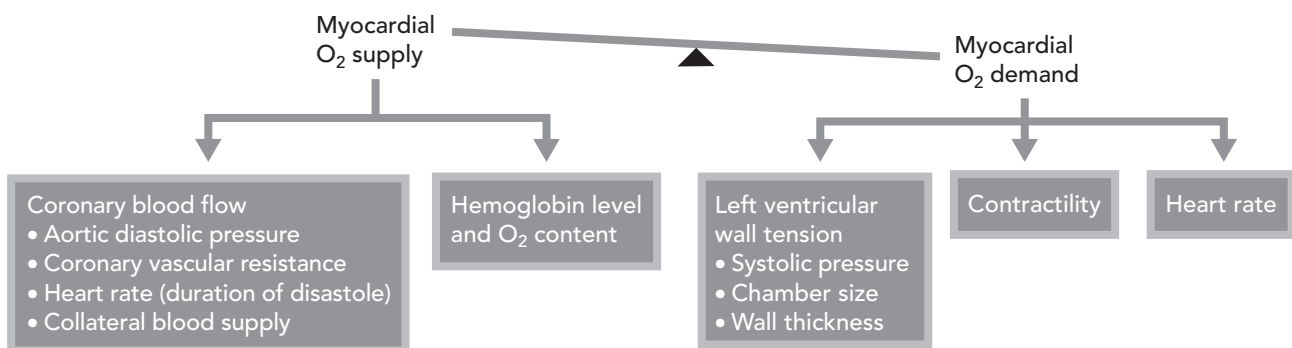

Figure 37.1 Major determinants of myocardial oxygen supply and demand.

plaque that is made up of only collagenous tissue is sometimes referred to as a “nonvulnerable” plaque, because it is not believed to pose a risk for rupture. In contrast, a “vulnerable” plaque has a core of soft, extracellular, highly thrombogenic, lipid-rich gruel (usually >40% of the plaque volume) and a fibrous cap that varies in composition, strength, and thickness. Most plaque ruptures start at the plaque shoulder, where the cap is often thinnest and most heavily infiltrated with inflammatory cells. It is unclear whether plaque rupture is caused by an inflammatory process at the shoulder of the plaque cap or by external triggers that physically disrupt the cap at its weakest point. The circadian patterns of major cardiac events suggest that sympathetic nervous system activity (which would increase blood pressure, heart rate, myocardial contractility, and coronary flow rates) can provide sufficient stress to disrupt a vulnerable plaque. Some plaque events appear to be caused by erosion of the plaque surface with subsequent thrombus formation. The relative importance of plaque erosion versus plaque rupture in unstable angina has been difficult to define because few unstable angina patients undergo autopsy examination. *Plaque “events” (rupture or erosion) underlie most episodes of acute coronary disease, which range from a worsening of effort angina at the lower-risk end of the spectrum to acute MI and sudden cardiac death at the other.*

Importantly, many of the plaques that are most predisposed to rupture appear angiographically as “insignificant” stenoses (i.e., stenoses that narrow the diameter of the arterial lumen by 50% or less). Lesions causing severe, subtotal stenosis of the arterial lumen tend more often to be bulky fibrous plaques and have a much lower propensity to rupture. Revascularization therapies directed at obstructive coronary disease can relieve symptoms and (indirectly) reduce the risk of death from a major plaque event, but they do not reduce the risk of a clinical plaque event. To achieve this latter goal, additional therapies must be directed at the pathophysiologic process of atheroma formation, the development of vulnerable plaques, and the thrombotic response to plaque rupture.

ISSUES AT THE TIME OF ADMISSION

The two major components involved in the initial assessment of the patient with suspected angina are assessment of the diagnosis and assessment of the short-term prognosis. Patients who require hospital admission either have a history of known CAD with recurrent or worsening symptoms or present with symptoms that are at least suggestive of possible CAD. In both of these scenarios (i.e., new presentation and patient with preestablished CAD), the clinician must assess the likelihood that the patient’s symptoms represent ischemic atherosclerotic disease (see Initial Assessment of Diagnosis). Concurrently, the clinician must decide whether the patient needs immediate therapy or can be

treated once the results of initial testing have been obtained (see Initial Assessment of Prognosis).

Initial Assessment of Diagnosis

Diagnostic Features of the History

When the patient gives a history that conforms closely to the template of characteristics initially described by Heberden and other early cardiologists, the terms “typical” angina or “definite” angina are often used. “Atypical” angina describes symptoms that are not classic in one or more key features. “Probable” angina and “possible” angina are alternative terms that define greater shades of uncertainty. “Non-anginal” symptoms clearly favor another diagnosis (e.g., gall bladder disease or peptic ulcer disease) or are completely inconsistent with typical angina. These terms summarize the likelihood that a patient’s symptoms are being caused by underlying obstructive CAD. Seven features of the history should be considered in this assessment: quality, location, duration, and severity of the discomfort; precipitants; factors providing relief; and associated symptoms.

Quality of Discomfort

Because the myocardium and the other thoraco-abdominal viscera are not well equipped with sensory nerves, ischemia in these organs produces sensations that are difficult for patients to describe. Some angina patients deny that they have “chest pain” because they do not consider the symptoms painful. Consequently, the patient should be asked about any *discomfort* and allowed to supply the descriptive terms that are most appropriate. Frequently, the patient with typical angina will use words such as *tightness, pressure, squeezing, aching, fullness, constriction, or heaviness*; terms such as *burning, indigestion, cramping, and gas* are also commonly used by patients with angina, but these sensations often occur in patients without angina and hence are less typically associated with the diagnosis. Descriptions that point to a diagnosis of non-anginal pain include knifelike, sharp, stabbing, and throbbing, or any discomfort that is clearly altered by a change in posture or respiratory movements.

Location

Myocardial ischemic discomfort can be perceived anywhere between the jaw and the diaphragm. The most typical location is substernal (retrosternal). Because of the visceral origin of these symptoms, patients may not only have trouble describing but also localizing them. Occasionally, a patient with typical angina will spontaneously clench a fist over the sternum while describing symptoms (*Levine’s sign*). In contrast, the patient who can point with one finger to the location of the discomfort does not have typical angina. Similarly, isolated right-sided chest discomfort is almost never anginal (unless the patient has dextrocardia), and

discomfort limited to the region below or lateral to the left breast is also unlikely to represent myocardial ischemia. Typical angina commonly radiates down one or both arms (the left more frequently than the right), to the neck, or to the left shoulder; some typical angina patients may have symptoms confined to these locations. However, symptoms of exertional tightness or less commonly an ache in more unusual locations—the lower jaw, teeth, or ear region—are also consistent with a diagnosis of angina. In the unstable angina patient who presents only with symptoms in these unusual locations at rest, the clinician must maintain a high index of suspicion to arrive at the correct diagnosis. Radiation of the discomfort to the lower abdomen or lower extremities, in contrast, is inconsistent with a diagnosis of typical or definite angina.

Duration

Typical stable anginal episodes usually last for ≤ 5 minutes unless the precipitating factors have not been removed. The discomfort characteristically resolves completely between episodes. A duration of discomfort of ≥ 20 minutes, particularly if the discomfort is severe, should prompt consideration of acute CAD (which is discussed further below). Symptoms that last only for seconds (sometimes described as “lightning-like”) are very unlikely to be caused by myocardial ischemia and are inconsistent with a diagnosis of typical angina. Symptoms that last for > 20 minutes but do not present the features of acute coronary disease are not characteristic of typical angina.

Severity

Anginal symptoms occur on a continuum ranging from mild effort-related angina at one end to acute MI with severe, unrelenting discomfort at the other. The most widely used classification of anginal symptom severity is the Canadian Cardiovascular Society Classification (Table 37.1). Although such information is useful in making treatment decisions, symptom severity does not help in making an assessment of the likelihood of underlying CAD.

Precipitants

Typical angina is characteristically precipitated by factors that increase the cardiac workload, such as exercise or psychological stress. However, not all patients with angina caused by myocardial ischemia can provide information about precipitants, especially if their symptoms are recent in origin or present with an unstable pattern.

Reproducibility of symptoms is a cardinal feature of typical angina. The patient who relates that certain exertional or stress-related activities predictably elicit the discomfort and that this discomfort is relieved promptly by rest or sublingual nitroglycerin has described the core features of typical angina. If the quality and location of the discomfort are consistent with typical angina but the episodes occur sporadically without any obvious precipitants, the diagnosis of atypical angina is more appropriate. The major exception is unstable angina, which may have all the features of typical angina except that symptoms occur at rest. Under these circumstances, a diagnosis of typical or definite angina would still be appropriate.

Factors Providing Relief

Stable exertional angina is characteristically relieved by rest in 3–5 minutes and by sublingual nitroglycerin within 1–3 minutes. If > 10 minutes is consistently required to obtain relief with nitroglycerin, acute coronary disease may be present; or, if this pattern is chronic and stable, a diagnosis of atypical angina may be more appropriate. Patients often say that relief of symptoms is obtained by belching or taking antacids or other over-the-counter medications. Although these features may sway the clinician away from a diagnosis of typical angina, it should be remembered that even patients with acute MI may occasionally make such associations. Thus, in patients with suspected acute coronary disease, these historical elements alone should not be used as reasons for rejecting a diagnosis of typical angina if other features are consistent with the diagnosis.

TABLE 37.1

CANADIAN CARDIOVASCULAR SOCIETY CLASSIFICATION OF ANGINAL SYMPTOM SEVERITY

Class	Description
I	No symptoms with ordinary activity (e.g., walking, climbing stairs). Symptoms may occur with strenuous, rapid, or prolonged exertion.
II	Slight limitation of ordinary activity. Discomfort induced by walking or climbing stairs rapidly, walking uphill, walking more than 2 blocks on level ground, or climbing more than 1 flight of stairs at a normal pace.
III	Marked limitation of ordinary activity. Symptoms may occur after walking 1 or 2 blocks on level ground or climbing 1 flight of stairs at a normal pace.
IV	Severe limitation. Inability to carry on any level of exertion without inducing discomfort. Discomfort may also be present at rest.

From Campeau L. Grading of angina pectoris. *Circulation* 1976;54:522–523, with permission.

Associated Symptoms

During an anginal episode, a variety of associated symptoms may occur, including dyspnea, nausea, sweating, weakness, and palpitations. These symptoms by themselves are of little use in deciding whether a patient’s symptoms represent typical angina. Dyspnea resulting from myocardial ischemia is common with anginal discomfort and may also occur in isolation as an “anginal equivalent”. In the latter situation, it should have the other features of typical angina (e.g., reproducibly provoked by exertion or stress and relieved by rest or nitroglycerin).

Diagnostic Features of the Physical Examination

The physical examination contributes relatively little to the diagnosis of typical angina with underlying coronary disease. The physician should be very wary of rejecting the diagnosis of angina just because the patient agrees that a particular type of palpation of the chest wall or a certain movement causes chest pain. For this sign to be reliable, the pain must be *completely reproduced* by palpation.

Occasionally, the clinician has the opportunity to examine the patient during an episode of angina. Although the results of such an examination may be unremarkable, if the patient is noted to have a transient systolic murmur of mitral regurgitation, an S₃, or a paradoxically split S₂, and if these findings resolve after the anginal episode has been relieved, the diagnosis of typical angina with underlying

ischemia is greatly strengthened. The presence of vascular bruits or pulse deficits suggesting extracardiac vascular disease (carotid, peripheral, aortic, renal) is associated with a higher likelihood of significant CAD. Physical examination can also provide useful information on alternative diagnoses, such as hypertrophic cardiomyopathy or aortic valve disease.

Diagnostic Features of Initial Laboratory Tests

At the initial evaluation of the patient with suspected angina caused by CAD, a resting 12-lead electrocardiogram (ECG) (Table 37.2) and a chest radiograph should be obtained. The chest radiograph is not useful for the diagnosis of CAD but may be helpful in the differential diagnosis and assessment of prognosis. Laboratory markers of myocardial necrosis are indicated for patients with a presumptive diagnosis of unstable angina to exclude acute MI (see Initial Assessment of Prognosis).

Assessment of the Likelihood of Coronary Artery Disease

The likelihood (i.e., probability) that a patient has significant CAD (defined as stenosis ≥75% of the vessel diameter on a coronary angiogram) can be estimated with moderate accuracy from five features of the initial clinical examination and ECG (in order of importance): the

TABLE 37.2
ELECTROCARDIOGRAPHIC FINDINGS USEFUL FOR ESTABLISHING THE LIKELIHOOD OF CORONARY ARTERY DISEASE

Finding	Most likely cause	Alternate causes
ST-segment elevation ≥1 mm in 2 or more contiguous leads	Acute MI	Acute pericarditis Early repolarization Left ventricular aneurysm
ST-segment depression ≥0.5 mm	Ischemia or acute MI	Coronary spasm Normal heart Hyperventilation LV hypertrophy with strain Digitalis Hypokalemia Hypomagnesemia
Inverted T waves in 2 or more contiguous leads (≥2 mm in leads with dominant R waves, or marked symmetric precordial T-wave inversion)	Ischemia or acute MI	Normal heart Central nervous system disease
Pathologic Q waves in 2 or more contiguous leads	Recent or old MI	Hypertrophic cardiomyopathy Myocarditis Hypertrophic cardiomyopathy Chronic obstructive lung disease Pulmonary embolism Left ventricular hypertrophy Idiopathic cardiomyopathy

LV, left ventricular; MI, myocardial infarction.

physician's assessment of the patient's symptoms (as typical angina, atypical angina, or non-anginal pain); evidence of a prior MI (by history and pathologic Q waves on the ECG); gender; age; and number of major risk factors (diabetes, hypercholesterolemia, smoking, hypertension). A summary estimate of the patient's likelihood of significant CAD can be generated either informally by the clinician or by using one of several quantitative tools developed to assist in that process (Table 37.3).

If the patient has known CAD (e.g., a history of prior revascularization or CAD established by coronary angiography), then the diagnostic question of interest is whether the patient's symptoms are caused by CAD. This judgment is best based on the elements of the angina history described earlier.

Definition of Unstable Angina

Unstable angina is conceptually defined as the clinical syndrome that falls between stable angina (lower risk) and acute MI (higher risk). Operationally, it is often not possible (nor is it necessary) to separate patients with unstable angina from those with non-ST-elevation acute MI during the initial assessment process. What is important is to recognize that the patient has an *acute coronary syndrome* (ACS) and to decide quickly about the proper pace of evaluation and treatment.

The 1994 Agency for Health Care Policy and Research (AHCPR) guideline for unstable angina proposed three

principal presentations of unstable angina (2). Prolonged (≥ 20 minutes) episodes of rest angina are what most clinicians think of as unstable angina. However, the unstable angina guideline proposed two other circumstances in which a patient's short-term risk of cardiac events may be increased. All patients with new-onset angina are considered by some to be "unstable" because they have changed from a state of no symptoms to at least one symptom. However, this increased risk does not relate to the onset of symptoms *per se* but rather to the tempo, severity, and frequency of symptoms. Thus, new-onset or preexisting effort angina that progresses to the point where the patient cannot perform less-than-ordinary activity (Class III, Table 37.1) without provoking angina would be considered unstable angina.

The 2000 American College of Cardiology (ACC)/American Heart Association (AHA) Guideline used the term *unstable angina/non-ST elevation myocardial infarction* (NSTEMI) to emphasize the continuum between these manifestations of acute coronary disease (3). The term *acute coronary syndrome* (ACS) serves a similar purpose. The distinction of greatest initial therapeutic importance is between the patient with acute ST-elevation MI, who is eligible for reperfusion therapy, and other types of ACS.

Initial Assessment of Prognosis

Predicting the presence of a vulnerable but unruptured atherosclerotic plaque is not yet possible with available technology. Thus, assessment of prognosis focuses on

TABLE 37.3

LIKELIHOOD OF SIGNIFICANT CORONARY ARTERY DISEASE IN PATIENTS WITH SYMPTOMS SUGGESTING UNSTABLE ANGINA

High likelihood (e.g., 0.85–0.99)	Intermediate likelihood (e.g., 0.15–0.84)	Low likelihood (e.g., 0.01–0.14)

two main concepts: identifying the CAD patient with a plaque event early enough in the course to prevent progression to a catastrophic complication, and identifying those CAD patients who lack sufficient cardiac reserve to survive should a major plaque event occur.

Clinical and Electrocardiographic Factors Related to Short-term Prognosis

The tempo of a patient's anginal syndrome is assessed from the cardiac history, the 12-lead ECG, and examination of the patient during a symptomatic episode (when possible). Important adverse prognostic elements of the history include: a higher current frequency of episodes, an increase in the frequency of episodes during the last 4–6 weeks (and particularly during the last week), an increase in the duration or severity of symptoms (with emphasis on any symptom episodes lasting ≥ 20 minutes), progression from effort- or stress-related symptoms to symptoms at rest, new onset of symptoms that awaken the patient from sleep, and a significant decrease in the amount of effort needed to provoke symptoms. By using these features, the clinician can separate patients into high-, moderate- and low-risk subgroups (Table 37.4).

Factors Related to Both Short-term and Long-term Prognosis

The four factors most strongly predictive of survival should an acute plaque event occur are LV function, extent of ob-

structive CAD, age, and comorbid conditions. *LV function is the single most important predictor*; the worse the LV function, the more likely that a major plaque event will be fatal. A fatal outcome is also more likely when all three coronary arteries have significant stenosis in comparison with lesser degrees of CAD. Among comorbidities, diabetes and chronic renal insufficiency are particularly important for identifying high-risk patients (4, 5).

Integrated Clinical Risk Stratification

Two generations of risk stratification models have been developed for use in ACS patients. Earlier models, such as that by Goldman and colleagues in the Multicenter Chest Pain Study, were designed to improve decision making and triage in the emergency department (Figure 37.2). These models use history and ECG data but not cardiac biomarker data. More recent models focus on management decisions for patients admitted with ACS. These are typified by the TIMI (Thrombolysis in Myocardial Infarction) risk score for unstable angina/non-ST elevation MI (6) (Table 37.5).

Laboratory Markers of Myocardial Necrosis

Traditional risk stratification for acute coronary syndrome patients has rested on the clinician's initial history and physical examination and on the interpretation of the 12-lead ECG. During the last several years, new approaches have been developed based on markers of myocardial necrosis (Table 37.6).

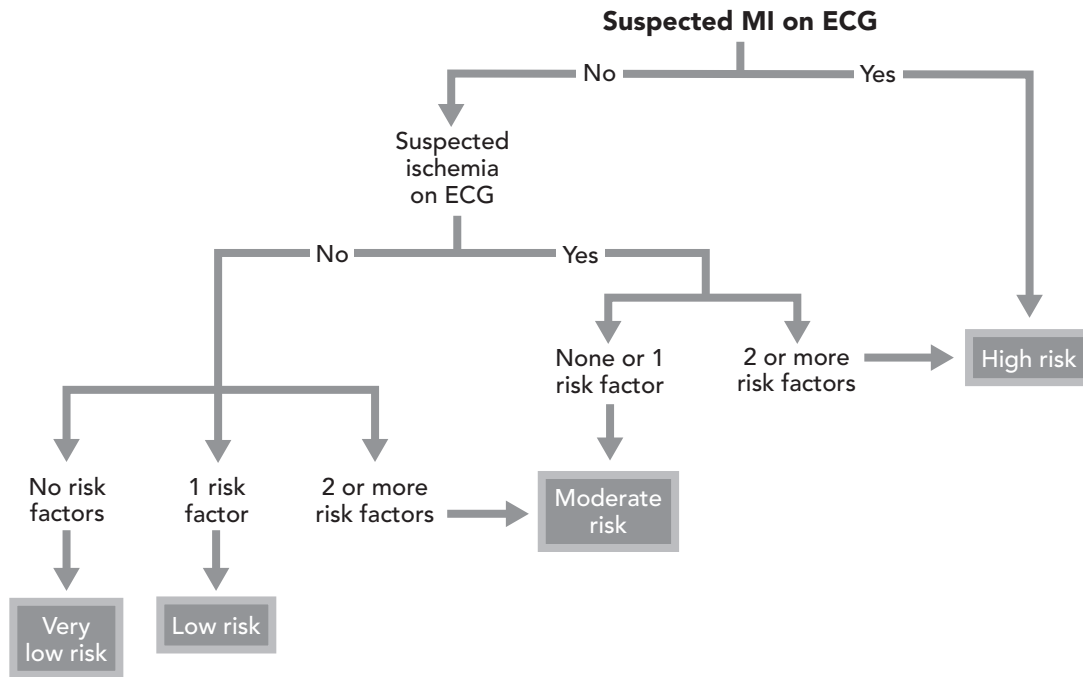

Figure 37.2 Stratification of patients with acute chest pain into 4 risk groups based on the initial electrocardiogram and the presence of clinical risk factors. Criteria for suspected myocardial infarction on the electrocardiogram were ST-segment elevation ≥ 1 mm or pathologic Q waves in 2 or more leads, with these findings not known to be old. Criteria for suspected ischemia were ST-segment depression ≥ 1 mm or T-wave inversion in 2 or more leads, with these findings not known to be old. Risk factors included systolic blood pressure < 110 mm Hg, rales above the lung bases bilaterally, and worsening symptoms of known ischemic heart disease. The recommended triage is generally admission to an intensive care unit for high- and moderate-risk patients. If appropriate, low- and very low-risk patients should generally be admitted to an intermediate care unit and a chest pain evaluation unit (if available), respectively. (Redrawn from Goldman L, Cook EF, Johnson PA, et al. Prediction of the need for intensive care in patients who come to emergency departments with acute chest pain. *N Engl J Med* 1996;334:1498–1504, with permission.)

Troponins have replaced creatine kinase (CK)-MB as the gold standard for detection of myocardial necrosis (7). The troponins are structural proteins that comprise part of the myocardial contractile apparatus. *Troponin T* (cTnT) exists in the myocyte, with about 95% bound to other structural proteins and 5% free in the cytosol. After damage to myocytes, elevated cTnT is detectable in the serum as early as 4–6 hours, and elevated levels remain detectable for 10–14 days. About 98% of *troponin I* (cTnI)

is bound to other myocyte proteins, and 2% is free in the cytosol. After myocardial damage, cTnI rises slightly later than cTnT, at about 6 hours, and remains elevated for 7–10 days. Both cTnT and cTnI are cleared more slowly in the presence of renal insufficiency. Thus, interpretation of elevated levels in this setting remains more difficult. Because cardiac troponins are immunologically distinct from troponins in non-cardiac muscle, they are extremely specific for the diagnosis of myocardial necrosis. Because of their prolonged period of elevation, they have also supplanted the use of lactate dehydrogenase (LDH) and LDH isoenzymes in the diagnosis of MI in patients who present late (i.e., > 24 –36 hours) after the onset of symptoms.

Studies of serial troponin testing have suggested that optimal risk stratification is obtained by measuring a troponin level at presentation and at 8 hours after presentation. Patients with negative troponin levels at 0 and 8 hours have a low mortality rate, and no further prognostic information is learned by obtaining a level at 16 hours. However, a negative finding before 8 hours does not provide the same level of reassurance and should not be used for purposes of triage.

TABLE 37.5
TIMI RISK SCORE FOR UNSTABLE ANGINA

Reprinted with permission from Newby LK, Ohman EM, Christenson RH. The role of troponin and other markers for myocardial necrosis in risk stratification. In: Topol EJ, ed. *Acute Coronary Syndromes*. New York: Marcel Dekker, 1998:405–435.

With the advent of these more heart-specific and sensitive troponin assays, some patients in whom unstable angina would have been diagnosed have been redefined as having small, non-ST-elevation MIs. Whether these patients should be labeled as “MIs” remains controversial and is actually less important than recognizing their positive troponin result as a marker of elevated risk. For example, in a meta-analysis of 16 studies involving around 4,500 non-ST elevation ACS patients, a positive troponin indicated a 5-fold increased risk (8). Mortality also increased linearly with increasing troponin levels. Troponin T and I had similar prognostic importance.

CK-MB, the myocardium-specific isoenzyme of creatine kinase, indicates myocardial necrosis but is not as specific as troponin (about 5% of skeletal muscle CK is of the CK-MB form). Non-heart-related elevations of CK-MB may be seen after surgery on or trauma to the small intestine, uterus, prostate, tongue, or diaphragm. Levels of CK-MB may also be elevated in chronic renal failure; in this situation, the absence of a characteristic rise and fall during several days should confirm the noncardiac etiology.

Initial Management

General Measures

When the patient is first seen, the clinician must decide if immediate stabilization measures need to be instituted during the initial diagnostic assessment. One of the most important initial questions the clinician must address is whether the patient is having an ST-elevation acute MI and has indications for emergency reperfusion therapy.

Patients with stable angina can usually be managed on an outpatient basis unless they have evidence of substantially increased risk, such as a high-risk result on a noninvasive stress test. Thus, most angina patients admitted to the hospital will have ACS.

As soon as the clinician has established a working diagnosis of unstable angina/acute coronary syndrome, therapy should be directed toward two goals: stabilizing the patient to prevent further disease progression and relieving symptoms (Table 37.7). Therapy should not be delayed until a decision has been made to admit the patient from the office or emergency department to the inpatient unit but rather should be guided by the prognostic risk assessment. For low-risk patients, further evaluation and therapy may be conducted on an outpatient basis. Generally, patients with intermediate- and high-risk features will require hospital admission. For some intermediate-risk patients, further evaluation and therapy can be performed in a chest pain unit or a short-stay unit, whereas others may be admitted to a step-down unit or an ICU. High-risk patients will typically start out in an ICU.

For all hospitalized ACS patients, initial therapy includes such general measures as bed rest until stabilization occurs, continuous ECG monitoring, and supplemental oxygen for those with respiratory distress or documented hypoxemia. As part of the early evaluation process, secondary causes for the development of a progressive or unstable course should be sought. These include tachyarrhythmias and bradyarrhythmias, high fever, hypotension or severe hypertension, and severe anemia. The initial evaluation may also suggest other responsible or contributory cardiac disorders (e.g., aortic valve disease, hypertrophic cardiomyopathy), hyperthyroidism, medical noncompliance (e.g., failure to refill prescriptions), or a recent increase in physical activity or emotional stress.

Antithrombin and Antiplatelet Therapy

In addition to these general measures, clinicians should generally use antithrombin and antiplatelet therapy in intermediate- and high-risk patients. All patients should promptly receive aspirin (an initial dose of 160, followed

TABLE 37.7**ACUTE MANAGEMENT OF ACS IN RELATION TO RISK FOR MYOCARDIAL INFARCTION OR DEATH**

	High risk	Intermediate risk	Low risk
General			
Treatment setting	ED → CCU	ED → CCU, step-down, or ward	ED → home
ECG monitoring	≥48 h	24 to 48 h	ED only
IV	Yes	Yes	No
Analgesic	IV opiate	Usually none unless recurrent chest discomfort	None

by 80 to 160 mg per day) unless it is contraindicated. For patients who are truly aspirin-allergic, clopidogrel (loading dose of 300 mg, followed by 75 mg/d) is a reasonable alternative. Based on the CURE trial, the ACC/AHA Guidelines recommend clopidogrel be administered in addition to aspirin in all non-ST elevation ACS patients who will not be referred for early intervention (i.e., first 24–36 hours) (9). In patients who are referred for early catheterization, clopidogrel should be held until the need for urgent coronary bypass surgery is assessed.

Intravenous heparin or subcutaneous enoxaparin (a low-molecular-weight heparin) should be started in most intermediate- and all high-risk patients who lack contraindications. Two randomized trials (ESSENCE and TIMI 11B) have demonstrated that enoxaparin reduced death or MI by 23% relative to unfractionated heparin in this population and has an equivalent risk of bleeding (10). In addition, it is more convenient to administer and does not require laboratory monitoring to assess the level of anticoagulation, as is necessary with unfractionated heparin (see Chapter 98).

Two intravenous glycoprotein IIb/IIIa (GP 2b/3a) receptor antagonists, eptifibatid and tirofiban, have been approved for use in acute coronary syndrome patients in the United States, and abciximab is approved for use in percu-

taneous coronary interventions (PCI). A GP IIb/IIIa antagonist should be administered in all ACS patients for whom catheterization and PCI are planned (11). Eptifibatid or tirofiban should also be given in high-risk patients (e.g., continuing ischemia, elevated troponin) who are not planned for PCI.

Symptomatic Therapy

Control of anginal symptoms is based on the use of nitrates, β-blockers, and opiates (Table 37.7). For patients with ongoing or recent prolonged or severe symptoms, parenteral therapy should be initiated. For others, nonparenteral (oral, topical) therapy may be sufficient. The use of calcium channel blockers in acute coronary syndromes remains controversial, but there is general agreement that these drugs should be reserved for symptom relief in patients in whom β-blocker therapy has failed or is contraindicated.

Response to Therapy

The vast majority of acute coronary syndrome patients respond within 30 minutes to the medical management described above with a clear improvement in symptoms and

other evidence of stabilization. Failure of patients to respond within this time frame should prompt the clinician to (re)consider other causes of severe chest discomfort (e.g., acute MI, aortic dissection, pulmonary embolus, or pneumothorax). If acute coronary disease still appears to be the correct diagnosis, consideration should be given to early referral for diagnostic cardiac catheterization and revascularization, placement of an intra-aortic balloon pump, or both. While arrangements are being made for these therapies, aggressive pharmacologic therapy should be continued in a carefully monitored setting.

Risk Stratification in a Chest Pain Unit

Approximately one-fourth of U.S. hospitals now have a chest pain unit in the emergency department. Patients admitted to a chest pain unit are typically those for whom the diagnosis of acute coronary syndrome or the risk level is uncertain after evaluation of initial clinical and ECG data (12).

Testing in the chest pain unit typically includes serial cardiac biomarkers: every 3 to 4 hours for CK-MB or at 0 and 8 hours for cTnT. Patients with positive biomarkers by 8–9 hours are admitted for further evaluation. In some centers, patients with nondiagnostic ECGs may also undergo acute imaging with echocardiography or a nuclear perfusion agent to detect evidence of severe ischemia or infarction. Patients with negative biomarkers may then undergo an exercise or pharmacologic stress test in the chest pain unit before the final triage decision is made. Numerous test combinations are possible to provide adequate risk stratification for clinical management and triage purposes (Chapter 36). In the experience of several large centers, only about 15% of chest pain unit patients will require hospital admission.

ISSUES DURING THE COURSE OF HOSPITALIZATION

The hospital course of patients with acute coronary disease can be conceptually divided into three major phases: completion of stabilization, risk stratification, and selection of definitive therapy.

Completion of Stabilization

It is desirable for patients initially requiring ICU or step-down care to experience a 24-hour period of freedom from recurrent ischemic episodes, hemodynamic abnormalities, decompensated heart failure, or other complications before being transferred to a less intensive environment. Patients who have been symptom-free for ≥ 24 hours before admission and do not have evidence of heart failure or other complications may proceed directly to the risk-stratification phase.

Aspirin should be continued at a daily dose of 80–160 mg. In general, patients who are at sufficiently high risk to

require therapy with either unfractionated or low-molecular-weight heparin should continue this therapy for 2–5 days or until a revascularization procedure is performed. In large clinical trials of acute coronary syndrome patients, U.S. physicians typically use antithrombin therapy for 2.5–3 days, whereas physicians in Canada and Western Europe tend to use such therapy for 4–5 days or more. These trials do not show any difference in event rates associated with the duration of therapy. Because the shorter duration of U.S. therapy is coupled with a substantially higher rate of revascularization procedures, it is unclear whether the U.S. pattern of care also defines the minimum duration of antithrombin therapy needed when a less invasive management style is practiced.

The duration of glycoprotein IIb/IIIa inhibitor therapy in clinical trials has generally been for 72 hours or until the time of revascularization. For patients undergoing percutaneous revascularization, eptifibatid and tirofiban are usually continued for another 24 hours after the procedure.

Risk Stratification

Management of the patient with ACS requires ongoing risk stratification with appropriate modification of therapy. Initial risk stratification is based on the admission evaluation and the clinical course during the early hospital stay. Once the patient's condition has stabilized, the clinician needs to assess the longer-term prognosis, especially for the next 3–6 months, and decide what additional tests and modifications of therapy are required to protect the patient from (further) cardiac complications, to reassure the patient, and to return the patient to as full and unimpaired a lifestyle as possible. Three main options are available: (1) proceed directly to diagnostic cardiac catheterization; (2) perform a noninvasive exercise or pharmacologic stress test; or (3) neither. For almost all patients hospitalized with ACS, some form of risk stratification testing should be performed once they have been stable without angina or heart failure for 48 hours. Patients with extensive comorbidity who would not be candidates for revascularization are a potential exception.

Two approaches to the use of cardiac catheterization in this setting have been studied: early invasive and early conservative (11). In the *early invasive strategy*, diagnostic catheterization is performed routinely in all hospitalized unstable angina patients who do not have contraindications, usually within 48 hours of admission. In the *early conservative strategy*, diagnostic catheterization is performed routinely in patients with one or more of the following high-risk indicators: persistent or recurrent angina/ischemia despite intensive medical therapy, elevated troponin, prior revascularization (coronary artery bypass graft, percutaneous coronary intervention), associated heart failure or depressed LV function (ejection fraction < 0.40) by noninvasive study, malignant ventricular arrhythmias, and a high-risk noninvasive stress test result.

If the early conservative strategy is chosen, choice of the stress testing modality for the non-high-risk patients should be based on a consideration of 3 factors: the patient's resting 12-lead ECG, the ability of the patient to walk on a treadmill or pedal a bicycle, and the local expertise and testing modes available. Although imaging stress tests have better sensitivity and specificity for the diagnosis of significant CAD than does an exercise ECG test, there is no convincing evidence that their improved accuracy translates into improved patient management among patients with a normal baseline ECG who are not taking digoxin. Hence, the exercise treadmill test is the standard choice for these patients. Patients with significant resting ST-segment depression (≥ 1 mm), ST changes associated with digoxin, left bundle branch block, intraventricular conduction delay, or LV hypertrophy should have an exercise imaging test (e.g., a sestamibi or thallium perfusion scan or an echocardiogram). Patients unable to exercise should have a pharmacologic stress imaging study. At centers where multiple testing options are available, choice of testing mode should be based primarily on local expertise (see also Chapter 36).

The results of stress testing can be partitioned into low-risk, intermediate-risk, and high-risk categories. Patients with low-risk test results generally have an annual cardiac mortality rate below 1% and can be safely managed medically. High-risk test results typically predict an annual cardiac mortality rate of 4% or more and should usually prompt referral for cardiac catheterization. Patients with intermediate-risk test results typically require either an additional stress test or cardiac catheterization to clarify their prognosis. Alternatively, a rest echocardiogram may be performed. If depressed resting LV function is found in a patient with an intermediate-risk stress test result, referral to catheterization should strongly be considered. If the resting LV function is normal, medical therapy or a second stress test are reasonable options.

Selection of Definitive Therapy

The available evidence supports three general conclusions: First, a patient who cannot be adequately stabilized with appropriate medical therapy or who has clear indication of high risk based on clinical or stress test criteria, as discussed in the previous section, should usually be referred promptly for coronary angiography. Second, with current medical therapy, there does not appear to be any excess risk if angiography is deferred for the remaining patients. For example, in patients in the conservative arm in TACTICS-TIMI 18 who did not undergo angiography (49%), the death and nonfatal MI rate at 30 days was 2.4% (13). Patients over age 65, however, may benefit from a routine aggressive strategy (14). Third, controlling the atherosclerotic disease process provides the key to reducing the risk for a future cardiac event. Hence, *all patients should have a careful evaluation of their modifiable cardiac risk factors*, particularly lipids, smoking, blood pressure, and diabetes. Patients

with a low-density lipoprotein (LDL) cholesterol level above 100 mg/dL should begin statin therapy, with an LDL goal of about 60 mg/dL (15). Blood pressure and blood glucose control should be reviewed in patients in whom these parameters are elevated. Smoking cessation resources in the local environment should be identified and offered to patients who smoke.

ISSUES AT THE TIME OF HOSPITAL DISCHARGE

The achievements of the hospitalization should be compared at least daily with the management goals established by the clinician in conjunction with the patient. These goals typically include stabilization of the clinical course, effective relief of symptoms, completion of the most important diagnostic tests, and design of a longer-term management strategy. The need for continued hospitalization is then based on whether these goals have been achieved. In the modern era, with its tremendous financial pressures on hospitals and providers, the clinician must decide which goals need to be achieved in the hospital and which can be shifted to the post-discharge outpatient phase. In general, effective stabilization of the clinical course, relief of symptoms, and risk stratification should be achieved in the hospital. Lower-risk patients who have responded well to therapy can then be targeted for accelerated discharge.

Patients who have undergone successful revascularization will usually have their post-procedure length of stay defined by the evolving standard practice for the given procedure. Patients who are treated medically include both a low-risk group that can be discharged virtually immediately after their primary risk stratification test (e.g., stress test or cardiac catheterization) and a higher-risk group. These latter patients, who are typically either unwilling to have or unsuitable for revascularization, may require additional time to stabilize their disease.

Unless the diagnosis of CAD has been effectively excluded during the hospitalization, all patients should be discharged on aspirin therapy at a daily dose of 80–160 mg. Recent data have suggested an increased risk of bleeding with chronic aspirin doses above 160 mg (16). There are also data indicating less complete platelet inhibition with lower doses of aspirin, so the optimal dose for the ACS patient remains controversial. Patients with a true aspirin allergy should be given 75 mg/day of clopidogrel as an alternative antiplatelet agent. Continued anti-anginal therapy is required after discharge except in patients who have undergone successful revascularization earlier in the hospitalization. β -blockers are the cornerstone of anti-anginal therapy and should be strongly considered for secondary prevention in all CAD patients without contraindications. Long-acting nitrates often provide incremental anti-anginal benefit. Calcium channel blockers should be reserved for patients who require triple anti-anginal drug therapy or

who truly cannot tolerate (or have contraindications to) β -blockers; current recommendations are to avoid short-acting dihydropyridine calcium channel blockers (e.g., nifedipine) in patients with CAD. Patients who are not revascularized and who required medical therapy to achieve stabilization should be continued on the regimen found to be effective (e.g., nitrates, β -blockers). In general, long-acting agents are preferred to maximize compliance. However, efforts should also be made to determine whether there are financial barriers for the patient to continue the prescribed regimen. It is better to have the patient take a few effective, affordable medications than to not take an elegant but expensive multidrug regimen. In addition to the longer-acting agents, all patients likely to experience recurrent angina should be given sublingual nitroglycerin and instructed in its use.

A well-defined risk factor modification plan should be in place at the time of hospital discharge. Because of the current brevity of many hospital stays, some of the objectives of the plan will necessarily have to be achieved on an outpatient basis. Specific issues to consider include the following:

- No patient who smokes at the time of admission should be allowed to leave the hospital without being strongly advised to quit smoking permanently. If the patient lives in a household where others smoke (e.g., spouse, children), these household members should also be strongly advised to quit.
- Pharmacologic assistance and smoking cessation counseling programs should be strongly considered.
- Blood pressure and blood glucose control are critical.
- A lipid panel (total, LDL, and HDL cholesterol; triglycerides) should ideally be checked within 24 hours of hospital admission and appropriate therapy started or adjusted. Otherwise, lipids should be checked 8 weeks after admission by the patient's outpatient physician.

An elevated level of *plasma homocysteine* has recently been added to the list of potentially modifiable risk factors for CAD (17). One recent clinical trial demonstrated that dietary folate supplementation significantly decreases plasma homocysteine levels, and epidemiologic studies have associated supplemental intake of folate and vitamin B₁₂ with reduced risk for coronary heart disease. Increasing numbers of clinicians are advising their CAD patients to take supplemental B vitamins on empiric grounds. Clinical trials of vitamin E have not shown overall benefit.

Whenever possible, the initial follow-up visit should be set at the time of discharge. Low-risk patients and those with successful uncomplicated revascularization should generally be seen for an outpatient visit 2–6 weeks after discharge. Higher-risk patients should usually be seen sooner (e.g., 1–2 weeks).

In the pre-discharge encounter, the patient should be given instructions about appropriate activities (e.g., resumption of sexual activity, driving), returning to work,

daily exercise, and diet. There is very little evidence to guide such recommendations, so they tend to be based on clinical judgment and experience. Referral to an outpatient cardiac rehabilitation program can help the patient achieve the dietary, behavioral, and exercise goals necessary to maximize recovery potential.

COST CONSIDERATIONS AND RESOURCE USE

In the admission phase, use of a chest pain unit with appropriate evaluation and triage protocols can reduce the cost and improve the efficiency of evaluation for patients about whom the clinician remains uncertain after initial evaluation (12). Appropriate risk stratification can also improve care efficiency and reduce costs by ensuring that only the highest-risk patients are admitted to the ICU, most expensive hospital unit.

As soon as the patient has been stabilized for 24 hours, the clinician can begin planning the approach to risk stratification, either early aggressive or early conservative. Although the early aggressive strategy is initially more expensive, in TACTICS-TIMI 18 the early conservative strategy lost some of its initial cost advantage because of an increased rate of follow-up rehospitalizations.

KEY POINTS

- Initial diagnostic and prognostic assessment in the emergency department or clinic is based on the history, physical examination findings, and 12-lead ECG data and determines the need for immediate therapy and the next set of diagnostic tests.
- A troponin level measurement at 0 and 8 hours provides powerful additional prognostic information.
- All ACS patients should receive daily aspirin therapy unless contraindicated. Addition of clopidogrel to aspirin for the first 9 months is supported by the CURE trial.
- Intermediate- and high-risk patients should also have parenteral antithrombin (heparin or enoxaparin) and parenteral antiplatelet (eptifibatid or tirofiban) therapy for 2–5 days.
- Patients who fail to stabilize or who have high-risk features should be considered for early coronary angiography.
- Non-high-risk patients with a 24-hour symptom- and complication-free period can be managed with either routine coronary angiography or noninvasive stress testing (angiography reserved for those with high-risk test results).
- All patients should have careful assessment of lipid levels, smoking status, blood pressure, and diabetes status.

Acute Myocardial Infarction

38

Daniel I. Simon James C. Fang Naomi Kenmotsu Rounds

INTRODUCTION

The contemporary management of acute myocardial infarction (MI) exemplifies the notion that evidence-based medical therapies save lives. Guided by prospective, randomized clinical trials in well over 250,000 patients worldwide and further refined by meta-analyses, current MI therapy has contributed significantly to the marked reduction of average in-hospital MI mortality. Rates dropped from approximately 30% in the 1960s to less than 10% in the present era of reperfusion (i.e., fibrinolysis and primary percutaneous coronary intervention [PCI]). An expedient approach to the assessment and treatment of patients with acute MI focuses on diagnosis, risk stratification, and evidence-based pharmacologic and mechanical interventions aimed at maximizing survival in the context of streamlined critical pathways.

MI commonly occurs secondary to atherosclerotic plaque rupture and thrombosis that results in acute coronary artery occlusion. Less commonly (<10% of cases), MI results from coronary artery embolism, spasm, spontaneous dissection, vasculitis, or a variety of congenital abnormalities (e.g., anomalous coronary artery origin, myocardial bridge). Clinical, pathologic, and experimental data have reshaped the current pathophysiologic understanding of acute ischemic syndromes. Angiography performed in the acute MI setting has demonstrated that mild or moderate (<50% of vessel diameter) rather than severe stenosis is responsible for plaque rupture in most infarct-related arteries. In vulnerable plaques populated by a variety of inflammatory cells, including macrophages and T lymphocytes, a thin, fibrous cap separates the thrombotogenic lipid core from the lumen. Inflammation secondary to metabolic, environmental, physical, and possibly infectious injury is an important mechanism of vulnerable plaque development. Clinical cardiologists and vascular biologists

now focus on the fine structure of the plaque and the integrity of extracellular matrix proteins in the vessel wall, such as collagen and elastin, as determinants of the clinical manifestations and complications of atherosclerosis.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

The alerting symptom of MI is chest pain, which is typically described as severe and prolonged pressure, crushing, burning, or constricting discomfort. However, many patients use different descriptors, such as aching, burning, fullness, or even indigestion or gas. Ischemic chest pain is classically located in the retrosternal, left thoracic, or epigastric regions and may radiate to the neck and shoulders, jaw, back, or arms. Accompanying symptoms may include nausea, vomiting, diaphoresis, dyspnea, and lightheadedness. Not all patients present with typical symptoms of MI. Up to 25% of nonfatal MIs occur silently or with vague, atypical symptoms. Atypical presentations, which occur more commonly in women, the elderly, and in patients with diabetes mellitus, are characterized by severe weakness, heart failure, neurologic manifestations resulting from cerebral hypoperfusion (syncope and mental status changes), and evidence of peripheral embolization.

DIFFERENTIAL DIAGNOSIS AND INITIAL EVALUATION

The differential diagnosis for patients who present with chest pain (Chapter 35) includes pericarditis, aortic dissection, pleuritis, pulmonary embolism, gastrointestinal disease, and

musculoskeletal pain. *Pericarditis* (Chapter 46) is characterized by retrosternal pain with positional change (improvement with sitting up and leaning forward). Its pain may be described in the same way as that of classic myocardial ischemia or may be pleuritic in nature. The pain of *aortic dissection* (Chapter 49) is described as sudden, severe, or “ripping” retrosternal discomfort that radiates to the back or legs, worst at its onset, and often associated with pulse deficits. *Pleuritis*, frequently associated with pneumonia, consists of a sharp, knifelike pain that is exacerbated with inspiration. *Pulmonary embolism* (Chapter 53) presents with pleuritic pain accompanied by dyspnea and occasionally hemoptysis. The pain of *costochondritis* is localized and often aggravated by palpation of costochondral joints. *Gastrointestinal causes of chest discomfort* include reflux esophagitis, esophageal spasm, peptic ulcer disease, and cholecystitis.

MI is a medical emergency. The rapid diagnosis of MI is prerequisite for early, life-saving treatment. The diagnosis of MI is based on the presence of at least two of three criteria: a clinical history of ischemic chest discomfort (Chapter 35), changes in serial electrocardiograms (ECGs), and a pattern of rise and fall in serum cardiac markers (Table 37.6). Within 10 minutes of a patient’s arrival at the emergency department, a 12-lead ECG should be obtained. ST-segment elevation of 1 mm or more in at least two contiguous leads or a new left bundle branch block is highly suggestive of ST-elevation MI (STEMI). These patients should be screened immediately for reperfusion therapy with fibrinolysis or primary PCI (see later in this chapter).

Patients with ST-segment depressions or new T-wave inversions may be experiencing a non-ST-segment elevation MI (NSTEMI) or unstable angina and should also be treated as if they are having an MI. Differentiating patients presenting with ST-segment elevation from those without ST-segment elevation is useful clinically, for both prognostic and treatment purposes. In general, STEMI are larger (as assessed by peak biomarker levels) and are associated with higher rates of in-hospital mortality. In contrast, NSTEMIs are smaller and associated with lower

in-hospital mortality, but they are notable for at least equivalent rates of recurrent ischemia and MI in the subsequent year. Importantly, from a management standpoint, certain interventions that have resulted in significant mortality reductions in STEMI, such as fibrinolysis, are not beneficial in patients who present with only ST-segment depression or T-wave inversion (i.e., NSTEMI).

Indications for Hospitalization

All patients with MI or suspected MI should be admitted to the hospital. The clinical presentation and outcomes of patients with MI are heterogeneous. Therefore, rapid risk stratification of MI patients is crucial for appropriate therapies and management. Mortality from MI ranges from 1.5% in low-risk groups to more than 80% in high-risk groups. The Killip and Forrester classifications were developed in the era before fibrinolysis and are based on simple physical examination findings or hemodynamic variables, respectively (Table 38.1). The more current Thrombolysis in Myocardial Infarction (TIMI) risk classification is based on nine risk factors easily obtained from clinical history, physical examination, and ECG (Table 38.2). Age is a particularly powerful independent predictor of both in-hospital and 6-month mortality rates. The GISSI (Gruppo Italiano per lo Studio della Sopravvivenza nell’Infarto Miocardico) investigators reported that in patients who presented with a first MI and received thrombolytic therapy, overall in-hospital mortality was 1.9% among patients less than 40 years old but nearly 32% among those more than 80 years old. Multivariate analysis showed that relative risk increased by about 6% annually.

Indications for Initial Coronary Care Admission

Patients with STEMI who present within 24 hours of symptom onset should be admitted to the cardiac care unit

TABLE 38.1

RISK STRATIFICATION OF PATIENTS WITH ACUTE MYOCARDIAL INFARCTION

A. Based on clinical examination			B. Based on invasive monitoring		
Class	Definition	Mortality	Subset	Definition	Mortality
I	Rales and S ₃ absent	6%	I	Normal hemodynamics, PCWP <18, CI >2.2	3%
II	Rales or S ₃	30%	II	Pulmonary congestion, PCWP >18, CI >2.2	9%
III	Rales over >50% of lung fields (pulmonary edema)	38%	III	Peripheral hypoperfusion, PCWP <18, CI <2.2	23%
IV	Shock	81%	IV	Pulmonary congestion and peripheral hypoperfusion, PCWP >18, CI <2.2	51%

CI, cardiac index; PCWP, pulmonary capillary wedge pressure.

Correlative classification of clinical and hemodynamic function after acute myocardial infarction. *Am J Cardiol* 1997;39:137–145, with permission.

TABLE 38.2
RISK STRATIFICATION: TIMI CLASSIFICATION

Risk factors (No.) ^a	Patients (%)	Mortality (%)
0	26	1.5
1	42	2.3
2	21	7.0
3	7	13.0
≥4	3	17.2

^a Risk factors: anterior myocardial infarction, prior myocardial infarction, age >70 y, female sex, diabetes, atrial fibrillation, rales >1/3 of lung fields, hypotension (systolic blood pressure <100 mm Hg), and sinus tachycardia (heart rate >100 beats/min). Reprinted with permission from Hillis LD, Forman S, Braunwald E, and the Thrombolysis in Myocardial Infarction (TIMI) Investigators. Risk stratification before thrombolytic therapy in patients with acute myocardial infarction. *J Am Coll Cardiol* 1990;16:313–315.

(CCU). In addition, all high-risk MI patients (large MI, Killip class II through IV, history of previous MI, age >70 years), patients with persistent ischemic chest pain, early sustained ventricular arrhythmias, or heart block, and patients requiring devices such as an intraaortic balloon pump or temporary pacemaker require CCU level of care. In some hospitals, low-risk MI patients (age <70 years, small MI, no previous MI, Killip class I) may be admitted directly to an intermediate care telemetry unit with ECG monitoring and defibrillation equipment.

Initial Therapy

The goal of MI therapy is to prolong survival by limiting infarct size, repeated infarction, and mechanical complications that lead to pump failure and by preventing sudden death secondary to arrhythmias. It is useful to categorize interventions into those that increase coronary blood flow—recanalization therapy (thrombolytic agents, primary PCI, antithrombotic agents), decrease myocardial oxygen consumption (β -blockers, nitrates, calcium channel blockers), or prevent sudden arrhythmic death (lidocaine, β -blockers) (Table 38.3). Some treatments such as magnesium and angiotensin-converting enzyme (ACE) inhibitors, have multiple effects that may together have a positive impact on MI therapy. Management of MI patients should focus on the pharmacologic and mechanical interventions that unequivocally save lives as determined by prospective, randomized trials: thrombolytic therapy, primary PCI, aspirin, β -blockers, and ACE inhibitors (Table 38.3).

ST Elevation MI

All patients with STEMI should be rapidly assessed for treatment with fibrinolysis or primary PCI with balloon angioplasty and/or stenting. The goal of early recanalization

therapy is to salvage ischemic but viable myocardium, thereby preserving left ventricular (LV) function. Because the wavefront of irreversible ischemic injury progresses over time from subendocardium toward the subepicardium, with nearly transmural necrosis occurring by 6 hours of coronary occlusion in animal models, the degree of myocardial salvage with reperfusion is highly time-dependent.

Although fibrinolysis remains the standard in many institutions, substantial data suggest the superiority of prompt primary PCI. Primary PCI at experienced centers is a superior method of canalization; its routine use in clinical practice is limited (presently about 20% of patients with STEMI in the United States) by lack of availability or unavoidable delays in mobilizing the cardiac catheterization laboratory. Rapid triage of patients to fibrinolysis or to the cardiac catheterization laboratory for PCI requires an algorithmic approach (Figure 38.1).

Recanalization Fibrinolysis

During the past decade, several intravenous (IV) fibrinolytic trials have demonstrated an unequivocal reduction in mortality. Meta-analysis of all trials of fibrinolytic therapy (versus control) that randomized more than 1,000 patients indicates that thrombolytic therapy reduces 35-day mortality on average by 18%, with significant benefits observed with treatment from 0 to 12 hours after the onset of symptoms. Thrombolytic therapy has been estimated to save 39 lives per 1,000 patients treated in the first hour, compared with fewer than 7 lives saved per 1,000 patients treated 13

APSAC, anisoylated plasminogen streptokinase activator complex; ASA, aspirin; IABP, intraaortic balloon pump; PTCA, percutaneous transluminal coronary angioplasty; rPA, recombinant plasminogen activator; SK, streptokinase; t-PA, tissue plasminogen activator.

to 24 hours after the onset of chest pain. Fibrinolysis may also be considered in certain patients who present late (>12 hours), but clinical benefit may be marginal, as suggested by the preponderance of trial experience (Table 38.4).

The comparative efficacy of different thrombolytic regimens (Table 38.5) is a controversial topic. Three large trials have directly compared these agents. GISSI-2 compared streptokinase (SK) and non-accelerated tissue plasminogen activator (t-PA), with or without subcutaneous heparin, and found no mortality difference (8.9% vs. 8.5%). ISIS-3 (Third International Study of Infarct Survival) examined SK, t-PA, and anisoylated plasminogen streptokinase activator complex (APSAC) and found all three were associated with sim-

ilar mortality rates (10.5%, 10.3%, and 10.6%, respectively). Because both trials were criticized for inadequate IV heparin therapy, especially with t-PA, GUSTO-1 investigated four thrombolytic strategies utilizing accelerated t-PA, SK, and IV or subcutaneous (SC) heparin (1). A 14% relative mortality reduction was seen with the accelerated t-PA regimen (6.3% t-PA vs. 7.3% SK), resulting in 9 net lives saved per 1,000 patients treated with t-PA in comparison with SK.

Several variants of t-PA have also been approved as fibrinolytic agents, including rPA (reteplase) and single bolus TNK-tPA (tenecteplase). Double bolus rPA does not offer any advantage over accelerated t-PA except for its ease of administration, which facilitates more rapid treatment and may reduce medication errors. Single-bolus

TABLE 38.4
REPERFUSION THERAPY

Recommendations	Class I	IIa	IIb	III	Level of Evidence
Reperfusion therapy is indicated in all patients with history of chest pain/discomfort of <12 h and associated with ST-segment elevation or (presumed) new bundle-branch block on the ECG	X				A
Primary PCI					
• preferred treatment if performed by experienced team <90 min after first medical contact	X				A
• indicated for patients in shock and those with contraindications to fibrinolytic therapy	X				C
• GP IIb/IIIa antagonists and primary PCI					
no stenting	X				A
with stenting		X			A
Rescue PCI					
• after failed fibrinolysis in patients with large infarcts		X			B
Fibrinolytic treatment					
In the absence of contraindications (see Table 38.5) and if primary PCI cannot be performed within 90 min after first medical contact by an experienced team, pharmacological reperfusion should be initiated as soon as possible	X				A
• choice of fibrinolytic agent depends on individual assessment of benefit, risk, availability, and cost					
In patients presenting late (>4 h after symptom onset), a more fibrin-specific agent such as tenecteplase or alteplase is preferred		X			B
For dosages of fibrinolytic and antithrombin agents, see Tables 39.5 and text					
• pre-hospital initiation of fibrinolytic therapy if appropriate facilities exist	X				B
• readministration of a non-immunogenic lytic agent if evidence of reocclusion and if mechanical reperfusion is not available		X			B
• if not already on aspirin, 150–325 mg chewable aspirin (no enteric-coated tablets)	X				A
• with alteplase and reteplase, a weight-adjusted dose of heparin should be given with early and frequent adjustments according to the aPTT	X				B
• with streptokinase, heparin is optional		X			B

Class I, evidence and/or general agreement that treatment is effective; Class II, conflicting evidence on efficacy (A-weight of evidence favors treatment; B-effectiveness less well established); Class III, evidence and/or general agreement that treatment is not effective and may be harmful. Management of Acute Myocardial Infarction in Patients presenting with ST-Segment Elevation *EurHeart J* 2003;24:28–66.

weight-adjusted TNK-tPA is equivalent to accelerated t-PA in terms of 30-day mortality and is associated with significantly lower rates of non-cerebral bleeding and need for transfusion.

Regardless of the choice of thrombolytic agents, the important goal appears to be early coronary artery patency. The angiographic substudy of GUSTO-1 demonstrated the lowest mortality (4.4%) in patients with normal coronary blood flow (TIMI grade 3) 90 minutes after fibrinolysis, in comparison with those having no or minimal flow (TIMI grade 0 or 1, 8.9% mortality) or delayed flow (TIMI grade

2, 7.4% mortality) (1). The most common complications of thrombolytic therapy involve bleeding. Although most bleeding is minor, vascular interventions after fibrinolysis may lead to more serious hemorrhagic complications at the groin site. The incidence of intracranial hemorrhage ranges from 0.26% to 2.2%; a higher risk is associated with older age (>65 years), hypertension, and use of t-PA rather than SK. Another potential complication of SK or APSAC involves allergic reactions, which may occur in 1.7% of patients; the risk is greater in those with previous exposure to streptococcal infection or SK products. Recent data suggest

TABLE 38.5**THROMBOLYTIC REGIMENS AND CRITERIA FOR FIBRINOLYSIS IN ACUTE MYOCARDIAL INFARCTION**

Indications	Contraindications
<ul style="list-style-type: none"> ■ Chest pain consistent with acute MI ■ Electrocardiographic changes ST-segment elevation >0.1 mV in at least two contiguous leads New or presumably new left bundle branch block ■ Time from onset of symptoms <12 h <p>Regimens</p> <ul style="list-style-type: none"> ■ APSAC 30-U IV bolus over 2–5 min ■ Reteplase (r-PA): 10-U IV bolus over 2–5 min, followed 30 min later by an additional 10-U IV bolus ■ Streptokinase (SK): 1.5 million IU IV over 60 min ■ Alteplase (t-PA): <ul style="list-style-type: none"> >67 kg: 15-mg IV bolus, followed by 50 mg infused over the next 30 min, and then 35 mg infused over the next 60 min <67 kg: 15-mg IV bolus, followed by 0.75 mg/kg infused over the next 30 min not to exceed 50 mg, and then 0.5 mg/kg over the next 60 min not to exceed 35 mg ■ Tenecteplase (TNK-tPA) <ul style="list-style-type: none"> single IV bolus 30 mg if <60 kg 35 mg if 60 to <70 kg 40 mg if 70 to <80 kg 45 mg if 80 to <90 kg 50 mg if ≥90 kg 	<p>Absolute</p> <ul style="list-style-type: none"> ■ Active internal bleeding (excluding menses) ■ Suspected aortic dissection ■ Recent head trauma or known intracranial neoplasm ■ History of cerebrovascular accident known to be hemorrhagic ■ Major surgery or trauma <2 wk previously <p>Relative^a</p> <ul style="list-style-type: none"> ■ Blood pressure >180/110 mm Hg on at least two readings ■ History of chronic, severe hypertension with or without drug therapy ■ Active peptic ulcer ■ History of cerebrovascular accident ■ Known bleeding diathesis or current use of oral anticoagulants regardless of INR ■ Prolonged or traumatic cardiopulmonary resuscitation ■ Diabetic hemorrhagic retinopathy or other hemorrhagic ophthalmic condition ■ Pregnancy

^a These should be considered on a case-by-case analysis of risk versus benefit. In instances in which these contraindications (particularly 1 through 5) have paramount importance, such as active peptic ulcer with history of bleeding, they become absolute contraindications when weighed against a less than life-threatening, evolving acute MI.

MI, myocardial infarction; APSAC, anisoylated plasminogen streptokinase activator complex; r-PA, recombinant plasminogen activator; t-PA, tissue plasminogen activator; SK, streptokinase; INR, international normalized ratio.

that routine post-thrombolysis coronary angiography and appropriate subsequent interventions improve 1-year outcomes compared with a conservative strategy.

Recanalization by Primary PCI

Canalization with primary revascularization by PCI or bypass grafting offers an alternative way to salvage ischemic but viable myocardium. Primary balloon angioplasty results in early and rapid patency recanalization of the infarct-related artery, with a technical success rate above 90% and in-hospital mortality rates <7–8%. The landmark Primary Angioplasty in Myocardial Infarction (PAMI) trial demonstrated significantly decreased death or nonfatal reinfarction at 6 months with immediate balloon angioplasty (9%), compared to fibrinolysis with t-PA (17%). In addition, angioplasty was accompanied by a 0% stroke rate and shorter mean time to resolution of chest pain (290 versus 354 minutes).

More than 20 head-to-head randomized trials have randomly assigned nearly 8,000 thrombolytic-eligible patients with STEMI to primary PCI (balloon angioplasty or stenting) or thrombolytic therapy. Recent meta-analysis of these trials

showed that primary PCI was better than thrombolytic therapy at reducing short-term death (7% vs. 9%, $P = 0.0002$), non-fatal reinfarction (3% vs. 7%, $P < 0.0001$), stroke (1% vs. 2%, $P = 0.0004$), and the combined endpoint of death, non-fatal reinfarction, and stroke (8% vs. 14%, $P < 0.0001$) (2). The results seen with primary PCI remained better than those with thrombolytic therapy during long-term follow-up, and were independent of the type of thrombolytic agent used and whether or not the patient was transferred for primary PCI. This meta-analysis suggests that for every 1,000 patients treated with primary angioplasty rather than thrombolytic therapy, an additional 20 lives are saved, 43 reinfarctions are prevented, 10 fewer strokes occur, and 13 intracranial hemorrhages are prevented. Myocardial salvage is greater with PCI, and primary PCI gives better results than thrombolytic therapy even in community hospitals without on-site surgical back-up (3). Most importantly, primary PCI reduces death, recurrent MI, or stroke compared with front-loaded t-PA (8.5% versus 14.2%, $P < 0.002$) even when patients need to be transferred by ambulance (taking up to 3 hours) to reach an interventional center (4).

Unfortunately, the current average door-to-balloon times in the United States exceed the 2-hour goal, and

transfer patients average more than 3 hours (4). Efforts to improve clinical outcome when timely angioplasty is unavailable have focused on “facilitated angioplasty,” which is the combination of pharmacologic reperfusion with mechanical revascularization (5). However, randomized trials have found that facilitated angioplasties are either inferior to or no better than primary PCI alone (6).

Treatments that may be Common to STEMI and NSTEMI

Treatment of patients with NSTEMI/unstable angina is covered extensively in Chapter 37. Differentiating patients with STEMI and NSTEMI is critical from a management standpoint, since certain interventions that have resulted in significant mortality reductions in STEMI are not beneficial in patients who present with NSTEMI. In general, all patients presenting with acute coronary syndromes should be treated with aspirin, heparin, and clopidogrel. In higher risk patients, such as those presenting with STEMI or NSTEMI/unstable angina with refractory ischemia, positive cardiac biomarkers, ST-segment depression, hemodynamic instability, signs of left ventricular dysfunction, or history of revascularization within 6 months, intravenous glycoprotein (GP) IIb/IIIa receptor antagonists are usually added. Planning for timely reperfusion with fibrinolysis (door-to-needle <30 min) or PCI (door-to-balloon <120 min) is mandatory for STEMI, but may be delayed in patients presenting with NSTEMI/unstable angina unless refractory ischemia develops. Based on clinical trial evidence, all patients with NSTEMI should proceed to the cardiac catheterization laboratory (after a period of medical stabilization) for delineation of coronary anatomy and revascularization by PCI or CABG. Although guidelines have recommended cardiac catheterization within 48 hours of presentation, a recent study found significant clinical benefit of an early (<6 hours) invasive strategy, compared to delayed cardiac catheterization (72–120 hours) after medical stabilization (7). There is no role for fibrinolysis in patients presenting with NSTEMI/unstable angina.

Antiplatelet Therapy

Aspirin

Platelet activation and aggregation play an important role in thrombus formation at the site of plaque rupture in acute MI. Aspirin functions as an antiplatelet agent by irreversibly acetylating cyclo-oxygenase and inhibiting thromboxane A_2 . In patients with acute MI, aspirin alone reduces mortality by 23% at 35 days and reduces nonfatal MI and stroke by 49% and 46%, respectively, in comparison with placebo (8,9). When aspirin is given with SK in STEMI, mortality is reduced by 42%. A daily dose of 81 to 325 mg of aspirin should be administered to all patients with an MI and continued indefinitely.

Clopidogrel

Clopidogrel blocks the platelet P2Y₁₂ ADP-receptor and provides potent platelet inhibition when added to aspirin therapy. Clopidogrel is an irreversible inhibitor of platelet function that is not correctable by platelet transfusion. Approximately 5 days are required for significant attenuation of clopidogrel’s anti-platelet effect. The combination of aspirin (325 mg daily) and clopidogrel (300 mg bolus dose followed by 75 mg daily) is now the standard anti-thrombotic regimen following PCI with stenting, based on the results of clinical trials demonstrating 3-5-fold reductions in subacute stent thrombosis compared with treatment with aspirin plus warfarin or aspirin alone. There is growing clinical evidence that pre-treatment with clopidogrel improves clinical outcomes in patients undergoing PCI. However, since clopidogrel is a pro-drug that requires hepatic cytochrome P450-dependent activation, pre-treatment with a 300 mg bolus dose requires approximately 6 hours to achieve clinically beneficial effects. This time lag may be reduced to 2 hours when a 600 mg bolus dose is utilized. The potential beneficial effect of pre-treatment must be balanced against the potential increased risk of bleeding in the event that emergency CABG is required because of unfavorable anatomy or PCI-induced complications.

Patients undergoing primary PCI for STEMI should be treated with aspirin and clopidogrel for a minimum of 30 days. Patients receiving a drug-eluting stent require more prolonged treatment (90 days for sirolimus- and 180 days for paclitaxel-eluting stent). Evidence guiding the use of clopidogrel after thrombolytic therapy for STEMI is lacking. Based on clinical trial results, patients with unstable angina/NSTEMI should receive clopidogrel for 9–12 months.

Glycoprotein IIb/IIIa Inhibitors

Newer, more potent antiplatelet agents block platelet GP IIb/IIIa fibrinogen binding, the final common molecular pathway of platelet aggregation. Two pharmacologic strategies have been employed in designing inhibitors of GP IIb/IIIa: blockade with a humanized monoclonal antibody Fab fragment (e.g., abciximab or ReoPro) or inhibition with agents that mimic the physiologic arginine-glycine-aspartic acid (RGD) ligand-binding sequence of fibrinogen (e.g., eptifibatid and tirofiban). Meta-analysis of three clinical trials in patients undergoing PCI for unstable angina or non-STEMI shows that GP IIb/IIIa inhibitors reduce death and MI by 33% in the 48–72 hours prior to PCI and by 45% peri- and post-PCI. Guidelines now recommend GP IIb/IIIa inhibitors in conjunction with aspirin and heparin in all high risk patients (refractory ischemia, ST-segment depression, troponin-positive, hemodynamic instability, prior PCI or CABG within 6 months) prior to diagnostic angiography and PCI, which is generally performed with 24–48 hours after admission.

Most interventionalists use GP IIb/IIIa blockers for patients undergoing primary PCI for STEMI based on a series

of randomized trials. Potent platelet inhibition with abciximab is associated with substantial reductions in death, reinfarction, and the need for urgent revascularization. Early use of eptifibatid, tirofiban, or abciximab in addition to aspirin plus heparin in the emergency department is strongly encouraged since angiographic studies have shown that each of these agents improves patency of the infarct-related artery as well as microvascular flow.

Antithrombin Therapy

Heparin

Trials document that low-molecular-weight heparin (enoxaparin or nadroparin) significantly reduces major adverse cardiac outcomes, including death, MI, and recurrent angina, compared with unfractionated heparin, in patients with non-STEMI. Studies also suggest perhaps a slight benefit for low-molecular-weight heparin in combination with fibrinolytic agents in STEMI (10), but data are conflicting (11). The current recommendation is heparin for patients who do not receive reperfusion therapy, those undergoing PCI or surgical revascularization, patients receiving t-PA, and patients who are at high risk for systemic emboli. The recommended dosing regimen for low-molecular-weight heparin is enoxaparin 1 mg/kg sc BID (requires dose adjustment for renal insufficiency and obesity). If unfractionated heparin is used, the recommendation is an IV bolus of 60 units/kg (maximum 4000 U) followed by an infusion of 12 units/kg per hour (maximum 1000 units/h) with subsequent adjustment (3, 6, 12, 24 h after start of treatment) to achieve an activated partial thromboplastin time (a PTT) of 50 to 70 seconds.

Direct Antithrombin Agents

Direct antithrombin agents such as hirudin, hirulog, and argatroban inhibit thrombin directly and do not require antithrombin III as a cofactor. Direct antithrombins offer the theoretical advantage of inhibiting clot-bound thrombin more effectively than unfractionated heparin or low-molecular-weight heparin. Two large trials evaluating the use of hirudin versus unfractionated heparin as adjunctive therapy to fibrinolysis in STEMI revealed no significant difference in mortality in the two groups. Bivalirudin with streptokinase compared to unfractionated heparin with streptokinase significantly reduced reinfarction for 48 hours with no effect on 30 day mortality, at the cost of a modest and non-significant increase in non-cerebral bleeding complications. Therefore, to date the direct antithrombin agents do not seem to provide additional benefits over heparin in STEMI. The use of bivalirudin in patients undergoing primary PCI for STEMI is under active investigation.

Warfarin

Trials of anticoagulants following MI demonstrate favorable reductions in late mortality, stroke, and recurrent MI

when compared to placebo (12). Some studies have also suggested that warfarin is superior to aspirin alone or that the addition of warfarin to low-dose aspirin may also be beneficial. However, the impact of other antiplatelet agents, such as clopidogrel, on the role of warfarin is unknown. Current guidelines suggest the use of warfarin anticoagulation when aspirin cannot be taken or when other indications for anticoagulation exist (atrial fibrillation, thromboembolic events, LV thrombus). If warfarin is added to aspirin, the aspirin dose should be lowered to 81 mg qd and the target INR should be 2.0–2.5.

Treatments to Decrease Myocardial Oxygen Consumption

β -blockers

β -blockers effectively reduce myocardial oxygen consumption by decreasing heart rate, contractility, and wall stress. Their anti-adrenergic properties also confer protection from significant ventricular arrhythmias. The use of immediate IV β -blockers followed by oral therapy reduces in-hospital mortality by 13%, repeated infarction by 19%, and cardiac arrest and ventricular fibrillation (VF) by 16%. Long-term β -blockade also plays an essential role in secondary prevention, with 22% and 27% reductions in mortality and repeated infarction, respectively, at 1 year. Data also support the use of early β -blockade, even in patients with moderate heart failure and significant left ventricular dysfunction. In one trial, carvedilol 25 mg PO bid reduced all cause mortality by 23% in patients who had a recent MI (day 3–21) and an ejection fraction of less than 40%, but who did not have uncontrolled heart failure or required ongoing diuretic or inotropic therapy, and who were taking a stable dose of an ACE inhibitor (13). The current recommendations are to initiate β -blockade as soon as possible in all patients without contraindications, especially in those with persistent or recurrent ischemic chest discomfort and those with atrial or ventricular tachyarrhythmias. Relative contraindications include bradycardia, systolic blood pressure below 100 mm Hg, presence of heart failure, history of chronic obstructive pulmonary disease or asthma, or signs of advancing atrioventricular (AV) block (PR interval >0.22 , type I or II second-degree AV block, complete heart block). β -blocker regimens include the following: (a) metoprolol, 5 mg IV every 15 minutes three times, followed by 25 to 50 mg PO every 6 hours; (b) propranolol, 0.033 mg/kg IV three times, followed by 20 to 80 mg every 6 hours; and (c) atenolol, 5 mg IV every 10 minutes two times, followed by 50 mg PO every 12 hours. If concerns about toxicity are substantial, a trial of the ultra-short-acting agent esmolol (500 mcg/kg per minute, then 50 to 250 mcg/kg per minute), which has a half-life of 9 minutes, may be warranted. In general, β -blockers should be titrated to the target doses used in the clinical trials (metoprolol 100 mg PO bid, atenolol 100 mg PO qd, and propranolol 60–80 mg PO tid) unless

heart rate, blood pressure, or other symptoms prohibit these doses.

Angiotensin-Converting Enzyme Inhibitors

Three trials have demonstrated that ACE inhibitors may be safely started in the early hours of MI (0 to 36 hours), with a statistically significant mortality benefit in all patients after acute MI at 4–6 weeks, irrespective of LV function (14). The average 7% reduction in mortality compared with placebo therapy translates into approximately 5 lives saved per 1,000 patients treated with ACE inhibitors. Sub-group analysis of these trials suggests that patients with anterior MI benefit to a much greater extent than those with inferior MI (11 lives saved per 1,000 patients treated vs. 1 life saved per 1,000 patients treated with inferior MI). Clinical trial data support a broad recommendation that ACE inhibitors should be considered in all patients with a systolic blood pressure above 100 mm Hg and no contraindications to ACE inhibitors and commenced within 1–2 days of acute MI. Acute ACE inhibitor regimens include (a) lisinopril, 5 mg PO on the first day, 5 mg PO at 24 hours, then 10 mg daily thereafter; (b) captopril, 6.25 mg PO on the first day, titrated up to 50 mg twice daily thereafter; and (c) zofenopril, 7.5 mg twice daily on the first day, titrated up to 30 mg twice daily thereafter. The mechanism of action of ACE inhibitors is multifactorial, and the clinical benefits observed may be secondary to a reduction in angiotensin II-mediated vasoconstriction and sodium retention; an increase in bradykinin and prostaglandins, which improves hemodynamics and ventricular remodeling; and a decrease in plasma levels of plasminogen activator inhibitor-1, which promotes endogenous fibrinolysis.

Like β -blockers, ACE inhibitors play an important role in secondary prevention by preventing recurrent ischemic events, heart failure and sudden death, thereby providing a 20% reduction in long-term mortality in patients with a previous MI and symptomatic LV dysfunction (14).

More complete blockade of the renin-angiotensin-aldosterone system with selective aldosterone blockade lowers mortality further. For example, the selective aldosterone blocker, eplerenone reduced total mortality by 15% in patients with acute myocardial infarction complicated by left ventricular dysfunction and heart failure (15), but the rate of serious hyperkalemia was 5.5% compared with 3.9% in the placebo group. Selective aldosterone blockade (eplerenone 25–50 mg PO qd) should be considered when heart failure complicates STEMI after ACE inhibitors and β -blockers have been maximized, but only if renal function is preserved (creatinine <2.5 mg/dL) and hyperkalemia (potassium level \geq 5.0 mmol/l) is not present.

Nitrates

Nitrates are venous and arterial vasodilators that reduce preload and afterload, thereby decreasing wall stress and

myocardial oxygen consumption. In addition, these agents improve coronary blood flow. However, recent randomized trials failed to demonstrate a reduction in mortality when nitrates were added to current standard therapy. Furthermore, they may cause excessive bradycardia and hypotension, especially when right ventricular infarction is present. IV or topical nitrate preparations followed by oral therapy reduce episodes of angina after infarction. Therefore, nitrates should be considered in patients with ongoing ischemic chest pain or uncontrolled heart failure if the systolic blood pressure is greater than 90 mm Hg, the heart rate is greater than 50 beats per minute, and right ventricular infarction is not present.

Calcium Channel Blockers

There is no survival benefit with use of calcium channel antagonists in the initial treatment or secondary prevention of MI. In fact, the use of nifedipine in acute myocardial infarction is contraindicated.

Prevention of Sudden Death

Sudden death, the most feared complication of MI, is usually caused by ventricular tachycardia or fibrillation and less frequently by complete heart block, asystole, or mechanical catastrophes such as free wall rupture or massive pulmonary embolism. Empowering trained nurses in the coronary care unit to recognize and defibrillate sustained ventricular arrhythmias without direct physician supervision has had the greatest impact on sudden death from MI. Other strategies include the use of medication and implantable cardiac defibrillators (ICDs) for patients at highest risk for sudden death.

Antiarrhythmic Medications

Lidocaine, a Vaughan-Williams class Ib (sodium channel blocker) antiarrhythmic agent, is indicated for treatment of VF or ventricular tachycardia (VT) in acute MI. Although the prophylactic use of lidocaine may decrease the overall incidence of VF, this potential clinical benefit is offset by an increased number of deaths associated with severe bradycardia, asystole, or pulseless electrical activity. The drug should therefore be reserved for the treatment of sustained or symptomatic VT. Its neurologic toxicity may produce confusion, tremor, and seizures, especially in the elderly and those with heart failure or impaired hepatic function.

Amiodarone blocks adrenergic β -receptors and various membrane channels including potassium (Vaughan-Williams Class III effect), calcium, and sodium. It is effective and is used for the treatment of recurrent ventricular fibrillation and hemodynamically significant ventricular tachycardia, especially in lidocaine-resistant patients. In two long-term post-MI studies in high-risk patients, amiodarone appeared to lower arrhythmic death and cardiac arrest but

not total mortality. Unfortunately, 40% of patients stopped the drug. When given intravenously, amiodarone may cause phlebitis (especially when given through a peripheral IV), heart block, hypotension, and heart failure.

Magnesium is not recommended in acute MI because its use has been associated with a nonsignificant increase in mortality and heart failure.

Implantable Cardiac Defibrillators (ICDs) are small devices (50–70 ccs) that implanted in the left pectoral region, continuously monitor the heart rhythm, and can be combined with pacing and hemodynamic monitoring. In two randomized trials of patients with previous myocardial infarction and reduced ejection fraction (less than 30–35% at 3–4 weeks post-infarction), prophylactic ICDs reduced mortality by 54% in patients with nonsustained ventricular tachycardia and by 31% when nonsustained VT was not an entry criteria, compared with standard medical therapy (16).

Indications for Early Consultation

Complicated MI patients with hemodynamic instability, recurrent ischemia, heart failure, or arrhythmias, and those requiring PCI, an intraaortic balloon pump, or temporary pacing should be evaluated and managed by a cardiologist. Consultation with an electrophysiologist should be considered in all post-infarct patients with severe left ventricular dysfunction (ejection fraction < 0.30), especially if they have nonsustained ventricular tachycardia.

ISSUES DURING THE COURSE OF HOSPITALIZATION

The early hospital management of acute MI focuses on pharmacologic and mechanical interventions that save lives (careful monitoring and treatment of arrhythmias, recurrent ischemia, and heart failure), assessment of risk factors, and patient and family education (Table 38.6; Figures 38.2, and 38.3). After initial assessment in the emergency department and institution of treatment with aspirin, β -blockers, heparin, nitrates, and fibrinolysis or PCI (for ST-segment elevation MI), the patient is admitted to the CCU. Following successful PCI of the infarct-related artery, low-risk patients (age <70 years, small MI, Killip class I, no previous MI) may be admitted directly to an intermediate care unit. Streamlined critical pathways for patients with MI treated either with fibrinolysis or PCI are outlined in Figures 38.2 and 38.3.

Activity should be restricted to bed rest for the first 12 hours. Hemodynamically stable patients may have bedside commode privileges. During hospital days 0 and 1, serial determinations of troponin levels or, less commonly, CK-MB (myocardium-specific isoenzyme of creatine kinase) are performed (every 8 hours three times), serial ECGs are obtained, and an ACE inhibitor is added to the above medical regimen if hemodynamically tolerated. If ischemia is detected at any time during the hospitaliza-

tion, the patient should undergo cardiac catheterization to guide revascularization. During the first 24 to 48 hours of an acute MI, the lipid profile remains near baseline levels (total, low-density lipoprotein [LDL], and high-density lipoprotein [HDL] cholesterol; triglycerides), and it should be checked on admission or soon thereafter. All patients should be started on a “heart-healthy” diet with subsequent nutritional education.

During day 1, low-risk patients (age <70, small MI, Killip class I, no previous MI) may be transferred to a step-down floor with continued ECG monitoring. These patients should increase activity, with frequent bed-to-chair transfers and ambulation in the room. Moderate- to high-risk patients should remain in the CCU; if hemodynamically stable, they should undergo active range-of-motion exercises to all extremities, with bed-to-chair transfers for 1 to 2 hours a day. All patients should be considered candidates for HMG CoA reductase inhibitors (statins), independent of lipid values, with an LDL goal of 60 mg/dL (17). Ezetimibe can be added if a statin cannot achieve this goal. Niacin or fibric acids can be used when triglyceride levels are greater than 200 mg/dl and/or the HDL is less than 35 mg/dl despite statins.

During day 2, low-risk patients should increase ambulation around the step-down floor. In the absence of ischemia, heart failure, or ventricular arrhythmia, non-low-risk pa-

TABLE 38.6

RISK STRATIFICATION FOLLOWING ACUTE MYOCARDIAL INFARCTION

Ischemia

Assessment: stress test (exercise or pharmacologic) with electrocardiography, perfusion scintigraphy, or echocardiography
 Low risk: absence of spontaneous or provokable ischemia
 High risk: presence of spontaneous or provokable ischemia
If high risk, catheterization and revascularization

Left ventricular dysfunction

Assessment: echocardiography
 Low risk: absence of heart failure symptoms, normal LVEF
 High risk: heart failure symptoms, LVEF <40%
If high risk, heart failure symptoms: ACE inhibitors, diuretics, digoxin
LVEF <40%: strongly consider catheterization to rule out three-vessel CAD given survival benefit with revascularization
LVEF <35%: strongly consider prophylactic AICD

Electrical instability

Assessment: routine clinical information; Holter monitor not routinely indicated
 Low risk: none or non-sustained VT or VF <48 h post-MI
 High risk: sustained VT or VF >48 h post-MI
If high risk, rule out ischemia, catheterization/revascularization if indicated; AICD indicated

ACE, angiotensin-converting enzyme; AICD, automated implantable cardioverter-defibrillator; CAD, coronary artery disease; EPS, electrophysiologic study; LVEF, left ventricular ejection fraction; VF, ventricular fibrillation; VT, ventricular tachycardia.

tients can be transferred to a step-down unit; their activity level should include increased bed-to-chair transfers with gradual ambulation. During the remaining hospitalization, β-blocker and ACE inhibitor doses should be titrated to achieve optimal heart rate and blood pressure response. Selective aldosterone blockers should be considered in patients with heart failure and significant LV dysfunction.

Risk Stratification After Myocardial Infarction

Risk stratification after MI should assess the presence of spontaneous or provokable ischemia, the status of the LV, and the risk for ventricular arrhythmias. An echocardiogram generally should be obtained in virtually all patients.

Figure 38.3 Critical pathway for the patient treated with percutaneous coronary intervention (PCI). ACEI, angiotensin converting enzyme inhibitor; ACT activated clotting time; ASA, aspirin; CATH, cardiac catheterization; CBC, complete blood count; CCU, coronary care unit; CHF, congestive heart failure; D/C, discharge or discontinue; Dx, diagnosis; ECG, electrocardiogram; EF, ejection fraction; ETT, exercise treadmill testing; Hx, history; IV, intravenous; MI, myocardial infarction; SL, sublingual; VT, ventricular tachycardia (Adapted from cardiovascular critical pathways developed at Brigham and Women’s Hospital by Drs. Elliott Antman, John Bittl, Christopher Cannon, James K. Kirshenbaum, Patrick O’Gara, and Peter Stone, Reprinted with permission.)

On day 3, low-risk patients should undergo a submaximal exercise test, during which they exercise until anginal symptoms occur, ECG ischemia is seen, or the exercise protocol is completed (approximately 5 METS [metabolic equivalents]). In patients with baseline ECG abnormalities that preclude interpretation of a stress ECG, an exercise perfusion scintigram or exercise echocardiogram should be performed. If patients are unable to exercise, stress perfusion scintigraphy or echocardiography with dipyridamole or dobutamine can mimic the stress of exercise and allow risk stratification (Chapter 36). The goals of post-MI stress testing are to (a) assess exercise capacity and the patient's ability to perform daily home and work activities; (b) evaluate the efficacy of the current medical regimen; and (c) assess the risk for a subsequent cardiac event. If the stress test result is strongly positive (≥ 2 mm ST-segment depression; large or multiple stress-induced perfusion abnormalities; stress-induced echocardiographic changes), the patient should undergo cardiac catheterization with a view toward revascularization. If the test result is negative, the patient can be discharged on a medical regimen consisting of aspirin, a β -blocker, a statin, and, if indicated, an ACE inhibitor. A symptom-limited exercise test should be obtained at 3 to 6 weeks after discharge.

Moderate- to high-risk patients should be continually monitored through day 3, with an increased level of ambulation; IV heparin can then be discontinued. These patients should undergo a submaximal exercise test on day 4 or 5. If the test result is negative, the patient can be discharged on a medical regimen consisting of aspirin, a β -blocker, a statin, and, if indicated, an ACE inhibitor.

Cardiac catheterization and revascularization should be strongly considered in patients with LV dysfunction, given the established survival benefits of coronary artery bypass grafting in patients with two- or three-vessel coronary artery disease and a reduced LV ejection fraction. For patients with nonsustained ventricular arrhythmias 24–48 hours after infarction, consultation with an electrophysiologist should assess the advisability of further testing to refine the risk of sudden death and/or placement of a prophylactic ICD before discharge.

COMPLICATIONS OF MYOCARDIAL INFARCTION

Heart failure, hypotension, and shock often require invasive hemodynamic monitoring with a pulmonary artery catheter and an arterial line. Measurement of filling pressures and cardiac output guide further management with regard to volume status, need for inotropic agents, and therapeutic response to afterload reduction. LV failure should be treated with diuretics, afterload reduction with easily titratable agents such as IV nitroprusside or IV nitroglycerin, and possibly inotropic agents, such as dopamine and dobutamine (Chapter 39). Right ventricular (RV) fail-

ure in the setting of RV MI requires aggressive volume repletion to raise right-sided filling pressures and right ventricular inotropic support until the RV recovers. Saline should be used to keep the central venous pressure 10–15 mm Hg and inotropic agents, such as dobutamine 1–5 mcg/kg/min, can be used to keep the systolic blood pressure > 90 mm Hg. Patients in cardiogenic shock or with persistent ischemia require intra-aortic balloon pumping, which functions to augment coronary perfusion pressure and reduce LV afterload; these patients should also be taken immediately to cardiac catheterization. Timely revascularization of patients with cardiogenic shock has been associated with significant reductions in in-hospital mortality.

Mechanical Complications

Mechanical complications such as *free wall rupture*, *ventricular septal defect*, and *papillary muscle rupture* most commonly occur 3 to 5 days after the MI. They occur dramatically and are associated with a high mortality rate (up to 90%) with medical management alone. Free wall rupture usually involves the anterior or lateral wall of the LV in a large Q-wave MI, resulting in hemopericardium. The clinical presentations range from sudden death to hypotension and pericardial chest pain. The diagnosis can be made by urgent pericardiocentesis or, if the patient is stable, by urgent echocardiography. Survival rate is low and depends on patient stability and prompt surgical intervention.

Ventricular septal defects occur in approximately 2% of patients with an acute MI. Defects in anterior MI are often apical, whereas those in inferior MI tend to be in the basal septum and are associated with a worse prognosis. The clinical presentation usually involves the new appearance of a harsh, loud holosystolic murmur at the left lower sternal border. Within a few hours or days, biventricular failure ensues. Diagnosis is made by echocardiographic visualization or shunt detection via pulmonary artery catheter sampling of oxygen saturation. Survival depends on early detection, RV and LV function, and size of the defect. Treatment consists of surgery or catheter-based clamshell device closure. Surgical mortality approaches 50%.

Papillary muscle rupture is a rare, dramatic, and often fatal complication of MI. Rupture of the posteromedial papillary muscle, which is associated with inferior MI, occurs more frequently than does anterolateral papillary muscle rupture (associated with anterolateral MI). Patients present with acute, severe mitral regurgitation, hypotension, and heart failure. The apical murmur is often subtle and may become inaudible as arterial hypotension occurs. The diagnosis is made by echocardiography or ventriculography. A pulmonary artery catheter will reveal large *c-v* waves in the pulmonary capillary wedge pressure tracings. Surgical treatment involves repair or replacement of the mitral valve and is associated with a mortality rate of 40% to 90%.

Arrhythmias

Arrhythmias in MI occur as a result of ischemia, increased adrenergic state, and electrolyte abnormalities. Frequent ventricular premature beats (VPBs) are commonly observed in patients with acute MI and do not predict the likelihood of progression to VF. Antiarrhythmic agents are not indicated in this setting and may increase the risk for adverse bradycardic events. Non-sustained VT (more than three consecutive ventricular beats at a rate >100 beats/min lasting <30 seconds) in the first 24–48 hours after acute myocardial infarction is not associated with an increased acute or long-term mortality rate after MI. In contrast, sustained VT (lasting longer than 30 seconds or causing hemodynamic compromise requiring intervention) is associated with a 20% in-hospital mortality. Hemodynamically compromised patients with sustained VT should be treated with synchronized cardioversion. Stable patients should be treated with an intravenous antiarrhythmic agent such as: (a) lidocaine, initial bolus of 1 to 1.5 mg/kg to a maximum of 3 mg/kg, and infusion of 1 to 4 mg/min; (b) procainamide, initial dose of 12 to 17 mg/kg over 30 minutes, followed by maintenance infusion of 1 to 4 mg/min; (c) amiodarone, initial dose of 150 mg over 10 minutes, followed by infusion of 1 mg/min for 6 hours and then maintenance rate of 0.5 mg/min. Primary VF during acute MI increases in-hospital mortality but is not a predictor for long-term risk. Secondary VF in the setting of significant LV dysfunction and cardiogenic shock is associated with in-hospital mortality rates of 40% to 60%. VF should be promptly treated with defibrillation. Pharmacologic prevention of recurrent episodes includes the use of β -blockers, lidocaine, amiodarone, or bretylium (5 to 10 mg/kg).

In acute MI, the incidence of atrial fibrillation (AF) is 10% to 16%. Atrial flutter and supraventricular tachycardia occur less frequently. In the hemodynamically compromised patient with AF, atrial flutter, or supraventricular tachycardia, immediate synchronized cardioversion is indicated. In the stable patient, IV intravenous β -blockers or digoxin should be administered. Although not considered first-line agents, calcium channel blockers may also be used in patients with preserved LV function. Because electrolyte abnormalities may exacerbate or precipitate both ventricular and atrial arrhythmias, all patients should have a potassium level above 4.0 mEq/L and a magnesium level above 2.0 mEq/L.

Bradyarrhythmias also occur in the acute MI setting. Inferoposterior MI is more often associated with sinus bradycardia resulting from vagal stimulation of the heart, first-degree AV block, and Mobitz type I second-degree AV block. These bradyarrhythmias are usually transient and do not require therapy unless associated symptoms are present. Treatment includes a reduction in β -blocker or calcium channel blocker dose, the use of atropine, or temporary pacing. Anteroseptal MI is associated with more advanced AV block, including Mobitz type II second-degree AV block and complete AV block. These patients should be

treated with temporary transvenous pacing. Temporary pacing should also be strongly considered in patients with new bifascicular bundle branch block or alternating right and left bundle branch block. Specific arrhythmias are covered in more detail in Chapters 42, 43, and 45.

Thromboembolism

Patients in the post-MI setting are at risk for venous thrombosis, pulmonary embolic, and arterial thromboembolic events. IV heparin during the first 48 to 72 hours of hospitalization and early ambulation reduces the risk for deep venous thrombosis and pulmonary embolism. Large anterior MI and LV dysfunction are risk factors for thrombus formation and systemic embolization; in such patients, an echocardiogram should be performed, and heparin anticoagulation should be instituted if a thrombus is found. Although the risk of ventricular mural thrombus in association with large infarctions has not been defined in the modern reperfusion and ACE inhibitor era, strong consideration should be given to the prophylactic use of antithrombotic agents such as coumadin when LV function is very poor or extensive wall motion abnormalities are present.

DISCHARGE ISSUES

Patients who have undergone recanalization therapy and have no heart failure, recurrent ischemia, or significant ventricular arrhythmias may be discharged after a submaximal exercise test at 3 to 5 days. Patients who have experienced any complications require a more prolonged hospitalization, with discharge dependent on clinical stability after appropriate medical and surgical interventions.

Before discharge, all patients and families should receive education regarding medications, secondary prevention, and risk factor modification. All patients should be discharged on aspirin, a β -blocker, a statin, and, if indicated, an ACE inhibitor. Patients should be instructed on how to use sublingual nitroglycerin. Patients with significant LV dysfunction and heart failure may also require a diuretic, a selective aldosterone antagonist, an ICD, and/or digitalis. Risk factor changes include dietary modification, lipid lowering medications, smoking cessation, blood pressure and diabetic management, weight loss, and exercise, if indicated. Nicotine patches or gum or bupropion are recommended (along with counseling) to aid in smoking cessation. Patients should receive instructions regarding physical activity in the immediate post-MI period. Low-level ambulation and aerobic activity should be encouraged, but isometric exercises such as heavy lifting should be avoided. Most patients should enroll in a cardiac rehabilitation program that includes both supervised physical exercise and education.

Patients should undergo a symptom-limited exercise test at 3 to 6 weeks, with subsequent follow-up by a cardiologist. Because significant improvement in LV function has

been observed in serial echocardiographic studies obtained in the peri- and post-infarction setting, many cardiologists obtain a follow-up assessment of ventricular function at 6 weeks post-MI.

ASSESSMENT AND MANAGEMENT OF THE PATIENT PRESENTING WITH MYOCARDIAL INFARCTION DURING A HOSPITALIZATION

MI in patients hospitalized for other illnesses or surgery can present with atypical signs and symptoms, including hypoxia, nausea and vomiting, hypotension, mental status changes, and heart failure on examination or chest radiography. In the setting of postoperative anesthesia/analgesia and ICU sedation, symptoms may be difficult to elucidate. Therefore, careful interpretation of the ECG and measurement of cardiac enzymes, especially troponin T or I, after surgery may be useful. In addition, echocardiography to assess regional wall motion abnormalities may aid in the diagnosis. All patients should receive β -blockers, in addition to aspirin and heparin, if not contraindicated. Reperfusion therapy with thrombolytic agents or primary PCI (especially in a patient who has undergone noncardiac surgery) should be considered for patients in whom the MI began within the last 24 hours or in whom symptoms persist. Because diagnostic uncertainty is common, cardiac catheterization is often required in patients presenting with an MI during hospitalization. In hemodynamically unstable patients, invasive monitoring with a pulmonary artery catheter may be used to assess filling pressures and cardiac output before and during pharmacologic management.

COST CONSIDERATIONS AND RESOURCE USE

For the treatment of MI, issues regarding cost and resource use are complex. Clinical investigators have applied cost-effectiveness analysis to a number of randomized clinical trials to help guide physician practice. Compared with t-PA treatment, reperfusion by primary PCI improves clinical outcome with similar or reduced costs; total hospital charges, including the cost of cardiac catheterization and physician charges for PCI, were not significantly different from those of patients treated with t-PA ($\$27,653 \pm \$13,709$ vs. $\$30,227 \pm \$18,903$; $p = .21$) (18). The choice of thrombolytic agent also has significant cost implications. Patients who received t-PA had higher costs ($\$2,845$) but also a higher survival rate (9 to 10 lives saved per 1,000 patients treated) than did SK-treated patients; the cost of t-PA was $\$32,678$ per year of life saved, a dollar amount that compares favorably with that of other therapies whose added medical benefit for dollars spent has been judged by society to be worthwhile (19). In the GUSTO trial, Canadian

patients underwent fewer invasive cardiac procedures and had fewer visits to specialists, but Canadian patients also had more cardiac symptoms and worse functional status 1 year after acute MI than the U.S. patients did. Cost issues will remain paramount as newer therapies, such as glycoprotein IIb/IIIa inhibitors and drug-eluting coronary stents, add significant charges (approximately $\$500$ – $\$1,000$ and $\$3,200$, respectively). However, by significantly reducing ischemic events and the need for repeated revascularization, these technologic innovations may be cost-effective.

In treating an individual patient, the treating physician has a significant impact on cost considerations with respect to length of stay. Critical pathways (Figures 38.2 and 38.3) provide a safe, streamlined approach to shortening hospital stays.

KEY POINTS

- The ECG and a focused history and physical examination are critical for early triage and treatment decisions.
- Recanalization therapy with primary PCI or fibrinolysis is indicated in all patients with ST-elevation myocardial infarction seen within 12 hours of the onset of symptoms.
- Routine coronary angiography with revascularization as indicated (an early aggressive strategy) improves outcomes in NSTEMI.
- Aspirin, β -blockers, and intravenous heparin are recommended in all patients who lack contraindications.
- Angiotensin-converting enzyme inhibitor therapy is often beneficial.
- Patients should be monitored for arrhythmia, heart failure, recurrent chest pain, and mechanical complications.
- Risk stratification should be performed before discharge.
- Risk factor management (especially aggressive lipid-lowering therapy, smoking cessation, and blood pressure control) is routinely indicated.
- Cardiac rehabilitation is usually beneficial.
- To assess the process of care, the following data should be collected: monitor door-to-needle time (goal: <30 minutes); monitor door-to-balloon time (goal: <120 minutes); maximize β -blocker, aspirin, angiotensin-converting enzyme inhibitor, and statin use; assess percentage of patients who undergo exercise testing for risk stratification; monitor cardiac catheterization and revascularization rates; tabulate length of stay for low- and high-risk patients.

INTRODUCTION

In addition to being a disabling and life-threatening condition, heart failure represents an ever-increasing financial burden to society. More than 5 million Americans carry the diagnosis of heart failure, and 400,000 new cases are discovered annually (1). The prevalence has steadily increased during recent years, and heart failure now represents the single most frequent diagnosis leading to hospitalization in patients older than age 65 (2).

Guidelines on the evaluation and management of patients with heart failure have been published by several entities, most notably the American College of Cardiology (ACC) and the American Heart Association (AHA). The ACC/AHA guideline categorizes patients into clinical subgroups of acute decompensation of chronic left ventricular (LV) failure, acute cardiogenic pulmonary edema, and cardiogenic shock (3). Although the groupings are useful, there is a fair amount of overlap in the pathophysiologic processes and therapeutic principles used in evaluating and treating these patients.

ISSUES AT THE TIME OF ADMISSION

The most common cause of LV systolic dysfunction in the United States is ischemic cardiomyopathy. Other causes include hypertension, valvular disease, and primary cardiomyopathies. Regardless of etiology, impairment of LV systolic function eventuates in a predictable sequence of hemodynamic and neurohormonal events. Although the precise triggers that activate these neurohormonal systems remain obscure, they are presumably linked to altered hemodynamics and altered responses of the cardiopulmonary barorecep-

tors. Activation of the sympathetic nervous system can lead to vasoconstriction, with consequent augmentation of afterload, which serves to maintain blood pressure at the expense of further reductions in cardiac output. Increased circulating levels of antidiuretic hormone lead to augmented preload by means of salt and water retention; these adaptations aid in maintaining cardiac output via the Frank-Starling mechanism but often lead to increases in LV filling pressure, which can cause alveolar edema and resulting dyspnea. Reduction in cardiac output is associated with reduced renal perfusion pressure, leading to enhanced formation of angiotensin II and aldosterone, which lead to further retention of salt and water in addition to vasoconstriction.

Indications for Hospitalization and Intensive Care Unit Admission

Published guidelines have delineated the patients with heart failure who typically benefit from hospitalization (Table 39.1). Patients with cardiogenic shock or with pulmonary edema that requires intubation require ICU admission. Other subsets of patients routinely admitted to an ICU are those in whom heart failure coexists with acute ischemia, and those with hypoxia or hypotension. Any patient in whom a pulmonary artery catheter is judged to be necessary (see later in this chapter) requires hospitalization in an ICU.

Initial Evaluation

General Principles

The initial evaluation and therapy of patients with acute heart failure proceed in tandem. It is important to clarify the precipitating cause and underlying disease in order to

TABLE 39.1

define the severity of the syndrome, to estimate prognosis, and to create a therapeutic protocol for all patients admitted with this syndrome. If an acute intervening problem has caused or led to acute heart failure, therapy must be targeted to the underlying disorder. Examples of such underlying causes include acute myocardial ischemia (MI), rapid atrial fibrillation, uncontrolled hypertension, valvular heart disease such as mitral or aortic stenosis, pulmonary embolism, pericardial constriction, sepsis, severe anemia, hyperthyroidism, and hypothyroidism (Table 39.2).

CLINICAL PRESENTATIONS

Acute Decompensation of Chronic Heart Failure

In this patient population, a directed history most frequently reveals a prior history of LV dysfunction. More than half of the patients have a prior MI as a cause of LV dys-

TABLE 39.2
SOME COMMON PRECIPITATING CAUSES OF HEART FAILURE

- Myocardial ischemia or infarction
- Atrial fibrillation or other supraventricular tachycardias
- Uncontrolled hypertension

- Ventricular tachycardia
- Pulmonary embolism
- Pericardial disease
- Sepsis
- Anemia
- Nutritional and medical noncompliance
- Adverse drug effects
- Hyperthyroidism or hypothyroidism

function. The clinical evaluation most frequently reveals signs and symptoms of pulmonary or systemic vascular congestion and low cardiac output. Patients often report increasing dyspnea on exertion and sometimes even at rest, fatigue, orthopnea, increasing edema, or paroxysmal nocturnal dyspnea, with most patients having symptoms for days to weeks before hospitalization (Figure 39.1). Physical examination frequently reveals elevated jugular venous pressure, pitting edema, and hepatomegaly. Chest auscultation commonly reveals pulmonary crackles. Cardiac examination frequently finds an inferolaterally displaced and sustained apical impulse, tachycardia, gallop rhythms, and systolic murmurs of mitral or tricuspid regurgitation.

In the initial evaluation of the patient with decompensation of chronic heart failure, it is critical to look for a precipitating cause. In addition to previously noted disorders, poor compliance with medications or diet contributes to half or more of admissions. Adverse drug effects (e.g., non-steroidal anti-inflammatory agents or medications, such as antibiotics, that contain a high concentration of sodium) are another common precipitant. In a substantial percentage of patients, however, no specific precipitant can be found because the decompensation relates to the progressive natural history of the underlying disease process.

In the patient with decompensated chronic heart failure, the most useful diagnostic information comes from a directed history and physical examination. In some patients, the history and physical examination may be inconclusive in assessing the cause of acute dyspnea. Rapid measurement of *B-type natriuretic peptide* (BNP) can help distinguish heart failure from other causes of dyspnea because a value ≤ 100 pg/mL makes heart failure very unlikely (4). Therefore, the use of BNP measurements in this setting can reduce unnecessary hospitalization and the costs of care (5). Conversely, an initial BNP level ≥ 200 pg/mL in the emergency department predicts a worse 90-day outcome (6). Routine blood work should exclude anemia, renal insufficiency, electrolyte disorders, and liver dysfunction. Electrocardiography should be performed, and there should be a low threshold for measuring cardiac biomarkers if there is any possibility that acute MI may have precipitated clinical deterioration. All patients should undergo noninvasive testing, usually with echocardiography or alternatively with radionuclide ventriculography, to assess LV function (Chapter 36), unless this measurement is already known. If the ejection fraction has already been demonstrated to be low, repeated testing is of less value unless there is a need to document possible further deterioration.

Some patients with heart failure have normal systolic function but abnormal diastolic function that causes high filling pressure and a clinical picture that is often undistinguishable from heart failure caused by reduced systolic functions (7). Patients hospitalized with diastolic heart failure are more likely to be older women than those with systolic heart failure (8). The entity of diastolic heart failure remains mostly a clinical diagnosis, often supported by

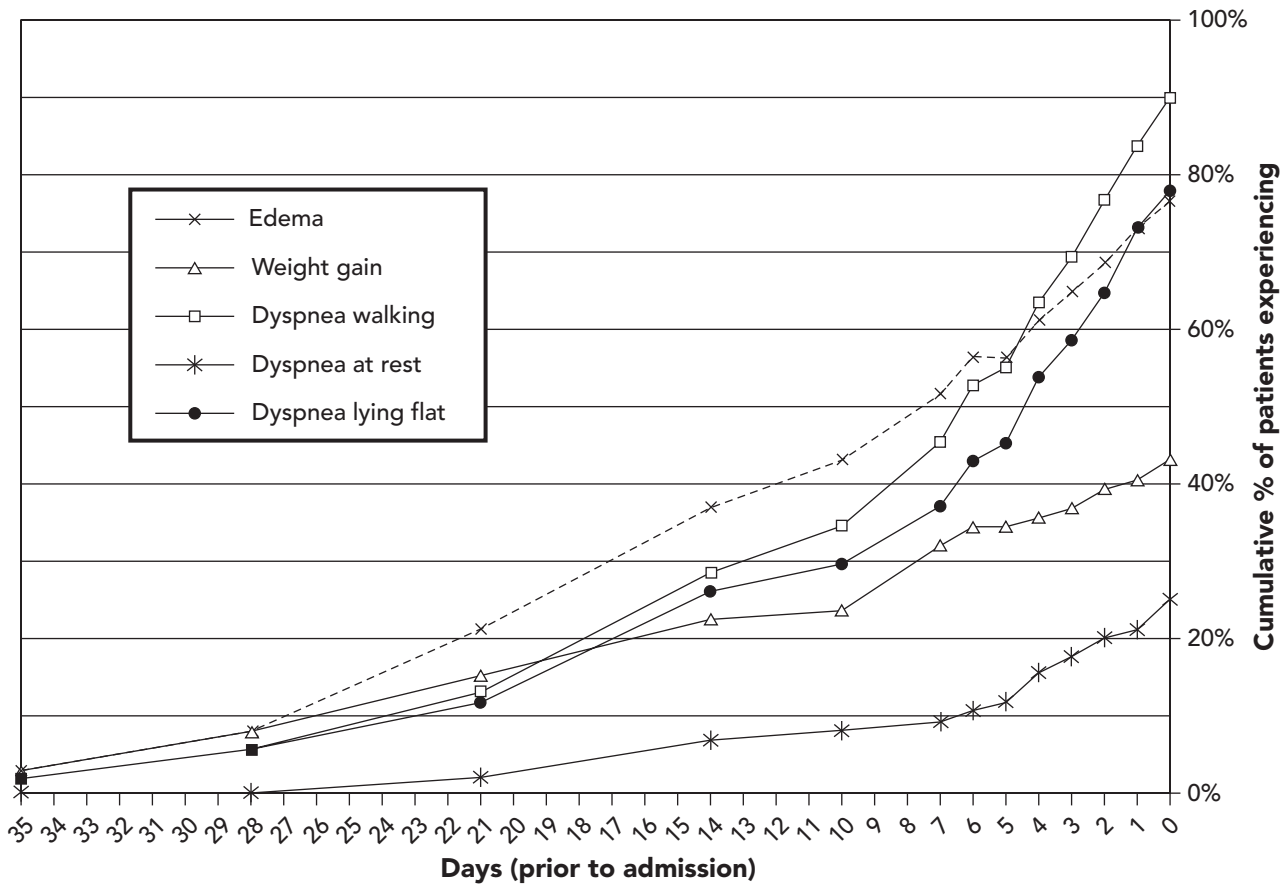

Figure 39.1. Number of days from onset of selected heart failure symptoms to hospital admission: cumulative percentage of patients. Reprinted with permission from Schiff GD, Fung S, Speroff T, et al. Decompensated heart failure: symptoms, patterns of onset, and contributing factors. *Am J Med* 2003;114:625–630.

BNP levels but without reliable, universally accepted echocardiographic criteria (9).

In patients hospitalized with heart failure, anemia is a risk factor for adverse outcomes, and limited data suggest that treatment is beneficial (10). Both renal function and the hematocrit should be routinely measured and followed during the hospitalization.

Myocardial ischemia in the absence of a frank MI may precipitate acute heart failure. In such patients, especially those with rest angina or exercise-limiting symptoms, coronary angiography should be performed, followed when possible by revascularization. Several studies have demonstrated the value of documenting myocardial viability as a guide for selecting patients for revascularization and for predicting subsequent outcomes. These studies have generally indicated lower rates of adverse events after revascularization in selected patients with heart failure.

Pulmonary Edema

Acute pulmonary edema represents a medical emergency, and its diagnosis is usually clear from the history and physical examination, although a chest radiograph may

sometimes be required for diagnosis. In patients with cardiogenic pulmonary edema, a relatively acute elevation in LV filling pressure (pulmonary capillary wedge pressure) secondary to LV dysfunction leads to transudation of fluid from pulmonary capillaries into the lung interstitium. As a consequence of this process, pulmonary compliance declines, and subjective breathlessness, frank hypoxia, or both, ensue. Physical examination usually reveals diffuse pulmonary rales. Cardiac examination is frequently difficult because of the patient's clinical status and labored breathing, but it often shows tachycardia with a third or fourth heart sound or a summation gallop. The extremities are often cool and diaphoretic, reflecting the low cardiac output with shunting of blood away from the periphery.

Occasionally, patients with pulmonary edema are mistakenly thought to have a pulmonary infectious process such as pneumonia (Chapters 65 and 66). Although patients with pulmonary edema are at risk for pulmonary sepsis, purulent cough and hyperpyrexia are typical in pneumonia. Exacerbations of chronic obstructive pulmonary disease (COPD) (Chapter 55) are usually not difficult to distinguish from pulmonary edema. Prominent use of ac-

cessory muscles of respiration, marked diminution of breath sounds, hyperresonance to percussion, subxiphoid location of the apical impulse, and a flattened diaphragm are all common in decompensated emphysema and unusual in pulmonary edema. Similarly, hypercarbia and cyanosis in the setting of a history of productive cough are commonly seen in decompensated chronic bronchitis but are not usually seen in patients with pulmonary edema. Cardiogenic pulmonary edema must be distinguished from *noncardiogenic pulmonary edema* (also known as acute respiratory distress syndrome, or ARDS), which is not secondary to poor LV performance with deranged hemodynamics but rather occurs as a consequence of altered capillary permeability, usually in the setting of trauma, sepsis, or aspiration (Chapter 24).

Cardiogenic Shock

Cardiogenic shock, which is defined as cardiogenic hypotension accompanied by fluid overload and pulmonary edema, represents a medical emergency that most commonly is caused by an acute MI. Cardiogenic shock develops when approximately 40% of the LV is affected by current or repetitive ischemic insult and occurs in about 10% to 15% of patients with acute MI (Chapter 38). Clinically, the diagnosis is usually not difficult to recognize. Patients present most frequently with hypotension, tachycardia, tachypnea, rales, and a reduced pulse pressure. When hypotension is not associated with pulmonary congestion, the diagnosis of cardiogenic shock cannot be made unless and until the low blood pressure fails to respond to the documented achievement of adequate left ventricular filling pressures. Signs of diminished cardiac output include diaphoresis, cool extremities, and confusion. Tissue hypoperfusion and pulmonary congestion usually cause hypoxia and a metabolic acidosis.

Indications for Early Consultation

Prompt specialty consultation (Table 39.3) is especially important in patients who are thought to have ongoing ischemia or a mechanical complication of a myocardial infarction (MI) as a precipitant of decompensation. In these patients, early catheterization can aid in the choice of appropriate and often life-saving therapies, such as revascularization or valve repair.

Pulmonary Artery Catheterization

Although not routinely indicated, a pulmonary artery catheter can help diagnostically and therapeutically when there is uncertainty regarding a cardiogenic etiology, when there is concomitant pulmonary congestion and low or

TABLE 39.3

INDICATIONS FOR EARLY CONSULTATION

- Failure to improve clinically
- Myocardial ischemia
- New murmur
- Abnormal renal function
- Uncontrolled hypertension
- Heart failure with normal left ventricular function
- Heart failure complicated by shock

borderline blood pressure or hypoperfusion, or when the patient has acute ischemia or MI that is thought to be complicated by acute mitral regurgitation or ventricular septal rupture (Table 39.4). Hemodynamic data derived from pulmonary artery catheters are also useful in patients whose clinical courses deteriorate despite application of appropriate therapies, and such data can help to guide therapy in patients in whom volume status cannot be reliably ascertained because of coexisting conditions such as morbid obesity or obstructive lung disease. It must be remembered, however, that a pulmonary artery catheter provides diagnostic information and is not in itself therapeutic (Chapter 25). The duration of catheterization should be minimized to avoid complications.

MEDICAL TREATMENT

General Principles

The goals of therapy in acute heart failure are to correct the hemodynamic derangement leading to decompensation while simultaneously improving symptoms. In all cases, the diagnosis of heart failure implies that pulmonary or

TABLE 39.4

SITUATIONS IN WHICH PULMONARY ARTERY CATHETERIZATION MAY BE BENEFICIAL IN PATIENTS WITH HEART FAILURE

- Uncertain etiology of pulmonary edema
- Pulmonary congestion with any of the following:
 - hypotension
 - acute ischemia or infarction
 - acute mitral regurgitation
 - ventricular septal rupture
- Clinical deterioration despite application of usual therapy
- Uncertain volume status
- Oliguria

systemic venous pressure is elevated, with or without reduction in cardiac output and blood pressure. Therapy, therefore, is directed at reducing venous pressure by the use of diuretics, venodilators, or both.

Whenever filling pressures are elevated or a significant amount of extravascular fluid (pulmonary or peripheral edema, or ascites) is present, diuresis should be attempted. In the presence of renal dysfunction or hypoperfusion, intravenous (IV) inotropic agents and vasodilators and/or diuretics should be used concomitantly. The response to therapy in these patients often suggests that their ventricles had been on the descending limb of the Starling curve; that is, a reduction in filling pressures *improves* cardiac performance through reductions in tricuspid and mitral regurgitation and relief of ventricular-interdependent constraints on LV filling. Diuresis-induced reduction in right-sided pressures may improve effective LV compliance, thereby improving cardiac output and renal perfusion. Agents with inotropic and arteriolar dilating action may also be used if a low-output state exists and diuretics are found to be ineffective or exacerbate renal dysfunction.

The hospitalization is also a crucial time to initiate or titrate chronic pharmacologic therapies that will have long-term benefit, including an angiotensin-converting enzyme (ACE) inhibitor (or other vasodilator if ACE inhibitors cannot be used), a β -blocker, and often an aldosterone antagonist. Device therapies also should be considered.

Although there is a great deal of individual variability, the hemodynamic goals of therapy are generally to maintain blood pressure above 90 mm Hg (preferably >100 mm Hg), pulmonary capillary wedge pressure below 20 mm Hg, and right atrial pressure below 10 mm Hg. In patients with chronic heart failure and systolic dysfunction, the pulmonary capillary wedge pressure may be persistently elevated, and “normal” filling pressures may not be achievable without inducing or aggravating shock.

Acute Decompensation of Chronic Heart Failure

Diuretics

Patients who require hospitalization are often unresponsive to oral diuretics, possibly because of malabsorption resulting from bowel edema. The recommended initial approach is therefore to use IV loop diuretics, such as furosemide. These agents usually begin to reduce right ventricular (RV) and LV filling pressures within 5 minutes because of rapid venodilation. Diuresis follows shortly thereafter and continues for up to 3 hours following IV administration.

Therapy typically begins with an IV furosemide dose equal to the usual oral dose, followed by upward titration; doses are increased as required to effect diuresis and lower filling pressures. In patients not previously receiving di-

uretics, low-dose therapy (e.g., 20 to 40 mg of furosemide) is initially recommended. In patients on chronic high-dose oral diuretic therapy, even IV agents may not yield a rapid diuresis. This refractoriness may be a consequence of diminished renal perfusion or renal tubular dysfunction induced by the nephrotoxic effects of medications such as aspirin and nonsteroidal anti-inflammatory drugs, antihypertensive agents, cimetidine, and occasionally ACE inhibitors. When there is no response within 1 hour after IV administration of a diuretic, the dose is increased by 50% to 100% and readministered. When patients exhibit resistance to initial therapy with intermittent parenteral doses of loop diuretics, alternatives include a continuous infusion (often 5 to 10 mg/h) of a loop diuretic, such as furosemide, or the combination of a loop diuretic with a thiazide diuretic (e.g., metolazone) that acts synergistically at a different segment of the nephron. If these alternatives fail or if diuresis is accompanied by increasing renal dysfunction, attempts should focus on increasing cardiac output with inotropic agents or reducing resistance to renal perfusion with dopaminergic doses of dopamine (≤ 2 g/kg per minute). In truly refractory cases with escalating renal failure, dialysis is the only alternative.

As long as filling pressures are elevated and a significant amount of extravascular fluid (edema, ascites, pulmonary fluid) is present, diuresis should be continued. Diuresis-induced reduction in right-sided pressures may improve effective LV compliance, thereby improving cardiac output and renal perfusion. Reductions in ventricular filling pressures will also improve cardiac performance if tricuspid or mitral regurgitation is reduced.

Angiotensin-Converting Enzyme (ACE) Inhibitors

ACE inhibitors should be considered a distinct class of drugs with vasodilator effects, instead of simply a subgroup of vasodilators. The long-term effectiveness of these agents in reducing morbidity and mortality in patients with heart failure and a reduced LV ejection fraction has been documented more clearly than that of any other class of agents (3). They have unequivocally been demonstrated to improve survival, reduce the frequency of hospitalization, prevent disease progression, and improve quality of life in both symptomatic and asymptomatic patients with ventricular systolic dysfunction and heart failure. At least some of these benefits are likely to be mediated by myocardial and vascular effects, including prevention or regression of myocardial and possibly vascular remodeling, independent of afterload reduction.

In the setting of an acute exacerbation of heart failure, vasodilation is most practically achieved with direct, short-acting vasodilators, such as nitrates, rather than with ACE inhibitors, which have relatively long half-lives and tend to reduce the glomerular filtration rate by means of renal

effluent arteriolar dilation. However, *given the clear long-term benefit of ACE inhibitors, one of the goals of hospitalization should be to initiate and titrate ACE inhibitors toward the target doses that have been identified in large-scale clinical trials and in clinical practice guidelines* (Table 39.5). ACE inhibitors should be introduced and titrated carefully in patients with marginal renal function and blood pressure. Other adverse effects include cough, which is seen in about 5% more patients treated with these agents than with placebo in randomized trials, and, rarely, angioedema. Treatment is often initiated with a shorter-acting agent, such as captopril, before or after hospital discharge; however, most patients can be switched to a longer-acting agent, such as enalapril, lisinopril, quinapril, or ramipril, to maximize long-term compliance.

Angiotensin Receptor Blockers

Angiotensin receptor blockers (ARBs) directly inhibit the angiotensin II (AT₁ type) receptor and do not induce cough as a side effect. These agents reduce mortality in patients who cannot tolerate an ACE inhibitor by about the same 25% seen for ACE inhibitors compared with placebo (11, 12), and in head-to-head studies, ARBs are at least equivalent to ACE inhibitors (13, 14). Although data are not conclusive, recent studies also suggest that ARBs can further reduce adverse outcomes by about 15% when added to an ACE inhibitor (15).

Based on aggregate data, it is reasonable to conclude first that the benefit on cardiovascular morbidity and mortality of primary ARB therapy is extremely close to that of ACE inhibitors. Although some believe that ACE inhibitors should remain the first-line therapy in patients with heart failure, and cost is a factor, ARBs are better tolerated, and some contend that these agents are an acceptable alternative first-line therapy. Second, ARBs should routinely be prescribed in patients who are intolerant of ACE inhibitors because of cough or angioedema. Third, the combination of ACE inhibitors and ARBs remains controversial. For patients in whom addition of an aldosterone blocker is indicated (see below), there are insufficient supportive data (and reason for safety concern) regarding the combination of an ACE inhibitor, an ARB, and an aldosterone blocker. At present, many would contend that addition of either an aldosterone blocker or an ARB (but not both) should be tried in patients already receiving an ACE inhibitor and a β -blocker and whose potassium levels are not elevated and can be closely followed.

Other Combinations

The combination of hydralazine and isosorbide dinitrate diminishes mortality and improves LV performance in heart failure when compared with placebo, but this combination did not achieve the same level of survival benefit as an ACE inhibitor in the largest study. In African American

patients, however, the combination of hydralazine and nitrates may be substantially more effective than in whites, with a benefit that appears to be at least of the magnitude found with ACE inhibitors (16). Whether this combination will become first-line therapy in African Americans will depend on clinical experience and side effects. In whites, the combination of hydralazine and isosorbide dinitrate should be considered a reasonable alternative only in patients who cannot tolerate either an ACE inhibitor or angiotensin receptor blocker therapy.

β -blockers, Aldosterone Receptor Blockers, and Digoxin

In patients with heart failure and reduced LV systolic function, augmented adrenergic tone may be helpful in the short term but cause long-term complications. Results with carvedilol (3.125 mg twice daily titrated up to 25 mg twice daily based on the patient's clinical condition, blood pressure, and heart rate), bisoprolol (1.25 mg daily titrated to 5 to 10 mg daily), and long-acting metoprolol (Table 39.5) document long-term benefit in reducing morbidity and mortality. Carvedilol appears to be the preferred β -blocker (17). These agents should be considered when patients are otherwise euvoletic and well compensated, usually a day or two before (18) or in the first week or so after hospital discharge. β -blockers have no documented short-term benefit, can be deleterious during an acute exacerbation, must be used cautiously in patients with bradyarrhythmias, but have been shown to be beneficial in patients with mild, moderate, and severe symptoms (i.e., including class IV) of heart failure (19).

Spirolactone 25 mg per day reduces morbidity and mortality when added to standard care for class III or IV heart failure (20). Gynecomastia will develop in about 10% of men. Hyperkalemia is uncommon even with concomitant ACE inhibitors. More recently, in patients with post-infarction heart failure, the addition of the selective aldosterone receptor antagonist eplerenone to standard therapy, on top of treatment with an ACE inhibitor and β -blocker, has been documented to reduce mortality (21). It is essential that serum potassium and renal function be carefully monitoring following initiation of treatment and during titration of aldosterone receptor blockers because a substantial minority of patients will develop sufficient hyperkalemia to mandate discontinuation of the aldosterone receptor antagonist.

Clinical trials have confirmed the long-term benefit of digoxin in preventing recurrent hospitalization and improving symptoms and functional capacity in patients with heart failure (22); it does not, however, reduce mortality. Although there is no evidence for a benefit of digoxin in the setting of an acute exacerbation, it is reasonable to initiate treatment during hospitalization, in the absence of abnormal atrioventricular conduction (first-, second-, or third-degree heart block or slow ventricular response to atrial

TABLE 39.5
MEDICATIONS USED IN THE TREATMENT OF HEART FAILURE

Agent	Usual initial dose	Target dose ^a	Comments
Diuretics			
Furosemide	20–200 mg IV intermittent therapy 5–10 mg/h continuous infusion 20 mg qd–240 mg bid PO	Titrate to clinical response	May cause metabolic alkalosis. When used with ACE inhibitors, may cause deterioration in renal function.
Bumetanide	0.5–3.0 mg IV 0.5 mg qd–10 mg qd PO	Titrate to clinical response	Same as furosemide.
Ethacrynic acid	5–100 mg IV (0.5–1.0 mg/kg)	Titrate to clinical response	Beware of ototoxicity.
Metolazone	50 mg qd–200 mg bid PO 2.5–10 mg qd PO	Titrate to clinical response	Enhanced sodium excretion when combined with loop diuretics.
Inotropic/vasopressor agents			
Dobutamine	2.5–20 mcg/kg per minute IV	Titrate to clinical response	Increases in contractility and stroke volume do not lead to increased myocardial oxygen consumption because of reduction in afterload and filling pressures. Major concerns relate to tachycardia and arrhythmogenesis.
Milrinone	Initial 50-mcg/kg bolus over continuous infusion at 10 min, followed by 0.25–1.0 mcg/kg per minute	Titrate to clinical response	Dose reduction necessary in presence of renal dysfunction. Greater vasodilatory potency than dobutamine, which may cause more profound reductions in filling pressures and BP. Major concerns related to tachycardia and arrhythmogenesis.
Dopamine	1–20 mcg/kg per minute	Titrate to clinical response	Dopaminergic doses (<2 mcg/kg per minute) promote renal and splanchnic vasodilation. Doses of 2–10 mcg/kg per minute are primarily inotropic. At 10–20 mcg/kg per minute, vasoconstriction predominates.
Norepinephrine	2–12 mcg per minute	Titrate to clinical response	May reduce cardiac output because of increased afterload.
Digoxin	0.125–0.375 mg	Titrate to clinical response	Narrow therapeutic-toxic ratio. Serum level increased by many medications. Dose adjustment necessary in renal dysfunction.
Vasodilators			
Nitroglycerin	0.3–0.6 mg SL	Titrate to clinical response	Continuous therapy for ≥24 h leads to tolerance.
Nitroprusside	0.2–10 mcg/kg per minute IV 0.2–10 mcg/kg per minute	Titrate to clinical response	Is light-sensitive. Must be carefully titrated to BP.
Hydralazine	10–75 mg qid PO	Titrate to clinical response	Used in combination with oral nitrates in African-American patients and other patients intolerant to ACE inhibitors and angiotensin receptor blockers. Can cause tachycardia and lupus-like syndrome.
Nesiritide	2 mcg/kg bolus 0.01–0.03 mcg/kg/min	Titrate to clinical response	May cause hypotension. Prolonged infusions of >48 hour have been poorly studied.
ACE inhibitors			
Enalapril	2.5–10 mg bid	10–20 mg bid	Reduction in dose or increase in dosing interval may be necessary in renal failure. Cough relatively frequent (about 5%) side effect.
Captopril	6.25–50 mg bid	50 mg tid	
Lisinopril	5–20 mg qd	20–35 mg bid	
Quinapril	5–20 mg bid	Not established	
Ramipril	1.25–5 mg bid	5 mg bid	

(continued)

TABLE 39.5
MEDICATIONS USED IN THE TREATMENT OF HEART FAILURE (continued)

Agent	Usual initial dose	Target dose ^a	Comments
Angiotensin II (AT₁ type) receptor antagonists			
Losartan	25–50 mg qd PO	Not established	Used in patients intolerant to ACE inhibitors or sometimes in those who need it added to an ACE inhibitor.
Valsartan	80–160 mg qd PO	Not established	
β-Blocking agents			
Carvedilol	3.125–25 mg bid	25–50 mg bid	Not for use in acute heart failure; indicated in patients with NYHA class II–IV heart failure resulting from systolic dysfunction.
Metoprolol	12.5–25 mg qd	200 mg qd	
Bisoprolol	1.25–5 mg qd	10 mg qd	
Aldosterone antagonists			
Spironolactone	12.5–25 mg qd	25 mg qd	Data indicate incremental benefit.
Eplerenone	25–50 mg qd	50 mg qd	Data indicate benefit in post-infarction LV dysfunction.

^a Dose shown to be beneficial in randomized trials. This dose often is not achievable acutely in the hospital, but it should be the goal in patients with chronic heart failure unless they cannot tolerate it.

fibrillation). A loading dose is not necessary. Treatment can begin with a dose of 0.25 mg/d; lower doses should be used in the setting of reduced renal function or concern regarding atrioventricular conduction. No data support the use of serum levels to guide the digoxin dose. In addition, it is not clear that higher doses are more efficacious than lower ones in the clinical management of heart failure.

Limited data suggest that the acute use of a vasopressin antagonist may be useful in hospitalized patients whose heart failure does not respond to standard measures (23). However, the therapy remains experimental at the current time.

Pulmonary Edema

In the presence of acute pulmonary edema, *nitrate therapy* may be begun with sublingual nitroglycerin, which, in the absence of hypotension, can be repeated at 5- to 10-minute intervals (Table 39.6). Nitroglycerin is especially useful in patients with known or possible myocardial ischemia. Ongoing treatment may then be initiated with IV nitroglycerin. More effective afterload reduction may be achieved with IV nitroprusside. This agent should particularly be considered when blood pressure is normal (≥ 110 mm Hg systolic) or elevated.

In patients who have pulmonary edema and who are experiencing ongoing dyspnea at rest, *morphine sulfate* given in doses of 2–6 mg IV can alleviate symptoms by reducing preload and relieving anxiety while more definitive therapy is being prepared. Care should be taken to avoid hypotension. Morphine should be used with great caution in patients with obstructive lung disease, especially those with respiratory acidosis.

Arterial dilation with ACE inhibitors, nitroglycerin, nitroprusside, nesiritide, or low-dose (< 2 mcg/kg per

minute) dopamine reduces afterload, augments cardiac output, increases renal perfusion, and improves responsiveness to diuretics. Nitrates also act as systemic and pulmonary arteriolar dilators, thereby reducing ventricular afterload. Nitrates may reduce myocardial oxygen demand via a decrease in wall stress. In addition, nitroglycerin acts as a coronary arterial dilator, increasing coronary blood flow in the presence of coronary artery disease. Nitroglycerin (1–50 mcg/kg/min) is suggested in patients with underlying ischemic heart disease. Nesiritide (2 mcg/kg bolus, followed by 0.01–0.03 mcg/kg/min) can also be used, although experience with it remains more limited. Inotropic agents, including dobutamine, dopamine, epinephrine, norepinephrine, and milrinone, increase cardiac output and peripheral perfusion and are indicated instead of or in addition to vasodilators in patients with marginal blood pressure.

TABLE 39.6
TREATMENT APPROACH TO PULMONARY EDEMA

- Supplemental oxygen.
- Nitrate therapy: initially sublingual, then IV—induces venodilation, which reduces filling pressures and relieves myocardial ischemia. If hypertension is present, use nitroprusside.
- Morphine sulfate—initial therapy for preload reduction and anxiety reduction.
- IV diuresis—reduces alveolar edema.
- Inotropic therapy (e.g., dopamine, dobutamine) in presence of hypotension, low cardiac output.
- Actively investigate possibility of myocardial ischemia and treat if present.

Cardiogenic Shock

For additional discussion of cardiogenic shock, the reader is referred to Chapter 25.

Pharmacologic management of heart failure in the presence of both hypotension and elevated filling pressures includes diuresis to relieve pulmonary and systemic venous congestion as well as inotropic therapy to increase cardiac output and systemic perfusion (Table 39.7). One approach is to use *furosemide with dopamine*, the latter at a dose of 5.0 mcg/kg per minute with upward titration as necessary (Table 39.5). Although the target systolic blood pressure is generally ≥ 90 mm Hg, this target must be tailored to the individual patient. Some patients manifest clinical hypoperfusion at a systolic blood pressure of 90 to 95 mm Hg, whereas others may be well compensated at a systolic pressure of 85 mm Hg or even slightly lower. Dopamine doses in excess of those required to maintain adequate blood pressures should be avoided because the progressive α -adrenergic agonism at increasing doses will reduce cardiac output through excessive afterload. Dopamine is dosed based on lean rather than actual weight. If increased doses of dopamine do not improve blood pressure, addition of a more selective α -adrenergic agonist, such as *norepinephrine*, should be considered. However, high-dose dopamine, norepinephrine, and other vasoconstrictors should be used judiciously so as to maintain adequate systemic and myocardial perfusion because progressive increases in afterload raise myocardial oxygen demand and diminish renal blood flow. Norepinephrine is usually initiated at a dose of 2 mcg/min

and titrated to blood pressure, with the dose usually increased every 15–20 minutes to a maximum of approximately 12 mcg/min.

Agents with both inotropic and vasodilator actions, such as *dobutamine* and *milrinone*, are valuable adjunctive agents. They reduce left- and right-sided filling pressures while augmenting cardiac output without reducing systolic blood pressure to the extent that pure vasodilators do. These agents may be combined with vasodilators when clinical or hemodynamic improvement is not otherwise achieved, particularly in diuretic-resistant patients. Long-term dobutamine infusion can be considered in refractory patients (24).

In patients in whom medical therapy is not successful in improving clinical status, *intraaortic balloon counterpulsation* should be considered, principally in patients with an identifiable, reversible precipitant of cardiogenic shock, especially if emergent percutaneous PCI coronary intervention (PCI) is not feasible. This technique improves tissue and coronary perfusion through augmentation of diastolic pressure, and it decreases ventricular afterload. The result is improved cardiac output and reduced myocardial oxygen consumption. Intraaortic balloon counterpulsation is specifically indicated in the setting of severe acute mitral regurgitation or ventricular septal rupture, situations in which considerable benefit may be derived from reduction in aortic impedance. It is contraindicated in the presence of significant aortic regurgitation because of the adverse effect of increases in aortic diastolic pressure.

TABLE 39.7
TREATMENT APPROACH TO CARADIOGENIC SHOCK

- Pulmonary artery catheterization to guide hemodynamic management.
- Supplemental oxygen/mechanical ventilation in patients with hypoxia/respiratory embarrassment.
- Blood pressure support (e.g., dopamine) increases cardiac output and systemic perfusion.
- Inotropic vasodilators (e.g., dobutamine, milrinone) reduce filling pressures while increasing cardiac output.
- Diuretics (e.g., IV furosemide) relieve pulmonary and systemic venous congestion.
- IV fluid administration in patients with depleted intravascular volume.
- Mechanical therapy (e.g., intra-aortic balloon counterpulsation), which unloads the ventricle while augmenting coronary perfusion, is recommended when pharmacotherapy is ineffective in patients with a reversible cause of shock (e.g., ischemia). It also can be used as a bridge to definitive therapy (e.g., PCI in patients with suitable anatomy).

PCI, percutaneous coronary intervention.

DEVICE THERAPY FOR HEART FAILURE

Cardiac Resynchronization Therapy

Pacing modalities that use left ventricular stimulation to optimize cardiac pump function through synchronization of right and left ventricular contraction are referred to as cardiac resynchronization therapy. In contrast to dual-chamber pacemakers, this therapy uses a third lead placed through the coronary sinus and into a left ventricular free wall vein to allow simultaneous pacing of the ventricles. An estimated 30% to 50% of patients with chronic heart failure have significant intraventricular conduction delay, which is most often exhibited as a left bundle branch block pattern. This conduction delay leads to loss of coordination between right and left ventricular (LV) contraction.

Several recent studies have demonstrated that cardiac resynchronization therapy improves patient quality of life, increases exercise capacity, and lowers NYHA heart failure classification (25, 26). Based on these data, cardiac resynchronization therapy should be considered in Class III–IV patients who remain symptomatic despite optimal medical therapy for heart failure.

Implantable Cardioverter Defibrillators

For patients with heart failure, as much as half the mortality resulting from LV systolic dysfunction can be attributable to sudden cardiac death. In contrast to antiarrhythmic agents, which have been either harmful or neutral when used in the treatment of patients with a prior myocardial infarction and impaired LV function, implantable cardioverter defibrillators (ICDs) have been of clear benefit for primary and secondary prevention of sudden death. Data from large, randomized clinical trials have demonstrated reduced mortality in patients with both ischemic and non-ischemic cardiomyopathy who undergo ICD implantation (27, 28). Based on available data, most symptomatic heart failure patients with marked reduction in LV systolic function should be viewed as candidates for ICD implantation. Furthermore, the combination of cardiac resynchronization therapy with an ICD significantly improves survival in patients with advanced heart failure and a prolonged QRS interval (26).

Ventricular Assist Devices

Ventricular assist device (VAD) therapy is an option for patients with end-stage heart failure whose symptoms fail to improve with medical therapy. However, given the risk of short- and long-term device-related complications following implantation, VAD therapy should be considered only after all meaningful medical therapeutic options have been exhausted (but before progression to irreversible end-organ failure has occurred). These devices have been successful as both a bridge-to-cardiac transplantation and permanent therapy for patients with end-stage heart failure (29). Two intracorporeal VADs approved by the U.S. Food and Drug Administration as a bridge-to-transplantation are the HeartMate VE (Thoratec, Pleasanton, CA) and the Novacor LVAS (Novacor World Heart Corporation, Oakland, CA). Both are pulsatile devices with external controllers and batteries that are connected to the pump by transcutaneous leads and have a flow rate of approximately 10 liters/min. These two devices have been very successful when utilized as a bridge-to-transplantation, with a success rate for survival to transplant of approximately 70%.

Limitations to existing treatment options for patients with end-stage heart failure, including the severe shortage of donor organs, have prompted the use of VADs not only as a bridge-to-transplantation, but also as an alternative to transplantation in patients who are ineligible for cardiac transplantation. One randomized trial showed a 48% reduction in the risk of death from any cause with an LVAD (30), but the frequency of serious adverse events in the device group was more than double that in the medical therapy group. Based on the results of the REMATCH trial, Medicare has approved payment for LVAD use as destination therapy in patients with chronic end-stage heart disease who are not eligible for cardiac transplantation (Chapter 40).

PATIENT SUBSETS

Patients with Predominant Right Ventricular (RV) Failure

Patients who present with signs and symptoms of RV dysfunction most frequently do so as a consequence of LV failure. Other causes include direct RV myocardial dysfunction, RV pressure or volume overload, or impediments to RV inflow. Examples of RV myocardial dysfunction include RV MI and dilated cardiomyopathy. RV pressure overload may be related to chronic LV failure, chronic mitral valve disease (e.g., mitral regurgitation), or cor pulmonale (e.g., COPD, pulmonary emboli). RV volume overload may be secondary to pulmonic or tricuspid regurgitation, a left-to-right intracardiac shunt, or other causes.

Clinical findings in RV failure are influenced by the elevated systemic venous pressure and the depressed cardiac output, and vary depending on the chronicity of these abnormalities. Patients with acute RV failure, as may be found in RV MI and acute pulmonary embolism, may exhibit signs of low cardiac output and elevated jugular venous pressure with prominent *v* waves. Other findings may include the murmur of tricuspid regurgitation, right-sided S₃ gallop, and Kussmaul's sign. In patients with chronic RV pressure overload, signs of pulmonary hypertension and RV hypertrophy are often present, including RV S₄ gallop, RV heave, and a loud pulmonic component to the second heart sound.

Regardless of the cause, patients with chronic RV failure most often present with edema and ascites. In addition, visceral edema may cause signs and symptoms of hepatic, renal, and gastrointestinal dysfunction. Impaired parietal pleural drainage may lead to pleural effusions.

In patients with chronic RV failure, IV diuretics are useful in decreasing sodium and water retention, central venous pressure, and edema. Diuretics can improve forward output by decreasing the degree of tricuspid regurgitation and by decreasing RV distention, thus reducing a ventricular-interdependent restraint on LV filling. In addition to loop diuretics, spironolactone can be effective in reducing edema resulting from RV failure because activation of the renin-angiotensin-aldosterone system is involved in sodium retention in these patients.

Systemic arteriolar dilators useful in LV failure (e.g., ACE inhibitors, nitrates, nitroprusside) also act as pulmonary vasodilators and thus improve RV output by reducing RV afterload. Because RV afterload may be augmented by hypoxia in patients with COPD, supplemental oxygen may decrease pulmonary hypertension and should be used acutely and perhaps on a long-term basis in decompensated COPD patients with RV failure. In addition, bronchodilators may improve symptoms and RV function in patients with decompensated COPD through a combination of bronchodilation, pulmonary vasodilation, and inotropy.

Concomitant Myocardial Ischemia

Myocardial ischemia or MI can precipitate heart failure by acutely diminishing systolic and diastolic performance and by causing mitral regurgitation. It is essential to maintain a low threshold for considering ischemia as a precipitant of heart failure because ischemia is reversible by medical therapy or coronary revascularization and because uncorrected ischemia is associated with a poor prognosis.

Heart failure and active ischemia may present together in a pathophysiologic vicious cycle. Heart failure is frequently characterized by LV dilation and tachycardia, which increase myocardial oxygen consumption and can precipitate ischemia in patients with coronary artery disease and diminished coronary reserve. Abnormal systolic and diastolic function lead to elevation in LV diastolic pressure; the resulting reduction in the transcatheter pressure gradient predisposes to subendocardial ischemia. Conversely, acute myocardial ischemia compromises both diastolic and systolic LV performance, which leads to a rise in filling pressures and to symptoms secondary to pulmonary congestion and low output.

Patients with regional asynergy and global LV dysfunction may have significant recovery of contractile function following revascularization with coronary artery bypass surgery or PCI. Such patients may have severe coronary stenosis with reduced myocardial blood flow that is adequate to maintain regional myocardial viability but not to provide normal function at rest or with minimal stress. The resulting “hibernating myocardium” can regain normal function following the restoration of myocardial blood flow after coronary revascularization.

Although there have been no randomized trials of revascularization among patients presenting with heart failure, revascularization in the setting of LV dysfunction appears to be associated with lower rates of morbidity and mortality than medical treatment. In addition, most studies of patients with angina and LV dysfunction suggest a survival benefit for those patients who undergo coronary revascularization.

It is currently recommended that *heart failure patients with exercise-limiting angina or recurrent pulmonary edema undergo coronary arteriography and subsequent revascularization when feasible*. Heart failure patients without significant angina but with a history of MI should undergo a physiologic test for myocardial viability (Chapter 36) and, when appropriate, angiography followed by revascularization.

When acute MI leads to cardiogenic shock, emergent cardiac catheterization is indicated (Chapter 38). Acute primary PCI is likely to result in improved survival in comparison with thrombolysis (31).

Heart Failure Caused by Valvular Heart Disease

For additional discussion of this topic, please see Chapter 41.

Several valvular lesions, when severe enough, can lead to symptoms of heart failure. Symptomatic patients with physical or imaging findings suggestive of *critical aortic stenosis* have improved survival following aortic valve replacement, which also usually improves LV performance. Medical management can provide short-term benefit but is not a substitute for prompt valve surgery. Patients with either heart failure symptoms or evidence of LV dysfunction and dilation secondary to *chronic aortic regurgitation* are best treated with aortic valve replacement. Therapy with vasodilators such as ACE inhibitors, hydralazine, and nifedipine can improve hemodynamics and symptoms of aortic regurgitation before surgery.

Patients with *mitral stenosis* should undergo correction (balloon valvuloplasty, open commissurotomy, or mitral valve replacement) whenever symptoms become difficult to manage with a combination of diuretics and heart rate control. Mitral valve repair or replacement is recommended as soon as it is feasible in *acute symptomatic mitral regurgitation*. Patients with *chronic mitral regurgitation* should, in general, undergo mitral valve repair or replacement when heart failure symptoms are present or when diagnostic testing documents abnormal LV function or LV dilatation (end-systolic dimension >45–50 mm).

Heart Failure with Normal Ejection Fraction

A majority of patients hospitalized for heart failure have a low resting LV ejection fraction. A significant minority, however, have a normal LV ejection fraction. In some patients, ejection fraction may be normal when measured but was abnormal when the symptoms developed; these patients may have transient ischemia, arrhythmias, toxic exposure (e.g., alcohol), or severe hypertension. Other patients may have a normal ejection fraction but heart failure related to mitral regurgitation. In some patients, the diagnosis of heart failure may be incorrect, and the symptoms may have other causes, such as pulmonary disease.

In other patients, a variety of different disorders can lead to abnormal ventricular relaxation and compliance, increased vascular stiffness, and/or reduced renal sodium clearance, with consequent elevation in ventricular filling pressures leading to pulmonary venous and capillary hypertension. Such patients cannot increase cardiac output in response to stress without inordinate increases in LV filling pressure and associated pulmonary congestion. The single most common etiology is hypertension. *Restrictive cardiomyopathies* are caused by conditions such as sarcoidosis, amyloidosis, hemochromatosis, and radiation injury. Other causes include hypertrophic cardiomyopathy and pericardial constriction. Echocardiography may suggest abnormal diastolic function in a patient with a thickened myocardium, a predisposing condition, or pericardial disease.

The ARB candesartan showed a trend toward reducing the primary endpoint of cardiovascular mortality or heart failure hospitalization in these patients, but this finding did not reach statistical significance (32). A number of additional studies are under way. Based on physiologic considerations, as well as findings in patients with hypertension and LVH (33), the general consensus is to recommend an ACE inhibitor or ARB in patients with heart failure, preserved ejection fraction, and a history of hypertension. In patients with heart failure with normal ejection fraction, diuretics are often needed to normalize fluid balance. Doses should be titrated carefully because these patients are often volume-sensitive and many have marginal renal function. Hypertension should be aggressively managed (monitoring renal function carefully) (Chapter 48). In patients who continue to be hypertensive despite ACE inhibitors and diuretics, a β -blocker or calcium blocker should be considered. β -blockers are particularly useful in patients with tachycardia, including those with atrial fibrillation, in whom rate control represents a major therapeutic goal. Myocardial ischemia should be treated with medications and, when appropriate, revascularization (Chapters 37 and 38).

ISSUES DURING HOSPITALIZATION

Patients with acute decompensation of chronic heart failure usually manifest rapid clinical improvement in response to IV diuretics, especially if coexisting illnesses are properly treated. Patients usually note marked symptomatic improvement, with resolution of rest dyspnea, by the end of the first hospital day. As the patient approaches his or her dry body weight, IV therapy is withdrawn and oral agents are reinstated.

For patients with pulmonary edema, the hospital course is influenced by whether or not a precipitant for decompensation is identified. If IV diuresis is effective and any concomitant ischemia is successfully treated, the patient may be asymptomatic on the first hospital day; attention should then be focused on definition of the coronary anatomy and potential revascularization. Similarly, if valvular disease (such as mitral regurgitation) is responsible for decompensation, valvular repair or replacement preceded by coronary angiography should be strongly considered (Chapter 41).

Patients with cardiogenic shock have a high mortality regardless of etiology. Emergent PCI is indicated for cardiogenic shock in the presence of acute MI. For patients with papillary muscle rupture or an acute ventricular septal defect, emergency repair is recommended (Chapter 38). In patients who are not eligible for these therapies, consideration should be given to intra-aortic balloon counterpulsation or ventricular assist devices if a definable acute and potentially recoverable event is responsible for the abrupt deterioration or if cardiac transplantation (Chapter 40) is being considered.

DISCHARGE ISSUES

In general, patients admitted to the hospital for heart failure may be discharged when symptoms have been controlled and reversible precipitants have been treated. Noncompliance with medication and dietary recommendations is the most common identifiable causes of readmission. Thus, care should be taken before discharge to initiate and reinforce education regarding a diet restricted to approximately 2 g of sodium per day, self-monitoring through daily weights, and the importance of compliance with medications. Unusual patients who have not recovered to the point of unassisted ambulation may benefit from a short stay in a skilled nursing facility for rehabilitation.

All patients should be on an ACE inhibitor or angiotensin receptor blocker unless it is absolutely not tolerated. β -blockers also reduce mortality in patients with class II–IV heart failure. Although initiation of these agents requires a degree of clinical stability, there is increasing evidence that they can be initiated safely in low doses and titrated slowly in patients hospitalized with heart failure (18). Aldosterone receptor blockade has been shown to be beneficial, in addition to ACE inhibitors, in patients with class IV, or recent class IV, symptoms, and in patients following myocardial infarction, reduced ejection fraction, and signs or symptoms of heart failure. These agents may ultimately prove to be useful in broader populations of patients with heart failure. Digoxin is beneficial for symptoms but not longevity.

A mechanism for achieving careful follow-up must be established before discharge. Such follow-up generally includes an office visit within 2 weeks of discharge. Programs in *heart failure disease management* may reduce the frequency of readmission and maintain or improve the quality of life (34, 35). These programs, which serve as an extension of care beyond hospitalization and the office visit, focus on optimizing patient compliance and providing a rapid medical response to subtle changes in the patient's condition. They are generally delivered by nurses linked to primary care physicians and utilize a mixture of home visits and telephone monitoring. Such programs have the potential to reduce length of stay by providing patients and hospital physicians with a sense of security regarding post-acute care. Effective programs may also reduce readmission rates and emergency department visits. Exercise training can improve functional capacity but its impact on reducing mortality is less certain (36).

The response to inpatient treatment typically results in reductions in BNP levels. High predischarge levels predict readmission and death, even among patients who have responded clinically during hospitalization (37, 38).

Loss of weight unrelated to diuresis portends a poor outcome in patients with heart failure (39), as does progressive renal dysfunction (40); the only known treatment is better control of the heart failure. For anemia, transfusion or erythropoietin to raise the hemoglobin level should be considered, but the target level remains uncertain (10).

WHEN HEART FAILURE PRESENTS DURING HOSPITALIZATION

The physiologic stresses associated with any of a variety of illnesses can cause decompensation in patients with known or unsuspected LV dysfunction. In addition, previously undiagnosed valvular disease may become clinically manifested during the tachycardia and fluid administration attendant to surgery. One example is the diagnosis of heart failure in a previously healthy young woman in whom pulmonary congestion develops after administration of fluid or blood products after parturition (Chapter 32). These patients are usually easily managed with diuresis.

In patients with known and previously undiagnosed LV dysfunction in whom heart failure becomes manifest during hospitalization for another illness, it is of primary importance to correct the underlying disorder that prompted hospitalization; heart failure should be managed according to symptoms and the clinical examination as detailed above. When heart failure occurs in the setting of acute MI, medications with inotropic and especially chronotropic action (e.g., dobutamine) should be avoided if possible because they may increase myocardial oxygen consumption and thereby potentially worsen ischemia and increase infarct size. Like patients admitted primarily for heart failure, patients with previously unrecognized LV dysfunction should have standard long-term therapy instituted before hospital discharge.

COST CONSIDERATIONS AND RESOURCE USE

Heart failure is the single most common cause for hospitalization among patients old enough to receive Medicare benefits. Care for patients with heart failure has been estimated to cost about \$20 billion annually, with approximately 75% of that cost expended within the hospital setting (1, 2). Importantly, there has been a focus on reducing the readmission rate, which has been reported to be as high as 40% during 6 months. Although it would also be valuable to reduce length of stay, hospitalization should not be shortened at the expense of a markedly increased readmission rate; it is essential that patients not be discharged before stability is achieved, needed medications are instituted, and adequate follow-up is arranged.

KEY POINTS

- Patients hospitalized with heart failure require simultaneous emergent evaluation of possible causes of decompensation and individualized therapy focusing on the principal hemodynamic perturbation.
- Once filling pressures have been reduced and depressed cardiac output and blood pressure treated, plans for long-term management should be addressed. Management

should include administration of pharmacologic agents with proven survival benefits: angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and β -blockers; aldosterone receptor blockers, at least in patients with class IV or recent class IV symptoms; and cardiac resynchronization therapy, implantable cardioventricular defibrillators, and coronary revascularization in appropriately selected patients. Renal function, electrolytes, hematocrit, and clinical status should be carefully monitored during up-titration of drug therapy.

- Plans for focused follow-up are crucial to ensure successful ongoing management. They include careful evaluation of dietary and medication compliance, optimization of medical treatment, constant re-evaluation, and early response to changes in volume status.

Heart Transplantation

40

Maria Ansari Teresa DeMarco

INTRODUCTION

Despite advances in pharmacologic therapy and mechanical assist devices, the mortality for end-stage heart failure remains 50% at 1 year. With improved surgical techniques and the availability of cyclosporine, the overall 1-year actuarial survival after heart transplantation is 85%, and the 5-year actuarial survival is 71% (1, 2). More than 40,000 transplants have been performed worldwide since 1982. In the United States, approximately 2,200 donor hearts are available per year, but nearly 10,000 patients are referred annually for cardiac transplantation.

EVALUATING A PATIENT FOR CARDIAC TRANSPLANTATION

Selection Criteria

Cardiac transplantation is indicated in patients with terminal heart failure in whom all other conventional therapies have failed or are inappropriate (Table 40.1). Cardiomyopathy, coronary heart disease, and valvular heart disease are the three most common indications for adult cardiac transplantation (2). Candidates are usually New York Heart Association class III or IV, with an unacceptable quality of life and a 1-year predicted survival less than could be achieved with transplantation. Patients with peak oxygen consumption (VO_2 max) during exercise of less than 14 mL/kg per minute have a 1-year survival of about 32% and should therefore be referred immediately for transplantation (3). By comparison, patients with a VO_2 max above 14 mL/kg per minute have a 1-year survival close to 90% with medical therapy and are not candidates for immediate transplant. It is important that patients undergo repeated testing if the clinical condition changes.

Exclusion Criteria

Contraindications for transplantation (Table 40.2) include comorbid conditions with a poor prognosis, ongoing unresolved medical diseases or neoplasms, and important psychosocial issues that may lead to life-threatening non-compliance. A physiologic age over 65 years is a controversial relative contraindication based on data showing a significant decrease in posttransplant survival for each decade of age and a clinically significant decrease in survival after the age of 65.

Short- and long-term survival postcardiac transplant is closely linked to the preoperative pulmonary vascular resistance (PVR). Patients with a PVR below 2.5 Wood units, pulmonary artery pressure below 50 to 60 mm Hg systolic, and a mean transpulmonary gradient (mean pulmonary artery pressure minus pulmonary capillary wedge pressure) of 15 mm Hg or less have a better prognosis than do patients with higher values (4). Patients with a high PVR who respond to intravenous (IV) nitroprusside (PVR <2.5 Wood units with adequate systemic pressure) also have a favorable prognosis.

Listing a Patient for Transplant

After patients have been selected as appropriate candidates for cardiac transplantation, they are placed on the United Network for Organ Sharing (UNOS) waiting list in one of two categories. Status I patients require IV vasoactive drugs or mechanical support in an ICU to maintain adequate hemodynamics. All other patients are Status II. Status I patients generally wait weeks-to-months for an available organ. Status II patients often wait 6 months to several years, and 20–40% of Status II patients die while awaiting a donor heart.

TABLE 40.1**INDICATIONS FOR CARDIAC TRANSPLANTATION**

- Refractory class III or IV heart failure despite optimal contemporary therapy
- Recurrent and refractory symptomatic ventricular arrhythmias with unacceptable quality of life
- Recurrent and refractory unstable ischemic heart disease with major functional limitations
- Maximum oxygen consumption ($VO_2\text{max}$) <14 mg/kg per minute

BRIDGE TO CARDIAC TRANSPLANTATION

The cardiac organ donor supply is inadequate to meet demands. When intense interventions (Chapter 39) fail to stabilize a patient with unstable refractory heart failure, mechanical support is required. Among patients who are at high risk for dying of irreversible myocardial failure despite maximum inotropic support with or without an intraaortic balloon pump but who do not have irreversible end-organ damage, *left ventricular assist devices* (LVADs) can provide a successful bridge to transplantation in about 75% of cases. Complications of LVADs include thromboembolism, infection, and right ventricular (RV) failure from increased PVR. Use of a LVAD is usually part of a two-step process: first the insertion of the device and correction of vital organ hypoperfusion; second, orthotopic heart transplantation as soon as a donor is available, usually within weeks to months. However, the LVAD is also being evaluated as a bridge to recovery in patients with reversible causes of heart failure, and even as a permanent ventricular support device. In selected patients with end-stage heart failure, these devices have been used for 3 years or longer with improved quality of life and an acceptable mortality rate (5), thereby serving as a reasonable alternative in patients who are not candidates for transplantation (Chapter 39).

CARDIAC TRANSPLANTATION SURGERY**Donor Organ Selection**

Donor hearts must be ABO-compatible with the recipient, but HLA matching is neither necessary nor feasible. All transplant recipient candidates are screened for allo-antibodies by means of a panel-reactive antibody (PRA) test of recipient serum against a panel of allogeneic lymphocytes with known HLA antigens. For potential recipients who react to 15% or more of the panel, prospective lymphocyte cross-matching is performed by mixing recipient serum with potential heart donor lymphocytes; a positive cross-

TABLE 40.2**EXCLUSION CRITERIA FOR CARDIAC TRANSPLANTATION**

- Physiologic age >65 y
- Active infection
- Active peptic ulcer disease
- Severe diabetes mellitus
- Severe peripheral vascular disease
- Severe chronic obstructive pulmonary disease
- Renal failure (creatinine >2 mg/dL and or creatinine clearance <50 mL/min, unless caused by low cardiac output)
- Liver disease with serum bilirubin >2.5 mg/dL, aminotransferases more than twice the upper limit of normal, prothrombin time >14 sec
- Pulmonary artery systolic pressure >60 mm Hg
- Pulmonary vascular resistance >3.0 Wood units despite vasodilator trial
- Mean transpulmonary gradient >15 mm Hg
- Active substance abuse
- Psychosocial impairment limiting medical compliance

Adapted from Stevenson LW. Candidates for heart transplantation: selection and management. In Poole-Wilson PA, Colucci WS, Massie BM, et al., eds. *Heart Failure: Scientific Principles and Clinical Practice*. New York: Churchill Livingstone, 1997:807–826.

match excludes that donor heart for the recipient. Potential donor hearts must also be free of significant infectious agents (i.e., viral hepatitis, HIV). Donor heart function is examined by echocardiography; coronary angiography should be performed if the donor is at high risk for coronary artery disease (CAD). Potential organ donor weight must be within 20% of the recipient weight to match cardiac size. Finally, the donor heart must be within a 1,000-mile radius of the recipient to ensure an ischemic time of less than 6 hours to minimize damage to the donor heart during transport.

Operative Methods

Orthotopic heart transplantation involves the partial removal of recipient atria and the entire removal of the ventricles. In the *bicaval technique*, which is now the standard of care, the recipient's right atrium is excised with a cuff left intact around both the superior and the inferior vena cava (6). Most of the recipient's left atrium and all of the interatrial septum are removed.

CARE OF THE HOSPITALIZED PATIENT**Early Post-transplant Care****Unique Physiologic Properties**

Because of preservation injury, the newly transplanted heart is a model of *stunned ischemic myocardium*, character-

ized by transient systolic and diastolic dysfunction, bradycardia, and RV dysfunction. It is also devoid of autonomic innervation. Inotropic and chronotropic support, usually with a combination of isoproterenol and dopamine, is generally needed for the first 3 to 5 postoperative days. The target heart rate for the early postoperative period is between 110 and 130 beats/min to maximize cardiac output (cardiac index >2.5 L/min per square meter.) When the above combination is inadequate to attain optimal hemodynamics, milrinone, epinephrine, or both may be required. RA filling pressures are maintained at 8 to 15 mm Hg to attain adequate cardiac output. Diuretics are usually initiated after the first day to achieve normal RA pressures. In cases of pulmonary hypertension, pulmonary vasodilators such as nitroprusside, prostacycline, or inhaled nitric oxide can be employed (Chapter 59).

Bradycardia and Tachycardia

In the early posttransplant period, bradycardia (sinus or junctional bradycardia, or AV block) is common as a consequence of preservation injury, sinus node edema from ischemia during surgery, conduction system injury inflicted at the time of harvest, electrolyte disturbances, preoperative administration of amiodarone, or allograft rejection (Table 40.3).

Treatment for bradycardia early after transplant includes isoproterenol or nonglycoside inotropes. Atropine, whose chronotropic action is based on a vagolytic mechanism, will not be effective in increasing donor sinus rate in a denervated heart but may reverse vagally-mediated peripheral vasodilation. Bradycardia generally resolves within several days after transplant. However, a small percentage of patients (3–15%) require permanent pacemakers.

Several weeks after transplantation, the denervated heart exhibits a resting sinus tachycardia because of the loss of parasympathetic tone. The heart rate rises more slowly with exercise and is attenuated at peak exercise. Compared with the normal heart, the denervated heart depends more on an augmented stroke volume than on an increased heart rate to increase cardiac output.

Ventricular and Supraventricular Dysrhythmias

Ventricular or supraventricular tachycardias (Table 40.4) after transplant may be signs of preservation injury (early posttransplant), allograft rejection, ischemia, or electrolyte disturbance. The most common cause of early posttransplant tachyarrhythmias is preservation injury, which tends to resolve in several days. Myocardial ischemia from transplant CAD is a cause of late dysrhythmias.

Drugs that primarily act through the autonomic nervous system will have no effect on the transplanted heart. For example, digoxin, a vagotonic agent, will not be effective in managing supraventricular arrhythmias in the usual clinical doses. Type Ia anti-arrhythmics (e.g., quinidine, procainamide) exert not only vagotonic properties (which will not be observed in the transplanted heart) but also direct effects (which will be observed); these agents slow both the sinus rate and AV conduction, which makes them effective agents for tachyarrhythmias. Calcium channel blockers and β -blockers directly slow the sinus rate and AV conduction in the transplanted heart; because of their negative inotropic and chronotropic effects, they must be used cautiously in the early transplant period, when allograft function is marginal.

TABLE 40.3
ELECTRICAL DISTURBANCES AFTER CARDIAC TRANSPLANT

Bradycardia

Cause	Onset	Treatment
Sinus node preservation injury	Early	Time/temporary pacer
Conduction system injury at harvest	Early	Time/temporary and/or permanent pacer
Amiodarone	Early	Time/temporary pacer
Electrolyte derangement	Early or late	Electrolyte normalization
Allograft rejection	Early or late	Increased immunosuppression

Ventricular or supraventricular tachycardia

Cause	Onset	Treatment
Preservation injury	Early	Time, antiarrhythmics
Hypomagnesemia, hypokalemia	Early or late	Electrolyte normalization
Allograft rejection	Early or late	Increased immunosuppression
Myocardial ischemia (transplant coronary artery disease)	Late	Nitrates, β -blockers, aspirin, lipid-lowering agents, revascularization, re-transplantation

TABLE 40.4
SIGNS AND SYMPTOMS OF ACUTE ALLOGRAFT REJECTION

Signs and symptoms	Pathophysiology
Fever	Cytokine release from injured myocardium and activation of inflammatory pathways
Fatigue, decreased exercise tolerance	Cytokine release, decreased cardiac function
Cough	Increased pulmonary vascular pressures from systolic or diastolic dysfunction
Syncope, near-syncope	Bradycardia/VT/SVT
Palpitations	VT/SVT
Dyspnea	Increased pulmonary venous pressures
Sudden death	Terminal arrhythmia
Decreased urine output	Decreased cardiac output and decreased renal perfusion
Pulmonary crackles	Increased pulmonary venous pressures
Loud pulmonic heart sound	Increased pulmonary arterial pressures
S ₃ gallop	High left ventricular end-diastolic pressures from low cardiac output
New regurgitant murmur (tricuspid or mitral)	Dilation of right and/or left ventricle
Jugular venous distention	Right or left ventricular failure

SVT, supraventricular tachycardia; VT, ventricular tachycardia.

Right Ventricular Failure

Heart transplant recipients with preexisting pulmonary hypertension are at high risk for the development of RV failure soon after transplant surgery. RV failure is initially treated with pulmonary vasodilators such as nitroprusside, prostacycline, or inhaled nitric oxide. Isoproterenol, milrinone, or both are often required to support the compromised RV. For RV failure refractory to pharmacologic intervention or in cases of concomitant systemic hypotension, an RVAD should be placed until intrinsic pulmonary hypertension reverses and RV function improves.

Biventricular Failure

Biventricular failure after transplantation should always prompt the suspicion of allograft rejection, although there are other causes (Table 40.4). Immediately after transplant, the cause is usually hyperacute allograft rejection from preformed allo-antibodies. In the early posttransplant period, biventricular pump failure can be a manifestation of organ preservation injury, tamponade, or acute allograft rejection. Posttransplant tamponade tends to occur in a posterolateral closed space and is almost always a consequence of postoperative bleeding; surgical decompression is necessary. Biventricular failure for 2–10 days postoperatively can be a manifestation of preservation injury; this is a diagnosis of exclusion and is treated with hemodynamic support.

Allgraft Rejection

Allograft rejection occurs at a rate of 0.5 to 2.5 episodes per patient during the first posttransplant year. *Hyperacute allograft rejection* presents in the operating room or immediately postoperatively and results in primary nonfunctioning of the graft. *Acute cellular allograft rejection* usually occurs within the first 6 months after cardiac transplantation but can occur later; it is the most common form of allograft rejection. *Chronic rejection* presents with slowly developing symptoms of fatigue and dyspnea suggestive of transplant CAD.

Prophylaxis

Prophylactic immunosuppression regimens are transplant center-specific. (For a general discussion of available immunosuppressive regimens, see Chapter 102, particularly Table 102.4.) Maintenance prophylaxis involves triple therapy: prednisone, azathioprine (or mycophenolate mofetil), and cyclosporine (or tacrolimus).

Indications for Hospital and Intensive Care Unit Admission

Because allograft rejection can be clinically silent, surveillance endomyocardial biopsies are performed to exclude occult allograft rejection (every week for the first four weeks, then every other week for two more weeks, then

quarterly twice, semi-annually twice, and then yearly thereafter). Additional endomyocardial biopsies are performed whenever allograft rejection is suspected.

Any patient with hemodynamic instability, signs of heart failure, or symptomatic dysrhythmias should be admitted to the ICU for cardiac rhythm monitoring, invasive hemodynamic monitoring, inotropic support, and intensified nursing care (Table 40.5). By comparison, moderate acute cellular rejection without hemodynamic compromise or dysrhythmias is usually treated in the outpatient setting, as supervised by a transplant center.

Treatment of Allograft Rejection

The treatment of acute cellular rejection includes optimization of immunosuppression (Table 40.5). Acute humoral rejection must be treated aggressively with immunosuppression and plasmapheresis to remove circulating im-

munoglobulin and reduce anti-allograft immunoglobulin titers.

Indications for Early Consultation

Every cardiac transplant patient admitted for possible allograft rejection to any hospital requires an urgent consultation with a transplant cardiologist. The cardiologist will assist in the evaluation of suspected allograft rejection, which includes an endomyocardial biopsy. Once the diagnosis is established, treatment should begin under the direction of the cardiologist.

DISCHARGE ISSUES

Patients admitted with cardiac allograft rejection often have hospital stays ranging from several days to several weeks, depending on the clinical manifestations of the rejection

TABLE 40.5
TREATMENT OF ALLOGRAFT REJECTION

Endomyocardial biopsy grade	Clinical status	Treatment
Acute cellular rejection		
1A, 1B, 2	Subclinical	No augmentation of immunosuppression
2	Overt ^a	Optimize immunosuppression ^b Prednisone pulse ^c
3A	Subclinical	Optimize immunosuppression Prednisone pulse
3A	Overt	Optimize immunosuppression Methylprednisolone pulse ^d
3B	Subclinical, ≤3 mo from transplant	Optimize immunosuppression Methylprednisolone pulse
3B	Overt, >3 mo from transplant	Optimize immunosuppression Methylprednisolone pulse
3B, 4	Overt, ≤3 mo from transplant, subclinical or overt >3 mo from transplant	Optimize immunosuppression ATG or OKT3 ^e
Acute humoral rejection		
Not applicable	Subclinical/overt	Plasmapheresis (60 mL/kg qod) Methylprednisolone pulse Cyclophosphamide 1 mg/kg per day PO Optimize immunosuppression IV immunoglobulin
Hyperacute rejection		
Not applicable	Overt	Mechanical ventricular assist devices Total artificial heart Urgent re-transplantation

^aOvert: Hemodynamic compromise, allograft dysfunction clinically or on echocardiogram, arrhythmias.

^bOptimize immunosuppression: Increased doses within conventional range as toxicity permits; consider changing azathioprine to mycophenolate mofetil (1–1.5 g PO bid); consider changing cyclosporine to tacrolimus (0.1 mg/kg PO bid); consider the addition of methotrexate 5–7.5 mg PO qd for 3–5 days for refractory rejection.

^cPrednisone pulse: 1.5 mg/kg PO qd (or divided doses) for 5 days, then rapid taper.

^dMethylprednisolone pulse: 1 g IV qd × 3, then subsequent prednisone taper.

^eATG (anti-thymocyte globulin): 10 mg/kg per day IV × 7–10 doses or OKT3 5 mg/d IV × 10 doses.

episode and the therapeutic response. A patient is ready for discharge when a clinical response to augmented immunosuppression leads to improved symptoms and acceptable hemodynamics on a stable oral medication regimen. Discharge planning is a coordinated effort between the inpatient hospital team, the transplant cardiology consult team, and the patient's primary care provider in the community. Patients often live far away from a center that provides transplant cardiology care, so outpatient follow-up with the patient's primary physician is extremely important.

Some immunosuppressive medications (e.g., cyclosporine, tacrolimus, mycophenolate-mofetil) may not be readily available at community pharmacies. It is critical to anticipate discharge and to have medications available when the patient leaves the hospital. The patient generally returns in 1 to 2 weeks for an endomyocardial biopsy to assess response to therapy. The scheduling of subsequent endomyocardial biopsies is adjusted based on the frequency of rejection episodes and the presence or absence of persistent rejection.

Late Posttransplant Care

Long-term immunosuppressive therapy in the cardiac transplant patient has many potential sequelae, including

infection, malignancy, and other organ-specific complications (Table 40.6).

Infections

For additional discussion of infection in immunocompromised hosts, see Chapter 63.

The blood and lungs are the most common sites of infection after heart transplantation. Cardiac transplant patients are particularly prone to pancreaticobiliary disease and especially acalculous cholecystitis, in which the usual signs and symptoms of cholecystitis may be blunted or absent. There should be a low threshold to image the gallbladder and biliary system when gastrointestinal complaints are present (Chapter 84).

Renal Insufficiency

Patients presenting with decreased urine output, lower-extremity edema, or easy bruisability should be evaluated for renal insufficiency, which may be caused by cyclosporine or tacrolimus. Cyclosporine and tacrolimus cause prerenal azotemia by constricting afferent renal arterioles; this effect can be modified by reducing doses when permitted. Cyclosporine and tacrolimus also produce a

TABLE 40.6
COMMON LONG-TERM COMPLICATIONS OF CARDIAC TRANSPLANTATION

Complications	Etiology
Opportunistic Infections	Immunosuppression
Renal failure	Cyclosporine alone or in combination with other drugs Renal hypoperfusion (e.g., because of sudden death, arrhythmias, or sepsis) Hemolytic uremic syndrome
Musculoskeletal	
Myopathy, rhabdomyolysis, gout	Drug-induced (lipid-lowering agents with cyclosporine)
Central nervous system	
Seizures, depression, psychosis, headache, tremor, focal deficits	Drug-induced (cyclosporine, steroids) Hemolytic uremic syndrome Infections (<i>Nocardia</i> , <i>Aspergillus</i>) Malignant hypertension
Metabolic	
Hyperglycemia, electrolyte abnormalities, adrenal crisis, hyperlipidemia	Drug-induced (cyclosporine, steroids)
Vasculopathy	
Transplant coronary artery disease	Endothelial injury and repair
Malignancy	
Lymphoproliferative disorders, skin, lips, solid organs	Immunosuppression

generally reversible renal tubular dysfunction characterized by potassium retention, magnesium wasting, and diminished uric acid secretion.

Cyclosporine/tacrolimus renal failure can be exacerbated by other nephrotoxic agents (nonsteroidal antiinflammatory agents, amphotericin B, aminoglycosides, angiotensin-converting enzyme inhibitors, or angiotensin II receptor blockers) or drugs that alter the metabolism of cyclosporine/tacrolimus (Chapter 102). Other causes of renal insufficiency include heart failure and hypotension. A rare complication of cyclosporine/tacrolimus is the hemolytic uremic syndrome (Chapter 98).

Musculoskeletal System

There is a small risk of rhabdomyolysis with the use of anti-hyperlipidemic agents (statins and fibrates) in combination with cyclosporine. Statins should be started at doses lower than usual, and creatine kinase levels should be checked, especially if there are any symptoms of myalgias or muscle weakness. Because pravastatin is not extensively metabolized by the cytochrome P450 system, it is less likely than other statins to cause myopathy in patients taking cyclosporine.

Central Nervous System

Cyclosporine/tacrolimus can lead to drug-induced central nervous system changes, such as alterations in cognition and personality, seizures, headaches, tremors, and cortical blindness. These changes are dose-related and generally resolve with a reduction (or discontinuation) of cyclosporine/tacrolimus doses.

Transplant patients are also subject to opportunistic central nervous system infections, such as nocardiosis and aspergillosis. Malignant (cyclosporine-induced) hypertension may also present with mental status changes and headaches.

Affective disorders are common after heart transplantation. Many patients will require antidepressants and long-term follow-up with a psychiatrist or psychologist; these interventions may enhance compliance with immunosuppressive therapy, as well as quality of life.

Metabolic Disturbances

Heart transplant patients are at risk for all the usual complications of high-dose steroids. Stress-dose corticosteroids (usually 100 mg of hydrocortisone three times a day for the first day) are required to avert adrenal crisis at times of increased stress (Chapter 109).

Transplant Coronary Artery Disease

Transplant CAD, which develops at a rate of about 10% annually, results in diffuse and concentric narrowing of distal intramural coronary arteries and veins in addition to typi-

cal focal stenoses of epicardial arteries; it is the primary determinant of long-term survival following cardiac transplantation. Because of cardiac denervation following transplant surgery, the classic signs of myocardial ischemia (angina pectoris) are usually absent. This primary presenting features of transplant CAD are heart failure, ventricular dysrhythmia, and sudden death. An elevated C-reactive protein level is a strong predictor of vasculopathy (7).

As a consequence of the absence of angina pectoris, cardiac transplant patients must be routinely screened for CAD. The combination of denervation and diffuse, distal CAD makes traditional noninvasive screening tests both insensitive and nonspecific; the current recommendation is annual coronary angiography.

Primary prevention of transplant CAD includes risk factor modification, such as smoking abstinence and control of hyperlipidemia with diet and aggressive use of statins (8). Diltiazem, verapamil, and nicardipine, which alter the metabolism of cyclosporine and tacrolimus, must be used carefully. Everolimus is better than azothioprine for the prevention of cardiac-allograft vasculopathy (9).

Because of the diffuse and concentric nature of transplant CAD, coronary interventions and coronary artery bypass surgery are not as successful as in non-transplant CAD. Repeated cardiac transplantation is the only reasonable alternative for many patients with severe, uncorrectable transplant CAD, but survival after a second cardiac transplant is not as good as after a primary transplant, mainly as a consequence of increased surgical mortality and an increased probability of malignancy.

Malignancy

All organ transplant recipients are at increased risk for the development of malignancy because of immunosuppressive therapy. *Posttransplant lymphoproliferative disorders*, particularly non-Hodgkin's lymphoma, are the most common malignancies and occur in 2% of the cardiac transplant population. The peak occurrence is 1 year after transplant, but they can develop as early as 1 week after transplant. The Epstein-Barr virus genome is found in these polyclonal/monoclonal B cells. Sometimes the presentation can mimic allograft rejection because of constitutional symptoms and involvement of the myocardium (20% of cases). Although not all posttransplant lymphoproliferative disorders are "malignant" (i.e., not all are monoclonal), they behave biologically like aggressive proliferative lymphomas. Once a diagnosis is made by biopsy of the affected organ, the usual practice is to lower immunosuppression and initiate full-dose IV ganciclovir. Lymphoma chemotherapy may also be given (Chapter 94) but the prognosis of patients requiring such therapy is poor.

Malignant solid tumors also occur at a rate greater than in the general population. Cancers of sun-exposed areas (lips and skin) are common, as are cancers of the gastrointestinal tract and lung.

KEY POINTS

- Cardiac transplantation is a viable treatment option to improve survival and quality of life in selected patients with terminal heart failure.
- Early postoperative complications include electrical and mechanical disturbances, often caused by allograft rejection, preservation injury, tamponade, immunosuppressive drugs, electrolyte disturbances, or sinus node dysfunction.
- Allograft rejection may present as an emergency or as a nonspecific complaint; a high degree of clinical suspicion is often required for the diagnosis to be made.
- Treatment of allograft rejection should be guided by a transplant cardiologist. Clinical responses are demonstrated by improvement in cardiac function, abatement of dysrhythmias, and resolution of cellular infiltrate on follow-up endomyocardial biopsies.
- Immunosuppression and rejection can lead to infection, malignancy, and transplant coronary artery disease, which is difficult to treat.

INTRODUCTION

Valvular heart disease affects tens of thousands of people annually in the United States and leads to more than 50,000 valve surgeries per year. It contributes to the development of heart failure, and in some subjects is responsible for sudden cardiac death. The pathophysiology and hemodynamic consequences of valvular disease are determined by the valvular abnormality and, to a lesser degree, by its underlying etiology and associated cardiac abnormalities. Of central importance in the management of the patient with valvular heart disease is a determination of the timing of surgical intervention.

AORTIC STENOSIS

Issues at the Time of Admission

Valvular aortic stenosis (AS) is most often caused by degeneration and calcification of (a) a congenitally bicuspid valve (in subjects who become symptomatic before 70 years of age) or (b) a tricuspid valve (in those who develop symptoms after age 70 years). Rheumatic disease usually causes a mixture of AS and aortic regurgitation and is almost always accompanied by mitral valve involvement. Regardless of the etiology of AS, the gradual increase in obstruction to left ventricular (LV) outflow causes compensatory LV hypertrophy, which serves to normalize LV wall stress and maintain forward output despite a stenotic valve orifice.

Clinical Presentation

The subject with AS usually is encountered initially in the ambulatory setting, often having been referred for the evaluation of a systolic murmur. The asymptomatic patient with AS (irrespective of its severity) can be followed

expectantly until the appearance of symptoms (1). The cardinal symptoms of AS are angina pectoris, syncope, and heart failure. Angina pectoris is the initial symptom in about one-third of patients with AS, many of whom do not have significant atherosclerotic coronary artery disease (CAD). In these subjects, angina pectoris results from a relatively fixed myocardial oxygen supply in the setting of increased oxygen demand (caused by an increased LV wall tension). Syncope or near-syncope, usually exertional, is the initial symptom in about 15% of patients with AS. The remaining 50% of subjects with AS first note symptoms of heart failure (dyspnea, orthopnea, or fatigue). Any patient with one of these cardinal symptoms and a systolic murmur consistent with AS requires further evaluation.

Differential Diagnosis and Initial Evaluation

A severely stenotic aortic valve delays LV emptying and results in the characteristic findings on physical examination. The carotid arterial pulse is diminished in amplitude, and its upstroke is delayed (*pulsus parvus et tardus*). The precordial impulse is usually normal. Auscultation reveals the typical systolic ejection (crescendo-decrescendo) murmur at the aortic area, with radiation to the carotid arteries. Because of slow LV emptying, the murmur peaks in mid to late systole. The electrocardiogram (ECG) usually shows LV hypertrophy. On the chest radiograph, the cardiac silhouette is usually normal in shape and size. In the symptomatic patient, the findings upon physical examination should be corroborated by noninvasive testing. Two-dimensional echocardiography typically reveals concentric LV hypertrophy and a calcified aortic valve with reduced leaflet mobility. Doppler examination permits estimation of the transvalvular pressure gradient and calculation of the valve area (Table 41.1). Although invasive assessment (by catheterization) remains the gold standard for determining valve area, the echocardiographically measured valve area

TABLE 41.1
RELATIONSHIP BETWEEN AORTIC VALVE AREA
AND THE SEVERITY OF AORTIC STENOSIS

Severe AS	<0.7 cm ²
“Critical” AS	<0.5 cm ²

^aWith a pressure gradient.
 AS, aortic stenosis; AVA, aortic valve area.

correlates well with that determined at catheterization. Catheterization should be reserved for the symptomatic patient who is being considered for valve replacement. Coronary angiography is indicated in subjects over 40 years old to assess the presence or absence of CAD that may require concomitant bypass graft surgery at the time of valve replacement. At the time of catheterization, pressures on either side of the stenotic valve are recorded simultaneously (Figure 41.1), and the flow across the valve is quantified. From these data, the valve area is calculated with the Gorlin equation:

$$\begin{aligned} \text{Valve Orifice Area (cm}^2\text{)} \\ &= \text{Flow across the Valve/Constant} \\ &\quad \times (\text{Mean Pressure Gradient})^{1/2} \end{aligned}$$

The mean pressure gradient is the average gradient during systole (for aortic or pulmonic valves) or diastole (for mitral or tricuspid valves).

The systolic ejection murmur of *hypertrophic obstructive cardiomyopathy* may be confused with that of AS. However, careful examination reveals the dynamic nature of obstruction in the patient with hypertrophic obstructive cardiomyopathy. The murmur of hypertrophic obstructive cardiomyopathy diminishes in intensity with squatting, handgrip,

Figure 41.1. Simultaneous pressure recordings from the left ventricle (LV) and aorta (Ao) demonstrating a systolic gradient in a patient with aortic stenosis. The pressure gradient is shaded. (Redrawn from Lange RA, Hillis LD. Diagnostic and therapeutic catheterization. In Humes DG, ed. *Textbook of Internal Medicine*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2002, p. 628, with permission.)

and other maneuvers that increase LV filling and reduce the outflow tract pressure gradient. It increases in intensity with standing and the Valsalva maneuver, since these maneuvers reduce LV filling. The murmur of AS does not change with these maneuvers, since LV outflow tract obstruction is fixed. Other infrequently encountered forms of LV outflow obstruction include congenital abnormalities, such as subvalvular membranes or supra-ventricular stenosis, which often resemble *valvular* AS symptomatically and on physical examination.

Indications for Hospitalization

The patient with severe AS and symptoms of unstable angina, syncope, or heart failure should be hospitalized. During hospitalization, the diagnostic evaluation should be completed and a decision reached regarding surgery.

Indications for Initial Intensive Care Unit Admission

Any patient with AS and decompensated heart failure is appropriate for admission to the ICU. Moreover, any patient whose hospitalization is complicated by a major comorbid condition (i.e., systemic infection, atrial fibrillation with a rapid ventricular response, uncontrolled diabetes mellitus, renal or hepatic failure, altered mental status) should be admitted to an ICU or step-down unit because of the risk of acute decompensation.

Initial Therapy

Occasionally, a discrete, identifiable event (i.e., a febrile illness or the onset of atrial fibrillation) precipitates symptoms of AS in a previously asymptomatic patient. The noncompliant, hypertrophied LV depends on a forceful atrial “kick” to maintain adequate filling and hence cardiac output. Because atrial tachyarrhythmias may cause hemodynamic deterioration, they should be treated promptly with pharmacologic rate control, direct current cardioversion, or both (Chapter 42). Other therapy often includes the judicious use of diuretics in the patient with AS and concomitant pulmonary congestion. Afterload-reducing agents generally are contraindicated in the patient with known AS. Similarly, exercise testing should be avoided.

Indications for Consultation

Consultation with a cardiologist is appropriate for the symptomatic patient with AS. The specialist can (a) assist with ongoing medical care, (b) suggest further studies (echocardiography, cardiac catheterization) when indicated, and (c) determine the appropriate timing for surgical intervention.

TABLE 41.2
INDICATIONS FOR VALVE SURGERY

Aortic stenosis (AS)	Onset of symptoms (angina, syncope, or heart failure) in the presence of moderate or severe AS
Aortic regurgitation (AR)	Onset of symptoms in the presence of moderate or severe AR -or- Asymptomatic LV systolic dysfunction (LV ESD ^a ≥5.5 cm or LV EF ^b ≤0.55)
Mitral stenosis (MS)	Symptoms refractory to medical therapy (heart failure, fatigue, systemic thromboembolism) in the presence of moderate or severe MS
Mitral regurgitation (MR)	Onset of symptoms in the presence of moderate or severe MR -or- Asymptomatic LV systolic dysfunction (LV ESD ^a ≥4.5 cm or LV EF ^b ≤0.65)

^aLeft ventricular end-systolic dimension determined by transthoracic echocardiogram.

^bLeft ventricular ejection fraction determined by radionuclide or contrast ventriculography.

Issues During the Course of Hospitalization

The symptomatic patient with severe AS treated *medically* has a poor prognosis, with a median survival of 5 years in those whose initial symptom is angina, 3 years in those whose symptom is syncope, and 2 years in those with heart failure. Therefore, *once symptoms develop in the patient with moderate or severe AS, valve replacement is imperative* (Table 41.2). Since balloon aortic valvuloplasty yields only temporary modest improvement in adults with AS, it is rarely indicated.

Discharge Issues

The asymptomatic patient with AS should be seen regularly and should receive antibiotic prophylaxis at the time of dental or genitourinary procedures (Table 30.10). Outpatient visits should focus on the appearance of the cardinal symptoms of AS (angina, syncope, heart failure), which, if they occur in the patient with moderate or severe AS, mandate surgery. On average, the aortic valve area decreases by about 0.1 cm² annually in patients with AS (2). Recent studies suggest that this rate of progression is slowed by the administration of a statin (e.g., HMG CoA reductase inhibitor) medication (3).

AORTIC REGURGITATION

Issues at the Time of Admission

Aortic regurgitation (AR) may be congenital or acquired and could be acute or chronic. The clinical presentation and management depend on the severity and chronicity of regurgitation. *Acute AR* is usually caused by (a) valve leaflet damage from infective endocarditis, (b) aortic dissection, or (c) trauma; and it usually requires urgent valve replacement.

Chronic AR may result from disease of the valve leaflets or dilatation of the ascending aorta, which distorts the leaflets and prevents their coaptation during LV diastole. Rheumatic involvement of the aortic valve frequently leads to AR, which may occur in subjects with certain systemic illnesses, including systemic lupus erythematosus, rheumatoid arthritis, ankylosing spondylitis, Whipple's disease, and Crohn's disease. Disorders that may lead to aortic dilatation and resultant AR include systemic arterial hypertension, coarctation of the aorta, bicuspid aortic valve, syphilitic aortitis, and diseases of connective tissue (i.e., Marfan syndrome, cystic medial necrosis, osteogenesis imperfecta, and idiopathic annulo-aortic ectasia).

In the patient with chronic AR, the LV is exposed to diastolic volume overload, which results in the development of LV hypertrophy and chamber dilatation. Early in the process, LV end-systolic volume is normal; therefore, LV stroke volume and ejection fraction are greatly increased. Myocardial function remains normal until relatively late in the disease process, at which time the LV begins to fail. With acute AR, the ventricle does not have time to dilate; therefore, the individual with acute AR has a markedly elevated left ventricular diastolic pressure, which usually leads to severe pulmonary vascular congestion. Severe, acute AR may cause premature closure of the mitral valve during diastole, because LV and LA pressures equalize before the end of diastole; in this situation, net forward cardiac output is markedly reduced. As a result, urgent valve replacement usually is indicated in the patient with severe, acute AR.

Clinical Presentation

Similar to the patient with AS, the patient with AR may be asymptomatic and come to medical attention for the evaluation of a murmur. In the asymptomatic individual with normal LV systolic function, endocarditis prophylaxis

(Table 30.10), and careful clinical follow-up are sufficient (4). Often, early symptoms of AR are attributable to the increased LV stroke volume and consist of an awareness of a forceful heartbeat and prominent carotid arterial pulsations. Eventually, the patient with AR notes symptoms of heart failure (dyspnea, orthopnea, and fatigue). Angina, syncope, and sudden death are less common in patients with AR than in those with AS.

Differential Diagnosis and Initial Evaluation

In the subject with chronic AR, the characteristic findings on physical examination include bounding peripheral arterial pulses with a rapid upstroke (from the increased LV stroke volume) and rapid runoff (from regurgitation into the LV). The precordial impulse is hyperdynamic and displaced inferiorly and laterally. Auscultation reveals a high-pitched, decrescendo murmur commencing immediately after S₂ and extending through part or all of diastole. A systolic ejection murmur in the absence of valvular stenosis is caused by the markedly increased LV stroke volume. An apical diastolic rumble (the Austin Flint murmur) represents turbulent flow across the mitral valve with its anterior leaflet held partially closed by aortic regurgitant flow.

The ECG typically shows LV hypertrophy. The chest radiograph reveals an enlarged cardiac silhouette and a dilated ascending aorta. Echocardiography permits a determination of LV dimensions during diastole and systole, an assessment of LV systolic function, and measurement of ascending aortic width. Doppler echocardiography, which can measure the regurgitant jet width at the valve orifice and the regurgitant jet volume (into the LV), permits an estimate of the severity of AR. Invasive evaluation by catheterization includes aortography (to assess the severity of AR) and left ventriculography (to determine LV volumes and function). The presence and severity of AR may be evaluated qualitatively by aortography, with which the amount

of radiographic contrast material that regurgitates into the LV during diastole can be observed (Table 41.3). To obtain a quantitative assessment of the severity of AR, the regurgitant fraction (RF) can be calculated. The RF is the percentage of total angiographic LV output that regurgitates into the LV:

$$\text{RF} = (\text{Angiographic Cardiac Output} - \text{Forward Cardiac Output}) / \text{Angiographic Cardiac Output}$$

Typically, valvular regurgitation with an RF of 0.6 or more is considered to be severe; 0.40–0.59, moderate; 0.20–0.39, mild; and below 0.2, trivial.

Indications for Hospitalization

Although heart failure often can be treated in the outpatient setting, hospitalization is required for the subject with refractory heart failure. Heart failure caused by moderate-to-severe AR is an indication for prompt evaluation for valve replacement.

Indications for Initial Intensive Care Unit Admission

Heart failure resistant to standard medical therapy (diuretics and vasodilators) is often seen in severe acute AR and may require invasive hemodynamic monitoring and intravenous sodium nitroprusside (for afterload reduction) as temporizing measures before valve replacement. These measures are rarely necessary in the patient with chronic AR, whose LV has adapted gradually to the altered loading conditions.

Initial Therapy

Initial therapy of the patient with chronic AR should include diuretics and afterload reduction (with hydralazine,

TABLE 41.3

RELATIONSHIP BETWEEN APPEARANCE OF REGURGITANT CONTRAST AFTER AORTOGRAPHY AND SEVERITY OF AORTIC REGURGITATION

3+	Regurgitant contrast does not clear from LV; LV density = aortic	Moderate
4+	Regurgitant contrast does not clear from LV; LV density > aortic or LV fills (from aorta) in one diastole	Severe

^a Contrast is injected into ascending aorta (aortogram) immediately above the aortic valve. Incompetent aortic valve permits regurgitation of contrast into left ventricle (LV).

an angiotensin-converting enzyme inhibitor, or a dihydropyridine-class calcium channel antagonist). Chronic afterload reduction has been shown to improve symptoms, reduce the need for hospitalization, and delay the need for valve replacement in patients with chronic AR.

Although the etiology of chronic AR is not usually important for guiding therapy, it is critical that the patient with acute AR be evaluated for possible infective endocarditis. Symptomatic acute AR is generally an indication for urgent surgery. In patients with endocarditis, however, the indications for surgery must be balanced against the benefits of administering antibiotics before surgery (Chapter 71).

Issues for Early Consultation

The cardiologist can assist with the choice of initial medical therapy, further evaluation (i.e., echocardiography, cardiac catheterization), and the decision to operate or to continue medical therapy. Early consultation may reduce hospitalization and procedural costs and improve outcome.

Issues During the Course of Hospitalization

The key issue during hospitalization is the determination of the need for and timing of surgical intervention. Unlike valvular stenosis, valvular regurgitation may progress insidiously and may cause LV compromise before symptoms develop. In general, the symptomatic patient with moderate-to-severe AR should be considered for valve surgery. In addition, the asymptomatic patient with moderate-to-severe AR and evidence of LV systolic dysfunction should be referred for evaluation and probable valve replacement (Table 41.2) (4).

Discharge Issues

The asymptomatic patient with AR and normal LV systolic function can be followed expectantly, with periodic echocardiographic assessments of LV function and chamber dimensions. The onset of symptoms or a deterioration in LV systolic function (manifested as an increased LV end-systolic dimension or a decreased LV ejection fraction) should prompt cardiac consultation with an eye toward valve replacement. Surgical intervention before the development of severe LV systolic dysfunction is imperative.

MITRAL STENOSIS

Issues at the Time of Admission

Mitral stenosis (MS) is almost always the result of previous rheumatic carditis. The mitral valve leaflets thicken and

become scarred and fused at the commissures, and the chordae tendineae shorten and become fused. Eventually, the valve leaflets become calcified and immobile. Symptoms attributable to MS usually do not develop until 15–20 years after the initial rheumatic injury.

Clinical Presentation

The patient with MS usually first notes dyspnea or fatigue. Dyspnea results from an elevated left atrial (LA) pressure, with resultant pulmonary congestion. Fatigue is caused by failure to augment cardiac output appropriately during exertion. When MS is mild, the patient may experience dyspnea only in association with a tachycardia (i.e., during physical exertion, pregnancy, infection, or the appearance of atrial fibrillation). Tachycardia shortens the LV diastolic filling period (when flow across the mitral valve occurs), thereby increasing LA pressure. As the stenosis becomes more severe, dyspnea occurs with less exertion and eventually at rest. Other, less common symptoms of MS include chest pain, hemoptysis, sequelae of systemic arterial thromboembolism, and hoarseness resulting from compression of the recurrent laryngeal nerve by an enlarged LA (Ortner's syndrome).

Differential Diagnosis Initial Evaluation

In the patient with MS, the carotid arterial pulsation usually is normal and the precordial impulse is normal. A right ventricular (RV) lift may be palpated if concomitant pulmonary hypertension is present. Auscultation reveals an opening snap (OS) usually between 0.08 and 0.12 seconds after S_2 , followed by a diastolic murmur. The opening snap is caused by sudden tensing of the mitral valve leaflets after the cusps have completed their opening excursion. A short A_2 –OS interval suggests severe MS. The diastolic murmur of MS is low-pitched, rumbling, and heard best with the bell of the stethoscope at the cardiac apex with the patient in the left lateral decubitus position. S_1 is typically loud, though it softens if the valve becomes progressively fixed and regurgitant. S_2 is normal initially, but P_2 becomes louder (and may be louder than A_2) as pulmonary hypertension develops. In the subject with pulmonary hypertension, a Graham Steell murmur of pulmonic regurgitation may be present.

In the patient with MS, the ECG frequently shows atrial fibrillation. LA enlargement is noted in most subjects with severe MS who are in sinus rhythm, RV hypertrophy may be seen in the setting of pulmonary hypertension, and the chest radiograph usually reveals LA enlargement. With pulmonary hypertension, the pulmonary arteries, RV, and right atrium (RA) may be enlarged. Echocardiography reveals LA enlargement and a thickened and usually calcified mitral valve with decreased leaflet mobility. LV systolic function is usually normal but may be mildly depressed in some patients. The severity of MS (Table 41.4) can be

TABLE 41.4

 MS, mitral stenosis; MVA, mitral valve area.

determined by (a) planimetry of the valve orifice by transthoracic echocardiography or (b) measurement of the decay of the transvalvular pressure gradient (pressure half-time method) by Doppler echocardiography. In addition, echocardiography allows one to assess the suitability of the valve for *percutaneous mitral balloon valvuloplasty* (PMBV), in that certain echocardiographic features of the mitral valve and its subvalvular apparatus (i.e., leaflet thickening, leaflet mobility and calcification, and subvalvular thickening) influence the results of PMBV (5). Catheterization permits the simultaneous measurement of LA (often measured as pulmonary capillary wedge) and LV pressures (pressure gradient across the valve) (Figure 41.2), a determination of cardiac output, and, therefore, calculation of the valve area by the Gorlin equation (see Aortic Stenosis). In addition, the presence and severity of concomitant mitral regurgitation (MR), aortic valvular disease, and CAD can be assessed.

Indications for Hospitalization

The patient with symptomatic MS requires hospitalization only if outpatient therapy is inadequate to control

Figure 41.2. Simultaneous pressure recordings from the left atrium (LA) and left ventricle (LV) demonstrating a diastolic gradient in a patient with mitral stenosis. The gradient is shaded. (Redrawn from Lange RA, Hillis LD. Diagnostic and therapeutic catheterization. In: Humes DG, ed. *Textbook of Internal Medicine*, 4th ed. Philadelphia: Lippincott Williams & Wilkins, 2002, p. 628, with permission.)

pulmonary congestion or if complications such as atrial fibrillation with a rapid ventricular response develop. Most subjects with dyspnea (from pulmonary congestion) and fatigue (from a low cardiac output) can be evaluated and treated as outpatients.

Indications for Initial Intensive Care Unit Admission

The patient with MS rarely has such severe pulmonary congestion that ICU admission is required. However, intensive care may be required for pulmonary edema or markedly diminished cardiac output, either of which may be caused by atrial arrhythmias.

Initial Therapy

Pulmonary congestion is treated with diuretics. Maintenance of sinus rhythm is important in patients with MS, in whom a normal atrial “kick” may account for 20%–25% of cardiac output. In subjects with atrial fibrillation, the ventricular response rate should be controlled (Chapter 42). Electrical cardioversion to sinus rhythm can be attempted after the patient has received anticoagulant therapy for at least 3–4 weeks or if a transesophageal echocardiogram shows no evidence of a left atrial thrombus. The restoration of sinus rhythm often improves symptoms and reduces the risk of systemic thromboembolism. Following successful cardioversion, the patient with MS and an enlarged left atrium should remain on chronic anticoagulant therapy indefinitely.

Issues for Early Consultation

Consultation with a cardiologist is appropriate as part of the care of any patient with symptomatic MS. As with patients with other valvular abnormalities, the cardiologist can help to determine initial medical therapy, appropriate diagnostic studies, and the need for nonmedical intervention (surgery or PMBV).

Issues During the Course of Hospitalization

The subject with MS often first seeks medical attention with pulmonary congestion associated with an inciting event, such as the onset of atrial fibrillation, pregnancy, or an infection. Unlike patients with the valvular abnormalities discussed previously, *the patient with MS should be managed medically until symptoms are limiting* (Table 41.2). In these “medically refractory” subjects, the choice of surgery or percutaneous valvuloplasty should be discussed with the consulting cardiologist. In general, PMBV is most efficacious in younger patients with minimal valvular calcification. It should be avoided in the patient with LA thrombus, heavy valvular calcification, subvalvular thickening, or moderate

or severe MR. If PMBV is not available or is contraindicated, mitral valve surgery (commissurotomy or valve replacement) should be performed.

Discharge Issues

Outpatient therapy includes endocarditis prophylaxis at the time of dental and genitourinary procedures (Table 30.10) and treatment of pulmonary congestion, when present. In addition, because the subject with MS and atrial fibrillation or an enlarged LA is particularly prone to LA thrombus formation, prophylactic warfarin anticoagulation to an International Normalized Ratio (INR) of 2.5–3.5 is indicated. The patient with atrial fibrillation may benefit from receiving a β -adrenergic or calcium channel blocking agent to slow the ventricular response and increase the LV diastolic filling time, thereby decreasing LA pressure and diminishing pulmonary congestion. Symptoms that persist despite therapy should prompt referral to a cardiologist for consideration of balloon valvuloplasty or surgery.

MITRAL REGURGITATION

Issues at the Time of Admission

Mitral regurgitation (MR) may be caused by any disorder that affects one or more of the components of the mitral valve apparatus, including the annulus, leaflets, chordae tendineae, and papillary muscles. In the United States, the most common cause of isolated, chronic MR is myxomatous valvular degeneration. Chronic MR also may result from rheumatic injury, rupture of the chordae tendineae, and papillary muscle dysfunction or rupture. LV enlargement of any cause results in annular dilatation, which may lead to incomplete leaflet coaptation and resultant MR. In addition, chronic MR may occur as a result of certain congenital or heritable diseases (i.e., Marfan syndrome, Ehlers-Danlos syndrome, endocardial cushion defects). *Acute MR* most often results from (a) ruptured chordae tendineae (due to myxomatous degeneration, infective endocarditis, trauma, or rheumatic disease), (b) papillary muscle dysfunction or rupture (caused by myocardial ischemia or infarction), or (c) leaflet damage caused by infective endocarditis.

When MR is present, total LV output consists of forward output (from the LV to the systemic arterial circulation) and regurgitant flow (from the LV to the LA). Forward output is maintained by compensatory LV dilatation and hypertrophy. The patient with *chronic MR* is often asymptomatic for years. Eventually, the chronic diastolic LV volume overload causes symptoms of pulmonary congestion or asymptomatic LV systolic dysfunction, which is signaled by an increased LV end-systolic dimension or a decreased LV ejection fraction.

Clinical Presentation

The patient with chronic MR may be asymptomatic for months or even years. The initial symptom is usually dyspnea (caused by pulmonary congestion) or fatigue (caused by a decreased forward output). As the disease progresses, the patient notes dyspnea with less exertion, orthopnea, and paroxysmal nocturnal dyspnea. In some patients with chronic MR, pulmonary hypertension develops, which may lead to right-sided heart failure, with peripheral edema, ascites, and hepatic congestion.

Differential Diagnosis and Initial Evaluation

On physical examination, the patient with MR has a normal carotid arterial upstroke. The precordial impulse is hyperdynamic (because of an increased LV stroke volume) and displaced inferolaterally. The typical MR murmur is holosystolic, blowing in quality, and heard best at the apex, with radiation to the axilla. There is no correlation between the intensity of the murmur and the severity of MR. Even a relatively soft murmur deserves further evaluation (with echocardiography) if the patient has pulmonary congestion, systemic arterial hypotension, or evidence of a diminished cardiac output. The murmur of MR may be confused with that of (a) a ventricular septal defect, which is heard best along the left sternal border and is often accompanied by a palpable thrill; (b) tricuspid regurgitation, which is heard best at the left lower sternal border and increases in intensity with inspiration; and (c) AS, especially in the elderly or in patients whose MR is due to dysfunction of the posterior mitral valve leaflet.

The ECG reveals LA enlargement in most patients with chronic MR and LV hypertrophy in about a third. Frequently, the patient is in atrial fibrillation. The chest radiograph demonstrates LA and LV dilatation. Two-dimensional echocardiography (a) reveals LA enlargement, (b) documents LV chamber dimensions and function, and (c) helps to define the underlying pathophysiology of MR (i.e., ruptured chordae tendineae or papillary muscle, mitral valve prolapse, vegetation of infective endocarditis). Doppler echo permits quantification of the MR. Invasive evaluation by catheterization allows an assessment of the severity of MR by left ventriculography (Table 41.5) and determination of a regurgitant fraction (see Aortic Regurgitation). Moreover, left ventriculographic volumes permit an assessment of LV systolic function. Finally, coronary angiography can be performed; in general, it should be reserved for patients being considered for valve surgery.

Indications for Hospitalization

Most patients with chronic MR can be managed in the ambulatory setting. As noted, the most common initial symptom is dyspnea (caused by pulmonary congestion), which

TABLE 41.5**RELATIONSHIP BETWEEN APPEARANCE OF REGURGITANT CONTRAST AFTER VENTRICULOGRAPHY AND SEVERITY OF MITRAL REGURGITATION**

Angiographic grade	Definition ^a	Descriptor
1+	Regurgitant contrast clears LA with each beat	Trivial
2+	Regurgitant contrast does not clear LA; LA density < LV	Mild
3+	Regurgitant contrast does not clear LA; LA density = LV	Moderate
4+	Regurgitant contrast does not clear from LA; LA density > LV or LA fills (from LV) in one systole or contrast refluxes into pulmonary veins	Severe

^a Contrast is injected into left ventricle (LV) (ventriculogram). Incompetent mitral valve permits regurgitation of contrast into left atrium (LA).

is treated with diuretics, digitalis, and afterload reduction. Once the patient with MR is symptomatic, evaluation of the severity of MR and its effect on LV systolic function is imperative (6). Referral for possible surgical intervention is indicated in patients with (a) persistent symptoms and normal LV systolic function or (b) evidence of mild or moderate LV systolic dysfunction even without symptoms (Table 41.2).

Indications for Initial Intensive Care Unit Admission

The patient with MR due to rupture of chordae tendineae (caused most commonly by trauma or infective endocarditis), papillary muscle dysfunction or rupture (from myocardial ischemia or infarction), or leaflet injury (from infective endocarditis) often has severe pulmonary congestion and, therefore, may require urgent intervention. On physical examination, the patient is tachypneic and often prefers the upright to the supine position. The acute process does not permit the development of LA enlargement and alterations in the pulmonary vasculature; as a result, LA pressure is markedly elevated. Acute MR usually requires prompt surgical intervention.

Initial Therapy

The patient with acute MR may be supported temporarily with inotropic agents and afterload reduction (vasodilators, intraaortic balloon counterpulsation, or both). Echocardiography should be performed preoperatively in an attempt to define the valvular pathology, assess reparability, determine LV function, and document other cardiac abnormalities. Coronary angiography should be performed in patients over 40 years of age or in those with previous myocardial infarction or risk factors for atherosclerosis. Subjects with severe MR and pulmonary edema require

diuretic therapy and afterload reduction (with sodium nitroprusside or intraaortic balloon counterpulsation) to alleviate pulmonary congestion. In the patient with only mildly decompensated heart failure, the combination of digitalis, diuretics, and angiotensin-converting enzyme inhibitors may render him or her asymptomatic. Importantly, no large, long-term studies demonstrating the efficacy of angiotensin-converting enzyme inhibitors or other vasodilators in patients with chronic MR have been performed. Therefore, once symptoms appear or LV systolic dysfunction is noted, surgery is the most appropriate therapy (Table 41.2) (7).

Issues for Early Consultation

For the patient with MR, the cardiologist can assist with the selection of appropriate initial medical therapy, further evaluation, and the decision regarding referral for valve surgery.

Issues During the Course of Hospitalization

Perioperative morbidity and mortality are influenced by the patient's clinical and hemodynamic condition, LV systolic function, the presence of concomitant CAD, and other comorbidities (renal, hepatic, or pulmonary disease). In addition, the ability to repair—rather than to replace—the valve has prognostic import (8). Until Carpentier and Duran popularized mitral valve repair, valve replacement with chordal transection was the only surgical option for the patient with MR. Nowadays, mitral valve repair (with or without an annuloplasty ring) or valve replacement with chordal preservation have improved short- and long-term outcomes in patients requiring mitral valve surgery. Patients who undergo valve repair do not require long-term anticoagulation if they remain in sinus rhythm, and they avoid possible late prosthetic valve dysfunction. In

addition, chordal and papillary muscle-sparing procedures help to maintain normal LV geometry and systolic function postoperatively.

Discharge Issues

Similar to patients with AR, the asymptomatic patient with MR should be seen and evaluated periodically for the development of symptoms or evidence of LV systolic dysfunction. Endocarditis prophylaxis should be administered for dental and other procedures (Table 30.10).

TRICUSPID REGURGITATION

Issues at the Time of Admission

Tricuspid regurgitation (TR) most often results from dilatation of the RV and, hence, the tricuspid annulus. Annular dilatation prevents normal leaflet coaptation and results in functional or “secondary” TR. RV enlargement usually is secondary to pulmonary hypertension from MS, LV failure, cor pulmonale, or pulmonary embolic disease. Other etiologies of TR include rheumatic valvular disease, endocarditis, tricuspid valve prolapse, Ebstein’s anomaly, phentermine–fenfluramine toxicity, and carcinoid heart disease (9).

Clinical Presentation

In the absence of pulmonary hypertension, TR is generally well tolerated. However, when pulmonary hypertension and TR coexist, cardiac output declines, and right-sided venous congestion ensues.

Differential Diagnosis and Initial Evaluation

Physical examination reveals jugular venous distention with prominent *v* waves and a prominent γ descent. The RV is hyperdynamic, as reflected by an RV lift. The liver is often enlarged and tender; it may even be pulsatile. Ascites and peripheral edema may be present. Auscultation reveals a high-pitched, pansystolic murmur heard best at the left lower sternal border. The murmur increases in intensity with inspiration (Carvallo sign). A right-sided S_3 may be heard, and P_2 is prominent in the setting of pulmonary hypertension. If tricuspid valve prolapse is present, a midsystolic click may be audible. Holosystolic murmurs that may be mistaken for TR include those of MR (see Mitral Regurgitation) and ventricular septal defect. With TR, the ECG may show an incomplete right bundle branch block, and the patient frequently is in atrial fibrillation. Chest radiography reveals distention of the caval and azygous venous systems. Echocardiography permits (a) detection and assessment of the severity of TR, (b) estimation of pulmonary

arterial systolic pressure, (c) assessment of RV function, and (d) assessment of RV and RA size. In addition, echocardiography may identify the etiology of TR (i.e., valvular prolapse, vegetation in the case of endocarditis, valvular thickening with carcinoid). At catheterization, RA pressure is elevated, increases with inspiration, and may even qualitatively resemble RV pressure if the TR is severe.

Issues During the Course of Hospitalization

In the absence of pulmonary hypertension, TR usually does not require surgery. The patient is often given diuretics to relieve peripheral venous congestion. Effective treatment of the underlying pulmonary hypertension (Chapter 59) usually leads to an improvement in secondary tricuspid regurgitation. When surgery is required, valve repair can be performed with or without an annuloplasty ring. When valve replacement is required, a bioprosthesis (rather than a mechanical valve) is preferred, as the relatively low velocity of flow in the right heart chambers increases the likelihood of thrombus formation on a mechanical valve. Because of the relatively low right-sided pressures, tricuspid valve bioprostheses have excellent longevity (10).

PROSTHETIC HEART VALVES

When a patient with a prosthetic heart valve develops fever or heart failure, a thorough evaluation of the prosthesis is mandatory. Prosthetic heart valves may be bioprosthetic or mechanical; the latter, in turn, may be composed of a tilting disc (single or bileaflet) or ball-in-cage. Central to the assessment of prosthetic valve function is an understanding of the normal auscultatory findings for each valve type in the mitral or aortic position (10). In patients in whom prosthetic valve dysfunction is suspected, several imaging modalities may be used to assess valve function. In subjects with mechanical valves, cinefluoroscopy is a simple, inexpensive technique for assessing prosthetic structural integrity. Diminished motion of the disk or ball suggests obstruction by thrombus or tissue ingrowth, whereas excessive tilt (“rocking”) of the base ring is consistent with partial dehiscence of the valve’s sewing ring. Cinefluoroscopy cannot be used to visualize the leaflets of bioprosthetic valves. Two-dimensional transthoracic echocardiography can be used to assess sewing-ring stability and leaflet motion of bioprosthetic valves, but mechanical valves are often difficult to visualize because of intense echo reverberations from the metal. Transesophageal echocardiography may better visualize the mitral valve, but assessment of a prosthesis in the aortic position may be limited (because of echo reverberations), especially when another prosthesis is present in the mitral position.

New-onset heart failure is an important complication following implantation of a prosthetic valve. Of the various causes of heart failure, *prosthetic valve thrombosis* is

potentially catastrophic; it is usually manifested as acute hemodynamic deterioration, pulmonary congestion, poor peripheral perfusion, or systemic thromboembolism. Valve thrombosis most often results from inadequate anticoagulant therapy; it affects mechanical valves more often than bioprostheses and involves those placed in the mitral position more commonly than the aortic. Once the diagnosis of valve thrombosis has been established, intravenous heparin therapy should be instituted promptly. More aggressive therapy (valve replacement or thrombolysis) is indicated when the thrombus burden is large (more than 5 mm in diameter) or when the patient does not improve with systemic heparinization alone.

In the subject with a prosthetic heart valve, other causes of heart failure include (a) perivalvular leakage (caused by spontaneous dehiscence of the suture line or endocarditis), (b) structural failure of the prosthetic valve (caused, for example, by disc dislodgement or ball fracture of mechanical valves or leaflet avulsion of a bioprosthesis), and (c) bioprosthesis leaflet damage (from thickening and retraction or endocarditis). Structural failure of a mechanical prosthesis is rare. One exception, the Bjork-Shiley single tilting disc valve, was withdrawn from use after reports of fracture of the valve ring structure, resulting in displacement and embolization of the disk. Structural failure of bioprosthetic valves necessitates replacement of 20%–30% over the ensuing 10–15 years. Most patients whose valves fail have severe regurgitation caused by a tear or rupture of one or more of the valve cusps, which have become calcified and rigid; only an occasional subject develops severe bioprosthetic valve stenosis. The incidence of bioprosthetic valve failure is particularly high in patients under 40 years old and in those with mitral prostheses. The magnitude of valve dysfunction can be assessed by echocardiography or catheterization.

Prosthetic valve infection occurs at some time in 3%–6% of patients. “Early” endocarditis (occurring less than 60 days after valve replacement) usually results from perioperative bacteremia that develops from skin or wound infections or contaminated intravascular devices. The most common offending organisms, therefore, are *Staphylococcus epidermidis*, *S. aureus*, gram-negative bacteria, diphtheroids, and fungi. “Late” prosthetic valve endocarditis (occurring more than 60 days postoperatively) is usually caused by the organisms responsible for native valve endocarditis, most often streptococci. The risk of endocarditis is similar in patients with mechanical and bioprosthetic valves.

Long Term Follow-up of Prosthetic Valves

The patient with a prosthetic valve should be seen and evaluated regularly to assess the presence of new symptoms or murmurs. The presence of either warrants a complete and thorough evaluation, including an echocar-

diogram. All patients with prosthetic valves should receive endocarditis prophylaxis for dental or other procedures. The possibility of prosthetic valve endocarditis should be entertained in the patient with an unexplained or persistent fever and should prompt the acquisition of several blood samples for culture prior to the administration of antibiotic therapy (Chapter 71). The causative organism can be identified by routine blood culture in over 90% of patients who have not recently received antibiotics. In addition to fever, other findings of prosthetic valve endocarditis include a new or changing murmur, systemic embolization, and heart failure. All patients with a mechanical valve should receive chronic anticoagulant therapy, with the precise target INR determined by the type of valve and its position (10).

COST CONSIDERATIONS AND RESOURCE USE

The asymptomatic patient with valvular heart disease can be followed in the outpatient setting until the onset of symptoms or the appearance of early, often asymptomatic, LV systolic dysfunction. At such time, the decision to continue medical therapy or to pursue surgical intervention should be made. Consultation with a cardiologist is the appropriate next step. The cardiologist can (a) provide guidance concerning medical therapy that may reduce the need for hospitalization and delay valve surgery; (b) help to determine which diagnostic studies are indicated, thereby avoiding costly and unwarranted testing; and (c) assist in the decision of when to operate by weighing the risks and potential benefits of surgery.

KEY POINTS

- The asymptomatic patient with *aortic stenosis* may be followed expectantly until symptoms develop. Once angina, syncope, near-syncope, or heart failure develops in the patient with moderate-to-severe aortic stenosis, valve replacement should be performed promptly.
- Symptomatic patients with *aortic regurgitation* should undergo valve replacement. Asymptomatic patients should be treated with afterload-reducing agents to slow disease progression. In addition, the patient should be monitored for evidence of LV systolic dysfunction, and surgical correction should be pursued if this develops.
- Patients with *mitral stenosis* should be managed medically until symptoms persist despite such therapy. Anticoagulation should be maintained to reduce the risk of systemic embolization.
- Similar to patients with aortic regurgitation, those with *mitral regurgitation* should undergo mitral valve surgery for the relief of symptoms or deterioration of left ventricular systolic function (even without symptoms).

Advances in mitral valve surgery, including valve repair and valve replacement with chordal preservation, have improved perioperative and long-term outcomes in patients with mitral regurgitation.

- *Tricuspid regurgitation* is usually caused by right ventricular dilatation (functional or “secondary” tricuspid regurgitation) resulting from pulmonary hypertension associated with mitral stenosis, left ventricular failure, cor pulmonale, or pulmonary embolic disease. In the absence of pulmonary hypertension, tricuspid regurgitation usually does not require surgical therapy.

Atrial Fibrillation, Atrial Flutter, and Other Supraventricular Tachyarrhythmias

Leonard I. Ganz

INTRODUCTION

Supraventricular tachyarrhythmias (SVTs) frequently cause emergency department visits and hospital admissions, and they also occur commonly in patients hospitalized for other reasons. SVTs require atrial or atrioventricular (AV) junctional tissue for their initiation and maintenance, whereas ventricular tachyarrhythmias require only ventricular tissue for their initiation and maintenance (Chapter 43). SVTs may be classified according to whether AV junctional or only atrial tissue is critical to the tachycardia (Table 42.1).

TACHYCARDIAS ARISING IN ATRIAL TISSUE

In *atrial fibrillation* (AF), the most common SVT, the orderly sequence of sinus rhythm (SR) is replaced by rapidly firing foci and/or multiple reentry circuits in the atria that bombard the AV node, resulting in a rapid and irregular ventricular rate. In some patients, the AF has a “focal” origin, typically in the pulmonary veins near where they enter the left atrium. In *atrial flutter*, a single macroreentry circuit in the right atrium inscribes regular, sawtooth flutter waves.

AF and atrial flutter may be *paroxysmal*, with episodes that revert spontaneously, or *persistent*, with episodes that persist unless the patient is cardioverted to sinus rhythm. If efforts at cardioversion are unsuccessful, AF is considered *permanent*. *Atrial tachycardia* (AT), also called ectopic or unifocal AT, occurs if an isolated atrial focus fires at a rate substantially higher than that of the sinus node. In *multifocal AT* (MAT), patients have at least three different P-wave morphologies with irregular ventricular rates greater than 100 beats/min.

TACHYCARDIAS ARISING IN THE AV JUNCTION

Most regular SVTs require the participation of the AV node. Two mechanisms, *AV nodal reentrant tachycardia* (AVNRT) and *AV reentrant tachycardia* (AVRT), constitute the majority of what are called paroxysmal supraventricular tachycardias (PSVT) (1, 2). In AVNRT, dual AV nodal pathway physiology provides the substrate for a reentry circuit involving the AV node (Figure 42.1). In AVRT, an accessory pathway, which connects an atrium and corresponding ventricle, can serve as a limb in a reentry circuit (Figure 42.2). Some patients with this arrhythmia manifest

TABLE 42.1

A-V, atrioventricular.

ventricular preexcitation, known as the *Wolff-Parkinson-White (WPW) syndrome*. In other patients, the accessory connection is concealed during sinus rhythm and becomes evident only during an SVT. AVRT has two forms, orthodromic and antidromic. In orthodromic AVRT, antegrade conduction is over the AV node, resulting in a narrow QRS complex, and retrograde conduction goes up the accessory pathway. These accessory pathways can be manifest or concealed accessory pathways. Much less common is an-

tidromic AVRT, in which the circuit is reversed, resulting in a wide and bizarre QRS complex. This phenomenon occurs only in WPW syndrome. Patients with WPW syndrome merit special attention because of the possibility of extremely rapid ventricular rates during AF or atrial flutter and the risk that these rhythms will deteriorate into ventricular fibrillation.

PREVALENCE AND ASSOCIATED CONDITIONS

Associated cardiovascular disease, including hypertension, is encountered frequently in patients with AF. The prevalence of AF increases with age as approximately 2%–5% of patients in their seventies and 4%–10% in their eighties have AF. Fewer epidemiologic data exist regarding other forms of supraventricular arrhythmia. PSVT may be seen in patients of all ages, both in the absence and presence of structural heart disease. Overall, the prevalence of PSVT is on the order of several per thousand; the prevalence of the WPW pattern on an electrocardiogram (ECG) is similar.

Figure 42.1. Mechanisms of atrioventricular nodal reentrant tachycardias. Each panel shows the AV node (top), a ladder diagram (middle), and surface ECG lead II (bottom). Solid lines indicate anterograde conduction and broken lines retrograde conduction; straight lines represent fast pathway conduction and wavy lines slow pathway. During sinus rhythm, the slow pathway is not apparent, as the impulse travels down the fast pathway, turns around, and retrogradely penetrates into the slow pathway. An atrial premature depolarization (APD) blocks in the fast pathway, conducts down the slow pathway, and then can conduct retrograde up the fast pathway, initiating atrioventricular nodal reentrant tachycardia. Less commonly, a ventricular premature depolarization (VPD) conducts up the slow pathway, initiating the uncommon form of atrioventricular nodal reentrant tachycardia. A, atrium; P, sinus P waves; P', atrial echoes from atrioventricular nodal reentry; V, ventricle. (Reprinted from Ganz LI, Friedman PL. Supraventricular tachycardia. *N Engl J Med* 1995;332:162–173, with permission.)

Figure 42.2. Mechanisms of atrioventricular reentrant tachycardias. During sinus rhythm the initial part of the QRS, the delta wave, results from ventricular preexcitation over the accessory pathway. During orthodromic atrioventricular reentrant tachycardia, antegrade conduction is over the normal His–Purkinje system, inscribing a normal QRS. Rarely, antidromic atrioventricular reentrant tachycardia causes a wide, bizarre QRS, because the entire ventricle is depolarized over the accessory pathway, with retrograde conduction over the normal His–Purkinje system and atrio-ventricular node. (Reprinted from Ganz LI, Friedman PL. Supraventricular tachycardia. *N Engl J Med* 1995;332:162–173, with permission.)

Wide-complex Tachycardia

SVTs usually present with a narrow QRS complex. Wide-complex tachycardias may be due to ventricular tachycardia (VT) or SVT with aberrant conduction into the ventricles. Aberrancy may be fixed (i.e., bundle branch block occurring at any heart rate), rate-related (i.e., narrow QRS at normal sinus rates but bundle branch block at rapid rates), or caused by antidromic conduction over an accessory pathway (i.e., only in patients with WPW syndrome). Whereas VT occurs primarily in patients with structural heart disease (e.g., coronary artery disease or cardiomyopathy) and can cause cardiac arrest, SVT is rarely life-threatening (except for WPW syndrome with AF or atrial flutter).

Algorithms can aid in determining whether a wide-complex tachycardia is VT or SVT (Figure 42.3) (3). Several issues warrant emphasis, however. First, among wide complex tachycardias, VT occurs much more frequently than SVT with aberrancy. Second, in patients with structural heart disease, particularly coronary artery disease or cardiomyopathy, wide-complex tachycardia is almost always caused by VT. Finally, misdiagnosis of SVT as VT rarely causes untoward consequences, but misdiagnosis of VT as

SVT and treatment with an intravenous (IV) AV nodal blocking agent can precipitate cardiac arrest. Thus, *unless a wide-complex tachyarrhythmia is known to be supraventricular in origin, it should be presumed to be VT and treated as such until proven otherwise.* Therapy should be direct current (DC) cardioversion in unstable patients and IV drug therapy in hemodynamically stable patients.

In hemodynamically stable patients, intravenous amiodarone is increasingly used because it is effective for both VT and SVT and is safe, even in patients with left ventricular dysfunction (4). Lidocaine may be most effective for VT caused by acute ischemia or myocardial infarction (MI). Procainamide may be more effective in other settings and is the agent of choice in patients with WPW and AF, or atrial flutter. IV adenosine has been proposed as a diagnostic or therapeutic challenge in patients with hemodynamically tolerated wide-complex tachycardia, because it terminates most PSVT and unmasks atrial flutter by transiently blocking AV conduction. However, in rare cases adenosine can cause hemodynamically-tolerated VT to deteriorate into cardiac arrest. Thus, if adenosine is to be administered to patients with wide-complex tachycardia, a defibrillator should be immediately available.

Absence of an RS complex in all precordial leads?**R to S interval > 100 msec in one precordial lead?****Atrioventricular dissociation?****Morphology criteria for VT present both in precordial leads V1–2 and V6?**

Figure 42.3. Algorithm for diagnosis of wide-complex tachycardia proposed by Brugada and colleagues. If there is no RS complex in any precordial lead, ventricular tachycardia (VT) is diagnosed. If an RS complex exists in any precordial lead, the longest RS interval (from onset of QRS to nadir of S wave) is measured in the precordium; if the longest RS interval is greater than 100 msec, VT is diagnosed. If not, atrioventricular dissociation is sought; if present, VT is diagnosed. If absent, morphologic criteria are applied to leads V₁ and V₆ to differentiate VT from a supraventricular tachycardia (SVT) with aberrancy. (From Brugada P, Brugada J, Mont L, et al. A new approach to the differential diagnosis of a regular tachycardia with a wide QRS complex. Reprinted with permission from *Circulation* 1991;83:1649–1659.)

ARRHYTHMIAS PRESENTING AT THE TIME OF ADMISSION

Clinical Presentation

Symptoms referable to AF and other supraventricular arrhythmias span a wide range (Table 42.2). Some AF

TABLE 42.2

SYMPTOMS ASSOCIATED WITH SUPRAVENTRICULAR TACHYARRHYTHMIAS

Mild	Moderate–Severe
Asymptomatic	Chest pain
Fatigue/malaise	Heart failure
Poor exercise capacity	Near syncope
Dyspnea	Syncope
Lightheadedness	Sudden death
Palpitations	

patients are truly asymptomatic, and severe symptoms most commonly are seen in patients with significant structural heart disease. Many patients with structurally normal hearts have fairly mild symptoms. However, patients with WPW syndrome and AF, or with atrial flutter, can develop hemodynamic instability or even ventricular fibrillation.

Differential Diagnosis and Initial Evaluation

A 12-lead electrocardiogram (ECG) should be obtained in all stable patients. Tachyarrhythmias should be classified as wide- or narrow-complex, and regular or irregular (Figure 42.4). Irregularly irregular rhythms without organized P-wave activity are AF; MAT is distinguished by multiple discrete P-wave morphologies. A normal dominant P-wave morphology distinguishes sinus tachycardia with premature atrial complexes. AF with conduction over an accessory pathway in patients with WPW syndrome presents as an irregular tachycardia with wide as well as variable-width QRS complexes; ventricular rates may be extremely rapid. Atrial flutter in these patients may be conducted 1:1 into the ventricle with uniformly wide QRS complexes.

Narrow-complex regular tachycardias are frequently atrial flutter with 2:1 AV conduction, AVNRT, AVRT, or, less commonly, AT with 1:1 AV conduction. Atrial flutter typically presents with an atrial rate of approximately 300 beats/min, 2:1 AV conduction, and a ventricular rate of about 150 beats/min. The underlying atrial rate may be slower in elderly patients or those on antiarrhythmic drugs. The typical sawtooth pattern usually is visible on an ECG, particularly in the inferior leads (II, III, aVF). If there are retrograde P waves, or if no P waves are visible at all, the diagnosis is usually AVNRT or AVRT. Tachycardias with an abnormal P-wave morphology that precedes the QRS complex may be AT or atypical forms of AVNRT or AVRT. ATs may present with 1:1, 2:1, or variable AV conduction. The distinction between AT and atrial flutter is based on the atrial rate and P-wave morphology: the atrial rate in atrial flutter tends to be more rapid than in ATs, and, in AT, discrete P waves are separated by an isoelectric segment in

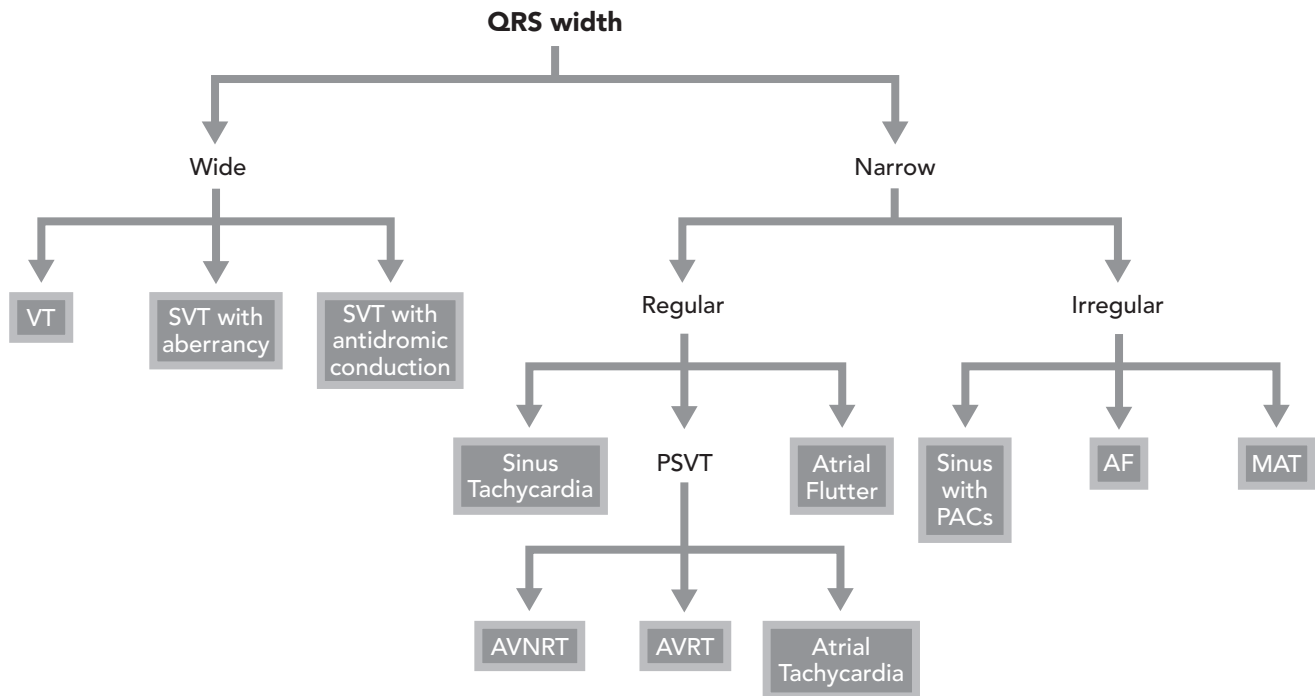

Figure 42.4. Decision algorithm for ECG diagnosis of supraventricular tachyarrhythmia (SVT). contrast with the sawtooth pattern of continuous atrial activity in atrial flutter.

The induction of transient block at the AV node is very useful diagnostically and therapeutically in patients with regular SVT (Figure 42.5). A rhythm strip, preferably in several simultaneous leads, should be recorded continuously during such maneuvers. Vagal maneuvers such as the Valsalva maneuver or carotid sinus massage should be tried first; if unsuccessful, IV AV nodal blocking agents may be administered. Induced block at the AV node with adenosine or verapamil (Table 42.3) terminates AVNRT and AVRT; tachycardias that persist in the atrium despite transient AV block must be AT or atrial flutter. Some ATs are adenosine-sensitive, so the ECG recording must be scrutinized to determine the mechanism of termination.

It is also important to identify conditions that may accompany or even may have triggered the SVT. AF may be associated with acute MI, pulmonary embolus, stroke, and thyrotoxicosis. MAT is seen almost exclusively in the setting of acute pulmonary disease. Digitalis toxicity may cause AT.

Indications for Hospitalization

If the tachyarrhythmia is secondary to an acute condition such as acute MI or pulmonary embolus, admission is

obviously necessary. Absent such associated conditions, many patients with AF or atrial flutter can be safely started on medical therapy without hospital admission. In particular, patients with minimal symptoms, a ventricular rate that is not too rapid, and no signs of ischemia, heart failure, or hemodynamic instability can be started on an AV nodal blocking agent and warfarin if careful outpatient follow-up is available. Patients with ischemia, heart failure, or hemodynamic instability caused by AF should be admitted. Frequently these patients have rapid ventricular rates as well as structural heart disease. Patients with AF of unknown duration but no acute symptoms do not necessarily require admission solely for the initiation of anticoagulation with IV heparin. For patients with AF of less than 24–36 hours' duration, cardioversion should be considered to avert the need for prolonged anticoagulation (see the section on "Issues During the Course of Hospitalization" later in this chapter).

If PSVT can be terminated in the emergency department, admission frequently is not required. Exceptions include patients with severe symptoms of angina, heart failure, syncope, or near-syncope resulting from SVT. These patients often have structural heart disease, and admission is frequently useful to expedite initiation of medical therapy or consideration of electrophysiologic studies and radiofrequency (RF) catheter ablation. Patients with WPW syndrome who have AF or atrial flutter or symptoms of syncope

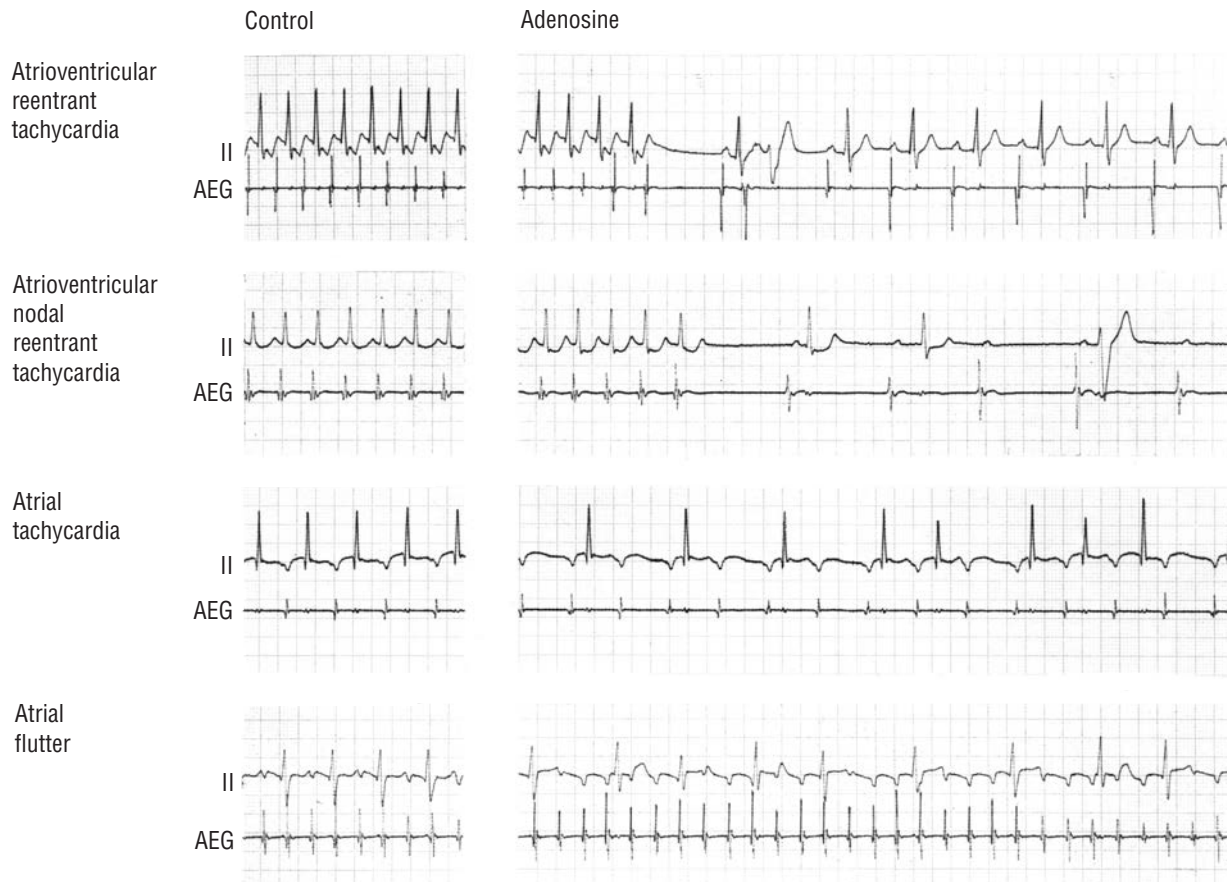

Figure 42.5. Use of adenosine to diagnose patients with a regular supraventricular tachyarrhythmia. Each panel shows surface electrocardiogram lead II and an intracardiac atrial electrogram (AEG) to show the timing of atrial depolarization, both at baseline and after adenosine administration. Adenosine induces transient atrioventricular block, terminating atrioventricular reentrant tachycardia and atrioventricular nodal reentrant tachycardia. With atrial tachycardia and atrial flutter, tachycardia continues in the atrium despite transient atrioventricular block, revealing the correct diagnosis. (Reprinted from Ganz LI, Friedman PL. Supraventricular tachycardia. *N Engl J Med* 1995;332:162–173, with permission.)

or near-syncope should be admitted for electrophysiologic studies and RF catheter ablation.

In general, patients admitted for SVT should have continuous cardiac monitoring. Exceptions include those with chronic AF admitted for noncardiac reasons.

Indications for Initial ICU Admission

Admission to an ICU is infrequent, unless the arrhythmia is a complication of a condition such as MI or pulmonary embolus that itself requires ICU admission. ICU admission is also reasonable in patients with symptoms of significant ischemia, heart failure, or hemodynamic instability caused by arrhythmia. Patients with the WPW syndrome and pre-excited AF or atrial flutter also might benefit from initial ICU admission.

Initial Management

The initial management strategy depends on the stability of the patient. Synchronized DC cardioversion should be considered for unstable patients. For stable AF and atrial flutter, initial efforts are directed at controlling the ventricular rate with AV nodal blocking agents (Table 42.3). *Intravenous calcium channel blockers and β -blockers are far more effective than digoxin for acutely slowing a rapid ventricular response.* Careful monitoring for complications, such as bronchospasm, hypotension, heart failure, or an excessively slow ventricular rate, is necessary.

For unstable patients with the WPW syndrome and AF, or with atrial flutter, cardioversion is appropriate. Hemodynamically stable patients should not initially receive AV nodal blocking agents (calcium channel

TABLE 42.3**DRUGS USED IN MANAGING SUPRAVENTRICULAR TACHYARRHYTHMIAS**

Arrhythmia	Goal	Drug	Dosage	
Atrial fibrillation and atrial flutter	Anticoagulation	Heparin (IV)	Varies; target aPTT 2 times control	
		Warfarin (po)	Varies; target INR 2.0–3.0	
	Acute termination	Ibutilide (IV)	Patient 60 kg or more: 1 mg ^a Patient less than 60 kg: 0.01 mg/kg ^a	
		Acute rate control	Diltiazem (IV)	0.25 mg/kg, then 5–15 mg/h
	Verapamil (IV)		2.5–10 mg q4h prn	
	Propranolol (IV)		1–3 mg q4h prn	
	Metoprolol (IV)		5–10 mg q4h prn	
	Esmolol (IV)		0.5 mg/kg, then 0.05–0.2 mg/kg/min	
	Chronic rate control	Sinus rhythm maintenance (suppression of recurrences of fibrillation/flutter)	Diltiazem ER (po)	120–300 mg qd
			Verapamil ER (po)	120–240 mg qd

		Digoxin (po)	0.125–0.25 mg qd	

^a Initial dose over 10 minutes, can be repeated one time.

^b Use in association with AV nodal blocker (β -blocker, diltiazem, verapamil, digoxin)

aPTT, activated partial thromboplastin time; ER, extended release formulation that permits once-daily dosing; INR, international normalized ratio; IV, intravenous; po, oral.

blockers, β -blockers, digoxin, or adenosine) because these agents can shunt conduction over the accessory pathway, thereby increasing the ventricular rate and the risk of degeneration to ventricular fibrillation. Intravenous procainamide, which slows conduction throughout the heart, is the agent of choice.

Induction of transient AV block with vagal or pharmacologic maneuvers is the initial approach for PSVT. AV block terminates AVNRT and AVRT, and it unmasks most ATs and atrial flutter. Following termination of the SVT, another ECG should be obtained; to diagnose WPW syndrome, an ECG must be obtained with the patient in sinus rhythm. Patients with WPW syndrome typically should not be treated empirically with digoxin or calcium channel blocking agents even if they present with PSVT, because of the risk of more rapid ventricular rates should AF or atrial flutter occur. Rather, patients with symptomatic WPW syndrome (i.e.,

SVT, AF, or atrial flutter) generally should be advised to undergo electrophysiologic studies and RF catheter ablation (1, 2). Symptomatic patients with WPW syndrome who refuse this approach typically require treatment with a membrane-active drug (i.e., class IA, IC, or III; Table 42.4), often in combination with an AV nodal blocking agent; chronic monotherapy with a β -blocker may be an alternative, though few data are available regarding safety and efficacy. In the past, most asymptomatic patients with ventricular preexcitation have been observed. Recent data suggest, however, that if atrial fibrillation or AVRT is inducible at diagnostic electrophysiologic studies, then prophylactic catheter ablation may be preferable, particularly in younger patients (5).

Most patients with PSVT without the WPW syndrome have either AVNRT or AVRT resulting from a concealed accessory pathway. In either case, the risk of sudden death is

TABLE 42.4

^d Sodium channel enhancer, rather than potassium channel blocker

^e Amiodarone has Class I, I, III, and IV electrophysiologic effects

extremely low. It is reasonable to follow the patient without chronic oral therapy after an initial episode of PSVT if symptoms were mild. For recurrent episodes or extremely symptomatic first episodes, choices for initial therapy include chronic therapy with an AV nodal blocking agent (e.g., β-blocker, diltiazem, verapamil, or digoxin) or electrophysiologic study and RF catheter ablation (1, 2).

Unless the clinical situation dictates otherwise, few tests are indicated in the routine evaluation of new AF or other SVTs. A careful history and physical examination, ECG, transthoracic echocardiogram, and a serum thyroid stimulating hormone (TSH) measurement should be adequate in most patients. Screening laboratory studies (e.g., complete blood count, electrolytes, and renal function) and a chest radiograph are reasonable, though supporting data are limited. Cardiac biomarker measurements to exclude MI, exercise stress testing to exclude ischemia, arterial blood gas measurement, and ventilation-perfusion or CT scanning to exclude pulmonary embolus are not routinely necessary.

Indications for Early Consultation

Cardiology consultation is reasonable if cardiac catheterization is being considered, especially in patients with MI, significant ischemia, or heart failure. Similarly, early cardiology consultation may be appropriate if transesophageal echocardiography (TEE; see the section on "Issues During the Course of Hospitalization" that follows) or DC cardioversion is contemplated. Consultation with a cardiac electrophysiologist is recommended in all patients with WPW syndrome and in other patients in whom the option of RF catheter ablation is being weighed. In patients with

tachycardia-bradycardia (tachy-brady) syndrome, consultation regarding permanent pacemaker implantation (Chapter 45) is often useful.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Atrial Fibrillation

Management of AF has three components: anticoagulation, control of the ventricular rate, and restoration and maintenance of SR. Each must be considered in developing a treatment strategy (Figure 42.6) (5–8).

The risk of stroke resulting from thromboembolism is markedly increased by AF (8); anticoagulation with warfarin significantly attenuates this risk (8–10). Although young patients with idiopathic AF are at low risk, most other patients with AF (Table 42.5) should be anticoagulated (target international normalized ratio [INR] 2.0–3.0) unless contraindications exist. The recently proposed CHADS₂ index (Figure 42.7) allows calculation of a given patient's risk of stroke without anticoagulation (11). The thromboembolic risk of atrial flutter probably approximates that of AF, and guidelines for anticoagulation are the same. Patients with contraindications to anticoagulation should receive aspirin, which attenuates the risk of stroke somewhat. Newer antithrombotic agents are under development. One promising oral agent, ximelagatran (12), was denied FDA approval in late 2004 because of reports of serious liver toxicity.

AF of very short duration frequently terminates spontaneously. If it does not, it is reasonable to have the patient fast

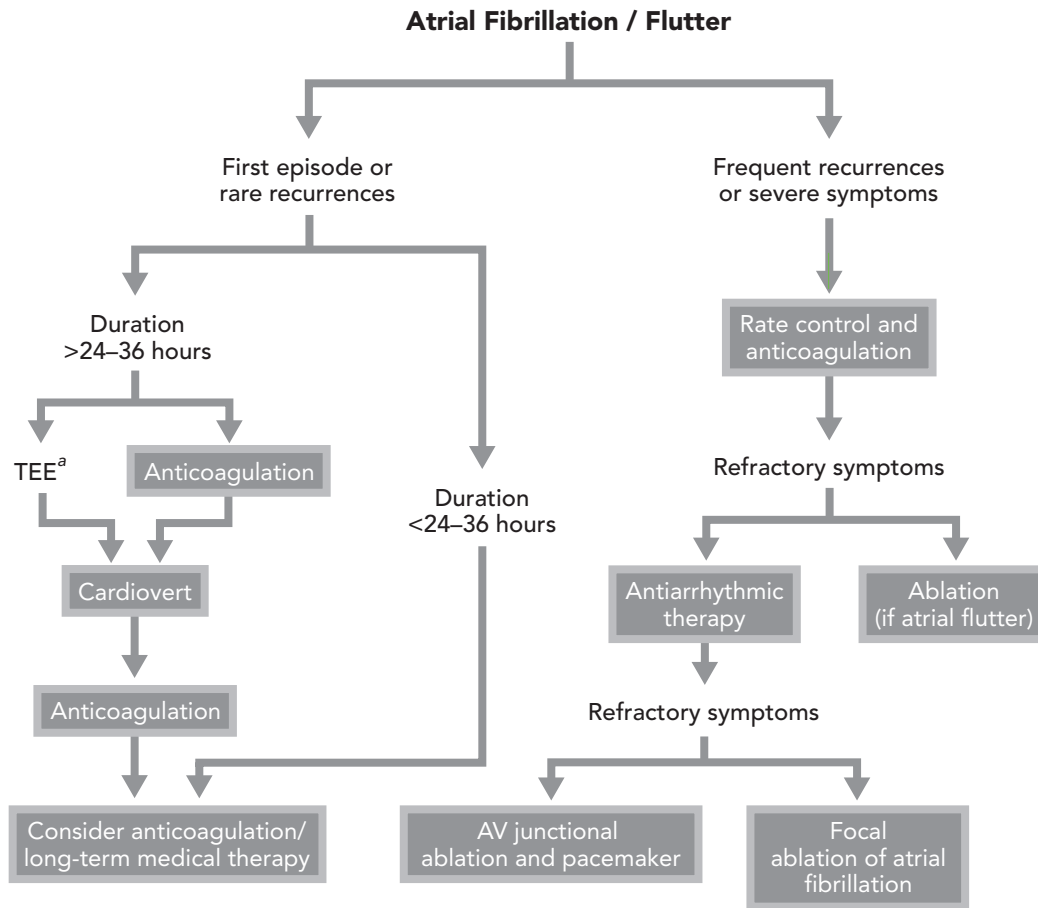

Figure 42.6. Management algorithm for atrial fibrillation or flutter. *TEE*, transesophageal echocardiogram. ^aWith appropriate anticoagulation.

overnight and cardiovert the next morning (see later in this chapter) to obviate the need for anticoagulation. If the duration of AF is not known to be extremely short, warfarin should be initiated immediately. For patients with new-onset AF that does not convert spontaneously, two alternative approaches with similar efficacy and outcomes may be

TABLE 42.5
ANTICOAGULATION IN ATRIAL FIBRILLATION

Age	Risk factors	Recommendation
<65	Present	Warfarin (INR 2.0–3.0)
	Absent	ASA
65–75	Present	Warfarin (INR 2.0–3.0)
	Absent	Warfarin or ASA
>75		Warfarin (INR 2.0–3.0)

Risk factors for embolism—Clinical: prior TIA/stroke, hypertension, congestive heart failure, diabetes mellitus, coronary artery disease, mitral stenosis, prosthetic heart valves (more intense anticoagulation indicated), thyrotoxicosis; Echocardiographic: left-atrial enlargement, left-ventricular dysfunction.

considered (13). In one approach, patients with AF of more than 24–36 hours' duration are anticoagulated for at least 3 weeks prior to any attempt at cardioversion, whether electric or pharmacologic. Because restoration of atrial mechanical function can lag behind establishment of sinus rhythm, anticoagulation should be continued for at least 4 weeks after successful cardioversion. An alternative to prolonged anticoagulation prior to cardioversion is an expedited approach using transesophageal echocardiography. Once anticoagulation is initiated, transesophageal echocardiography is performed. If the atria are free of thrombus, cardioversion is performed. Anticoagulation must continue for at least 4 weeks following restoration of sinus rhythm. It is reasonable to administer heparin during hospitalization. Target activated partial thromboplastin times (aPTTs) are typically two times control. In patients who have tachy-brady syndrome and in whom permanent pacemaker implantation may be required, initiation of warfarin may be delayed.

Direct current cardioversion can be performed in the presence or absence of antiarrhythmic drug therapy. It carries a low risk of systemic embolism if patients have been in AF for less than 24–36 hours, have no evidence of clot on transesophageal echocardiography, or are on chronic

Clinical Risk Factor	Points
C Recent CHF	1
H Hypertension	1
A Age ≥ 75 years	1
D Diabetes mellitus	1
S₂ Prior Stroke or TIA	2

Figure 42.7. CHADS₂ index for calculating risk of stroke in patients with AF. For each point, the annual risk of stroke increases by 50%. Left: CHADS₂ index. Right: Annual risk of stroke. therapeutic anticoagulation. If cardioversion is contemplated, the patient should receive nothing orally after midnight. Biphasic external defibrillators are far more effective at restoring sinus rhythm than the older monophasic devices. Because of the efficacy of biphasic external cardioversion, pharmacologic cardioversion is used less frequently. If pharmacologic cardioversion is preferred, *ibutilide*, a novel type III agent, is approved for the acute conversion of AF and flutter of relatively short duration. Administered as an IV bolus, *ibutilide* is more effective for atrial flutter than for AF. As with other type III agents, there is a risk of *torsades de pointes*; *ibutilide* should not be used in patients receiving other antiarrhythmic drugs. If *ibutilide* fails to restore SR, DC cardioversion can then be performed.

Four weeks following cardioversion should be the absolute minimum period of anticoagulation. Contemporary practice generally recommends anticoagulation for much longer periods, often indefinitely, even if efforts at maintaining sinus rhythm appear to be successful. Exceptions are situations in which the AF had a well-defined trigger (e.g., hyperthyroidism, cardiac surgery, etc.) and the risk of AF recurrence therefore seems extremely low.

Reduction of the ventricular rate with AV nodal blocking agents often markedly improves symptoms of AF. Few data exist comparing the available agents, which include β -blockers, the nondihydropyridine calcium channel blockers diltiazem and verapamil, and digoxin. Digoxin has a delayed onset compared with other agents and is the least effective agent if catecholamine tone is high, as in postoperative patients or with physical exertion. Frequently, a combination of digoxin with a β -blocker or calcium channel blocker is necessary to achieve adequate rate control. In patients with extremely poor ventricular function or acute congestive heart failure, though, digoxin may be the only agent that is tolerated.

Intravenous agents frequently are used initially to manage the ventricular rate (Table 42.3). Diltiazem and esmolol are given as a continuous infusion; verapamil, metoprolol, and propranolol can be given as IV boluses. The target heart rate depends on the clinical scenario; rates of 60–80 at rest and 90–110 with mild-to-moderate exertion are reasonable. Oral agents should be started as soon as rate control is achieved with the IV agent.

The use of antiarrhythmic drugs to suppress recurrences of AF and maintain sinus rhythm is being reassessed, given their limited efficacy and adverse effects, including life-threatening proarrhythmia (14). With a first episode of AF, it is reasonable to cardiovert without maintenance antiarrhythmic therapy. For recurrent episodes, either rate control with long-term anticoagulation or rhythm control with antiarrhythmic therapy can be chosen (Table 42.6). In several trials (15–17), the strategy of rate control and anticoagulation provided very similar functional and clinical outcomes to a strategy of aggressive attempts to maintain sinus rhythm. Antiarrhythmic drug therapy should therefore be reserved for patients who remain symptomatic despite attempts at rate control. If antiarrhythmic therapy is selected, the particular agent should fit the clinical scenario (Table 42.4). DL-sotalolol, dofetilide, and amiodarone are reasonable in patients with coronary artery disease. For younger patients with paroxysmal AF and structurally normal hearts, flecainide and propafenone are often well tolerated and effective. With flecainide and propafenone, an AV nodal blocking agent (Table 42.4) should be used as well. Procainamide, quinidine, and disopyramide, though used frequently in the past, are neither safer nor more effective than newer agents, and they are less well tolerated. Amiodarone may be the most effective agent and likely poses the smallest risk of ventricular proarrhythmia, but its noncardiac adverse effects must be carefully considered. Amiodarone is

TABLE 42.6
RHYTHM CONTROL VERSUS RATE CONTROL IN
ATRIAL FIBRILLATION

Rhythm control	Rate control
Theoretic advantages	
Symptomatic improvement	Safe
Hemodynamic improvement	Medications well tolerated
Reduced risk of thromboembolism	Medications fairly inexpensive
Possible discontinuation of anticoagulation	
Theoretic disadvantages	
Adverse extracardiac effects	Bradycardia
Proarrhythmia	Life-long anticoagulation
Frequently ineffective	Cardiomyopathy if rate poorly controlled chronically
Expensive	Incomplete resolution of symptoms

the most frequently used antiarrhythmic agent in patients with cardiomyopathy or significant left-ventricular dysfunction; dofetilide may also be reasonable in these patients. Prescription of dofetilide is limited to physicians who have completed a training program regarding its use.

For selected patients with symptomatic and refractory AF, catheter ablation of triggering foci typically in and around the pulmonary venous ostia may be curative. These procedures are currently being performed at tertiary care centers. Patients with idiopathic paroxysmal AF are the best candidates for curative ablation; recently, many centers have extended the indications for curative ablation to include patients with mild structural heart disease and persistent AF (18). Success rates vary by center and type of patients treated, and truly long-term follow-up is not yet available. With improvements in techniques, procedural complications such as pulmonary vein stenosis, stroke, and tamponade have decreased in frequency.

Patients whose AF is extremely refractory to pharmacologic therapy may benefit from RF catheter ablation of the AV junction and implantation of a permanent pacemaker (Chapter 45). Although this approach generally markedly improves symptoms, potential downsides include pacemaker dependence and the adverse effects related to chronic right ventricular pacing. Biventricular pacing (known as cardiac resynchronization therapy [CRT]) is preferable to standard right ventricular pacing in many patients who undergo catheter ablation of the AV junction.

Atrial Flutter

For patients with recurrent atrial flutter in the absence of AF, RF catheter ablation of the tricuspid annulus–inferior vena

cava isthmus is effective in preventing recurrent flutter, though AF may recur. Atrial flutter may occur in association with or independent of AF. Pharmacologic rate control is typically much more difficult to achieve with atrial flutter than with AF. Recommendations for anticoagulation of atrial flutter mirror those for AF.

With a first episode of atrial flutter, direct current cardioversion after appropriate anticoagulation is reasonable. If atrial flutter is recurrent, or if a first episode is accompanied by 1:1 A:V conduction or severe symptoms, radiofrequency catheter ablation should be strongly considered. Catheter ablation in the tricuspid valve–inferior vena cava isthmus offers approximately 90% likelihood of freedom from recurrent atrial flutter. AF may occur after atrial flutter ablation (even in patients who have not previously manifested it), but this is generally easier to manage pharmacologically than atrial flutter.

Multifocal Atrial Tachycardia (MAT)

In MAT, efforts should be focused on correcting the underlying metabolic or pulmonary abnormalities. Digoxin or theophylline excess rarely plays a role, while repletion of potassium and magnesium may be helpful. Verapamil lowers the ventricular rate (Table 42.3); β -blockers have similar effects but may be contraindicated by obstructive lung disease. Unlike most SVTs, MAT is nonreentrant, and cardioversion is unlikely to be beneficial.

PSVT (AVNRT, AVRT, and AT)

For patients admitted with AVNRT, AVRT, or AT, attention should immediately be turned to long-term therapy (Figure 42.8). For patients with symptomatic WPW syndrome, electrophysiologic testing and catheter ablation generally are recommended as initial therapy. In the absence of WPW syndrome, either medical therapy or catheter ablation can be used initially for other PSVTs (AVNRT, AVRT utilizing a concealed accessory pathway, and AT). If catheter ablation is to be performed during the same admission, no long-acting agent should be given, as this therapy might render the patient noninducible at electrophysiologic testing. In the absence of WPW syndrome, the initial choice for chronic drug therapy should be an AV nodal blocker; digoxin, a calcium channel blocker, or a β -blocker (Table 42.3). Combinations of agents also can be used. Given the risks of proarrhythmia, catheter ablation should be recommended in these patients rather than the use of type I or III antiarrhythmic agents (Figure 42.8).

DISCHARGE ISSUES

In patients with AF or atrial flutter, careful follow-up is required to monitor the INR and the dose of warfarin. If AF is chronic or of unknown duration, discharge need not always be delayed until the INR is therapeutic. Rather,

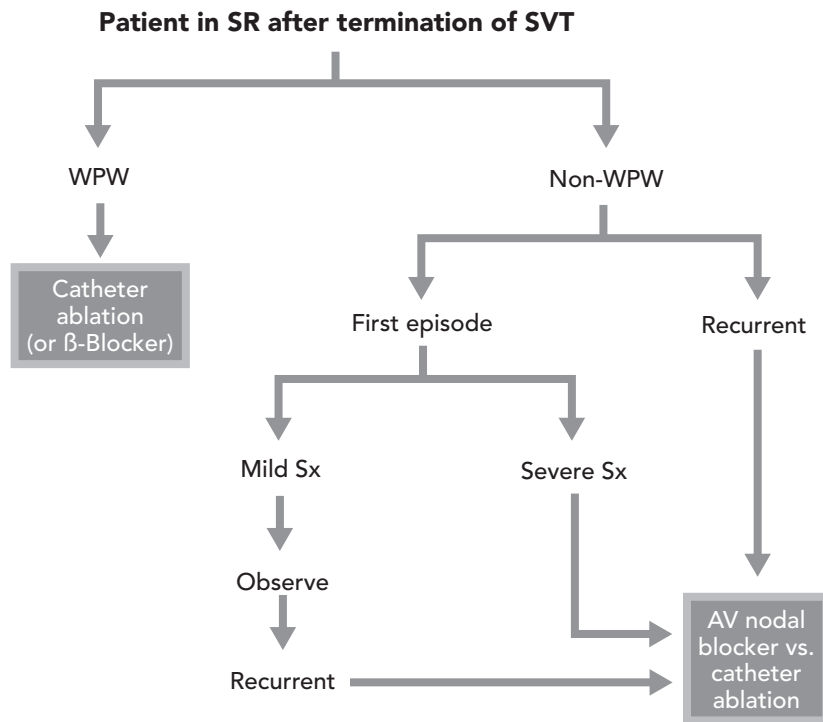

Figure 42.8. Management algorithm for paroxysmal supraventricular tachycardia. SR, sinus rhythm; SVT, supraventricular tachycardia; Sx, symptoms; WPW, Wolff-Parkinson-White syndrome.

warfarin may be started and the patient discharged with a plan in place quickly to realize a therapeutic INR (2.0–3.0). If a patient undergoes TEE-expedited cardioversion, IV heparin should be administered until the INR is therapeutic. Subcutaneous low-molecular-weight heparin is equivalent to unfractionated heparin as a “bridge” to a therapeutic INR in this setting (19). Because confusion ensues if several physicians modulate warfarin dosing, a single physician or office should be designated for this task. Dedicated anticoagulation clinics or services have been shown to improve outcomes compared with less organized approaches. Weekly INR checks are reasonable until a steady maintenance dose is established (Chapter 98).

Despite the high prevalence of AF and atrial flutter, optimal long-term treatment strategies remain uncertain. Clinical trials (15–17) document that long-term anticoagulation and rate-control is a more attractive strategy than vigorous antiarrhythmic use in many patients, particularly those with few or mild symptoms (Table 42.6). In high-risk patients, the combination of moderate intensity warfarin anticoagulation plus an antiplatelet agent may be better than warfarin alone (20).

Patients who are receiving rate-control agents should be followed carefully to assess adequacy of therapy, symptomatic status, and potential side effects. *Patients on antiarrhythmic drugs require meticulous follow-up because of the risk of adverse effects* (14). The QT_c interval and heart rate must be monitored in patients on procainamide, quinidine, disopyramide, amiodarone, dofetilide, and DL-sotalol. Ventricular proarrhythmia in these patients is torsade de pointes, typically precipitated by bradycardia or pauses; this compli-

cation appears much more rare in patients treated with amiodarone compared with other QT-prolonging drugs. For patients started on flecainide or propafenone, exercise stress testing on a steady state of drug is useful to screen for exercise-induced proarrhythmia. Patients on amiodarone must be followed for pulmonary, thyroid, and hepatic dysfunction; annual or biannual pulmonary function testing or chest radiographs and biannual or quarterly blood testing is recommended. Finally, an annual ophthalmologic evaluation is also recommended, as rare cases of optic neuritis have been reported in patients taking amiodarone.

Patients who are considering RF catheter ablation may desire a visit with a cardiac electrophysiologist to discuss the procedure. After successful RF catheter ablation for PSVT, patients are frequently treated with antithrombotic agents (e.g., aspirin) for 4–6 weeks to reduce the risk of procedure-related thromboembolism. After catheter ablation of AF or atrial flutter, patients are anticoagulated with warfarin; the optimal duration of anticoagulation following successful ablation has not yet been established. A follow-up visit in several weeks to confirm healing of the femoral catheterization sites and assess procedural success is reasonable.

SUPRAVENTRICULAR ARRHYTHMIAS DEVELOPING IN THE HOSPITAL

SVTs, primarily AF and to a lesser extent atrial flutter, are frequent complications in both medical and surgical patients. Because PSVT requires a conducive electrophysio-

logic substrate (i.e., dual AV nodal pathways or an accessory pathway), these arrhythmias occur de novo much less frequently in patients admitted for other reasons. AF and atrial flutter are particularly difficult to control in acutely ill patients with problems such as sepsis, pain, and hemodynamic instability. SVTs that develop in hospitalized patients are commonly precipitated by conditions such as infection, hypoxia, drugs, electrolyte abnormalities, or other causes of hypo- or hypervolemia. Although attention must be paid to acute hemodynamic stability, ischemia secondary to the SVT, and rate control, treatment of the underlying condition is also necessary and often sufficient to control the arrhythmias. Some important precipitants are reviewed here.

Acute Myocardial Infarction

AF is an occasional complication of MI (Chapter 38). β -blockers are the agents of choice for ventricular rate control, given their other beneficial effects in acute MI. If AF persists for more than 24 hours, cardioversion should be considered, particularly if no other indication for long-term anticoagulation is present. No data exist regarding the use of low-molecular-weight heparins, clopidogrel, glycoprotein IIa-IIIb inhibitors, or thrombolytic agents in the management of AF; data are few with respect to antiarrhythmic drug use for AF in acute MI. Nonparoxysmal junctional tachycardia also has been reported infrequently during MI.

Acute Pulmonary Embolus

Initial treatment of AF due to acute pulmonary embolus (Chapter 53) should be directed at controlling the ventricular rate using IV calcium channel blockers or β -blockers. As patients with pulmonary emboli routinely are anticoagulated, AF does not pose an additional burden in this regard. Antiarrhythmic drug data are scarce in this setting.

Thyrotoxicosis

SVTs resulting from thyrotoxicosis are extremely refractory, in terms of both ventricular rate control and maintenance of sinus rhythm. Amiodarone is a common cause of hyperthyroidism (as well as hypothyroidism) and complicates its management; since amiodarone loads the thyroid gland with iodine, radioactive iodine ablation is generally ineffective. β -blockers are most effective, given the hyperadrenergic state, in combination with antithyroid therapy (Chapter 108). Anticoagulation should be undertaken as well. If AF persists after a euthyroid state is reached, cardioversion should be performed.

Pulmonary Disease

MAT, AT, AF, and atrial flutter all may accompany acute or chronic lung disease. In chronic pulmonary conditions,

these atrial arrhythmias recur frequently. Other than the fact that β -blockers are frequently contraindicated in these patients, management is just as in other patients with these arrhythmias. Atrial arrhythmias may be refractory in patients with elevated right heart pressures and right atrial enlargement. Amiodarone must be used cautiously in patients with advanced pulmonary disease.

Postoperative Atrial Fibrillation

AF is a common postoperative complication (Chapter 31), particularly after cardiac, thoracic, and vascular surgery. AF also may occur following other major operations such as hip replacement or abdominal surgery. Potential causes of AF after any operation include atrial stretch from volume overload, high catecholamine levels, and β -blocker withdrawal in patients on these agents preoperatively. Pericarditis likely plays an important role in the high incidence of AF and atrial flutter after cardiac and thoracic surgery. Other contributory factors after cardiac surgery may include atrial ischemia and inadequate atrial protection during cardiopulmonary bypass. If left-ventricular function is unknown, a transthoracic echocardiogram may help guide drug selection. In patients who are otherwise doing well, serial cardiac biomarker studies need not be obtained to exclude perioperative MI just because AF has developed. Patients should be transferred, however, to a cardiac telemetry unit.

Noncardiothoracic Operations

Postoperative AF typically occurs with very rapid ventricular rates; unstable patients should be cardioverted. Stable patients should be treated with IV β -blockers or calcium channel blockers. Frequently, AF in this setting terminates spontaneously. If not, it is reasonable to cardiovert if AF persists more than 24–36 hours to avoid the need for anticoagulation. Oral β - or calcium channel blockers may be continued for several weeks to attenuate the ventricular rate if AF recurs. If AF is recurrent or persists for more than 24–36 hours, anticoagulation is recommended, and antiarrhythmic drug therapy may be considered.

Thoracic Surgery

Ventricular rates are frequently extremely rapid in AF after thoracic surgery. Aggressive use of IV β -blockers or calcium channel blockers is necessary to reduce the ventricular response. Though commonly used in this setting, procainamide is of uncertain efficacy in effecting conversion to sinus rhythm and preventing recurrent AF. A 4- to 6-week course of oral β -blockers or calcium channel blockers is reasonable, as pericarditis may provoke recurrent AF after hospital discharge. It is reasonable to consider cardioversion if AF persists for 24–36 hours to obviate the need for anticoagulation. If AF is recurrent or persists for more than 24–36 hours, then careful

anticoagulation is recommended and antiarrhythmic therapy may be considered.

Cardiac Surgery

AF, and to a lesser extent atrial flutter, are the most common complications after cardiac surgery (21). The prevalence is 20%–40% after coronary artery bypass grafting, and significantly higher after valvular procedures. β -blockers should be initiated prophylactically as early as possible postoperatively in all patients without contraindications to reduce the likelihood of postoperative AF (Chapter 31). Digoxin and verapamil are less effective prophylactically than β -blockers; few data exist for diltiazem. Prophylactic amiodarone also reduces the incidence of AF after cardiac surgery.

Despite the importance of this problem, the optimal treatment strategy for AF in this setting is unknown. Though frequently used, procainamide is neither particularly effective nor well tolerated. Initial efforts should be directed at control of the ventricular rate with IV β -blockers or calcium channel blockers; digoxin should be used initially only if ventricular function is poor. If AF does not convert spontaneously, cardioversion after 24–36 hours is reasonable. Patients who remain in sinus rhythm after a single brief episode of AF are typically discharged on aspirin and oral β -blockers or calcium channel blockers. If AF is recurrent or persists for more than 24–36 hours, careful anticoagulation is recommended, and AF suppression with antiarrhythmic drugs may be considered.

Discharge Issues

Most patients who develop AF in the postoperative setting need not be discharged on medications if the AF was transient and clearly related to serious noncardiac problems that are not expected to recur. If recurrence is a major concern, discharge on an oral AV nodal blocking agent is reasonable. Patients who have AF of more than 24–36 hours' duration or have paroxysmal AF, and certainly those discharged in AF, require anticoagulation with warfarin. Postoperative patients are at very high risk of developing a supratherapeutic INR and having bleeding complications, perhaps because of poor oral intake and/or the use of broad-spectrum antibiotics. Cardioversion should be considered following appropriate anticoagulation if AF persists for more than a few weeks postoperatively, particularly in patients who have not had AF previously. Patients treated with antiarrhythmic agents require the careful follow-up care described previously.

COST CONSIDERATIONS

Few data exist regarding the cost effectiveness of various therapeutic approaches to AF and other SVTs. By preventing strokes, chronic anticoagulation for AF is not only cost-

effective but also likely cost-saving. Cost-effectiveness data generally support TEE-expedited cardioversion compared with the traditional approach, and rate control compared with the rhythm control strategy. In PSVT, RF catheter ablation is clearly cost-effective for medically refractory patients, but data are unavailable for less refractory patients. Similarly, data are not yet available regarding the cost effectiveness of catheter ablation for atrial flutter. In refractory AF, AV junctional ablation with permanent pacemaker implantation improves quality of life and reduces health care resource utilization; biventricular pacing (CRT) will likely prove to be preferable to standard right ventricular pacing. Subcutaneous low-molecular-weight heparins may have the potential to shorten hospital stays by replacing prolonged courses of IV unfractionated heparin anticoagulation until the INR is therapeutic on warfarin; clinical trials are ongoing. Clinical trials are also currently evaluating newer antithrombotic compounds that may provide clinical efficacy similar to warfarin for preventing strokes, but without the need for INR monitoring and dose adjustments, and perhaps with a lower risk of bleeding (12). AF after cardiac surgery increases length of stay and costs significantly, highlighting the importance of defining an optimal treatment strategy.

KEY POINTS

- Wide-complex tachycardia should be presumed to be VT until proven otherwise and treated as such.
- Long-term anticoagulation is indicated in the majority of patients with AF or atrial flutter to reduce the risk of thromboembolic complications such as stroke.
- Aggressive use of AV nodal blocking drugs to attenuate the ventricular rate is frequently very effective in improving symptoms due to AF.
- The potential risks and benefits should be weighed carefully prior to starting antiarrhythmic drug therapy in any patient with AF or other SVT.
- In the absence of WPW syndrome, PSVT is rarely life-threatening, and hospital admission is not routinely necessary.
- Symptomatic WPW syndrome patients should generally undergo diagnostic electrophysiologic studies and RF catheter ablation; diagnostic electrophysiologic testing and catheter ablation should be considered in selected asymptomatic patients as well.
- Electrophysiologic studies and RF catheter ablation should be considered early in the management of patients with recurrent or refractory PSVT or atrial flutter.
- Routine exercise stress testing, ventilation–perfusion scanning, and assays of cardiac biomarkers are unnecessary in patients with SVTs, unless the clinical scenario is suggestive of ischemia, pulmonary embolus, or MI, respectively. Transthoracic echocardiography and serum TSH screening are reasonable in the diagnostic workup of new SVTs.

- Patients treated with amiodarone and other antiarrhythmic drugs require extremely careful follow-up, because of the potential for both cardiac and extracardiac toxicity.

Ventricular Arrhythmias and Cardiac Arrest

43

Graham Gardner H. Leon Greene Peter Zimetbaum

INTRODUCTION

Epidemiology

Sudden cardiac death is the most common cause of mortality in the United States. Approximately 250,000 people each year die within one hour of the onset of cardiovascular symptoms. The most common mechanism for sudden cardiac death is an arrhythmia, usually ventricular fibrillation (VF). Though the overall mortality rate from cardiovascular diseases has been decreasing in the past few years, sudden arrhythmic cardiac death remains a major problem.

Epidemiologic studies clearly show an association between the number of cardiac risk factors and the occurrence of sudden cardiac death. Nearly three-quarters of all patients who experience a cardiac arrest resulting from ventricular arrhythmias have previously recognized cardiac disease, either angina pectoris, prior myocardial infarction (MI), hypertension, or heart failure. Many patients are completely asymptomatic until collapse (or have no change in their chronic symptoms), although others, in whom MI precipitates the ventricular arrhythmias, may have chest pain prior to the collapse. Nevertheless, prospective identification of the patient who will develop serious ventricular arrhythmias, so that appropriate therapy can be instituted, remains an elusive goal.

Several cardiac rhythms can produce cardiac arrest. The initial rhythm identified on the monitor depends on how quickly monitoring is begun. Most patients who suffer cardiac arrest in the community are believed to have VF as the mechanism of arrest (1). The incidence of VF in the community may be declining, such that VF is now thought to be responsible for a minority of in-hospital and fully monitored cardiac arrests (2, 3). This trend may be related to im-

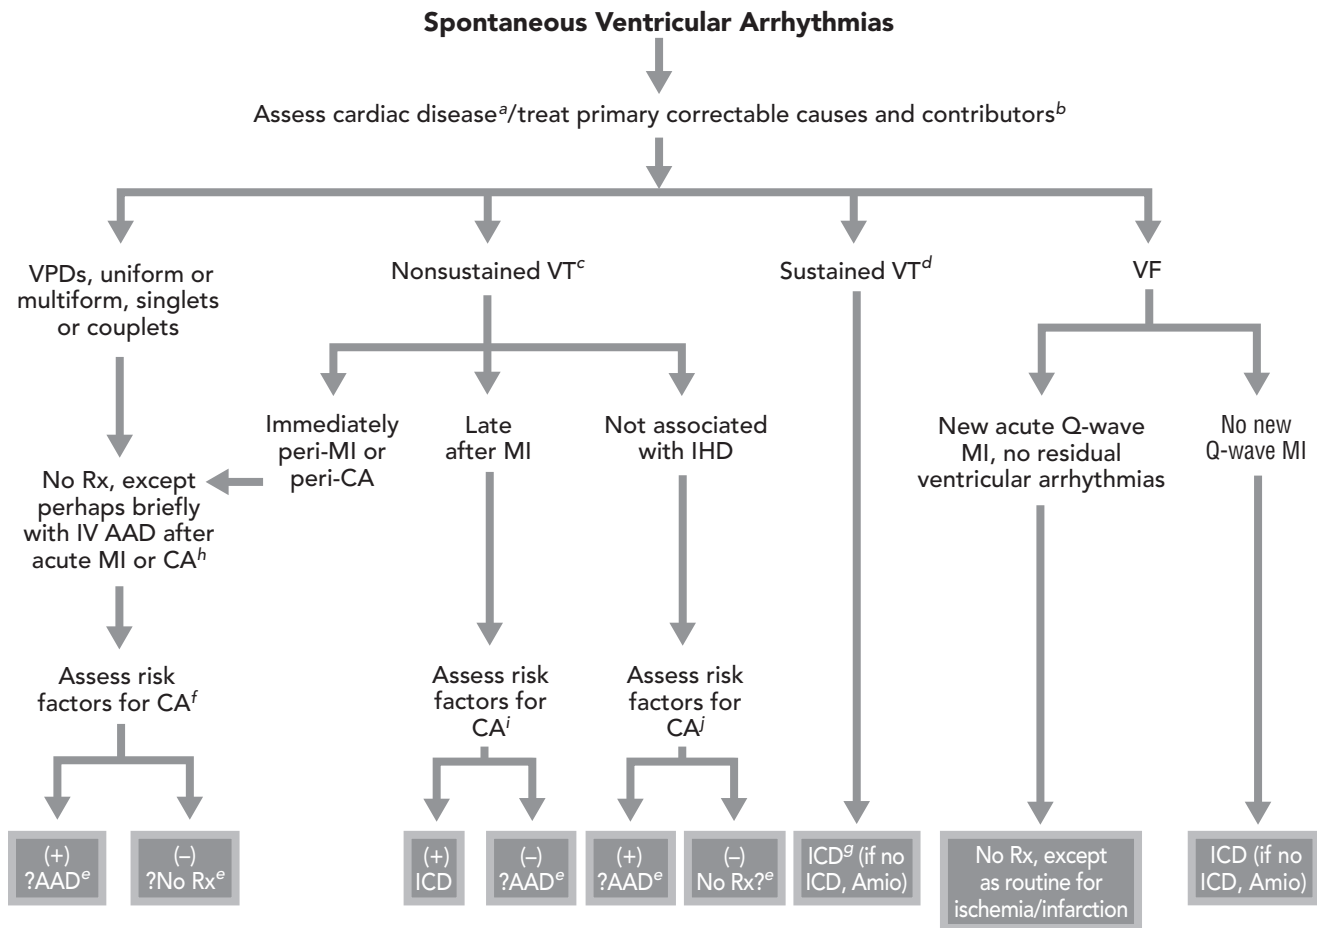

provements in treating underlying coronary artery disease as a result of better revascularization and more aggressive pharmacologic management. In addition, patients with symptoms of acute coronary syndrome may be presenting to medical attention earlier—leading to a shift in the occurrence of cardiac arrest from the outpatient to the inpatient setting. To date, however, no evidence supports such a trend (2). Still, telemetry monitoring for hospitalized patients could lead to the earlier identification of aberrant rhythms. Often VF is preceded by a short run of ventricular tachycardia (VT), but sustained VT without subsequent VF rarely causes clinical cardiac arrest. Patients seen late after their cardiac arrest commonly have asystole recorded as the initial rhythm, although the rhythm actually responsible for collapse is more likely to have been VT/VF (4). Pulseless electrical activity or electromechanical dissociation is less common but may be increasing in relative frequency.

The success of resuscitation depends on many factors, which may be different for the patient resuscitated in the hospital as opposed to the patient resuscitated out of the hospital. Reported resuscitation success varies. It is less than 1% in some inner-city areas in which medic response time is prolonged, but the success rate is over 40% in Seattle, in patients who have VF as the initially recorded rhythm and who receive early defibrillation followed by the administration of amiodarone en route to the hospital (5). Under the best circumstances, approximately two-thirds of patients who have VF on the arrival of medics are resuscitated and survive to hospital admission. Approximately half these cardiac arrest patients who are admitted to the hospital (one-third of the total VF population) ultimately are discharged from the hospital alive and well. However, in settings in which the medic response time is longer, resuscitation efforts are less successful. If patients have electromechanical dissociation or

asystole as the first recorded rhythm, their prognosis is poor, with a long-term survival of only about 6% with electromechanical dissociation and 1% with asystole.

The most important factor determining survival in VF is rapid defibrillation (6). Provision of early cardiopulmonary resuscitation (CPR), although useful, is a temporizing measure. Even excellent CPR provides only about 15% of normal cerebral blood flow and 5% of normal cardiac perfusion.

Recurrent risk of cardiac arrest is high in survivors of VF, and aggressive risk factor modification is necessary to help prevent subsequent episodes. In addition, antiarrhythmic medications and implantable cardioverter defibrillators (ICDs) have been shown to improve survival in this group (7). However, survivors of VF represent only a small percentage of the total cardiac arrest population. For this reason, identifying high-risk patients and initiating primary prevention have taken on increasing urgency.

CATEGORIZATION OF VENTRICULAR ARRHYTHMIAS

Ventricular arrhythmias can be classified as sustained or nonsustained, symptomatic or asymptomatic, and tolerated or nontolerated. *Sustained VT* is defined as 30 seconds or more of a ventricular rhythm at greater than 100 beats per minute. Sustained VT that is one uniform morphology is called monomorphic. If sustained VT is multiform in morphology, it is called polymorphic VT. *Nonsustained VT* is characterized by three or more ventricular beats at a rate of greater than 100 beats per minute that last less than 30 seconds. *Symptomatic VT* refers to VT with the sensation of palpitations, chest pain, shortness of breath, dizziness, presyncope, or syncope. *Tolerated VT* suggests an absence of associated significant hypotension or cardiac ischemia. Isolated ventricular premature beats (VPBs) or couplets can also be symptomatic or asymptomatic (Figure 43.1). They may represent an independent risk for recurrent ventricular arrhythmia in patients with coronary artery disease or other cardiac pathology—particularly when they are frequent (greater than 6–10 beats per hour).

GENERAL PRINCIPLES OF THERAPY

Though ventricular arrhythmias identify patients at higher risk of sudden arrhythmic cardiac death, specific treatment of these ventricular arrhythmias is not always indicated. Treatment strategy should first focus on the primary disease process and then on assessing the risk of further symptomatic ventricular arrhythmias. No single test adequately predicts serious ventricular arrhythmias, which means that evaluating the risk of sudden death often involves several testing modalities. These include echocardiogram, Holter monitoring, stress testing, cardiac catheterization, and electrophysiologic study. The role for some of these tests remains controversial, and the extent of workup may depend on the goals of the patient and the patient's family, as well as the experience of the cardiologist.

WHEN VENTRICULAR ARRHYTHMIAS PRESENT ON ADMISSION

Clinical Presentations and Indications for Admission

Symptomatic ventricular arrhythmias requiring hospital admission include resuscitated VF (cardiac arrest) as well as sustained and nonsustained VT with symptoms of syncope, near-syncope, dizziness, or lightheadedness. Patients with any of these symptoms should be admitted to the ICU, coronary care unit, or (for patients with tolerated VT who have not suffered loss of consciousness) a telemetry unit. If

a patient is asymptomatic and (a) it has been previously demonstrated that the ventricular arrhythmia is chronic, (b) the arrhythmia has been completely evaluated, and (c) the arrhythmia has not been associated with serious hemodynamic compromise or symptoms (e.g., idiopathic VT), hospital admission may not be necessary. Patients with ICDs who present with recurrent ventricular arrhythmias that have been appropriately treated by their ICD (e.g., defibrillation or pacing) also do not require hospitalization.

Etiology

A wide range of diseases and conditions is associated with ventricular arrhythmias and may produce sudden cardiac death (Table 43.1). These conditions must be distinguished from nonarrhythmic conditions that can also cause sudden collapse, such as cardiac tamponade, aortic dissection, sudden blood loss, stroke, tension pneumothorax, sepsis, and pulmonary embolus.

On the initial evaluation, it is useful to distinguish the more typical monomorphic sustained VT (Figure 43.2 A) from polymorphic VT (Figure 43.2 B and C). *Polymorphic VT* is characterized by beat-to-beat alterations in the morphology of the QRS complex. If the polymorphic VT has a pattern that appears to be rotating around a baseline and is associated with QT prolongation (Figure 43.2 C), it is called *torsade de pointes*. Torsade de pointes may be caused by congenital prolongation of the QT interval, either at rest or with

TABLE 43.1
DISEASES ASSOCIATED WITH SUDDEN ARRHYTHMIC CARDIAC DEATH

Coronary artery disease	Congenital heart disease
Acute ischemia/infarction	Coronary artery anomalies
Chronic coronary disease	Valvular heart disease
with prior myocardial	Tetralogy of Fallot
infarction	Left ventricular diverticulum
Ruptured myocardium	Right ventricular dysplasia
Coronary arteritis	Wolff-Parkinson-White
Coronary spasm	syndrome
Cardiomyopathy	Long QT syndromes
Dilated	Congenital
Hypertrophic	Acquired
Symmetric	Drug toxicity
Asymmetric	Electrolyte abnormalities
Myocarditis	Toxins (e.g., cocaine)
Infiltrative myocardial disease	Proarrhythmic effects of
Tumor	antiarrhythmic drugs
Infection	Electrolyte abnormalities
Sarcoid	Mitral valve prolapse
Other	Cardiac tumors
Valvular heart disease	Pulmonary hypertension
	Cardiac trauma
	Electrocutation
	Primary electrical disease (e.g.,
	Brugada syndrome,
	idiopathic VF)

Figure 43.2. Electrocardiographic monitor strips from three different patients. **A.** Monomorphic sustained ventricular tachycardia (VT) in a patient with a previous myocardial scar. The QRS morphology is identical from beat to beat. **B.** Polymorphic VT in a patient with ongoing ischemia. The QRS changes from beat to beat, and the VT terminates spontaneously. Though it is difficult to measure on this single lead, the QT interval was normal on a 12-lead electrocardiogram. **C.** Torsade de pointes VT in a patient taking quinidine. The QT is prolonged. The QRS changes dramatically from beat to beat, twisting around an imaginary baseline. This VT also ultimately terminated spontaneously, as is common for torsade de pointes VT.

exercise. More commonly, however, polymorphic torsade de pointes is acquired and is caused by antiarrhythmic drugs (especially quinidine, procainamide, disopyramide, dofetilide, sotalol, or rarely amiodarone), tricyclic antidepressants, phenothiazines, some antibiotics (especially erythromycin and pentamidine), some antihistamines (terfenadine and astemizole), and other drugs (probuco and cisapride). It also may be precipitated by electrolyte disorders such as hypokalemia, hypocalcemia, and hypomagnesemia. Polymorphic VT in the absence of a prolonged QT may occur after MI or with myocardial ischemia. By comparison, *monomorphic sustained VT* (Figure 43.2A) has a constant appearance from beat to beat and is commonly seen in patients with underlying coronary artery disease (especially with left-ventricular scar) or other myocardial disease. Only rarely do patients with monomorphic sustained VT lack underlying heart disease (when they do, this is termed idiopathic VT, and it is rarely life threatening).

Sudden death in the young person or athlete carries its own differential diagnosis (8). The most common causes are hypertrophic obstructive cardiomyopathy (HOCM)

and anomalous coronary arteries. Direct trauma to the heart (commotio cordis) is also an important cause. Other etiologies include arrhythmogenic right ventricular dysplasia (ARVD), long QT syndrome, Brugada syndrome, and idiopathic VF (VF without underlying structural heart disease).

Wolff-Parkinson-White syndrome (WPW) is a special circumstance in which atrial fibrillation conducted over an accessory pathway can precipitate VF. Administration of drugs that directly or indirectly accelerate conduction of atrial fibrillation over the accessory pathway (e.g., digoxin, verapamil) can facilitate the development of VF in patients with WPW. Definitive therapy is radiofrequency ablation (Chapter 42).

Differential Diagnosis

Ventricular arrhythmias can usually be distinguished from wide-complex supraventricular arrhythmias (Chapter 42) by the presence of atrioventricular dissociation, the axis of

the QRS vector, the width of the QRS complex, and several morphological criteria. *In patients with pre-existing heart disease or risk factors for sudden cardiac death, any arrhythmia about which there is a question should be evaluated and treated as ventricular in origin until proven otherwise.*

Initial Evaluation and Treatment

Evaluation

The evaluation for the etiology of the cardiac arrest should begin immediately after the resuscitation because the treatment of any provoking factors will help stabilize the patient and prevent an immediate recurrence of the arrhythmia (Figure 43.3). An electrocardiogram (ECG) and cardiac biomarker levels should be obtained to identify patients with active ischemia or infarction who may benefit from early revascularization. Evaluation of telemetry and any rhythm strips provided by the paramedics is also critical. Unfortunately, complications from the arrest, such as acidemia, electrolyte abnormalities, and myocardial stunning, can sometimes make the interpretation of noninvasive tests more difficult. Similarly, because arrests are frequently unwitnessed and patients may not be responsive, the history is often unhelpful in determining whether cardiac ischemia preceded the arrest. In these circumstances, physicians may choose to proceed with cardiac catheterization to exclude the possibility of coronary artery disease. Cardiac catheterization with catheter-based revascularization, if available, is preferred to thrombolysis in the patient with active ischemia who has received CPR (9).

For patients with polymorphic VT, attention must be paid to possible precipitating causes, including illicit drugs, prescribed medications, and electrolyte abnormalities. Electrolyte abnormalities should be corrected aggressively, although it is important to remember that certain abnormalities, such as hypokalemia, may be the consequence of the high catecholamine state associated with cardiac arrest and not necessarily the precipitating factor. For this reason, a full cardiac workup should be simultaneously pursued in these patients. Potentially offending medications must be discontinued immediately.

Approximately 20% of patients develop new Q waves, and 50% develop biomarker abnormalities consistent with MI. Cardiac troponin assays are more specific and more sensitive than creatine kinase MB levels for myocardial damage, especially after CPR. Patients who have an acute Q-wave MI at the time of VF have only about a 2% risk of recurrent VF and do not warrant aggressive long-term antiarrhythmic drug or device therapy, particularly if they have been revascularized. By comparison, *patients who have neither new Q waves nor biomarker elevations are at the highest risk for recurrent VT/VF*, and patients without new Q waves but with biomarker elevations have an intermediate risk. Other risk factors for the recurrence of VT or VF include

male sex, advanced age, history of prior MI, low ejection fraction, and a history of heart failure.

Early attention should also be directed toward the patient's underlying neurologic status. Although diffuse anoxic encephalopathy is the most common cause of stupor or coma after cardiac arrest, persistent abnormal mental states after admission or any suggestion of localizing central nervous system signs should prompt computed tomography or magnetic resonance imaging of the head to evaluate for treatable intracranial pathology. It is important to realize, and to help the family understand, that dramatic recovery can occur, particularly within the first 72 hours. Families often insist upon withdrawal of support immediately, based on the patient's previously expressed wishes to avoid "being hooked to machines," without realizing that nearly full recovery may be possible following a brief period of mechanical support. Supportive efforts should not be withdrawn based upon lack of return of neurologic function if the patient has been exposed to drugs that might depress central nervous system function or if seizures are uncontrolled (e.g., barbiturate overdose).

Finally, the initial workup of a cardiac arrest should focus on conditions that can accompany an arrest (Figure 43.3). This workup includes a chest radiograph to evaluate for pulmonary edema or aspiration pneumonia. A nasogastric tube must be placed to prevent gastric distention and to evaluate for gastrointestinal bleeding. Urinary output should be monitored by Foley catheter. Laboratory data to monitor the patient's renal function and acid-base status will also help identify complications such as acute renal failure, rhabdomyolysis, and lactic acidosis. Frequently, an initial lactic acidosis may be caused by poor peripheral tissue perfusion; however, persistent lactic acidosis should be a clue to additional damage, such as bowel ischemia.

Management

Management of recurrent VF or pulseless VT begins with early defibrillation, along with administration of intravenous antiarrhythmic medication (Table 43.2). Patients who undergo a primary arrest in the hospital or who develop recurrent VF after presentation should be defibrillated with 200–360 joules of energy applied to the chest wall. Defibrillation should be performed as quickly as possible because the chance of success in terminating the arrhythmia decreases with time (6).

Antiarrhythmic medications may also have a role in the acute setting. In the ARREST trial, early administration of intravenous amiodarone, given as a 300 mg intravenous push, led to a significant improvement in survival to hospitalization among patients who experienced a cardiac arrest from VF or VT that was initially unresponsive to defibrillation (5). Although the study failed to detect a difference in long-term survival between the groups that received amiodarone versus placebo, *amiodarone is now considered first-line therapy for the management of VF or*

VT-mediated cardiac arrest. Lidocaine may have a role in the acute management of ischemia-mediated VF or VT, although the ALIVE trial indicated that amiodarone was more effective than lidocaine in improving survival to hospitalization (10). Magnesium sulfate is recommended for the treatment of torsade de pointes and hypomagnesemic states.

The induction of mild-to-moderate hypothermia (target core body temperature of 32–34°C for 24 hours) has been shown to improve neurologic recovery in patients who are successfully resuscitated after cardiac arrest (11–13). At this time, the logistics involved in cooling patients quickly and effectively has limited its broad application. However, newer technologies designed to achieve efficient and isolated CNS cooling may prove useful in helping patients retain their functional status after suffering an arrest.

Prognosis

Even in the acute phase, long-term prognosis can be estimated with simple prognostic indices such as the Glasgow Coma Scale (Table 117.1), the APACHE classification

system (Chapter 22), or other simple algorithms (Table 43.3) (14). The time elapsed in the coma itself is also predictive of subsequent awakening. For example, the patient who has not awakened by the end of day 2 has only a 27% probability of ever awakening; the probability remains about 20% even at three weeks (14). The probability of awakening without gross motor and cognitive deficits, however, is much lower. Fully one-third of even those patients who are awake on admission have some neurologic impairment in the long term, and after four days of coma, essentially 100% of patients have both motor and cognitive deficits in the long term. Seizures and myoclonus are also bad prognostic signs. Patients may be observed for a variety of post-resuscitation complications (Table 43.4).

Measurement of *cerebrospinal fluid creatine kinase BB* at 48 to 72 hours following cardiac arrest is predictive of the patient's awakening (15). If the level of cerebrospinal fluid creatine kinase BB is less than 50 units/L, substantial neurologic recovery is likely; values of more than 204 units/L are associated with nearly zero chance of awakening.

8, 9	95

Acute Cardiac Issues

In patients surviving cardiac arrest, the rhythm usually stabilizes within the first 24 hours, and acute antiarrhythmic drugs can often be discontinued 48–72 hours after admission. Frequent recurrent arrhythmias, particularly during the first 24 hours after admission, may indicate an ongoing ischemic process. However, other causes should be sought, such as drug intoxication and electrolyte abnormalities, especially in patients with prolonged QT intervals and polymorphic VT. Likewise, cardiac output and blood pressure usually stabilize by 48 hours, although dramatic fluctuations in blood pressure may continue, requiring variable doses of vasodilating and vasopressor drugs.

Definitive Cardiac Evaluation

Definitive cardiac evaluation should begin as soon as possible after hospital admission (Chapter 36). Echocardiography is useful to measure left ventricular ejection fraction, to assess valve function, and to exclude pulmonary hypertension and the presence of dilated or hypertrophic cardiomyopathies. Remember, however, that transient myocardial stunning may follow cardiac arrest from any cause. Thus, an accurate measurement of left ventricular function may need to be delayed 48–72 hours. If it is suspected that transient myocardial ischemia triggered the ventricular arrhythmia, an invasive or noninvasive

assessment of coronary perfusion should be performed. Holter monitoring and electrophysiologic testing may be critical for diagnosis, but studies have suggested that expedited progression to placement of an ICD is often appropriate in patients who have suffered a near-fatal cardiac arrest (7).

Risk factors for recurrence of sustained VT or VF include male sex, advanced age, lack of development of a new Q-wave MI with the episode of VF, history of prior MI, low ejection fraction, and history of heart failure. The only reliable single indicator of low risk of recurrent VT/VF is the development of a new Q-wave MI at the time of VF.

WHEN THE DISEASE PRESENTS DURING HOSPITALIZATION

Cardiac Arrest

Frequently, cardiac arrest resulting from VT or VF occurs in a patient already hospitalized for another condition. Patients with in-hospital arrests may have the same spectrum of diseases as patients who present with arrests that occurred out of the hospital, but inpatients are more likely to have had an arrest because of an MI, pulmonary embolus, or blood loss related to their coexisting diseases. Nevertheless, the evaluation and treatment of these patients should be as extensive as it is in the patient with an out-of-hospital presentation. Often the patient is unconscious or in the operating room at the time of the arrhythmia and cannot provide the history of chest pain that might otherwise have been noted as an ischemic precipitant. These patients often are sicker because of the combination of the cardiac disease and other coexisting pathology, and the success of the initial resuscitation in fact may be lower than that for out-of-hospital arrest, even though the response time is faster. However, under certain circumstances, such as in the cardiac catheterization laboratory, resuscitation rates can approach 100% because of nearly immediate defibrillation of VT or VF.

A VT/VF arrest that occurs in an already critically ill patient often portends irreversibility of the underlying disease process. If such an arrest occurs in a patient with a preterminal condition, such as an advanced malignancy, aggressive resuscitation may be inappropriate (Chapter 17). It is critical that the physician quickly understand the patient's overall situation to guide in-hospital CPR attempts. It is tempting to blame a low potassium level, catecholamines, drugs, or hypoxia for the arrhythmia, but hospitalized patients commonly also have an underlying propensity to ventricular arrhythmias unrelated to any transient condition. They may well need even more extensive testing than out-of-hospital patients to be certain that the VT/VF has a reversible cause. Furthermore, they ultimately have worse long-term outcomes than patients with out-of-hospital VT/VF.

TABLE 43.4
COMPLICATIONS OF CARDIAC ARREST AND RESUSCITATION

Early	Late
Rib fractures/flail chest	Acute respiratory distress syndrome
Pneumothorax/hemothorax	Sepsis
Stomach/esophageal rupture	Gastrointestinal bleeding
Liver laceration	Anoxic encephalopathy
Rhabdomyolysis	
Limb ischemia	
Bowel ischemia	
Aspiration pneumonia	
Renal failure	
Coma	
Trauma (especially head trauma) related to fall, automobile accident, etc., secondary to cardiac arrest	
Pericardial effusion

Laceration of subclavian artery or vein	
Hematoma	
Arteriovenous fistula	
Complications related to endotracheal intubation	
Selective intubation of right or left mainstream bronchus	
Vocal-cord damage	
Cardiac laceration or rupture	
Splenic laceration	
Skin burns from repeated defibrillation	

Because hospitalized patients usually have other comorbid diseases that precipitate the arrhythmia, the first step is to identify these causes and correct them if possible. It is critical to distinguish polymorphic VT from monomorphic VT because of the often differing underlying causes and their therapeutic implications.

For the patient with *drug-induced polymorphic VT with a long QT interval*, electrolyte abnormalities must be corrected, and potentially causative medications must be discontinued. A bolus of magnesium (1–2 g over 10 minutes, followed by a continuous infusion) followed by emergent insertion of a temporary transvenous pacemaker or administration of intravenous isoproterenol to increase the cardiac rate is indicated. In a patient with unstable ischemic heart disease and polymorphic VT, aggressive treatment with β -blockers, nitrates, and possibly intravenous amiodarone may be effective; prompt revascularization is the ideal treatment. For patients with congenital or idiopathic long QT syndrome, cardiologic consultation is required to plan therapy.

For the patient with *monomorphic VT*, direct-current cardioversion is the treatment of choice. Lidocaine, procainamide, or amiodarone (Table 43.2) can be used as adjunctive therapy after successful cardioversion or for loading doses prior to repeat cardioversion in patients in whom initial cardioversion has been unsuccessful. In some instances, tolerated sustained monomorphic VT can be ablated in the electrophysiology laboratory. In most cases of tolerated VT associated with structural heart disease, or in cases of intolerated VT, an ICD is indicated.

OTHER PRESENTATIONS OF VENTRICULAR ARRHYTHMIAS

Patients may present not with VF and cardiac arrest, but rather with more well-tolerated arrhythmias such as hemodynamically stable sustained VT (30 seconds or more of VT), nonsustained VT, or frequent VPBs. Many patients with VPBs or nonsustained VT require no specific antiarrhythmic therapy. These arrhythmias are commonly seen in hospitalized patients (especially those who are critically ill) and often are related to marked sympathetic stimulation from hypotension, fluid overload, sepsis, respiratory failure, or other critical illnesses. If the VPB or nonsustained VT is a manifestation of an exacerbation of ischemic heart disease, aggressive therapy should target the ischemic heart disease itself (Chapter 37). If the nonsustained VT or frequent VPBs themselves cause hemodynamic complications, suppression with intravenous antiarrhythmic drugs (Table 43.2) may be helpful and generally is indicated. However, the patient's ultimate prognosis depends more on the outcome of treatment of the underlying severe illness than on the treatment of the ventricular arrhythmias themselves. In some critically ill patients, VPBs may be precipitated by a right heart catheter; withdrawal of the catheter back into the central venous system is curative. Remember that *VPBs in patients without structural heart disease do not carry an increased risk for cardiac events*.

Nonsustained VT may herald more serious arrhythmias, however. For that reason, basic evaluation is essential, though it need not necessarily be performed completely in the hospital, nor need it always result in long-term treatment. On occasion, a patient may have recurrent episodes of nonsustained VT documented for a considerable length of time without symptoms. In such cases, in-hospital evaluation is not required. Nonsustained VT or even torsades de pointes VT usually can be managed in either the critical care unit or a monitored telemetry unit. Patients with coronary artery disease or with heart failure or low left ventricular ejection fraction who have nonsustained VT are at higher risk of cardiac arrest than similar patients without these arrhythmias. Higher-risk patients should be managed in consultation with a cardiac electrophysiologist as they often require specialized electrophysiologic testing, ICD implantation, or antiarrhythmic drugs.

With the proliferation of ICDs, more patients are presenting to hospitals with a history of a shock or shocks from the ICD. These shocks may be either single, isolated events or repeated shocks over a short period of time. Single, isolated ICD shocks require an evaluation for acute factors such as electrolyte abnormality, drug intoxication, ischemia, or device malfunction. However, most patients with ICD shocks can be discharged from the physician's office or the emergency department without hospitalization. Frequent, closely spaced shocks or symptomatic episodes may require hospitalization for evaluation for primary causes, the initiation of antiarrhythmic drugs, or electrophysiologic study with VT ablation.

Another common issue is the question of whether to replace an ICD at the time of battery depletion if no shocks or antitachycardia pacing therapies have been delivered since the original implantation. In general, it is appropriate to replace these devices because patients have a continued moderate risk for recurrence of ventricular arrhythmias.

DISCHARGE ISSUES

Long-Term Therapy

It is important to address the primary cause of the arrhythmia, usually coronary artery disease. Evidence of reversible ischemia will usually lead to a percutaneous coronary intervention or to coronary artery bypass graft (CABG) surgery. However, unless transient ischemia was responsible for the arrhythmia, revascularization alone may not be sufficient to prevent further arrhythmic episodes. Aortic or mitral valve disease should be corrected if appropriate, but patients with valve disease probably remain at risk for further VT/VF even after correction of their valvular abnormality.

In patients with polymorphic VT, avoidance of precipitating medications may be the only treatment needed. However, many patients with polymorphic VT have myocardial ischemia or an ongoing tendency to develop precipitating electrolyte abnormalities and may require more definitive therapy.

Based on the results of multiple clinical trials (7, 16–20), *it is now widely accepted that the ICD is the most efficacious therapy for patients with a history of VF or sustained VT with syncope or serious hemodynamic compromise*, except in situations in which there are contraindications (7) (Tables 43.5 and 43.6). In fact, in patients with heart failure that remains symptomatic, an ICD can be combined with cardiac resynchronization therapy to improve outcome (16). Multiple trials suggest that high-risk patients, even those without a previously documented history of VT or VF arrest, also benefit from implantation of an ICD for the primary prevention of sudden cardiac death (17–21).

In addition to ICD implantation, other therapies can be considered in consultation with a cardiac electrophysiolo-

TABLE 43.5
WHEN AN IMPLANTABLE CARIOVERTER DEFIBRILLATOR IS NOT INDICATED FOR THE PATIENT WITH SUSTAINED VENTRICULAR TACHYCARDIA/FIBRILLATION

Temporarily
Patient has ongoing infection
Patient has a poor neurologic recovery, soon after arrest
Permanently
VF associated with new Q-wave myocardial infarction
Patient fails to improve neurologically over time
Patient refusal
Coexisting disease that will seriously limit chance of survival
? Class IV CHF, unless the patient is a transplant candidate

CHF, congestive heart failure; VF, ventricular fibrillation; VT, ventricular tachycardia.

gist. Radiofrequency ablation in patients with monomorphic VT may reduce symptoms and decrease device firing. Antiarrhythmic medications (Table 43.7) may also help to suppress recurrent arrhythmias, although medications should not replace the implantation of an ICD in appropriate candidates. Concomitant use of antiarrhythmic medications with an ICD is common practice (in as high as 70% of patients). Amiodarone is generally considered first-line therapy (particularly for patients with heart failure), although it has a number of potential toxicities. Because of this, amiodarone should be loaded in the hospital in patients with VT who do not have an ICD. In general, decisions about the use of amiodarone or alternative antiarrhythmic medications should be made in consultation with a cardiologist.

Other Long-Term Issues

Patients who do not survive the hospitalization after initial resuscitation from their ventricular arrhythmias usually die of either cardiogenic shock or devastating neurologic impairment. Lack of neurologic function itself may limit the ability to perform diagnostic tests or even to obtain

TABLE 43.6
CONDITIONS FOR WHICH TREATMENT OF CHOICE IS UNCERTAIN

consent for procedures. It is common for a patient to be discharged to a nursing home or a rehabilitative facility without definitive cardiac evaluation or treatment for ventricular arrhythmias, with subsequent cardiac evaluation deferred for weeks or even months until the patient's neurologic status renders evaluation appropriate.

Return of neurologic function is commonly slow and progressive. Patients often retain excellent long-term memory but virtually no short-term memory. In fact, patients who have had a VF arrest almost always have total amnesia for the event, including the minutes or hours preceding the arrest, whereas patients with only sustained VT (and therefore maintenance of at least some cardiac output) usually have preserved memories.

Activities that could put the patient or others at risk should an arrhythmia recur should be addressed. Guidelines for driving are variable from state to state and often ill defined (22). Most physicians restrict driving for approximately six months after the most recent cardiac arrhythmia that caused loss or near loss of consciousness. Restriction is not directly related to subsequent therapy, such as the ICD, but it reflects the hazards that may occur should the patient become temporarily incapacitated and lose control of a vehicle because of an arrhythmia.

Other potentially risky activities, such as traveling to remote areas, swimming, climbing ladders, working in exposed areas (e.g., on the roof of a house), and piloting an airplane must also be restricted. Recommendations should be individualized, based upon the characteristics of the patient's myocardial function and symptoms with arrhythmias. In considering these recommendations, the physician should also take account of risks to other parties.

OUTPATIENT FOLLOW-UP

The patient can be discharged after complete cardiac evaluation and definitive therapy for both the primary and

secondary conditions. Except for some specific situations, an ICD is now the recommended therapy for survivors of sustained VT/VF; hospital discharge is appropriate soon after recovery from anesthesia for implantation. Patients can usually be discharged home, although they sometimes must be discharged to a nursing home or rehabilitation facility for further neurologic and cardiac recovery.

A return outpatient visit with the primary care physician and cardiologist should be scheduled for one to four weeks after hospital discharge. In addition, close follow-up with a device clinic is required for patients who have undergone ICD implantation. Patients usually are seen at two- to four-month intervals thereafter.

COST CONSIDERATIONS AND RESOURCE USE

Two weeks is the average length of hospital stay for the patient who survives a cardiac arrest from out-of-hospital sustained VT/VF and who has an ICD implanted. Patients who have severe myocardial dysfunction often die soon after hospital admission; other patients with severe neurologic impairment may require prolonged hospital stays, including time in a rehabilitation facility or nursing home. Therefore, the treatment of cardiac arrest is expensive.

The development of the ICD has raised major issues regarding the cost and quality of care for patients with VT and VF. In the Multicenter Automatic Defibrillator Implantation Trial (MADIT) (17), the average hospitalization cost for patients treated with antiarrhythmic drugs was about \$19,000, compared with \$45,000 for patients treated with an ICD (23). Nevertheless, compared with antiarrhythmic drugs, the cost per year of life saved by an ICD was only about \$23,000, well within the range of other commonly offered therapies in the United States. However, in another trial, the cost was considerably higher (7). Clearly, careful selection of patients is essential to avoid implantation of ICDs in patients who are unlikely to have a recurrence of VT/VF.

KEY POINTS

- In patients presenting with ventricular arrhythmias, investigation for the cause of the arrhythmia should begin immediately after successful resuscitation.
- Clinicians should search vigorously for treatable other conditions that may accompany cardiac arrest.
- Neurologic recovery may be slow, and one needs to allow adequate time for recovery before estimating prognosis with certainty.

- Randomized trials have concluded definitively that patients with a history of VF or symptomatic VT benefit from implantation of an ICD and that this intervention is relatively cost effective.
- Polymorphic VT must be differentiated from monomorphic VT because the former has different causes and treatments.
- Do not overtreat otherwise asymptomatic patients with nonsustained VT or VPBs in the absence of structural heart disease.

INTRODUCTION

Syncope is a common problem that accounts for 1%–6% of hospital admissions and 3% of visits to emergency departments. The incidence is about six first episodes of syncope per 1,000 person-years among adults (1). The differential diagnosis of syncope is broad, and assigning a cause of syncope can be challenging. Furthermore, subgroups of patients, especially those with cardiac disease, have a high risk of sudden death. Because of these issues, patients with syncope are often admitted and subjected to a large number of tests that have low yield (1–3).

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

Syncope is defined as a sudden transient loss of consciousness associated with a loss of postural tone, with spontaneous recovery. Usually, the first issue to determine is whether a given patient had syncope or another state of altered consciousness that resembles syncope. Patients requiring chemical or electrical cardioversion are defined as having survived sudden death rather than as having experienced syncope. The absence of loss of consciousness defines dizziness and presyncope, as well as “drop attacks.” Vertigo has an associated sense of motion.

Seizure and syncope can be difficult to separate clinically for several reasons. First, hypotension leading to cerebral ischemia may cause convulsions; experimental cerebral ischemia lasting 15 seconds or more has been associated with seizure-like activity. Second, akinetic seizures have been described despite a negative interictal electroencephalogram (EEG). Finally, many patients with syncope may have myoclonic jerks or urinary incontinence, which may mistakenly be attributed to seizures. The patient may not recall convulsive symptoms during

an unwitnessed spell. In differentiating seizures from syncope, disorientation after the loss of consciousness is the best distinguishing feature suggesting seizure rather than syncope. Patients whose loss of consciousness lasts more than five minutes are also more likely to have had a seizure than an episode of syncope. Features suggesting syncope rather than seizure include pallor during the episode, sweating, nausea, and vomiting.

Differential Diagnosis and Initial Evaluation

The causes of syncope can be divided into four broad categories (Table 44.1). A brief general description of these disorders is provided here, and greater details are found elsewhere.

1. *Neurally mediated syncope.* This category encompasses the most common causes of syncope and includes vasovagal, situational (micturition, cough, defecation, swallow), and carotid sinus syncope, as well as many other types of syncope such as neuralgia, panic and generalized anxiety disorders, and spells associated with exercise in athletes without heart disease. Neurally mediated syncope is also termed neurocardiogenic or vasovagal syncope.
In these disorders, syncope results from sudden reflex-mediated hypotension and/or bradycardia. Although the exact mechanism is poorly understood, these disorders may be triggered by stimulation of receptors that respond to stretch (mechanoreceptors). These receptors are located diffusely throughout the body (such as in the bladder, esophagus, respiratory tract, and carotid sinus). In susceptible individuals, the stimulation of these receptors results in transmission of impulses to the medulla. Efferent discharges from the medullary centers lead to hypotension and/or bradycardia.
2. *Orthostatic hypotension.* Orthostatic hypotension is defined as a decline of 20 mm Hg or more in systolic pressure or 10 mm Hg or more in diastolic pressure after the patient assumes an upright position. The clinical diag-

TABLE 44.1**CAUSES OF SYNCOPE ACCORDING TO SEX AND THE PRESENCE OR ABSENCE OF CARDIOVASCULAR DISEASE AT BASELINE**

Cause	Cardiovascular disease absent (N = 599)		Cardiovascular disease present (N = 223)		Total sample (N = 822)

Other ^b	13.0	6.8	3.5	3.7	7.5

^a When a participant did not seek medical attention for syncope and the history, physical examination, and electrocardiographic findings were not consistent with any of the specific causes, the cause was considered to be unknown.

^b Cough syncope, micturition syncope, and situational syncope were included in the category of other causes.

From Soteriades ES, Evans JC, Larson MG, et al. Incidence and prognosis of syncope. *N Engl J Med* 2002;347:881, with permission.

nosis of orthostatic hypotension requires the presence of symptoms in association with a decrease in blood pressure. Symptoms of orthostatic hypotension include dizziness or light-headedness, blurring or loss of vision, weakness, and syncope. Loss of consciousness is usually brief. These symptoms are often worse when a person arises in the morning and may be especially prominent after meals or exercise.

Orthostatic hypotension has many causes. Decreased intravascular volume and adverse effects of drugs are the most common causes of symptomatic orthostatic hypotension. Elderly patients are especially vulnerable to symptoms from drugs and volume depletion because of decreased baroreceptor sensitivity, decreased cerebral blood flow, excessive renal sodium wasting, and a reduced thirst response with aging. Any condition that impairs peripheral sympathetic tone, such as the use of many antihypertensive medications and the neuropathy of diabetes mellitus, also predisposes patients to orthostatic hypotension and syncope.

3. **Neurologic diseases.** Syncope is a rare manifestation of cerebrovascular disease. Only about 15% of patients with vertebrobasilar transient ischemic attacks (TIAs) have drop attacks, and syncope is even less common. Loss of consciousness is almost always accompanied by other neurologic symptoms of brain stem ischemia. Syncope is generally not a manifestation of carotid artery ischemia unless accompanied by disease of the vertebrobasilar arteries. Subclavian steal syndrome due to subclavian stenosis and reversal of blood in the ipsilateral vertebral artery may also lead to brain stem is-

chemia. A difference in blood pressure (usually >20mm Hg) and pulse intensity between arms is a helpful clue to this diagnosis. A "faint sensation" is reported in 12%–18% of patients with migraine and may often be a vasovagal reaction to pain. Basilar artery migraine, a rare disorder that affects adolescents, may cause syncope because of spasm of the basilar arterial tree. The clinical presentation includes syncope and headaches in association with symptoms of brain stem ischemia. Seizures can also mimic syncope and are important to recognize, as discussed earlier.

4. **Cardiac diseases.** Cardiac etiologies include those diseases associated with severe obstruction to cardiac output (4), various other cardiac diseases associated with sudden decrease in cardiac output, and rhythm disturbances. Although cardiac disease is sometimes first discovered after a patient presents with syncope, it is more typical for patients with known, preexisting cardiac disease to present cardiogenic syncope (see Table 44.1).

Outflow obstruction can critically reduce cerebral blood flow and may be caused by structural lesions of the left or right side of the heart. All types of heart disease may produce exertional syncope when the cardiac output is fixed and does not rise (or even falls) with exercise. Examples include severe aortic stenosis, hypertrophic cardiomyopathy, pulmonary hypertension, pulmonary stenosis, and pulmonary emboli. All can result in both exertional or nonexertional syncope.

Other organic cardiac diseases that cause syncope include myocardial infarction, unstable angina, coronary

artery spasm, aortic dissection, and other conditions where cardiac output suddenly decreases.

Arrhythmias may cause syncope by reducing cardiac output. Excessive vagal tone, decreased sympathetic tone, or sinus node disease may cause sinus bradycardia. Many parasympathomimetic agents, sympatholytic agents, and β -blocking agents can cause bradycardia (Chapter 45). Syncope occurs in 25%–70% of patients with sick sinus syndrome. Electrocardiographic manifestations of this disorder include sinus bradycardia, pauses, arrest, or exit block. Supraventricular tachycardia or atrial fibrillation may also occur in association with bradycardia or atrial fibrillation with slow ventricular response (tachycardia-bradycardia syndrome).

Ventricular tachyarrhythmias almost always occur in the setting of known organic heart disease (Chapter 43). Torsade de pointes (or polymorphic ventricular tachycardia) occurs in patients with congenital prolongation of the QT interval (with or without associated deafness) as well as acquired long QT syndromes caused by drugs (such as quinidine, procainamide, amiodarone, and sotalol), electrolyte abnormalities, and central nervous system disorders. Other tachyarrhythmias that may cause syncope include atrial fibrillation or flutter with rapid ventricular response, AV nodal re-entrant tachycardia, and supraventricular tachycardia in patients with Wolff-Parkinson-White syndrome (Chapter 42). About 18% of patients have multiple causes of syncope (5). Such patients have a significantly worse prognosis than patients with a single cause.

Diagnostic Evaluation

Figure 44.1 shows a flow diagram for approach to patients with syncope. Initial history, physical examination, and electrocardiography (ECG) form the cornerstone of the evaluation of syncope. This initial assessment may be diagnostic of a cause (such as orthostatic hypotension), in which case treatment can be initiated without the need for additional workup for the etiology of syncope. Alternatively, history, physical examination, and ECG may suggest a cause (such as symptoms consistent with pulmonary emboli). In these instances, specific tests can be done, and if diagnostic, treatment can be started. The remainder of the patients have unexplained syncope after history, physical examination, and ECG. These patients can be considered under three categories: those with organic heart disease, the elderly, and those without heart disease. The evaluation of patients with structural heart disease revolves around assessment of the extent and severity of underlying heart disease and detection of arrhythmias. In patients without heart disease or when arrhythmias are not likely, the evaluation centers on neurally mediated syncope, psychiatric illnesses, or, rarely, bradyarrhythmias.

Some specific observations and recommendations follow:

1. The history and physical examination identify a cause in 45% of cases. Examples of such diagnoses include orthostatic hypotension, situational syncope, and drug-induced syncope. Baseline laboratory tests rarely point to a cause of syncope but may be needed for evaluation and management of comorbid conditions and effect of drugs.
2. The ECG directly identifies the cause of syncope in less than 5% of patients, but ECG abnormalities are found in up to 50% of patients and can be important clues to possible causes. Examples include bundle-branch block and long QT interval.
3. Electroencephalography provides diagnostic information in less than 2% of patients, almost all of whom have symptoms suggestive of seizure or a history of a convulsive disorder. Computed tomographic (CT) scans of the head provide new diagnostic information in about 4% of patients, almost all of whom have focal neurologic findings or history consistent with a seizure.
4. Testing for arrhythmias: Arrhythmias are found mainly in patients with structural heart disease or an abnormal ECG. Predictors of arrhythmic syncope or cardiac death at one year include: age greater than 45 years, history of congestive heart failure, abnormal ECG other than nonspecific ST changes, and history of ventricular arrhythmias (frequent or repetitive premature ventricular contractions [PVCs]). Arrhythmia testing is recommended in patients who have at least one predictor of arrhythmic syncope or cardiac death and whose symptoms are suggestive of cardiac syncope (sudden brief loss of consciousness without prodrome). In patients with structural heart disease, a cardiovascular evaluation (such as stress testing and echocardiogram) is often needed in addition to tests for arrhythmias, because management of underlying heart disease is closely linked to treatment plans for arrhythmias. The tests for arrhythmias include the following:
 - *Ambulatory monitoring.* In studies of ambulatory Holter monitoring performed for 12–24 hours, symptoms with concurrent arrhythmias are found in 5% (leading to diagnosis of arrhythmic syncope) and symptoms without arrhythmias, in 17% (potentially excluding arrhythmic syncope) (6). In 79%, brief arrhythmias or no arrhythmias are found, and there is no clear link to symptoms. Arrhythmic syncope cannot be excluded in these patients.
 - *External loop event monitoring.* External loop recorders can be used for monitoring patients for weeks to months, making it possible to capture a rhythm strip during symptoms in patients with infrequent events. Arrhythmias during syncope are found in 8%–20%, and normal rhythm during symptoms in 12%–27% of patients by the use of external event monitoring. Overall, event monitors are significantly more likely to establish or exclude arrhythmias as a cause of

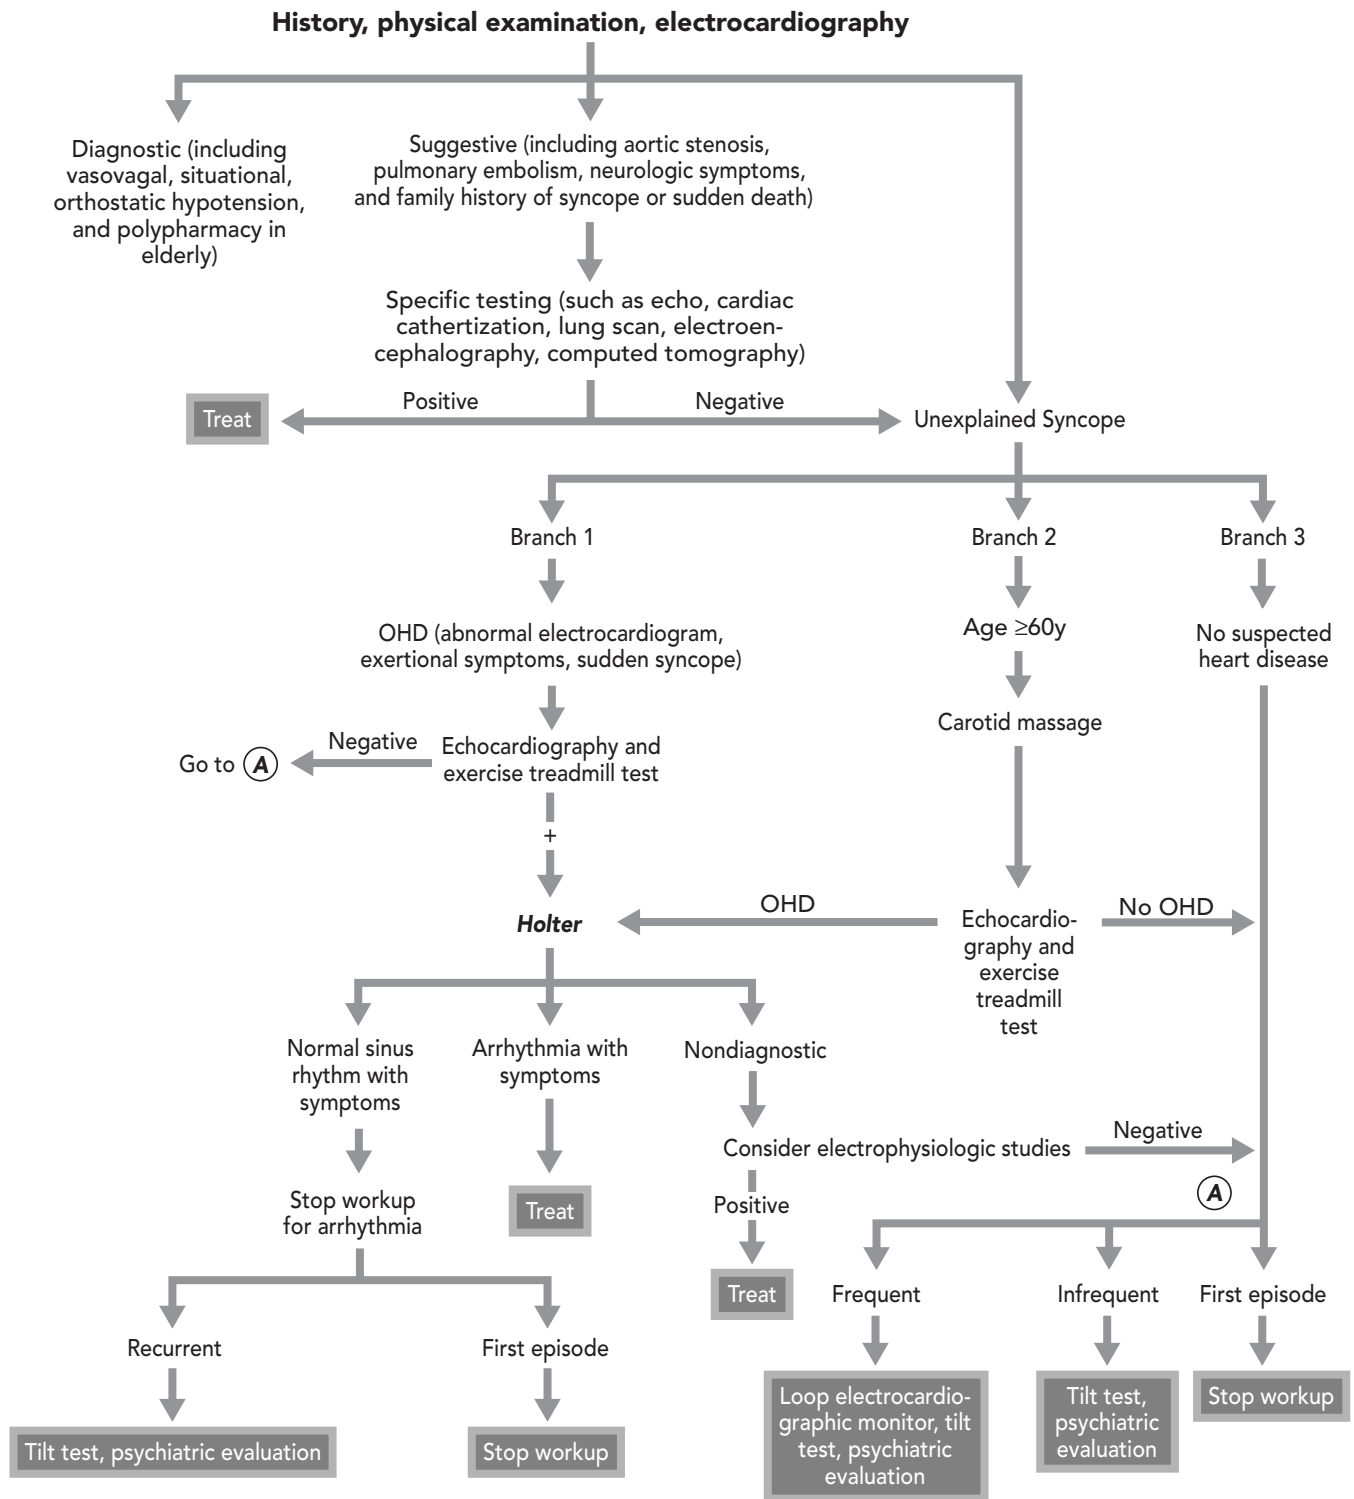

Figure 44.1 A flow diagram for the evaluation of syncope. *OHD*, organic heart disease. (Adapted from Linzer M, Yang EH, Estes NA 3rd, Wang P, Vorperian VR, Kapoor WN. Diagnosing syncope. Part 1: Value of history, physical examination, and electrocardiography. *Ann Intern Med* 1997;126: 989–996, with permission.)

syncope than is Holter monitoring. Major limitations of external event monitoring include lack of an event during monitoring and failure of the patient to activate the device during symptoms, sometimes because symptoms are so severe. Implantable loop recorders, which are inserted surgically and can provide continuous monitoring for 12–18 months, can diagnose arrhythmias in approximately 25% of patients who have previously undiagnosed syncope despite prior monitoring (8). In a randomized trial, a diagnosis of the cause of syncope was made significantly more often in patients who were evaluated with prolonged implanted loop recorders (55%) than in patients who had “conventional” evaluation with tilt-table testing, external loop monitors, and electrophysiologic studies (19%). The most frequent arrhythmia found was bradycardia (9).

- **Electrophysiologic studies.** In syncope patients, electrophysiologic tests are abnormal mainly in those with structural heart disease or an abnormal ECG. In patients with heart disease, approximately 21% have inducible ventricular tachycardia and 34%, bradycardia (14% have multiple diagnoses). In patients with ECG abnormalities, 3% have inducible ventricular tachycardia and 19%, bradycardia. In patients without heart disease, 1% have ventricular tachycardia and 10%, bradycardia. Several studies have suggested that the sensitivity and specificity of electrophysiologic tests for bradyarrhythmias is poor.
 - **Signal-averaged ECG (SAGE).** The presence of late potentials demonstrated by SAGE has a high sensitivity and specificity (approximately 70%–90%) for inducible ventricular tachycardia by electrophysiologic testing. A normal SAGE may help avoid electrophysiologic studies if ventricular tachycardia is the only concern (9). However, electrophysiologic tests in patients with syncope often are done for other arrhythmias in addition to ventricular tachycardias. Thus, SAGE testing rarely obviates the use of electrophysiologic testing.
5. Upright tilt testing: Upright tilt testing is used for evaluation of the autonomic nervous system. In patients presenting with syncope, it is generally used to evaluate the predisposition to neurally mediated or vasovagal syncope, although dysautonomic responses and postural tachycardia syndrome are also rarely diagnosed by tilt testing. To test for predisposition to vasovagal syncope, methodologies include passive tilt testing (without the use of chemical stimulation) or the use of various drugs (most commonly isoproterenol in the United States and nitroglycerin in Europe) during testing. In patients with unexplained syncope, positive responses occur in approximately 50% with passive testing and in approximately 66% with isoproterenol protocols. The results with nitroglycerin appear similar to those with isoproterenol. The specificity of tilt testing without chemical stimulation is approximately 90%, and approximately

75% with isoproterenol. Specificity with isoproterenol appears to be higher when a high-dose (5 mcg/min) infusion is not used. This test is often (15%–35%) not reproducible when repeated on the same day or later.

Indications for tilt testing include recurrent unexplained syncope when arrhythmias are either unlikely (such as in patients without structural heart disease or abnormal ECG) or have been excluded by appropriate testing in patients with structural heart disease. Rarely, tilt testing is suggested for the evaluation of a single episode of unexplained syncope associated with trauma or in certain high-risk occupations (e.g., pilots), but these indications are controversial.

6. Unsuspected abnormalities by echocardiogram are found in 5%–10% of patients but only rarely lead to the determination of the cause of syncope. Examples include aortic stenosis or hypertrophic cardiomyopathy, but these disorders are usually suspected from the history and physical examination. Echocardiography is indicated whenever valvular diseases are suspected clinically, and it is often needed for the evaluation of cardiac function in patients suspected of having arrhythmic syncope. The yield of stress testing for the diagnosis of syncope is less than 1%, although the test is widely used for this purpose.

Indications for Hospitalization

Table 44.2 shows common indications for admission for syncope. Hospitalization is considered if there is a concern

TABLE 44.2
INDICATIONS FOR HOSPITAL ADMISSION IN PATIENTS WITH SYNCOPE

Indicated:

History of coronary-artery disease, heart failure, or ventricular arrhythmia
 Accompanying symptoms of chest pain
 Physical signs of significant aortic stenosis, hypertrophic cardiomyopathy, heart failure, stroke, or focal neurologic disorder
 Electrocardiogenic findings of ischemia, arrhythmia (serious bradycardia or tachycardia), prolonged QT interval, or bundle-branch block

Often indicated:

Sudden loss of consciousness with injury, rapid heart beat, or exertional syncope
 Frequent spells, suspicion of coronary disease or arrhythmia (for example, use of medications associated with torsade de pointes)
 Moderate-to-severe orthostatic hypotension
 Age over 70 years

Adapted from Linzer M, Yang E, Estes NA 3rd, Wang P, Vorperian VR, Kapoor WN. Diagnosing syncope. Part 1: Value of history, physical examination, and electrocardiography. *Ann Intern Med* 1997;126:989–996, with permission.

for arrhythmic syncope and sudden cardiac death or if immediate treatments need to be initiated. The predictors of arrhythmic syncope or cardiac death (at one year) include history of congestive heart failure, history of ventricular arrhythmia, abnormal ECG (other than nonspecific ST changes), and age over 45 years. The presence of two or more of these factors is associated with 10% or greater incidence of syncope or cardiac death. These predictors, along with symptoms suggestive of cardiac syncope in patients with underlying structural heart disease, can be used to guide admission decisions.

Indications for Initial ICU Admission

Telemetry or monitoring in a cardiac unit (see Tables 44.3 and 44.4) is indicated for patients with structural heart disease or abnormal ECG when arrhythmias are clinically suspected.

Initial Therapy

Initial therapy depends on the etiologies of syncope under consideration. Many of the etiologies of syncope have specific known treatment approaches; a full discussion is beyond the scope of this chapter. The following issues are important in initial therapeutic approaches:

1. If a cause of syncope can be identified based on initial evaluation (history, physical examination, and ECG), treatment of those disorders can be initiated without the need for further diagnostic evaluation for other causes of syncope. Examples include orthostatic hypotension, drug-induced syncope, and symptomatic supraventricular tachycardia.
2. When a disease has been identified as suggestive of causes of syncope, further testing is done in a directed fashion. If specific entities are confirmed, treatment is

TABLE 44.3
INDICATIONS FOR INITIAL ICU ADMISSION

Acute cardiovascular conditions
Aortic dissection
Acute myocardial infarction or unstable angina
Pulmonary edema
Circulatory collapse (cardiogenic shock or other types of shock)
Long QT with ventricular arrhythmias
Massive pulmonary embolism
Acute noncardiac problems
Multiple seizures or status epilepticus
Drug overdoses
Gastrointestinal bleeding
Acute stroke or intracranial bleed

Adapted from Linzer M, Yang E, Estes NA 3rd, Wang P, Vorperian VR, Kapoor WN. Diagnosing syncope. Part 1: Value of history, physical examination, and electrocardiography. *Ann Intern Med* 1997;126:989–996, with permission.

TABLE 44.4
INDICATIONS FOR CONSULTATION

Recommended at the time of admission

Structural heart disease
History of ventricular arrhythmias
Diagnosis of bradyarrhythmias
Acute cardiovascular disease
Bundle-branch block and unexplained syncope
Suspected seizure or other neurologic events

Evaluation and management of findings during hospitalization

Severe aortic stenosis
Aortic dissection
Treatment of arrhythmias found on monitoring
Tilt testing for recurrent syncope
Evidence of possible seizure or other neurologic events

- initiated. An example would be a patient with syncope and findings consistent with severe aortic stenosis. Further assessment with echocardiogram, possible cardiac catheterization, and consultation with cardiology and cardiothoracic surgery are needed for management.
3. When syncope occurs in an elderly patient, it is important to recognize that such patients often have multiple comorbid illnesses and take medications that may result in alterations of vascular tone or in volume depletion. Additionally, elderly patients may have physiologic impairments that predispose them to syncope (decreased baroreceptor sensitivity, renal sodium wasting, decreased cerebral blood flow, and impaired thirst). The initial approach is to search for a single cause of syncope. If a specific cause cannot be identified, treatment of multiple abnormalities should be initiated prior to considering invasive or extensive diagnostic testing. Medications should always be reviewed in detail, and unnecessary ones should be discontinued.
 4. For patients with neurally mediated syncope, initial therapy should focus on avoiding situations that trigger symptoms, increasing fluid and salt intake, avoiding alcohol, and reducing or discontinuing diuretics and vasodilators (10). These measures alone will effectively treat many patients, especially those with a single or rare episodes. Uncontrolled studies suggest that tilt training (repeatedly subjecting the cardiovascular system to orthostatic stress as a means of fatiguing the symptomatic response) may decrease recurrences of syncope. Drinking 500 ml of water acutely can significantly reduce orthostatic hypotension (11). Patients can also be taught to use isometric handgrip exercise to increase systemic blood pressure and thereby abort impending neurally mediated syncope (12).

The effectiveness of most drugs currently used in the treatment of neurally mediated syncope is unclear.

Despite a lack of controlled studies, fludrocortisone and increased salt intake are widely utilized. One short-term (one-month) randomized trial of β -blockers showed a lower rate of recurrent syncope, but several controlled trials have not confirmed their effectiveness (13). Midodrine has been effective in reducing recurrences in small studies (14). A small randomized trial of paroxetine showed a reduction of recurrent episodes at two years (15). The effectiveness of permanent pacemakers in highly symptomatic patients with positive tilt tests (consisting of hypotension and bradycardia) has been assessed in four randomized trials; of these, the three unblinded studies showed decreased recurrences, but the one blinded study did not (16–18).

ISSUES DURING THE COURSE OF HOSPITALIZATION

The issues during the course of hospitalization fall into the following categories:

1. *Establishing a cause of syncope.* Figure 44.1 shows an approach to the evaluation of a patient with syncope. The sequence of testing is the major issue in the course of hospitalization. In patients with structural heart disease or when arrhythmias are considered likely based on clinical presentation and risk stratification, cardiac testing (e.g., stress testing and echocardiogram) should be done prior to considering electrophysiologic studies. In patients with moderately severe coronary disease, revascularization or medical therapy should be considered prior to electrophysiologic testing or tilt testing because of the risk from possible provocation of hypotension during these tests. Once arrhythmias are excluded, further evaluation can generally be planned on an outpatient basis. Most laboratories perform tilt testing immediately after electrophysiologic testing; this approach is recommended in patients with recurrent syncope. To use resources efficiently, hospitalization should be limited to that required to confirm or exclude serious causes of syncope and to treat disorders that need inpatient care. The remainder of the workup can be done in the outpatient setting. Coordination and communication with the referring physician or patient's primary care physician is vitally important.
2. *Treatment of disorders found in the hospital.* Many of the diseases and disorders found during the hospital course have specific treatments. Once these diagnoses are made, treatments can be initiated. Examples include severe aortic stenosis (for which aortic valve replacement is indicated) or a seizure disorder (for which anticonvulsants can be started).
3. *Recurrent unexplained syncope.* In patients followed over the past two decades, no cause of syncope was found in approximately 36% of patients (Table 44.1) (1). However, most observers believe that the wider use of tilt

testing, event monitoring, attention to psychiatric illnesses, and recognition that syncope in the elderly may be multifactorial has decreased the size of the "syncope of unknown origin" (SUO) group to less than 10% in the modern era. Currently, it is estimated that approximately 50% of the SUO group has neurally mediated syncope that is not diagnosed clinically but can be provoked by upright tilt testing. An additional 10%–20% have psychiatric disorders (panic, anxiety, somatization, major depression, alcohol and substance abuse). Other etiologies are found in follow-up in less than 5% of the SUO group (e.g. supraventricular tachycardia, seizure). A small fraction is elderly patients in whom comorbid illnesses and medications may interact to cause syncope.

In patients with recurrent syncope and without heart disease or an abnormal ECG, the diagnoses to focus on are neurally mediated syncope, psychiatric disorders, and, rarely, bradyarrhythmias (11). A consultation with cardiology (particularly for tilt testing) and with psychiatry may be needed to arrive at a cause. Prior to considering psychiatric causes, screening psychiatric instruments (such as PRIME-MD) or a focused psychiatric interview is recommended. Loop event monitoring is recommended if symptoms are recurrent and suggestive of cardiac syncope.

DISCHARGE ISSUES

Patients should be instructed in the following areas:

1. *Preventing loss of consciousness.* Examples of patient instructions are shown in Table 44.5.
2. *Driving.* The risk of syncope during driving depends on frequency of syncope and length and duration of driving. Injury (to the patient or bystanders) during driving is estimated to be quite unusual (up to 0.33% per driver per year), but there are few data on this issue. Restrictions on driving vary from state to state and may change over time. Physicians caring for syncope patients should consult their state's motor vehicle departments and follow their state's regulations.

TABLE 44.5
PATIENT INSTRUCTIONS

Preventing syncope or vasovagal spells

Avoid alcohol, lack of sleep, hot environment
 Maintain adequate hydration and food intake
 Avoid drugs that lead to hypotension (e.g., vasodilators, diuretics)
 Avoid activities that precipitate syncope (e.g., exercise for exertional syncope)

Preventing loss of consciousness or injury

Assume supine position upon onset of prodrome
 Avoid driving and other activities that could lead to injury

3. *Preventing injury from recurrent syncope.* Patients should be instructed to assume a supine or at least sitting position at the first hint of prodromal symptoms. A patient with recurrent spells should swim with a companion who knows that patient has had recurrent syncope. Patients can play team and contact sports unless they have had post-exercise syncope, in which case exercise should be avoided until symptoms are controlled with therapy. Climbing ladders, taking hot showers, standing by fires, and using power tools pose risks and should be avoided until the patient has been symptom-free for several months. Alcohol should be avoided. Patients should also not be employed as police officers, airline pilots, drivers, or heavy machinery operators.
4. *Follow-up.* The recurrence rate of syncope is approximately 30% at three years. Unfortunately, the patient whose initial episode of syncope eluded diagnosis will only rarely be diagnosed after a recurrence (19). Therefore, patients with recurrent, undiagnosed syncope should be followed closely to determine whether therapy was effective.

KEY POINTS

- A cause of syncope is currently identified in more than 90% of patients.
- Initial clinical assessment (history, physical examination, and ECG) leads to a diagnosis in approximately 50% of patients.
- EEG and CT scan of the head provide diagnostic information in 2%–4%; almost all these patients have a history of a seizure disorder or focal neurologic signs and symptoms.
- Arrhythmias are mainly of concern in patients with structural heart disease, a history of ventricular arrhythmias, or an abnormal ECG (other than nonspecific ST changes).
- In diagnosing arrhythmias as a cause, attempts should be made to correlate arrhythmias with symptoms by using Holter, external, or implantable loop recorder monitoring. Implantable loop recorders are preferred when the diagnosis is elusive and the need to establish a diagnosis is high.
- Sensitivity and specificity of electrophysiologic studies is poor for the diagnosis of bradyarrhythmias.
- Upright tilt testing provokes vasovagal syncope in the laboratory and shows positive responses in 50%–66% of patients with unexplained syncope. Tilt testing is recommended in patients with recurrent unexplained syncope because treatments are available (although not widely tested by randomized controlled trials).
- Treatment should be directed toward the cause of syncope. Patients with rare or single episodes of neurally mediated syncope can be treated without medications. Neurally mediated syncope may respond to volume loading (fludrocortisone plus salt), but β -blockers, paroxetine (a selective serotonin reuptake inhibitor), or permanent pacing may be required.

Bradycardia and Pacemakers

45

Richard H. Hongo *Nora F. Goldschlager*

INTRODUCTION

This chapter outlines an approach to the two most common indications for hospitalization because of bradycardia and for permanent pacemaker implantation: sinus node dysfunction and acquired atrioventricular (AV) block. Conditions occurring during hospitalization that may warrant temporary cardiac pacing are also addressed. In addition, the chapter contains a review of the basic features of permanent pacemakers and discusses potential problems encountered with pacing systems.

ISSUES AT THE TIME OF ADMISSION

Sinus Node Dysfunction

Sinus node dysfunction, a degenerative process involving the sinus node and sinoatrial area, includes a variety of disorders such as sinus bradycardia, sinus node exit block, sinus pause, and sinus arrest. The AV node and intraventricular conduction system are also involved in up to 25%–30% of patients who have sinus node dysfunction (1).

Sinus bradycardia is generally defined as a sinus rate of less than 50 beats per minute (bpm). This rate is not necessarily pathologic but is a marker of sinus node dysfunction in specific clinical contexts. In sinus node exit block, impulses are formed within the sinus node but encounter varying degrees of blockage in the surrounding sinoatrial tissue as they try to exit to the atrial conduction system. Sinus pauses are caused by disorders of impulse formation within the sinus node. Sinus arrest, which is total failure of sinus impulse generation, cannot be distinguished from complete sinoatrial exit block on the surface electrocardiogram.

Clinical Presentation

If an inadequate heart rate causes cerebral hypoperfusion, clinical symptoms result, including presyncope, syncope, confusion, memory loss, and, rarely, seizure activity. Inability of the heart rate to increase in response to increased physiologic demand results in effort intolerance, fatigue, weakness, and breathlessness. Sudden death from ventricular asystole or bradycardia-dependent polymorphic ventricular tachycardia can also occur. Occasionally, patients with AV block complain of no symptoms; many of these patients, however, feel significantly better after pacemaker implantation. Patients with a variant of sinus node dysfunction, the *tachycardia-bradycardia syndrome*, can present with palpitations. These patients have concomitant supraventricular tachycardias (Chapter 42) that may include atrial tachycardia, atrial flutter, atrial fibrillation, or AV nodal reentrant tachycardia. Symptoms are related to either the rapid heart rate or the pauses in atrial rate, caused in part by overdrive suppression of the sinus node. It is often necessary to treat the tachycardia with medications that further slow the sinus rate (e.g., β -blockers or class I or III antiarrhythmic agents) (Table 42.4). As a result, a permanent pacemaker commonly is required for rate support.

Differential Diagnosis and Initial Management

Sinus node dysfunction can result from medications, vagally mediated states, and, rarely, acute myocardial infarction. Medication profiles should be examined, and potassium and drug levels should be obtained. In patients who present with the tachycardia-bradycardia syndrome, thyroid disease must be considered, although it is a rare cause. Initial management of patients with bradycardia should be directed at identifying and treating reversible causes and at providing

rate support. Oral theophylline has been used with some success in the treatment of bradycardia caused by sinus node dysfunction. Symptomatic patients without reversible causes are candidates for permanent pacemaker implantation.

Indication for Hospitalization

Patients who require permanent pacemaker therapy according to the American College of Cardiology/American Heart Association Task Force guidelines should be hospitalized for pacemaker implantation (Table 45.1). All patients should be admitted to a monitored setting to ensure prompt diagnosis and treatment of any severe bradycardia.

TABLE 45.1
INDICATIONS FOR PERMANENT PACING IN SINUS NODE DYSFUNCTION

Class I (conditions for which there is evidence and/or general agreement that a given procedure or treatment is useful and effective)

1. Sinus node dysfunction with documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms; in some patients, bradycardia is iatrogenic and occurs as a consequence of essential long-term drug therapy of a type and dose for which there are no acceptable alternatives
2. Symptomatic chronotropic incompetence

Class II (conditions for which there is conflicting evidence and/or divergence of opinion about the usefulness/efficacy of a procedure or treatment)

Class IIa (weight of evidence/opinion is in favor of usefulness/efficacy)

1. Sinus node dysfunction, occurring spontaneously or as a result of necessary drug therapy, with heart rate <40 bpm, when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented
2. Syncope of unexplained origin when major abnormalities of sinus node function are discovered or provoked in electrophysiological studies

Class IIb (usefulness/efficacy is less well established by evidence/opinion)

1. In minimally symptomatic patients, chronic heart rate <40 bpm while awake

Class III (conditions for which there is evidence and/or general agreement that a procedure/treatment is not useful/effective and in some cases may be harmful)

1. Sinus node dysfunction in asymptomatic patients, including those in whom substantial sinus bradycardia (heart rate <40 bpm) is a consequence of long-term drug treatment
2. Sinus node dysfunction in patients with symptoms suggestive of bradycardia and clearly documented as not associated with a slow heart rate
3. Sinus node dysfunction with symptomatic bradycardia due to nonessential drug therapy

Adapted from Gregoratos G, Abrams J, Epstein AE, et al. ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices—summary article. *J Am Coll Cardiol* 2002;40:1703–1719. TABLE 45.2
COMMON INDICATIONS FOR TEMPORARY CARDIAC PACING

1. Therapeutically, for symptomatic bradycardia
 - a. Persistent bradycardia, until permanent pacemaker implantation can be accomplished
 - b. Transient bradycardia (e.g., acute myocardial infarction or Lyme myocarditis)
2. Therapeutically, to maintain or restore AV synchrony
 - a. In acute myocardial infarction (especially inferior-wall and right-ventricular)
 - b. In congestive heart failure
 - c. In ventricular hypertrophy states (e.g., hypertrophic obstructive cardiomyopathy)
3. Prophylactically, for potential bradycardia that may produce symptoms or hemodynamic embarrassment in acute myocardial infarction
 - a. New bundle-branch block
 - b. New bi- or trifascicular block with 1st-degree AV block
 - c. Type I 2nd-degree AV block with wide QRS complexes at slow rate
 - d. Type II 2nd-degree AV block or higher degrees of AV block
4. Prophylactically, to prevent pause-dependent ventricular tachyarrhythmias

AV, atrioventricular.

Indications for Initial Coronary Care Unit Admission

Patients should be admitted to the coronary care unit (CCU) if the cause of the sinus node dysfunction itself necessitates a CCU admission (e.g., myocardial infarction) or if temporary rate support by pacing is needed while awaiting definitive therapy (Table 45.2).

Acquired Atrioventricular Block

In AV block, the delay in conduction can be at the level of the AV node or can be infranodal (at or below the His bundle). In first-degree AV block, the PR interval exceeds 200 ms. Second-degree AV block indicates that not all supraventricular impulses are conducted. Second-degree AV block can take the form of progressive delay in conduction followed by failure of conduction (Wenckebach, or type I second-degree block) or abrupt failure of conduction (type II second-degree block). In third-degree (complete) AV block, no impulses are conducted. Accurate differentiation between type I (Wenckebach) and type II second-degree AV block is difficult if there is 2:1 conduction, because a single PR interval prior to a nonconducted P wave does not allow evaluation of successive PR intervals. However, certain features may be helpful in distinguishing the two. If the PR interval of the conducted P wave is prolonged and the QRS complexes are narrow and appear normal, type I second-degree AV block is probably present. If the PR interval of the conducted P wave is normal and the

QRS complexes have a bundle-branch block pattern, type II second-degree AV block is probably present. The two can be more definitively differentiated either by recording a long rhythm strip that might document changing AV conduction ratios or by using various maneuvers. Intravenous atropine and exercise improve AV conduction at the AV nodal level but often worsen AV block at the infranodal level. Conversely, carotid sinus massage can worsen AV block at the AV nodal level and improve AV conduction at the infranodal level because a slower sinus rate permits conduction to occur. *High-grade AV block* is defined by the presence of more nonconducted P waves than conducted ones (e.g., 3:1 AV conduction). High-grade AV block should be considered a precursor to complete AV block and, as such, should be managed aggressively.

Clinical Presentation

Symptoms depend on the severity and site of AV block. In the absence of an adequate escape rate, symptoms of AV block are similar to those of sinus-node dysfunction, and the two conditions often coexist. If there is complete AV block or prolongation of the PR interval to more than 300 ms, asynchronous atrial and ventricular depolarization-contraction sequences can result in elevated atrial pressures, pulmonary congestion, and, at times, peripheral edema and refractory hypotension.

Differential Diagnosis and Initial Management

The most common causes of AV block are idiopathic sclerodegeneration of the conduction system, acute myocardial infarction, medications, and vagal stimulation. Rarer causes of block include inflammation (e.g., myocarditis), infection (e.g., infective endocarditis, especially involving the aortic valve ring), infiltrative disease (e.g., amyloidosis), and trauma (e.g., following aortic valve surgery).

AV block associated with anterior-wall myocardial infarction often indicates extensive myocardial necrosis and disruption of the infranodal conduction system. This combination results in a wide QRS complex escape rhythm with a slow rate and in variable constancy that is unresponsive to autonomic nervous system input. AV block associated with inferior-wall myocardial infarction generally indicates AV nodal ischemia that is often transient, and, in part, vagally mediated; a narrow, relatively normal-appearing QRS

complex escape rhythm arises from the AV junction and is variably responsive to autonomic input. Medications that precipitate AV block include β -blockers (oral and ophthalmic), some calcium channel blockers (e.g., verapamil, diltiazem), digoxin, and some antiarrhythmic drugs. Serum digoxin levels should be obtained, although a normal level does not exclude digoxin toxicity. Vagally mediated AV block is suggested by the transient nature of the episode, concomitant slowing of the sinus rate, inconstant PR intervals, and reversal with atropine or enhanced sympathetic tone (Figure 45.1). Vagally mediated AV block is common in hospitalized patients (e.g., during suctioning, vomiting, coughing, and endoscopic procedures) and generally does not require specific treatment. Hyperkalemia can exacerbate AV nodal block.

Pharmacologic rate support is often achievable with atropine; however, infranodal block may worsen or be unresponsive to vagolytic agents. Intravenous infusion of isoproterenol generally is not recommended because of the risk of precipitating myocardial ischemia and producing or aggravating ventricular arrhythmias.

Indication for Hospitalization

Reversible causes of AV block should always be excluded. Patients with a Class I indication for permanent pacemaker therapy according to the American College of Cardiology/American Heart Association Task Force guidelines (see Tables 45.3 and 45.4) should be admitted to the hospital for pacemaker implantation (2). This heterogeneous group includes all patients with symptomatic AV block, regardless of severity. The management of asymptomatic patients is less straightforward, and identifying high-risk patients who would not tolerate bradycardia because of an inadequate escape mechanism is important. These asymptomatic high-risk patients include those with the following: third-degree AV block and asystole lasting longer than 3 seconds or an escape rate less than 40 bpm; third-degree AV block that precipitates bradycardia-dependent ventricular arrhythmias; third-degree AV block caused by drugs that are needed for coexisting medical conditions; and bifascicular block associated with type II second-degree or higher degrees of AV block (2). Patients with Class II indications for pacing therapy (see Table 45.1) are less well defined; a decision not to implant a pacemaker requires close outpatient follow-up.

Figure 45.1 Vagally mediated atrioventricular block. The MCL1 rhythm strip illustrates slowing of the sinus rate prior to the nonconducted P wave; the PR intervals also vary. These findings are commonly seen in states of high vagal input and during sleep, when sympathetic tone is low. Vagally mediated rhythms are almost always benign and do not require treatment.

TABLE 45.3
INDICATIONS FOR PERMANENT PACING IN ACQUIRED
ATRIOVENTRICULAR BLOCK

Class I

1. 3rd-degree and advanced 2nd-degree AV block at any anatomic level, associated with any one of the following conditions:
 - a. Bradycardia with symptoms (including heart failure) presumed to be due to AV block
 - b. Arrhythmias and other medical conditions that require drugs that result in symptomatic bradycardia
 - c. Documented periods of asystole ≥ 3.0 s or any escape rate < 40 bpm in awake, symptom-free patients
 - d. After catheter ablation of the AV junction
 - e. Postoperative AV block that is not expected to resolve after cardiac surgery
 - f. Neuromuscular diseases with AV block (e.g., myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb's limb-girdle dystrophy, and peroneal muscular atrophy) with or without symptoms, because there may be unpredictable progression of AV conduction disease
2. 2nd-degree AV block with associated symptomatic bradycardia, regardless of the type or site of block

Class IIa

1. Asymptomatic 3rd-degree AV block at any anatomic site with average awake ventricular rates of ≥ 40 bpm, especially if cardiomegaly or left ventricular dysfunction is present
2. Asymptomatic type II 2nd-degree AV block with narrow QRS; when type II 2nd-degree AV block occurs with a wide QRS, pacing becomes a Class I recommendation
3. Asymptomatic type I 2nd-degree AV block at intra- or infra-His levels found at electrophysiologic study performed for other indications
4. 1st- or 2nd-degree AV block with symptoms similar to those of *pacemaker syndrome*^a

Class IIb

1. Marked 1st-degree AV block (> 0.30 s) in patients with left ventricular dysfunction and symptoms of congestive heart failure in whom a shorter AV interval results in hemodynamic improvement
2. Neuromuscular disease (e.g., myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb's limb-girdle dystrophy, and peroneal muscular atrophy) with any degree of AV block (including 1st-degree AV block) with or without symptoms, because there may be unpredictable progression of AV conduction disease

Class III

1. Asymptomatic 1st-degree AV block
2. Asymptomatic type I 2nd-degree AV block at the supra-His (AV node) level or not known to be intra- or infra-Hisian
3. AV block expected to resolve and/or unlikely to recur (e.g., drug toxicity, Lyme disease, or during hypoxia in sleep apnea syndrome in absence of symptoms)

See Table 45.1 for definitions of classes.

^a A symptom complex of fatigue, weakness, dizziness, hypotension, effort intolerance, and pulmonary and central venous hypertension caused by inappropriate relationships between atrial and ventricular depolarization-contraction sequences.

AV, atrioventricular.

Indications for Initial Coronary Care Unit Admission

Patients should be admitted to the CCU if the cause of the AV block necessitates admission (e.g., acute myocardial infarction) or if temporary pacemaker support is needed while awaiting definitive therapy. Temporary pacing may be needed for both transient and persistent AV block. Patients not requiring a CCU admission should be observed

in a telemetry setting. Atropine should be readily available. Transcutaneous pacing allows rate support in emergent situations.

Pacemakers

The basic pacing system includes the pulse generator, lead(s), and electrodes. The permanently implanted pulse generator is a hermetically sealed titanium “can” contain-

TABLE 45.4
INDICATIONS FOR PERMANENT PACING AFTER
THE ACUTE PHASE OF A MYOCARDIAL
INFARCTION

Class I

1. Persistent 2nd-degree AV block in the His-Purkinje system with bilateral bundle-branch block or 3rd-degree AV block within or below the His-Purkinje system
2. Transient advanced (2nd- or 3rd-degree) infranodal AV block and associated bundle-branch block; if the block site is uncertain, an electrophysiologic study may be necessary
3. Persistent and symptomatic 2nd- or 3rd-degree AV block

Class IIa

None

Class IIb

1. Persistent 2nd- or 3rd-degree AV block at the AV node level

Class III

1. Transient AV block in the absence of intraventricular conduction defects
2. Transient AV block in the presence of isolated left anterior fascicular block
3. Acquired left anterior fascicular block in the absence of AV block
4. Persistent 1st-degree AV block in the presence of bundle-branch block that is old or age-indeterminate

See Table 45.1 for definitions of classes.

AV, atrioventricular.

Adapted from Gregoratos G, Abrams J, Epstein AE, et al. ACC/AHA/NASPE 2002 guideline update for implantation of cardiac pacemakers and antiarrhythmia devices—summary article. *J Am Coll Cardiol* 2002;40:1703–1719. ing a lithium power source and circuitry for sensing cardiac electrical activity. The pacing lead contains a metal wire (or wires) insulated by either polyurethane or silastic rubber. The lead can be either bipolar or unipolar. Bipolar leads contain two electrodes: a proximal (ring) electrode and a distal (tip) electrode. The interelectrode distance is small, usually 1–3 cm. Unipolar leads contain only a tip electrode (cathode); the pulse generator serves as the anode. The interelectrode distance is, therefore, much greater in a unipolar system than in a bipolar one, which results in both larger stimulus artifacts on the surface electrocardiogram and a larger “antenna” that senses electrical activity.

A “demand” pacing system provides a stimulus output when no electrical activity is sensed. Conversely, it inhibits its output when electrical activity is sensed. The magnitude of the stimulus output can be described in terms of voltage or current (usually the former), and the duration of the stimulus output is the pulse width. The capture threshold is the minimum stimulus output required to initiate a depolarization. The sensing threshold is the smallest intracardiac signal that can be detected by the sensing amplifier. Appro-

priate sensing is important in preventing unwanted inhibition of output or competitive output from the pacemaker.

The North American Society of Pacing and Electrophysiology—Heart Rhythm Society has adopted a five-letter code to describe the function of pacing systems. The first letter describes the chamber or chambers in which pacing occurs (*V*, ventricle; *A*, atrium; *D*, dual [atrium and ventricle]). The second letter describes the chamber or chambers in which sensing occurs (and has the same codes as for pacing). The third letter describes the response to a sensed event (*T*, triggered output in response to a sensed event; *I*, inhibited output in response to a sensed event; *D*, dual [triggered and inhibited, e.g., an atrial sensed event inhibits atrial output and triggers a ventricular output after a preset AV interval]). In today’s pulse generators, the fourth letter, *R*, indicates rate modulation. The fifth letter describes anti-tachycardia functions (Table 45.5). More recent codes incorporate designations for multisite pacing and special lead features such as steroid elution.

The mode of function that is programmed depends upon the underlying atrial rhythm, the status of AV conduction, the need for AV synchrony (appropriate relationships between atrial and ventricular depolarization-contraction sequences), and the presence or absence of chronotropic competence (ability of the sinus rate to increase in response to increases in metabolic need). Although intact AV conduction theoretically can reduce or eliminate

TABLE 45.5
COMMONLY USED PACING MODES
AND FUNCTIONS

Mode	Definition
AAI	Atrial pacing on demand; output inhibited by sensed atrial signals
AAIR	Atrial pacing on demand; output inhibited by sensed atrial signals; atrial pacing rates can increase and decrease in response to sensor input, up to the programmed sensor-based upper rate limit
VVI	Ventricular pacing on demand; output inhibited by sensed ventricular signals
VVIR	Ventricular pacing on demand; output inhibited by sensed ventricular signals; ventricular pacing rates can increase and decrease in response to sensor input, up to the programmed sensor-based upper rate limit
DDD	Paces and senses in both the atrium and the ventricle; paces the ventricle in response to sensed atrial activity, up to the programmed upper rate limit
DDDR	Paces and senses in both the atrium and the ventricle; atrial and ventricular pacing rates increase and decrease in response to sensor input, up to the programmed sensor-based upper rate limit

Asynchronous pacing (sensing function eliminated) is the usual mode of function in response to magnet application to the pulse generator.

TABLE 45.6
PACEMAKER EMERGENCIES

Postimplantation complications
Immediate
Pneumothorax, hemothorax
Cardiac tamponade
Myocardial perforation
Late
Subclavian vein thrombosis
Superior vena cava syndrome
Lead thrombus
Pulmonary emboli
Infection of pacing system
Pericarditis
Undersensing (“failure” to sense)
Failure to output (no pacing stimulus delivered)
Failure to capture (pacing stimulus delivered, but no myocardial depolarization)
Inappropriate changes in pacemaker rate
Inappropriately slow rate (most often because of oversensing; can indicate end of life of pulse generator)
Inappropriately fast rate (most often because of normal tracking of atrial arrhythmias or inappropriately programmed rate-adaptive settings)

the need for a ventricular lead, up to 30% of patients with sinus node dysfunction also have AV block or bundle-branch block. AV dyssynchrony that results in loss of atrial contribution to ventricular filling is tolerated poorly in patients with noncompliant ventricles, including patients with acute ischemia and infarction. Chronotropic incom-

petence can result in exercise intolerance; sensors for rate adaptation lead to increases and decreases in pacing rate in response to parameters such as body motion, minute ventilation, and QT interval. Programmed modes of function and rates may not be appropriate in specific patients or circumstances, and changes in programmed parameters often become necessary in hospitalized patients to adapt to specific clinical situations.

Pacemaker Emergencies

Pacemaker emergencies (Table 45.6) include complications of the implant procedure itself, “failure” to sense (undersensing) (Table 45.7 and Figure 45.2), failure to output, failure to capture (Table 45.8 and Figure 45.3), and inappropriate or unwanted changes in pacemaker rate. Undersensing is manifested on the surface electrocardiogram by delivered pacing stimuli when inhibition of output is expected. Absence of output, which results in pauses in paced rhythm, can be caused by normal inhibition, oversensing (unwanted sensing of noncardiac electrical signals) (Figure 45.4), or end of life of the pulse generator. Unanticipated end of generator life, which is rare today because most patients are followed in specialized pacemaker clinics, is a medical emergency. Failure to capture is manifested by pacemaker stimuli that do not initiate a depolarization, provided that there is temporal opportunity to do so; “functional” noncapture exists if the pacemaker stimulus falls in the atrial or ventricular refractory period and thus cannot initiate depolarization. For a patient with potential pacemaker dysfunction or a pacemaker emergency, urgent

TABLE 45.7
DIFFERENTIAL DIAGNOSIS OF UNDERSENSING (“FAILURE” TO SENSE)

Normal pacing system function	Comment/management
Inappropriately low programmed sensitivity	Reprogram sensitivity
Poor intracardiac signal	Most common cause of undersensing; reprogram sensitivity
“Functional” undersensing	Sensing amplifier is transiently refractory to incoming electrical signals as part of its normal operation; causes confusion in electrocardiogram interpretation; program new parameters of function where appropriate
Abnormal pacing system function	
End of battery life	Requires generator replacement
Open circuit	
Poor connection between lead and pulse generator	Requires revision
Lead fracture	Chest radiograph may reveal subclavian crush; interrogation documents high lead impedance; revision required
Insulation failure	Chest radiograph can help detect; interrogation documents low lead impedance; revision required

Figure 45.2 Atrial undersensing (“failure” to sense) in a DDD pacing system. Spontaneous P waves do not inhibit the atrial output from the pulse generator, resulting in atrial stimulus outputs at the programmed base rate. This rhythm strip also illustrates “functional noncapture” of atrial stimulus outputs due to myocardial tissue refractoriness rather than to a true noncapture problem.

Figure 45.3 Intermittent failure to capture with a ventricular pacing system in a patient with hyperkalemia resulting from renal failure. The first, second, and fourth QRS complexes are paced. Most pacing stimuli do not stimulate myocardial tissue despite the temporal opportunity to do so. This problem should be managed by correcting the electrolyte abnormality. On occasion, programming a higher pacemaker output can be a successful temporary measure to restore pacing function.

Figure 45.4 Pause in paced rhythm resulting from myopotential oversensing. The ventricular lead senses the myopotentials (which can reach amplitudes of 3–5 mV), with resulting inhibition of output. The asystolic period is terminated by a narrow QRS complex escape beat. The problem is best managed by lowering the sensitivity (increasing the signal amplitude that the pacemaker will sense); take care to avoid undersensing (“failure” to sense) spontaneous QRS complexes. Reprogramming the lead from a unipolar to bipolar mode of function may also solve this problem. In this example, myopotentials are readily visible in the rhythm strip; in most instances, however, the oversensed signal is not appreciable from the surface electrocardiogram and must be inferred. The presence of oversensing can be confirmed by visualizing the signal from the intracardiac lead using the pacemaker analyzer.

cardiologic consultation is mandatory. Physicians unfamiliar with the intricacies of pacemakers should not attempt to reprogram the pacemaker.

Temporary Cardiac Pacing

Temporary (Table 45.2) pacing provides effective rate support for transient bradycardias and can serve as a bridge to permanent pacing. Temporary pacing can be accomplished using transcutaneous, transesophageal, and transvenous routes. *Transcutaneous pacing* involves application of two large surface patch electrodes (70 to 120 cm²) on the torso (negative cathodal electrode positioned anteriorly; positive anodal electrode positioned posteriorly). Programmable parameters of the transcutaneous pacemaker include rate, output, and sensitivity. Stimulus output ranges from 0 to 200 mA. The capture threshold usually ranges between 35 and

80 mA; the stimulus output should be set at 5 to 10 mA above the capture threshold. Successful temporary pacing can be achieved in up to 70% of patients. Complications of transcutaneous pacing include uncomfortable, often painful, cutaneous nerve stimulation at stimulus outputs greater than 30 mA. Ease of application has made transcutaneous pacing a valuable tool in the emergent treatment of bradycardias as a bridge to permanent therapy. However, transcutaneous pacing is much less reliable than transvenous pacing, and, in patients who are pacemaker-dependent (spontaneous QRS rate of less than 30 bpm or symptoms at slow rates), transcutaneous pacing should serve only as a temporary measure until a transvenous lead is inserted.

Transesophageal pacing, which is a relatively simple form of pacing, involves swallowing an electrode. The proximity of the esophagus to the left atrium allows access to atrial pacing. The ideal atrial pacing site is indicated by the atrial

TABLE 45.8
DIFFERENTIAL DIAGNOSIS OF FAILURE TO CAPTURE

Cause	Chest radiograph	Capture threshold	Lead impedance	Comment/management
Inappropriately low programmed output	Normal or unchanged	Normal	Normal	Interrogation confirms the programmed output; determine capture thresholds and reprogram output
High pacing thresholds	Normal or unchanged	High	Normal	Hyperkalemia, flecainide, acidosis are usual causes
Battery failure	Normal or unchanged	High	Normal	Interrogation confirms end of life
Open circuit				
Lead fracture	Often abnormal	High	High	Lead fracture may not be visible on chest radiograph
Lead dislodgment	May be abnormal	High	High	May be able to program increased output; pacing system revision may be required
Insulation failure	Often abnormal	High	Low	Insulation break may not be visible on chest radiograph
"Functional" noncapture	Normal	Normal	Normal	Stimulus falls in refractory period of myocardial tissue; assess electrocardiogram; identify cause; reprogram if warranted

electrogram that has the largest magnitude (about 35–40 cm from the teeth). Ventricular pacing can be performed through the esophagus but with less reliability than atrial pacing because of the greater distance between the esophagus and the ventricles. Thus, esophageal pacing should not be used in patients with AV block. Complications are minimal and include epigastric discomfort and phrenic-nerve stimulation with high stimulation outputs.

Transvenous pacing is the most reliable method of temporary pacing. The left subclavian vein should be avoided, if possible, so that it can be used for a permanent pacing lead if required. The temporary pacing lead is positioned under fluoroscopic guidance in the right-atrial appendage for atrial pacing and right-ventricular apex for ventricular pacing. Stimulus outputs range between 0.1 mA and 20 mA and should be set two to three times above the capture threshold. The ideal atrial and ventricular capture thresholds are no more than 1.0 mA. Sensitivity is usually set at 25%–50% of the sensing threshold.

Indication for Early Consultation

Cardiology consultation is recommended if the patient has a life-threatening cardiac disorder associated with bradycardia, if the patient is pacemaker-dependent and is admitted to the CCU for rate support, or if the patient has (or is suspected of having) a malfunctioning pacemaker. Implantation and follow-up of permanent pacing systems are usually performed by a cardiologist with expertise in the field. Interrogation of the pulse generator is the only

method by which programmed values, battery status, and lead impedances can be determined. Optimal programming, sensing, and capture threshold evaluations require familiarity with pacemaker technology and appropriate equipment. These determinations are best performed by an experienced cardiologist, whether the pacing system is a temporary or a permanent one.

ISSUES DURING THE COURSE OF HOSPITALIZATION

The major issues accompanying hospitalization of the patient with bradycardia include identifying and treating the cause of bradycardia, deciding whether or not permanent pacemaker implantation is necessary, arranging for implantation of a permanent pacemaker if appropriate, and subsequent postimplant evaluation. The initial goals are to stabilize the patient and evaluate the cause and severity of the bradycardia. After the exclusion of or failure to rectify potentially reversible causes of bradycardia, a permanent pacemaker should be implanted on day 2 unless there is active infection. Rhythm monitoring in a telemetry facility is recommended until hospital discharge, usually on the day after implant.

Following pacing-system implantation and prior to discharge, a 12-lead electrocardiogram should be obtained to document the patient's spontaneous rhythm and rate, if possible, and the morphology and axis of paced P waves and QRS complexes. Normal sensing and pacing function must be established prior to discharge. After permanent or

temporary pacemaker placement, a chest radiograph should be obtained to exclude pneumothorax and to assess lead position as well as connector block (lead connections to pulse generator) integrity.

Pacemakers can have unexpected and unwanted decreases or increases in rate. A decrease in pacemaker rate can be caused by sensor-driven rate reduction, by magnet application with a device-specific rate reduction, by phantom programming (with the pacemaker unknowingly reprogrammed by either someone else or electromagnetic noise), or by end of battery life. Increases in paced rates can result from sensor-driven rate increases, tracking of atrial tachyarrhythmias, and pacemaker-mediated tachycardias in which the pacemaker lead itself participates in a reentry pathway; pacemaker-mediated tachycardias rarely occur with newer pacemaker systems.

Rate-adaptive pacing is designed to increase and decrease the heart rate to meet the physiologic demands of the patient. Depending on the sensor and the programmed parameters, however, increases in paced rate can be inappropriate for a given clinical circumstance (e.g., body motion sensor input in a shivering patient or minute ventilation sensor in a hyperventilating patient).

Pacemaker Malfunction

Medical sources of electromagnetic interference can have adverse effects on pacemakers. Direct-current cardioversion and defibrillation deliver a large current of energy and can adversely affect pacemaker function. These effects can be minimized by maintaining a cardioversion/defibrillation vector perpendicular to the vector of the pacing system and by keeping the cardioversion/defibrillation electrodes more than 5 cm from the pacing system.

Magnetic resonance imaging should not be performed in patients with pacemakers because of potential complications, including reports of postimaging death (3). Surgeons must be careful to use electrocautery according to established recommendations (4) to avoid pacemaker oversensing and output inhibition.

Patients with pacemakers who require therapeutic radiation should avoid high-energy neutron radiation. Direct exposure of the pulse generator to the radiation beam should be prevented by shielding. Complete pacing system replacement should be anticipated if the pulse generator is within the radiation field. Lithotripsy can damage the pacemaker. Transcutaneous electrical nerve stimulation therapy can result in oversensing and output inhibition (particularly in unipolar pacemakers), as well as in atrial oversensing and triggered rapid ventricular pacing.

DISCHARGE ISSUES

In the absence of medical conditions necessitating continued hospitalization, the patient can be discharged as early

as on the day of implant. The patient should be instructed not to perform vigorous upper-extremity activities for at least a week to prevent lead dislodgment. Fever or any abnormality over the pocket site (pain, warmth, swelling, redness, discharge, or bleeding) should be reported immediately, as should palpitations, syncope, presyncope, and shortness of breath. These symptoms should prompt immediate outpatient evaluation.

Pacemakers can interact with nonmedical sources of electromagnetic interference. The most common sources are cellular phones, which can result in oversensing, output inhibition, and noise-reversion pacing (temporary asynchronous pacing in response to electrical signals sensed as "noise"), particularly if the phone is used ipsilaterally in proximity (<10 cm) to the pulse generator and if the phone is digital (5). Cellular phone users with pacemakers should use the ear contralateral to the pulse generator and should avoid placing the telephone directly over the pacemaker. Airport-security metal detectors and anti-theft surveillance systems generally do not cause a problem if patients do not linger in the vicinity of the detectors (6). Sporadic cases of transient output inhibition or noise-reversion pacing have been reported with the use of some household appliances (microwaves, electric shavers, electrical blankets, and ham radios) and also with acupuncture. Scuba diving can cause deformation of the titanium pulse generator at depths greater than 132 feet.

At discharge, the patient should be given a card identifying the manufacturer of the pulse generator and lead(s), including model and serial numbers. Copies of the interrogated data should be given to the patient and placed in the patient's medical record. The patient should have a follow-up pacemaker check within one week and again at one month and then be enrolled in a telephone pacemaker-surveillance program. Careful medical follow-up is also important because more than 50% of patients will die of noncardiac causes (7).

Postimplantation pocket infections occur in 1% to 6% of patients. Clinical manifestations include warmth, erythema, and discharge from the pocket site, as well as fever. Although some studies report successful outcomes using intravenous antibiotics alone, the preferred therapy is removal of the entire pacemaker system accompanied by use of antibiotics (8). Blood cultures should be obtained prior to administration of antibiotics. Initial antibiotic therapy should be intravenous and cover the two most common offending organisms, *Staphylococcus aureus* and *Staphylococcus epidermidis*. The latter is more often associated with late infections (occurring later than one month after implantation).

COST CONSIDERATIONS AND RESOURCE USE

The most effective strategy for the efficient use of resources is early identification and implantation of a permanent

pacing system in patients who require lifelong rate support. Early implantation avoids the use and associated cost of temporary pacing and, in the absence of medical conditions necessitating continued hospitalization, reduces length of hospital stay. Data from randomized trials suggest that dual-chamber pacing (atrial-based pacing) does not significantly reduce stroke or death compared with single-chamber ventricular pacing in patients with sinus node dysfunction (9,10). However, dual-chamber pacing does appear to reduce the frequency of atrial fibrillation and the development of chronic atrial fibrillation. Its use also results in fewer hospitalizations for heart failure and improved quality of life (9, 11–13). As a result, it is cost effective compared with single chamber ventricular pacing (14).

Evidence suggests that ventricular dyssynchrony caused by right ventricular apical pacing can be detrimental in patients with depressed left ventricular function (ejection fraction of 40% or less), evidenced by the development of heart failure and a higher mortality rate (15). Although biventricular pacing has been found to be effective in improving heart failure symptoms and signs in patients with ventricular dyssynchrony (Chapter 39), the benefit of biventricular pacing in patients with bradycardia who do not have heart failure (for the sole purpose of correcting right ventricular pacing-induced dyssynchrony) has yet to be established.

KEY POINTS

- All patients with symptomatic bradycardia should be treated with permanent cardiac pacing unless the cause of bradycardia is clearly reversible.
- Permanent cardiac pacing is indicated in patients with bradycardia caused by necessary drug therapy.
- Vagally mediated bradycardia is common in hospitalized patients and usually does not require temporary or permanent cardiac pacing.
- Transcutaneous pacing should not be used in patients for prolonged periods because it is both uncomfortable and unreliable.
- In patients with chronotropic incompetence, always attempt to implant a permanent pacing system that allows the heart rate to adapt to changing metabolic needs.
- Data from randomized controlled trials show that in patients with sinus node dysfunction, dual-chamber pacing does not significantly reduce stroke or death compared with ventricular pacing; however, dual-chamber pacing does appear to reduce the frequency of atrial fibrillation and the progression to chronic atrial fibrillation, prevent hospitalizations for heart failure, and improve quality of life.
- Magnetic resonance imaging is contraindicated in patients with pacemakers; special precautions may be required during electrocautery, ionizing radiation,

lithotripsy, transcutaneous nerve stimulation, and cellular-phone use.

- When patients present with pacemaker pocket infections, explantation of the entire pacing system is recommended.

INTRODUCTION

Although pericardial disease is a rare cause of hospital admission, it can be life threatening, and it may be the first manifestation of other systemic illnesses. After diagnostic testing, pericardial disease usually still is considered idiopathic, and the disease is often self-limited without specific therapy. Thus, the challenges for the clinician are to decide when to hospitalize, when to proceed with further testing, and when to prescribe empiric treatment. In the case of a pericardial effusion, the physician also must decide when to perform pericardiocentesis, either diagnostic or therapeutic.

PERICARDIAL ANATOMY AND PHYSIOLOGY

Hippocrates (c. 460–370 BC) described a normal pericardium as “a smooth mantle surrounding the heart and containing a small amount of fluid resembling urine” (1). In truth, the pericardium comprises two distinct layers in continuity with each other. The visceral pericardium is a single cellular layer that covers the surface of the heart. At the origins of the great vessels, this layer reflects back on itself and acquires an outer fibrous layer to form a sac around the heart. The pericardial sac is tethered in place by ligamentous attachments to the sternum, spine, and diaphragm. Normally, the potential space enclosed by the inner and outer layers of the pericardium is filled with about 50 ml of clear fluid. The function of the pericardium is unclear, and its congenital absence may have little consequence (1). The intact pericardium does serve as a barrier to the spread of infection from the pleural space. Because the parietal layer is stiff, the pericardium may provide support to the more compliant walls of the right atrium and right ventricle, limiting their distention under pressure loads. The hemodynamic consequences of pericardial disease can arise from changes in the elastic properties of the pericar-

dial layers or from inflammation and fluid accumulation within the pericardial sac.

CLINICAL SYNDROMES

Acute pericarditis (2) is an inflammation of the pericardium from any of a variety of causes (Table 46.1). The syndrome may be self-limited, or it may be associated with an enlarging pericardial effusion that can lead to pericardial tamponade or that requires drainage because of suspected purulent bacterial pericarditis. In some patients, chronic or recurrent pericarditis leads to *constrictive pericarditis*. It is critical to differentiate among these various syndromes to guide decisions regarding need for admission as well as subsequent diagnostic and therapeutic interventions.

The physical examination remains the single most important test in evaluating the type and severity of pericardial disease. Careful evaluation of the jugular venous pulse and pressure is essential. In uncomplicated pericarditis and in the absence of other complicating heart disease, the jugular venous pressure (JVP) is normal. Pericardial effusion leads to an increase in JVP, with a blunting of the γ descent if there is an increase in intrapericardial pressure. Patients with cardiac tamponade will nearly always have elevated neck veins, along with hypotension and tachycardia. The two exceptions to this general rule are seen in patients who have had recent open chest surgery (which can lead to localized hematoma behind the left atrium, leaving the JVP normal) and in patients who are frankly hypovolemic (who may also have normal JVP). In constrictive pericarditis, the JVP is elevated with prominent x and γ descents. Paradoxical inspiratory increase of the JVP (*Kussmaul's sign*) is seen in constrictive pericarditis but usually not in cardiac tamponade. *Pulsus paradoxus*, present in cardiac tamponade, is a lowering of systolic blood pressure more than 10 mm Hg during inspiration. The cause is an increase in filling of the right cardiac chambers during inspiration, resulting in compression

of the left cardiac chambers and subsequent decrease in left-ventricular stroke volume.

Auscultation of the heart may reveal a pericardial friction rub in cases of acute pericarditis. The sound has been likened to the crunch of walking on dry snow. The rub may occur only during ventricular systole; the presence of additional distinct components during atrial systole and ventricular diastole leads to the classic (but often not heard) three-component rub. In constrictive pericarditis, a pericardial knock, representing the end of rapid diastolic filling, sometimes is heard. The timing is similar to an S3 gallop, but the sound's character is distinctly different. Distant, muffled heart tones may imply the presence of a pericardial effusion. Cardiac gallops usually are not seen in tamponade and imply the coexistence of heart failure.

If a pericardial effusion is present, the echocardiogram may provide corroborative evidence of tamponade, including diastolic collapse of the right ventricle and right atrium. Nevertheless, tamponade remains a clinical diagnosis, suggested by a *triad of hypotension, elevated JVP, and tachycardia*

in the presence of a pericardial effusion. Echocardiographic signs may be less reliable in the presence of severe heart failure or in ventilated patients. Occasionally, a therapeutic pericardiocentesis with subsequent improvement of vital signs may be the only way to confirm the diagnosis of tamponade.

In constrictive pericarditis, transthoracic echocardiography has a low sensitivity for detecting pericardial thickening. However, the absence of normal "sliding" between the pericardial layers suggests adhesion. Transesophageal echocardiography has been shown to be accurate in measuring pericardial thickness (3). Doppler echocardiography can assess the velocity of blood flow across tricuspid and mitral valves, which in constriction (as in tamponade) shows excessive respiratory variation. As in tamponade, the inferior vena cava is dilated because of high right-atrial pressures. Other echocardiographic signs are not diagnostic of constriction. On chest radiograph, the pericardium may appear as a calcified shell surrounding the heart. Computed tomography and magnetic resonance imaging can help assess pericardial thickening, but normal pericardial thickness does not exclude constrictive pericarditis. Invasive hemodynamic measurements in the cardiac catheterization laboratory are usually necessary to support the diagnosis of constrictive pericarditis and differentiate it from restrictive cardiomyopathy.

ACUTE PERICARDITIS

Issues at the Time of Admission

Clinical Presentation

Classic pericarditis presents as a sharp retrosternal discomfort that improves on sitting up and worsens on lying down. The pain can be quite severe, burning in nature, radiating to the shoulder or back, and sudden in onset. It is frequently pleuritic and worsens with inspiration. The pain is variable in nature and location and may mimic cardiac ischemia, an acute abdomen, or aortic dissection. Dyspnea may be present in the absence of pulmonary edema on the chest radiograph. Often pericardial pain follows a prodrome of fever, malaise, and myalgia. A pericardial friction rub is commonly present. The usual electrocardiographic manifestation early in the course of acute pericarditis is widespread ST elevation (concave upward and usually less than 5 mm) with depression of the PR segment below baseline (the T-P segment) (Figure 46.1). These changes (stage I) are diagnostic of acute pericarditis. Occasionally, ST-segment elevation can be confined to the inferior or anterior electrocardiogram (ECG) leads in pericarditis, simulating myocardial infarction. The clinician must take care not to confuse stage I changes of pericarditis with those of acute myocardial infarction (leading to inappropriate thrombolysis) or to mistake a large antero-

Figure 46.1 Electrocardiogram (stage I) from a patient with acute pericarditis. Widespread ST elevations are present with PR-segment depression in lead II. In stage II, the ST segments return to baseline with flattening of the T waves. In stage III, the T waves become inverted, and in stage IV, the electrocardiogram returns to normal. The evolution typically occurs over two weeks, although the T-wave inversions may persist.

lateral infarction for pericarditis. In stage II, the ST segments return to baseline with flattening of the T waves. In stage III, the T waves invert, and in stage IV, the electrocardiogram returns to normal. The evolution typically occurs over two weeks, although T-wave inversions may persist. If pericarditis presents as a manifestation of a systemic illness, it can be asymptomatic and found incidentally on the ECG or echocardiogram.

Differential Diagnosis and Initial Evaluation

Because the hallmark of acute pericarditis is chest pain, the clinician must rapidly consider and exclude other more life-threatening illnesses, including aortic dissection, pulmonary embolism, esophageal rupture, and either acute or recent myocardial infarction. Thus, the initial evaluation must include (a) rapid assessment of hemodynamic status, noting the presence of tachycardia, hypotension, jugular venous distension, and pulsus paradoxus; (b) cardiac auscultation; (c) ECG; and (d) chest radiograph. Initial laboratory evaluation should include electrolytes, blood urea nitrogen, creatinine, complete blood count, activated partial thromboplastin time, and prothrombin time. Cardiac biomarkers (e.g., troponins or creatine kinase MB levels) should be obtained to exclude myocardial infarction or coexisting myocarditis. However, it is important to recognize that cardiac biomarkers are frequently elevated in acute pericarditis because of coincident subepicardial myocarditis (2,4). When these biomarkers are abnormal, acute myocardial infarction must be excluded definitively before concluding that the diagnosis is acute pericarditis.

Early in the evaluation, echocardiography reveals a pericardial effusion in about 60% of cases of acute pericarditis (5,6) and can help distinguish between myocardial infarction and pericarditis if the ECG changes are nondiagnostic. Occasionally, coronary angiography is required to exclude an acute coronary syndrome definitively, especially if wall motion abnormalities are present on echocardiography. If mediastinal widening appears on chest radiography or aortic root dilation on echocardiography, a transesophageal echocardiogram should be obtained to exclude aortic dissection.

Once the diagnosis of pericarditis is clear, the clinician must consider the available history, physical examination, and initial laboratory results to look for clues to a cause (see Table 46.1). For example, a patient with a fever and an elevated, left-shifted neutrophil count may have purulent pericarditis or endocarditis. A history of breast cancer or the presence of a breast mass might suggest neoplastic invasion and a malignant pericardial effusion. Possible causes should be pursued further by prompt and appropriate additional testing. Pericardiocentesis should be performed if infection or neoplasm is suspected, but it is not required for an asymptomatic effusion discovered incidentally. As most cases of pericarditis remain idiopathic, extensive testing early in the course is discouraged.

In the initial evaluation and triage of patients with acute pericarditis, the sensitivities of low frontal-plane voltage and electrical alternans for cardiac tamponade are only 25% and 8%, respectively (7), rendering the ECG a poor tool for this diagnosis. The presence of an enlarged cardiac silhouette on the chest radiograph suggests a large pericar-

dial effusion, for which echocardiographic assessment and pericardiocentesis are indicated, given the correlation of large effusions with poor outcomes (8).

Emergent echocardiography is not required in patients with normal blood pressure, no tachycardia, normal JVP, normal cardiac biomarkers, and normal cardiac silhouette (Figure 46.2), but such patients should have an echocardiogram at the earliest convenience. Echocardiography may show a large pericardial effusion or evidence of right-atrial or right-ventricular collapse, greatly raising the level of concern regarding the risk for, or presence of, tamponade.

Indications for Hospitalization

The main reasons for hospital admission include pain control and observation for the development of tamponade. In two large Spanish series of consecutive admissions for acute pericarditis, the development of cardiac tamponade in acute idiopathic pericarditis was as high as 15% (5,6). Some high-risk indicators generally are acknowledged (Table 46.2), but no prospectively validated criteria exist by which to risk-stratify patients for development of cardiac tamponade.

Young patients (age under 40 years) with normal vital signs, normal jugular venous pressure, negative cardiac biomarkers, and pain that is easily controlled in the emergency department might be considered candidates for outpatient management if family or friends can carry out adequate observation. Echocardiography before discharge from the emergency department is indicated to exclude a very large pericardial effusion, because effusion size correlates with outcome (8). Patients over age 40 or with other significant coronary risk factors should be routinely evaluated in a coronary observation or chest-pain evaluation unit for 8–12 hours or admitted to a telemetry unit, given the risk of missing an atypical presentation of acute myocardial infarction.

Indications for Initial ICU Admission

Without question, the most important diagnostic test in the triage of patients with primary acute pericarditis is a careful examination of the JVP. Presence or absence of pulsus paradoxus should be ascertained. Elevated JVP in the presence of tachycardia or a positive pulsus paradoxus forewarns early tamponade. Such patients should have emergent echocardiography. If a large effusion is present, then these patients should be monitored in an ICU and receive early cardiology consultation. Patients with suspected pericarditis secondary to another condition warranting ICU admission, such as myocardial infarction, should be triaged appropriately.

In pericardial tamponade, stroke volume falls and heart rate increases in an attempt to maintain cardiac output; therefore, tachycardia is an early clinical sign of impending tamponade. Pulsus paradoxus may be difficult to diagnose

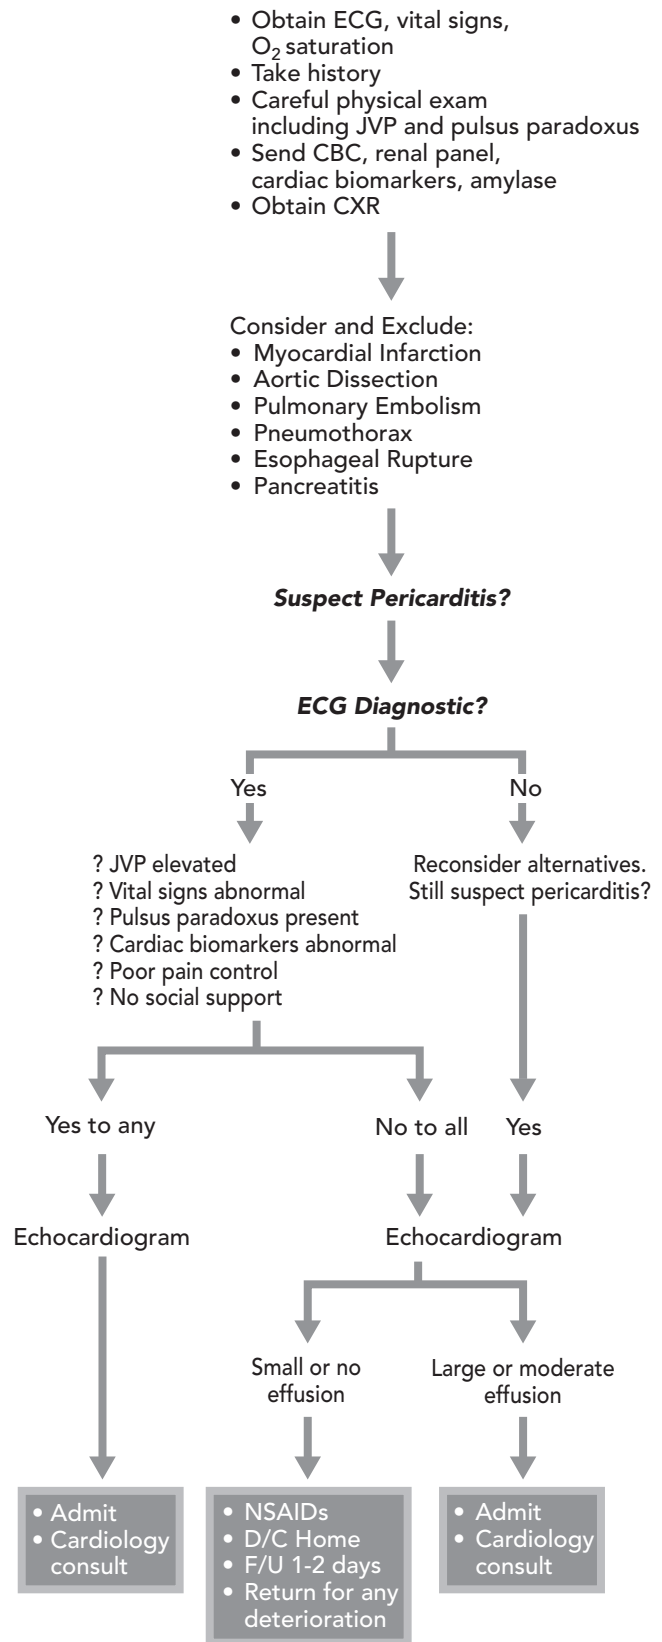

Figure 46.2 Emergency evaluation of possible acute pericarditis. CBC, complete blood count; CXR, chest radiograph; D/C, discharge; ECG, electrocardiogram; F/U, follow-up; JVP, jugular venous pressure; NSAIDs, nonsteroidal anti-inflammatory drugs.

TABLE 46.2
INDICATORS OF HIGH RISK FOR
COMPLICATIONS OF PERICARDITIS

Study	Indicator
Physical examination	Tachycardia Pulsus paradoxus Elevated jugular venous pressure
Laboratory examination	Leukocytosis Uremia Elevated cardiac biomarkers
Chest radiograph	Enlarged cardiac silhouette
Echocardiogram ^a	Large pericardial effusion Right-atrium or -ventricle collapse Respiratory variation of mitral and tricuspid inflow

^a Echocardiogram should be obtained immediately if other high-risk indicators are present.

in patients with severe hypotension or atrial fibrillation. However, in patients with pulsus paradoxus, a systolic arterial pressure less than 120 mm Hg, tachycardia, dyspnea, or any evidence of systemic hypoperfusion, pericardial tamponade must be suspected seriously. Echocardiography should be performed unless the patient is so ill that there is no time for it. Echocardiography usually shows exaggerated leftward motion of the interventricular septum and exaggerated increase in right-ventricular filling during inspiration. Right-atrial or right-ventricular collapse during diastole indicates equilibration of intrapericardial pressures with right-ventricular diastolic pressures and also indicates cardiac tamponade (Figures 46.3 and 46.4). These findings often are seen even before the patient has decompensated.

Once pericardial tamponade has been diagnosed clinically, the patient should be moved to a cardiac catheteriza-

tion laboratory emergently to undergo catheterization and pericardiocentesis in a controlled setting. In hospitals without catheterization laboratories or in situations that are too emergent to permit catheter guidance, pericardiocentesis can be performed at the bedside (Figure 46.5). Echocardiography can identify the location on the chest wall where the fluid is closest to the transducer. Care is taken to avoid the intercostal and internal mammary arteries, and the transducer angle is used to determine the optimal trajectory of the needle (9). After pericardiocentesis, an intrapericardial catheter generally is left in place as part of a closed drainage system for about 24 hours to be sure that tamponade does not recur. Subsequently, the catheter may be removed. If fluid recurs, percutaneous balloon pericardiectomy or a limited subxiphoid pericardiectomy may be required.

Initial Therapy

If cardiac tamponade is absent and no specific cause is readily apparent, the early management of acute primary pericarditis is focused on relief of symptoms. Treatment is initiated with high-dose nonsteroidal anti-inflammatory drugs, such as 650 mg of aspirin every three to four hours or 800 mg of ibuprofen every eight hours. In patients with severe pain in need of more immediate relief, 60 mg of parenteral ketorolac may promote the more rapid resolution of symptoms (10). *Anticoagulants generally should be avoided* because of the risk of intrapericardial hemorrhage; for patients requiring anticoagulant therapy, levels should be maintained in the lower end of the indicated therapeutic range.

In some patients, pericarditis may be caused by infectious conditions, uremia, tumor, radiation, or autoimmune diseases. *Tuberculous pericarditis* is not usually associated with evidence of pulmonary tuberculosis. It should be suspected in patients with persistent fever and otherwise unexplained pericardial effusion, especially in

Figure 46.3 Right-atrial (RA) collapse (arrow) in a patient with pericardial tamponade.

Figure 46.4 Right-ventricular diastolic collapse (RVDC) in a patient with pericardial tamponade. PE, pericardial effusion.

Figure 46.5 Pericardiocentesis using the subxiphoid approach, which avoids the major epicardial vessels. A hollow needle, which is attached via a stopcock to an aspiration syringe and to a short length of connecting tubing leading to a transducer, is used to enter the pericardial space. If fluid is aspirated initially, the pressure waveform at the needle tip should be examined briefly to confirm that the needle tip is in the pericardial space. A floppy-tipped guide wire then is passed through the hollow needle, and the needle is exchanged for a soft flexible catheter with end and side holes to facilitate safe and thorough drainage of the pericardial sac. ECG, electrocardiogram. (Adapted from Lorell BH, Grossman W. Profiles in constrictive pericarditis, restrictive cardiomyopathy, and cardiac tamponade. In Grossman W, Baim DS, eds. *Cardiac Catheterization, Angiography, and Intervention*. Philadelphia: Lea and Febiger, 1991:643, with permission.)

patients who are otherwise at high risk for tuberculosis. Both pericardial fluid and tissue often are required to make the diagnosis. In many patients, the effusion may resolve spontaneously and progress insidiously to constrictive pericarditis. Multidrug antituberculosis therapy is required and usually is supervised by an infectious-disease specialist.

Bacterial pericarditis (often referred to as purulent pericarditis) is usually a complication of an adjacent pneumonia with *Staphylococcus*, *Pneumococcus*, or *Streptococcus* organisms or is associated with thoracic surgery or bacterial endocarditis. It is usually an aggressive, acute illness with fevers, chills, and evidence of sepsis. Cardiac tamponade may develop rapidly. Treatment requires early surgical drainage, often including pericardiectomy, and appropriate intravenous antibiotics.

Fungal pericarditis is unusual. Most cases are caused by histoplasmosis, which can cause massive pericardial effusions. The diagnosis of fungal pericarditis is made based on known exposure to histoplasmosis or coccidioidomycosis, positive titers, and often confirmatory biopsy material.

Uremic pericarditis may occur prior to or during dialysis. Treatment is usually intensification of dialysis and use of nonsteroidal anti-inflammatory drugs.

Malignant pericarditis is usually caused by lung cancer, breast cancer, leukemia, or lymphoma. Patients often have other evidence of tumor in the chest, liver, or lymphatic system. Pericardiocentesis is diagnostic in about 85% of cases. The preferred treatment is catheter drainage of the pericardial space or subxiphoid pericardiectomy. It is critical to realize that some patients with malignancies may have idiopathic pericarditis or radiation pericarditis. For example, radiation pericarditis develops in about 0.5%–5% of patients after radiation for Hodgkin's disease or breast cancer. Pericardiocentesis should be performed only in patients with possible pericardial tamponade.

Autoimmune pericarditis occurs in 20% or more of patients with systemic lupus erythematosus or rheumatoid arthritis. It is more likely to occur if the underlying disease is active. Patients commonly have chest pain and a pericardial rub. Pericarditis usually responds to aggressive treatment of the underlying disease.

Indications for Early Consultation

Prompt cardiology consultation is indicated if there is clinical suspicion of cardiac tamponade, such as the presence of pulsus paradoxus, hypotension, tachycardia, or elevated JVP. Patients with these symptoms are more likely to require pericardiocentesis, which is most safely performed in a cardiac catheterization laboratory with echocardiographic or fluoroscopic guidance. Other indications for cardiology consultation include the failure to improve in the first 24 hours, more than mild elevations of cardiac biomarkers, unexplained electrocardiographic changes, and new arrhythmias.

Issues During the Course of Hospitalization

The purpose of hospitalization in acute pericarditis is the relief of pain and monitoring for the development of cardiac tamponade. As most cases of pericarditis are idiopathic, early conservative therapy is justified. The prognosis is favorable in patients who do not have tamponade and who have early relief of symptoms. Such patients do not require further testing, as the likelihood of discovering significant underlying disease is reported to be less than 3% (5). Failure to improve over 24 hours or the development of tamponade warrant a more aggressive approach to establishing an etiologic cause (Figure 46.6).

In the first 24 hours, patients who do not present with cardiac tamponade should be treated aggressively with nonsteroidal anti-inflammatory drugs. The patients' vital signs and JVP should be evaluated three to four times a day. Patients with deteriorating vital signs or increasing JVP should receive immediate echocardiography and cardiology consultation. In stable patients, repeat cardiac biomarker studies and an ECG should be obtained at 24 hours.

Although pericardial chest pain and fever in acute idiopathic pericarditis may persist for up to a week, patients who fail to show improvement after 24 hours should have further evaluation, including an echocardiogram to assess the presence and size of the pericardial effusion. Additional laboratory testing should be considered to screen for common underlying etiologies of acute pericarditis: occult infection, rheumatoid arthritis, hypothyroidism, HIV disease, malignancy, or tuberculosis. Patients should remain hospitalized until it is clear that they do not have enlarging pericardial effusions (on serial echocardiograms) or life-threatening causes of pericarditis, such as bacterial infection. If pain is refractory to nonsteroidal anti-inflammatory drugs, a one-week course of prednisone 60 mg/d, followed by a one-week taper, usually provides relief. Tuberculosis and bacterial infection should be excluded before beginning corticosteroids. Table 46.3 briefly outlines the management of specific causes of pericarditis; for further discussion, see the "Additional Reading" list at the end of the chapter.

Patients with acute pericarditis frequently have pericardial effusions regardless of the underlying cause. Routine diagnostic pericardiocentesis is generally not useful; the appearance of the fluid (e.g., serous compared with sanguinous) does not reliably distinguish between idiopathic and nonidiopathic causes (11). In one series, only 7% of patients presenting with pericarditis had specific diagnoses (which included tuberculosis, purulent pericarditis, and neoplasm) established by examination of pericardial fluid (5). Pericardial biopsy was not useful. The findings of a large pericardial effusion, impending cardiac tamponade, or failure to resolve fever and illness after five to seven days of conservative treatment predict poorer outcome and a higher diagnostic yield of pericardiocentesis (5,8). In patients with AIDS, the presence of a pericardial effusion portends a dire prognosis (12). Patients with any

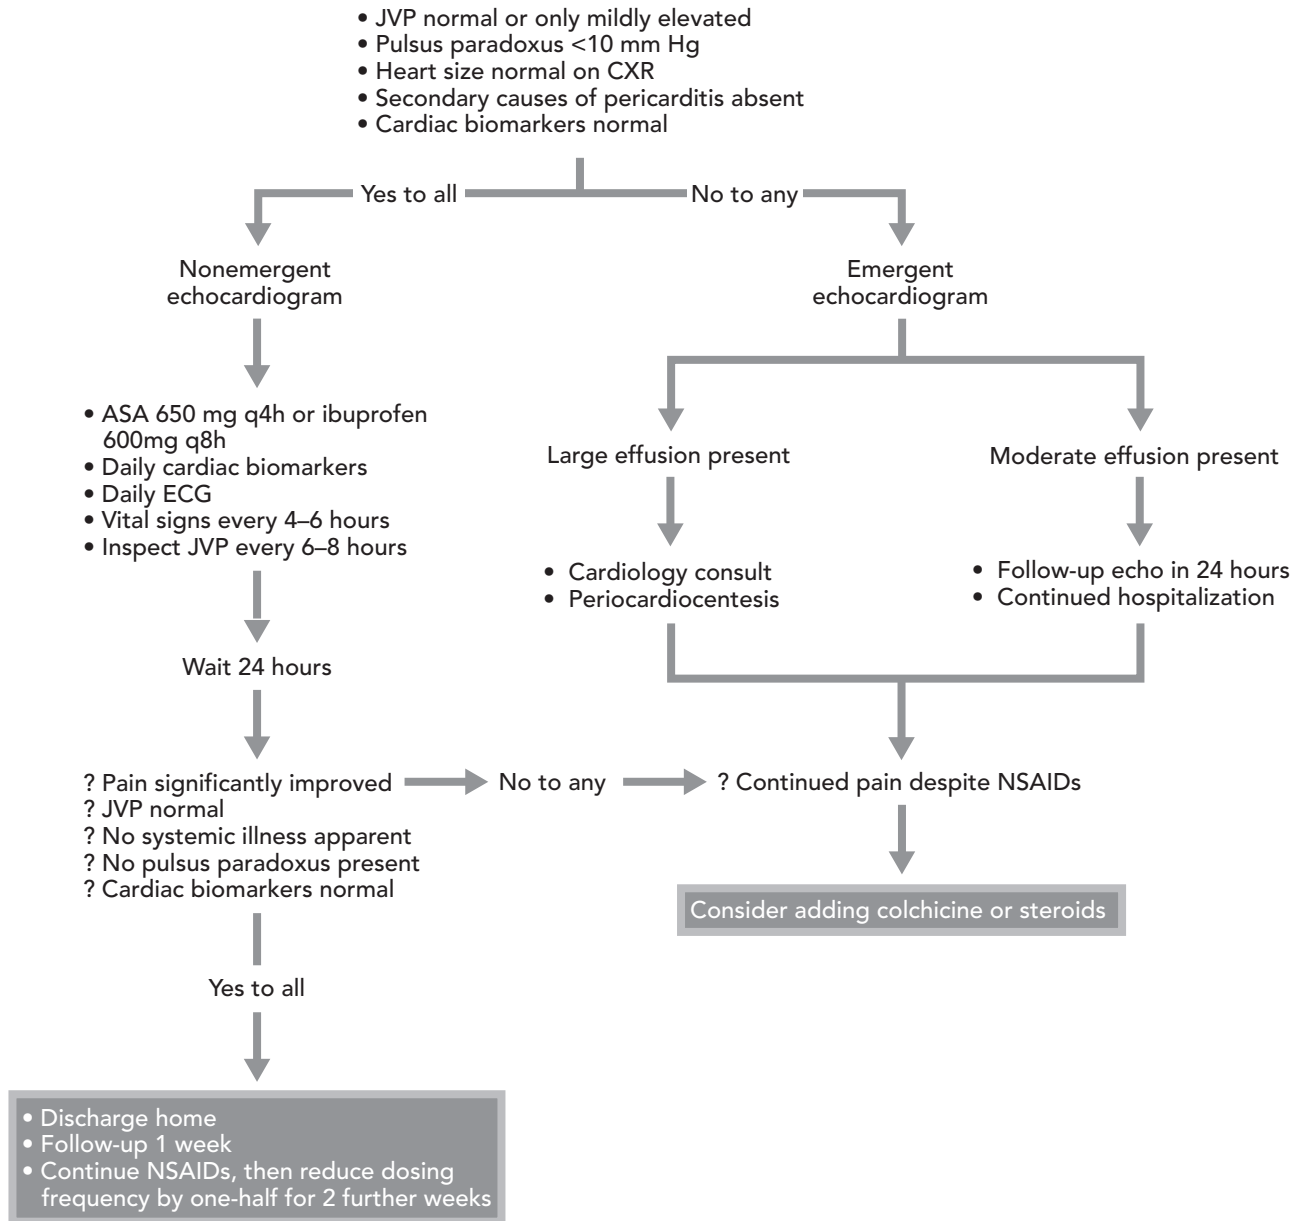

Figure 46.6 Initial hospital management of patients with pericarditis. ASA, aspirin; CXR, chest radiograph; ECG, electrocardiogram; JVP, jugular venous pressure; NSAIDs, nonsteroidal anti-inflammatory drugs.

of these characteristics merit cardiology consultation for consideration of diagnostic or therapeutic pericardiocentesis. Patients with moderate-size effusions and no other evidence of underlying disease may continue conservative management with nonsteroidal anti-inflammatory drugs and undergo a second echocardiogram in 24 hours to document stable effusion size. Small effusions may be followed clinically.

Elective pericardiocentesis should be done in a cardiac catheterization laboratory by a physician experienced in the procedure. Rare emergency situations may require bed-

side pericardiocentesis with only electrocardiographic monitoring. As large a volume as possible should be removed and sent for cell count, bacterial culture, mycobacterial culture, and cytology. If tuberculous pericarditis is suspected, elevated levels of adenosine deaminase activity (>40 units/L) support the diagnosis, but culture or biopsy are the standards of diagnosis (2,13). Other laboratory tests generally have low specificity. A follow-up echocardiogram should be performed the next day. If the effusion reaccumulates rapidly, it may be necessary to repeat the pericardiocentesis to avoid the development of cardiac tampon-

TABLE 46.3**PRESENTATION AND TREATMENT OF THE MOST COMMON SPECIFIC CAUSES OF PERICARDITIS**

Type of cause	Pathogenesis/etiology	Diagnosis	Treatment	Complications	Comments
Viral	Coxsackie B Echovirus type 8 Epstein–Barr	Leukocytosis Elevated erythrocyte sedimentation rate Mild cardiac biomarker elevation	Symptomatic relief NSAIDs	Tamponade Relapsing pericarditis	Peaks in spring and fall
Tuberculosis	Mycobacterium tuberculosis	1. Isolation of organism from fluid or biopsy 2. Granulomas not specific	1. Triple drug antituberculosis regimen 2. Pericardial drainage followed by early (4–6 wk) pericardiectomy if signs of tamponade or constriction develop	Tamponade Constrictive pericarditis	1%–8% of patients with tuberculosis pneumonia; R/O HIV infection
Bacterial	Group A <i>Streptococcus</i> <i>Staphylococcus aureus</i> <i>S. pneumoniae</i>	1. Leukocytosis with marked left shift 2. Pericardial fluid purulent	1. Pericardial drainage by catheter or surgery 2. Systemic antibiotics 3. Pericardiectomy if constrictive physiology develops	Tamponade in one-third of patients	Very high mortality rate if not recognized early
Post-myocardial infarction	12 h–10 d post-infarction	1. Fever 2. Pericardial friction rub 3. Echo: effusion	1. ASA 2. Prednisone	Tamponade rare	More frequent in large Q-wave infarctions Anterior > inferior Avoid NSAIDs
Uremic	Untreated renal failure: 50% Chronic dialysis: 20%	Pericardial rub: 90%	1. Intensive dialysis 2. Indomethacin: probably ineffective 3. Steroids: high complication rate 4. Catheter drainage 5. Surgical drainage	1. Tamponade 2. Hemodynamic instability on dialysis	About 50% respond to intensive dialysis
Neoplastic	In order of frequency: Lung cancer Breast cancer Leukemia/lymphoma Others	1. Chest pain, dyspnea 2. Echo: effusion 3. CT, MRI: tumor metastases to pericardium 4. Cytologic examination of fluid positive in 85%	1. Catheter drainage 2. Subxiphoid pericardiectomy 3. Chemotherapy directed at underlying malignancy	Tamponade Constriction	

ASA, aspirin; CT, computed tomography; MRI, magnetic resonance imaging; NSAIDs, nonsteroidal anti-inflammatory drugs; R/O, rule-out.

ade. In refractory cases with recurrent effusions, surgical creation of a pericardial “window” (with samples sent for pathological examination and culture) may be necessary. However, note that these pericardial “windows” may not remain patent, so recurrent tamponade may occur.

Following complete drainage of the pericardial fluid ei-

ther percutaneously or surgically, a small percentage of patients develop constrictive physiology because of coexistent pericardial thickening. This entity, “effusive–constrictive” pericarditis, is most common with neoplastic invasion of the pericardium. Further treatment depends on the prognosis of the patient.

Pericarditis Developing in the Hospital

Patients hospitalized with other illnesses may develop a pericardial effusion or symptoms of acute pericarditis. Frequently, the cause is related to the underlying illness; however, evaluation still requires consideration of other unrelated causes (Table 46.1). Silent myocardial infarction with resulting pericarditis is an example. Intrapericardial bleeding also should be considered in hospitalized patients, especially those on anticoagulants or who have had intracardiac procedures. Echocardiography is warranted as initial evaluation to assess for presence and size of effusion as well as to evaluate ventricular wall motion. Evaluation, therapy, and indications for pericardiocentesis are otherwise similar to primary acute pericarditis.

Discharge Issues

After 24 hours, patients with improving clinical status, defined by marked improvement of chest pain, normal vital signs, lack of elevated JVP and pulsus paradoxus, normal cardiac biomarkers, and no evidence of myocardial ischemia on ECG, may be considered ready for discharge to home. In the absence of a large cardiac silhouette on the chest radiograph or evidence of cardiac tamponade, echocardiography is not necessary prior to discharge. If high-dosage nonsteroidal anti-inflammatory treatment was begun in the hospital, it should be continued for one to two weeks. The dose may then be halved, and treatment should continue for a total duration of four weeks. Patients should be instructed on discharge to return for evaluation if their symptoms worsen or if they develop shortness of breath, palpitations, or light-headedness.

Follow-up may consist of outpatient visits to the primary care physician or consulting cardiologist at one- to two-week intervals until complete resolution is documented. Development of mild cardiac constrictive disease may occur in the first month (9% of cases) but usually resolves spontaneously (14). Persistently elevated neck veins and new peripheral edema should prompt further investigation. The most common complication of acute pericarditis is recurrent pericarditis, which develops in one-quarter of cases (14) and occasionally becomes refractory. Patients with such complications may require courses of colchicine, steroids, or immunosuppressive agents under the care of a cardiologist.

Patients who improve more slowly require longer hospitalizations. Patients with stable moderate-size or small effusions documented during hospitalization but otherwise negative evaluations generally may be discharged home after 2–3 days of hospitalization. These patients should be followed at 2- to 3-day intervals initially as outpatients and undergo repeat echocardiography to ensure stable effusion size. Continuing fever, pain, or growing effusion size should prompt referral for pericardiocentesis as discussed earlier.

CONSTRUCTIVE PERICARDITIS

Issues at the Time of Admission

Clinical Presentation

Constrictive pericarditis usually has a slow, insidious onset resembling heart failure or chronic liver disease. Patients complain of fatigue and dyspnea and often note growing abdominal girth and increasing lower-extremity edema. Careful history might reveal a predisposing condition such as mediastinal irradiation, cardiac surgery, tuberculosis, neoplasm, connective tissue disease, renal disease, or previous history of pericarditis; however, most cases are idiopathic. Physical examination reveals elevated neck veins. The classic finding on physical examination is *Kussmaul's sign*, which is an increase in jugular venous pressure during deep inspiration because of the inability of the right ventricle to accommodate the increase in venous return caused by the negative intrathoracic pressure. Pulsus paradoxus is not seen in constrictive pericarditis unless the patient has effusive-constrictive pericarditis, which is a clinical syndrome with some characteristics of both pericardial tamponade and constrictive pericarditis. A pericardial knock may be heard. The chest radiograph may show pericardial calcification, although this finding occurs in fewer than half of the cases. The ECG is non-specific; atrial fibrillation occurs in about one-third of cases (1).

Differential Diagnosis and Initial Evaluation

Although constrictive pericarditis may resemble chronic liver disease with ascites and abnormalities of the liver function tests, the presence of elevated neck veins points to a cardiac cause. Primary pulmonary hypertension, pulmonic or tricuspid stenosis, or right-heart failure resulting from mitral stenosis or chronic left-to-right shunting may give the same clinical picture as constrictive pericarditis. Restrictive cardiomyopathies also may have a similar clinical presentation. Distinguishing constrictive pericarditis from a restrictive cardiomyopathy can be difficult, even after careful hemodynamic assessment on cardiac catheterization (Figure 46.7). Moreover, these two entities can coexist.

Initial evaluation of the patient with possible constriction consists of careful history and physical, ECG, chest radiograph, and laboratory tests as outlined for acute pericarditis. There are no pathognomonic electrocardiographic changes in constrictive pericarditis, although atrial fibrillation and nonspecific repolarization changes are common. Given evidence of elevated JVP and edema, the patient should also have an echocardiogram to evaluate ventricular and valvular function. Because the diagnosis of constrictive pericarditis includes documentation of pericardial thickening or adhesion and confirmatory hemodynamics, early magnetic resonance imaging or computed tomography, as

Figure 46.7 Intracardiac pressures in a patient with constrictive pericarditis. Simultaneous pressures obtained in left (LV) and right ventricles (RV) show equalization of the diastolic pressures. In both ventricles, there is an early diastolic dip (dd) that rises rapidly to a plateau (P). The patient is in atrial fibrillation. (Adapted from Spodick DH. *The Pericardium: A Comprehensive Textbook*. New York: Marcel Dekker, 1997:243, with permission.)

well as cardiac catheterization, should be part of the initial evaluation. Additional evaluation for specific causes should be guided by the history and index of clinical suspicion.

Indications for Hospitalization

Constrictive pericarditis is slowly progressive, so hospitalization is usually not necessary. However, severe heart failure occasionally may require admission. Patients with anasarca, hypotension, excessive tachycardia, abnormal renal function, or failure to oxygenate adequately should be admitted.

Indications for Initial Intensive Care Unit Admission

Patients with hypotension requiring intravenous vasopressors or patients in a low cardiac output state manifested by renal failure and poor urine output should be admitted to a cardiac care unit. Patients with hypoxia and excessive oxygen requirements or respiratory rate also should be triaged to a cardiac care unit.

Initial Therapy

Patients with evidence of volume overload (elevated JVP, ascites, and edema) should be sodium restricted and receive an intravenous diuretic such as furosemide. The desired rate of diuresis is for output to exceed intake by

500–1,000 mL per day. Patients should have careful assessment of fluid intake and output, vital signs, and daily weights. Patients in atrial fibrillation should be treated with digoxin alone to achieve a target heart rate of 90–100 beats/min. β -blockers and calcium channel blockers are poorly tolerated because of their negative inotropic effects and excessive slowing of heart rate. Medical therapy is usually only palliative for constrictive pericarditis. Patient care is facilitated by rapidly confirming the diagnosis and proceeding with definitive surgical management.

Indications for Early Consultation

Patients with suspected constriction who are admitted to cardiac care units or who have deteriorating renal function should have initial cardiology consultation. Consultation is also indicated in any patient in whom the diagnosis of constrictive pericarditis is established. Cardiac catheterization is required to confirm the hemodynamics of constriction and to exclude coronary artery disease. Myocardial biopsy may be indicated to exclude infiltrative myocardial disease (such as amyloid) if other clinical data do not clearly differentiate restrictive compared with constrictive physiology.

Issues During the Course of Hospitalization

The goal of hospitalization is to relieve the congested state, to establish the diagnosis of constrictive pericarditis, and to proceed to pericardial stripping if appropriate. Diuresis should proceed as described previously while renal function and electrolytes are monitored daily. Once the diagnosis is confirmed, cardiothoracic surgery consultation should be obtained. The decision to recommend surgery should not be made lightly, especially in the severely debilitated elderly patient. The surgical mortality rate ranges from 6%–19% in optimally selected patients and is as high as 40% in the most severely affected individuals (15). The coexistence of restrictive cardiomyopathy and radiation-induced constriction may be associated with poorer surgical outcome, as may the coexistence (with constriction) of coronary artery disease, valvular disease, and renal or hepatic insufficiency. Involvement of the visceral pericardium also negatively impacts surgical outcome.

Patients in atrial fibrillation should be anticoagulated. Cardioversion to normal sinus rhythm may improve cardiac function, but it is unlikely that this sinus rhythm will be sustained. Medications that control the ventricular response rate should be employed judiciously because excessive slowing of the heart rate may lead to clinical deterioration.

Discharge Issues

In postsurgical patients, time to discharge depends on the postsurgical course. If the patient is not considered to be a surgical candidate, discharge depends on the relief of congestion. In general, patients should be able to ambulate

and perform their activities of daily living. Elderly or debilitated patients are candidates for referral to a short-term rehabilitation facility. If surgery is delayed, patients may proceed to discharge if their vital signs normalize and effective diuresis is maintained using oral diuretics.

Even after pericardial stripping, it may take several weeks or months for the filling pattern of the heart to return to normal. Patients should continue oral diuretics and have follow-up every 2–4 weeks to be observed for fluid retention. After several weeks, the patient may attempt to taper and eventually discontinue diuretics under supervision. Failure to improve may be a result of inadequate pericardiectomy or any of the other factors discussed previously.

COST CONSIDERATIONS AND RESOURCE USE

Limited diagnostic testing in low-risk patients with acute pericarditis is the primary means of reducing hospitalization costs. Clinical criteria and simple diagnostic tests remain the most effective tools for risk stratification of patients. Selective discharge from the emergency department using echocardiography as a risk-stratification tool may be a cost-effective strategy that does not compromise patient safety. Cost-effectiveness studies are not available and are unlikely to be forthcoming owing to the relative infrequency of acute pericarditis.

KEY POINTS

Acute Pericarditis

- The chest pain of pericarditis is usually pleuritic but can mimic the pain of myocardial infarction, aortic dissection, and pulmonary embolus.
- Patients at high risk for complications include those with fever, tachycardia, pulsus paradoxus, or elevated jugular venous pressure.
- Other indicators of high risk include uremia, history of neoplasm, enlarged cardiac silhouette on chest radiograph, and a large effusion on echocardiography.
- Initial treatment is with nonsteroidal anti-inflammatory drugs for pain relief, except in uremic pericarditis, in which dialysis is indicated.
- Pericardiocentesis is always indicated if there is clinical evidence of tamponade and usually indicated if patients fail to improve with conservative management.

Constrictive Pericarditis

- The onset is usually insidious with symptoms and signs of venous congestion.

- Hospitalization is recommended to relieve symptoms of severe congestion and for low cardiac output.
- Definitive diagnosis requires demonstration of both pericardial thickening and adhesions, as well as hemodynamics consistent with constriction.
- Pericardial stripping carries a 5%–10% or higher mortality rate and should not be recommended lightly.

INTRODUCTION

Peripheral arterial disease (PAD) is the term most commonly applied to the clinical syndrome that accompanies chronic obstruction of the arterial blood flow to one or more extremities. Most commonly, but not exclusively, this disease is encountered in the legs and represents a manifes-

tation of atherosclerosis. As such, PAD often coexists with identifiable occlusive disease in other major arterial conduits, most notably in the heart and the extracranial cerebral vasculature. Approximately 40% of patients with PAD have concurrent coronary artery or cerebrovascular disease, and 8.6% of patients have disease in all three vascular beds.

Although there has been a substantial increase in the awareness of PAD within the medical community, this disease remains under-diagnosed in usual medical practice. This under-diagnosis poses a barrier to effective secondary prevention of the substantial ischemic cardiovascular and cerebrovascular risk associated with PAD.

SYMPTOMS

A detailed medical history is mandatory for proper evaluation and management of the patient with suspected lower extremity arterial insufficiency. The initial history should include questions designed to define the walking distance, velocity, and incline that are required to elicit the patient's

symptoms. These variables constitute a baseline measure of disability and assist in the future monitoring of the efficacy of therapeutic intervention.

Claudication

Intermittent claudication is the hallmark symptom of peripheral arterial insufficiency. Claudication is classically described as a sensation of fatigue or cramping that is elicited during muscular activity (e.g., walking) of the involved extremity. The symptom usually arises after a consistent, reproducible level of exertion and resolves promptly within minutes of cessation of effort, either by sitting or standing still. The location of pain within the extremity is useful in the identification of the likely vascular site of hemodynamically significant arterial stenosis. Disease of the superficial femoral or popliteal arteries typically elicits claudication in the calf muscles, whereas disease of the iliofemoral arteries or obstruction of the aorta leads to claudication in the buttocks, hips, or thighs. Ankle or foot claudication more often arises with stenosis of the tibial and peroneal arteries.

The symptom of claudication is primarily caused by an inadequate blood supply to the extremity caused by a flow-limiting lesion of a conduit artery. If a pressure gradient is present, its magnitude increases in a non-linear manner, thereby magnifying the symptomatic importance of an arterial stenosis as the arterial flow rates increase. A stenosis that does not provoke a gradient at rest may very well cause a gradient during exercise, as a consequence of the augmented cardiac output and reduced vascular resistance. Thus, as the stenosis increases, the distal perfusion pressure is not maintained. The increase in the intramuscular pressure during exercise, if it exceeds the arterial pressure distal to the stenosis, can further compromise blood flow.

When the impaired blood supply is insufficient to meet the increased metabolic demands of the exercising muscle, anaerobic metabolism supervenes in the recipient muscular bed. Accumulation of lactate and other metabolites, such as acylcarnitines, adenosine diphosphates, and hydrogen ions, ensues. Increasing local concentrations of these metabolites activates local sensory receptors: the patient perceives limb discomfort, which, in peripheral arterial disease, is called claudication.

Several standard questionnaires have been developed to identify the patient with claudication and to help assess its severity. The Rose, San Diego, and Edinburgh Questionnaires have been developed for the epidemiologic assessment of the prevalence of angina and claudication. The Medical Outcomes Short Form 36 (SF-36) Questionnaire is intended to evaluate the functional status and well-being of patients with chronic conditions. The Walking Impairment Questionnaire, the most recently developed of these instruments, evaluates the symptoms and assigns a point score to the elicited responses. Although these instruments were developed to facilitate prospective studies of PAD,

they can be utilized as the source for a series of questions for the patient. The questions can be particularly helpful in assessing the patient's functional impairment as a consequence of the suspected vascular insufficiency (Table 47.1). By comparison, clinicians who rely on a classic history of claudication to detect PAD are likely to miss the diagnosis in 85%–90% of patients.

Dynamic leg discomfort is the hallmark of PAD, but nonvascular causes of exertional leg pain should be considered in the differential diagnosis of true claudication (Table 47.2). Alternate, nonvascular diagnoses include lumbosacral radiculopathy and spinal stenosis, arthritis of the hips and knees, and various musculoskeletal diseases.

Venous claudication (defined as exertional lower extremity aching in the absence of peripheral arterial insufficiency) can be observed in patients with venous regurgitation and produces discomfort that occurs during exertion and that might mimic the calf claudication of arterial insufficiency. Various clinical characteristics, including peripheral edema, stasis, pigmentation, and varicosities, help to identify the patient with chronic venous insufficiency. A symptomatic Baker's cyst or a chronic compartment syndrome can similarly cause discomfort at the level of the calf, although the nature and location of the pain, which is characteristically associated with a particular position, should help distinguish these patients from those with PAD.

TABLE 47.1

SUBJECTIVE ASSESSMENT OF THE PATIENT WITH POSSIBLE PERIPHERAL ARTERIAL DISEASE

These questions are derived from the Walking Impairment Questionnaire (WIQ)

Walking distance

How much difficulty do you experience in walking

- Around your home?
- 50 feet?
- 1/2 block?
- 1 block?
- 2 blocks?
- 3 blocks?
- 5 blocks?

Walking speed

How difficult is it for you to

- Walk 1 block slowly?
- Walk 1 block at an average speed?
- Walk 1 block quickly?
- Run or jog 1 block?

Stair climbing

How difficult is it for you to climb

- 1 flight of stairs?
- 2 flights of stairs?
- 3 flights of stairs?

TABLE 47.2
DIFFERENTIAL DIAGNOSIS OF INTERMITTENT CLAUDICATION

Calf	Hip/thigh buttock	Foot
Venous claudication	Arthritis	Arthritis
Chronic compartment syndrome	Spinal cord compression	Inflammation
Nerve root compression		
Baker's cyst		

Arthritis of the hips and knees clearly can be responsible for leg discomfort and pain with ambulation. However, the resulting pain is characteristically a persistent ache, typically localized to the affected joints, and, unlike the pain of PAD, is commonly precipitated by exercise of variable intensity. The clinician should attempt to elicit complaints of arthralgia using range-of-motion examinations.

Lumbosacral radiculopathy typically presents as a consequence of degenerative disc disease or spinal stenosis. In this condition, walking short distances may evoke pain with a quality very similar to claudication, but relief is obtained not with rest alone, but rather by sitting or leaning against a support. This symptom complex, which is called neurogenic claudication or pseudoclaudication, is common in the elderly and often coexists with PAD.

Symptoms of Critical Leg Ischemia

Pain at Rest

Patients with critical limb ischemia present with relentless lower extremity pain (Table 47.3). The classic description is a burning discomfort in the ball of the foot and in the toes, typically exacerbated at night, in the supine position. The latter manifestation can be explained by the loss of gravity-assisted blood flow to the lower extremities. The patient may try to minimize discomfort by suspending the legs over the side of the bed or sleeping in an upright or semi-sitting position. The protracted dependency of the lower extremities produces considerable peripheral edema, which

TABLE 47.3
DIFFERENTIATING CRITICAL LIMB ISCHEMIA FROM CLAUDICATION

Critical limb ischemia	Claudication
Rest pain with legs horizontal	Ischemic symptoms are present only during exercise
ABI <0.5	ABI typically >0.5
Ischemic ulcers or lesions on foot	No loss of skin integrity

might not otherwise be characteristic of arterial insufficiency in the absence of venous disease.

Non-healing Wounds

In critical leg ischemia, non-healing wounds of the lower extremity and/or foot are common. Failure to heal is typically defined after a 4–12 week trial of therapy. Such wounds often result from trauma caused by an injury or improperly fitted shoe. When the blood supply falls to extremely low levels, gangrene, usually of the toes, may develop.

Differential Diagnosis

Other clinical entities, such as night cramps, arthritis, or diabetic sensory neuropathy, must be considered in the differential diagnosis of critical leg ischemia. Patients with night cramps usually have relief after muscle massage, walking, or the administration of an antispasmodic drug. Arthritis typically produces intermittent pain at defined intervals, in contrast to the constant pain that is characteristic of critical limb ischemia. The pain of diabetic sensory neuropathy is not necessarily associated with recumbency.

The differential diagnosis of critical limb and digital ischemia should also include the connective tissue disorders, such as systemic lupus erythematosus and scleroderma (Table 51.1). Other entities to be considered include vasculitis (in particular, thromboangiitis obliterans), atheroembolism, diabetic sensory neuropathy, reflex sympathetic dystrophy, and acute gouty arthritis.

General Symptomatic Evaluation for Atherosclerosis

Because PAD may represent only one of several manifestations of systemic atherosclerosis, a detailed interrogation for the symptoms of coronary and cerebrovascular insufficiency should be undertaken. Hospitalized patients with coronary artery disease are particularly likely to harbor the undetected diagnosis of PAD (1). Hypertension is a major risk factor for the development of PAD (2), and poorly controlled hypertension predisposes patients to a higher incidence of coronary and cerebrovascular events.

SIGNS

Pulse Examination

A careful pulse examination must be performed in all extremities. It is most practical to grade pulses according to whether they are absent (0), diminished (1), or normal (2). Unusually prominent pulses should also be noted. Auscultation for bruits is an integral part of the circulatory examination and includes the neck, abdomen, flank, and groin.

Patients with aortoiliac disease will often have attenuated femoral pulse amplitudes, at times accompanied by audible femoral bruits. In the presence of hemodynamically significant disease in the superficial femoral artery, the femoral pulse will be palpable, but popliteal and tibial pulses will be diminished or absent. A history of calf claudication with absent pedal pulses and preserved pulse amplitude in the femoral and popliteal vessels is likely to represent tibioperoneal disease, seen commonly in diabetics.

The general examination may reveal hypertension, arrhythmias, abnormal heart sounds, or findings suggestive of the presence of anemia. Blood pressure should be measured in both upper extremities, and any observed pressure gradients should be noted. The abdomen must be palpated to exclude the presence of a pulsatile mass.

Pallor and Rubor

Pallor on elevation and dependent rubor represent reciprocal, physical changes of ischemia. The rapidity with which the pallor occurs can be used as a semiquantitative bedside assessment of the severity of ischemia. The leg of a supine patient is passively elevated by the examiner to a 60-degree angle. Pallor will be observed within 25 seconds with severe disease, within 30 seconds with moderate insufficiency, and within 60 seconds in the presence of mild obstructive disease. With dependency after elevation (i.e., the patient resumes the sitting position, with the legs descending passively from the edge of the exam table), a venous filling time of 20–45 seconds denotes more severe disease; in a normal patient, the venous filling time is nearly instantaneous. In severe disease, capillary refill (the return of color to the skin after blanching) will be comparably delayed: whereas capillary refill is nearly instantaneous in the normal patient, delays of 20 seconds or more are commonly seen in severe arterial insufficiency. Rubor on dependency (the reddish-purple hue assumed by the skin with sitting or standing) can similarly be elicited in such patients.

Dependent rubor is characteristic of poor arterial inflow, but can only be qualitatively defined as present or absent. Cutaneous changes in the affected extremity indicate the presence of significant longstanding arterial disease. It is only over many months that cutaneous and subcutaneous atrophy, along with hair loss and poor nail plate growth, become evident.

Cyanosis

Livedo reticularis or cyanosis of the digits suggest a recent atheroembolic event. Additional manifestations of acute arterial occlusion can include painful cyanosis of one or more of the digits. Acute occlusion can occur de novo in patients at risk for thromboemboli, or can punctuate the natural history of patients with pre-existing PAD; such events are highly characteristic after thrombotic occlusion of a pre-existent bypass graft.

Prompt assessment of limb viability is mandatory. Signs of irreversible ischemia include major tissue loss, absent capillary return (marbling), profound muscle weakness or paralysis, profound sensory loss, and inaudible arterial and venous Doppler signals (see Ankle-Brachial Index). Critical limb ischemia is characterized by severe ischemic pain at rest, often accompanied by skin breakdown, gangrene, and ineliminable tissue infection.

LABORATORY TESTS AND IMAGING STUDIES

Ankle-Brachial Index

Bedside quantification of lower extremity arterial insufficiency is eminently feasible and should be considered an element of the standard physical examination of patients with suspected PAD. The results of this diagnostic maneuver, performed with a hand-held Doppler probe and a sphygmomanometer, is commonly called the *Ankle-Brachial Index* (ABI). The ABI is expressed, for each leg, as a ratio of the greater of the 2 ankle systolic pressures, measured at the malleolar level, and the greater of the 2 brachial systolic pressures. Systolic blood pressure is measured by Doppler ultrasonography in each arm and in the dorsalis pedis (DP) and posterior tibial (PT) arteries at each ankle (Figure 47.1). An ABI of ≥ 1.0 is considered normal, recognizing that systolic blood pressure is normally higher in the legs than in the arms. Patients with PAD typically have Ankle-Brachial Index values between 0.41 and 0.90. Critical leg ischemia, to be discussed later, is typified by an ABI < 0.4 . However, the predictive accuracy of the ABI relies upon normal compressibility of the infrapopliteal arterial vasculature. In older patients, and especially in patients with diabetes, vascular calcification reduces the elasticity of the arterial wall. As a result, the higher external pressures that are required to compress these inelastic vessels will produce an overestimation of the true, intraluminal arterial pressure. An ABI > 1.30 suggests the presence of noncompressible, calcified vessels. In such patients, pulse volume recordings (see later) may be required to validate the presence of an attenuated pulse volume characteristic of arterial insufficiency.

The ABI is particularly useful to identify and evaluate asymptomatic patients with risk factors or other symptoms suggestive of atherosclerosis (3, 4). In one study, about 7% of persons ages 45–74 years had an ABI of ≤ 0.95 , but only 22% of these patients had symptoms (3). An ABI < 0.5 is the most important measure of the severity of disease and predictor of the subsequent need for surgery or amputation (5). Skin perfusion pressure on the foot may be an even better predictor of the likelihood of leg amputation or the need for revascularization in patients with critical leg ischemia (6).

Figure 47.1 Measurement and calculation of the Ankle-Brachial Index (ABI). For details, please see text. (Reproduced from Hiatt WR. Medical treatment of peripheral arterial disease and claudication. *N Engl J Med* 2001;344:1608–1621, with permission.)

Blood Tests

Routine laboratory testing of the suspected claudicant should include a complete blood count (CBC), fasting glucose level and/or hemoglobin A_{1C} level, a fasting lipid profile, a creatinine level, and levels of lipoprotein (a) and serum homocysteine. In patients with premature atherosclerosis or very aggressive, rapidly progressive vascular disease, additional investigations may include plasma fibrinogen levels, an antiphospholipid antibody screen, assay for antithrombin III antibodies, and coagulation studies designed to detect deficiencies in protein C and S, Factor V Leiden, and others. Identification of such so-called “novel” risk factors for PAD, such as hyperhomocysteinemia, may help to explain the racial disproportions in disease prevalence that have been observed in population

studies. Laboratory confirmation of limb-threatening arterial occlusion can be sought in the form of elevated serum levels of muscle enzymes and myoglobinuria.

Exercise Testing

Treadmill exercise testing can evaluate the severity of the peripheral arterial stenosis and provide objective evidence of the patient’s walking capacity. Two accepted treadmill protocols are: the constant-workload protocol, which uses a constant speed and grade (typically 2 mph and 12% grade), and the graded test, which provides constant speed but varies the grade from an initial horizontal position in predefined steps (e.g., 2%) at predefined intervals (e.g., 2 minutes). The reproducibility of the two testing methods is

comparable except when claudication distances are very short, in which case the graded test is superior (7).

The initial claudication distance is defined as the workload at which symptoms of claudication first develop, and the absolute claudication distance is the point at which the patient is no longer able to continue walking because of severe leg discomfort. Together, these two measures provide a useful, quantitative assessment of the patient's disability and can be monitored after therapeutic interventions (8).

Segmental Pressure Analysis

Segmental pressure analysis, which quantifies systolic blood pressure at selected sites along the length of each extremity, is one of the most useful ways to evaluate PAD. Blood pressure cuffs are applied at the thigh, above and below the knee, and above the ankle. A hemodynamically significant stenosis should be suspected if a segmental pressure decrement of $\geq 15\%$ is observed. Segmental pressure analysis is often supplemented by color flow Doppler ultrasound of the major conduit vessels. The Doppler probe is placed over an artery distal to the cuff to assess the velocity of blood flow. In the lower extremities, the probe is usually placed over the posterior tibial artery behind and below the medial malleolus. The dorsalis pedis artery can also be interrogated on the dorsum of the metatarsal arch. In the upper extremity, the brachial, radial, and ulnar arteries are suitable imaging targets.

Pulse Volume Recording

Pulse volume recordings are obtained along the axis of the limb with specifically placed transducers. The goal is to record segmental pulse volumes at the thigh, calf, ankle, and toes. The morphology of the arterial waveform can be analyzed when the changes in volume are displayed with a graphic recorder. In the presence of a hemodynamically significant stenosis, the amplitude of the pulse volume is reduced, and the normal dicrotic notch is lost, with conversion from the normal biphasic waveform to an abnormal monophasic pattern.

Imaging Studies

Duplex Ultrasound Imaging

Duplex imaging provides a direct noninvasive means of assessing both the anatomic characteristics of peripheral arteries and the functional significance of stenoses that are detected. The acoustic properties of the vascular wall can be discriminated from those of the surrounding tissues, thereby enabling them to be imaged readily. Normal arteries have laminar flow, with the highest velocity of flow detected at the center of the artery. The representative image

is usually homogeneous, with a nearly constant hue and intensity. With a stenosis, blood flow velocity through the narrowed lumen increases; proportional desaturation of the color display and flow disturbance distal to the lesion provoke changes in hue and color. A doubling of peak systolic velocity at the site of the lesion serves to identify a 50% reduction in diameter. If the artery is occluded, no signal can be obtained. The sensitivity and specificity of this technique for the identification of arterial stenosis have been reported to be 85% and 95%, respectively.

Magnetic Resonance Angiography

Magnetic resonance angiography provides a noninvasive technique to visualize the peripheral arterial vasculature and the aorta. The technique has been reported to be highly sensitive and specific. Resolution of the vascular anatomy with gadolinium-enhanced magnetic resonance imaging approaches that of conventional contrast digital subtraction angiography. Its greatest current utility may be in patients who require anatomic definition of disease for therapeutic decision making but who are at high risk for renal, allergic, or other complications of conventional angiography.

Contrast Angiography

Conventional angiography is performed when the arterial anatomy must be defined prior to a revascularization procedure. Occasionally, a diagnostic procedure is performed when the diagnosis is in doubt, but revascularization would be warranted if the symptoms and/or signs could be linked to PAD.

EVALUATION AND TREATMENT

The evaluation and management of patients with peripheral arterial disease is covered in Chapter 51. For most patients with critical leg ischemia, early consideration will be given to an attempt at revascularization of the ischemic limb, using a variety of thrombolytic, catheter-based, and surgical approaches. In all such cases, angiographic documentation of the relevant anatomy is mandatory. In patients who are not amenable to surgery or endovascular intervention, the primary, urgent management issues include control of pain, treatment of non-healing wounds and/or infection, improvement of tissue perfusion, and prevention of tissue loss.

When critical limb ischemia occurs, patients require palliation of pain, aggressive wound care, antibiotic therapy of supervening infections, and interventions to prevent the loss of limb. Other long-term management goals include control or elimination of modifiable risk factors such as smoking, diabetes, hypertension, and dyslipidemias.

KEY POINTS

- The medical history is crucial to the diagnosis of PAD and to avoiding substantial underdiagnosis.
- Physical findings usually occur late in PAD.
- The ABI is the key diagnostic test for PAD.

Urgent and Emergent Hypertension

48

William B. White

INTRODUCTION

Hypertensive emergencies are defined not by the absolute value of blood pressure (BP) but by the presence of acute end organ damage secondary to a rapidly increasing blood pressure with attendant vascular injury (Table 48.1). Hypertensive patients with longstanding blood pressure elevations tolerate much higher pressures prior to manifesting rapid decompensation of vital organ function compared with previously normotensive patients, who may present with clinical signs of accelerated disease at lower pressures that have developed more acutely (e.g., pregnancy and acute glomerulonephritis). Hypertensive emergencies dictate immediate hospitalization with management in a critical care unit setting and reduction of blood pressure within minutes to hours. In contrast, severe, uncontrolled hypertension without acute or ongoing end-organ damage is typically defined as a *hypertensive urgency*. This type of patient can be managed vigilantly on an outpatient basis with the aim to reduce blood pressure within 1 to several days.

The incidence of uncontrolled and severe hypertension has been significantly reduced in the United States over the past few decades, driven by increased awareness regarding the importance of managing high blood pressure as an outpatient. In fact, the seventh report of the Joint National Committee (1) demonstrated this improvement in control rates for hypertension (systolic BP <140 mm Hg and diastolic BP <90 mm Hg). Because of this progress, hypertensive emergencies now occur in less than 1% of the hypertensive population (2). Despite these successes, however, many Americans remain unaware of their hypertension, and hypertensive urgencies continue to be relatively common.

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

Patients presenting with severe hypertension (>180/110 mm Hg) are usually asymptomatic. On the rare occasion at which the patient becomes symptomatic or has evidence of acute target-organ injury, it becomes an “emergent” syndrome. There is no “typical” presentation; emergent hypertension can present with symptoms ranging from headaches, visual disturbances, confusion, weakness, and seizures to chest pain and shortness of breath.

Initial Evaluation

The history is an important first step in determining the level of urgency. The focus should be on eliciting cerebrovascular or cardiac symptoms. Questions that should be priorities are those regarding cardiovascular decompensation (myocardial ischemia, acute pulmonary edema, or aortic dissection), central nervous system compromise (encephalopathy, cerebral hemorrhage, or ischemic stroke), and acute renal failure. Other important details include a previous history of hypertension, current medications including oral contraceptives, drug abuse (e.g., cocaine), alcohol intake, smoking, peripheral vascular disease, and pregnancy. If the history is unrevealing, pain or anxiety can also elevate blood pressure and need to be excluded.

The physical examination first should establish that the elevated blood pressure reading is accurate. Inaccurate measurement is a simple but common issue in severe hypertension. A large sphygmomanometer bladder should be used if the arm circumference exceeds 32 cm; during the measurement, the arm should be at heart level. Second, the physical

Grade IV Keith-Wagner retinopathy—papilledema

Miscellaneous

Eclampsia
Dissecting renal artery
Adrenergic crisis (pheochromocytoma, cocaine, monoamine-oxidase inhibitors with tyramine interactions, hyperthyroidism)

examination should focus on signs of acute end organ damage. Examinations that should be expedited are funduscopic (flame hemorrhages, exudates, and papilledema; Figure 48.1 A, B), cardiovascular (S_3 gallop, rales, or new regurgitant murmur), renal (abdominal or flank tenderness associated with a dissecting artery), and neurologic (focal signs).

Laboratory investigations should include an electrocardiogram (ECG). This will alert the physician to underlying ischemia/infarction, conduction abnormalities, and electrolyte disturbances (e.g., hyperkalemia) and guide the optimal form of therapy, which should begin immediately. Serum electrolytes, blood urea nitrogen, creatinine, and hematocrit should be ordered at the time of presentation. A urinalysis should assess for proteinuria, red blood cells, and red cell casts. A chest radiograph should be performed to assess for pulmonary vascular congestion (which should first be established clinically) as well as for a widened mediastinum that may be due to aortic dissection. It should be emphasized, however, that therapy should be instituted immediately after obtaining the focused history, physical examination, and electrocardiogram without waiting for the results of these other tests.

Other radiographic or biochemical evaluations should be performed, depending on the emergency at hand. For example a computed tomographic scan of the chest or a transesophageal echocardiogram may be necessary to exclude an aortic dissection (Chapter 49). Computed tomography would be warranted if neurologic symptoms are present and especially to differentiate between hemorrhage and ischemia (Chapters 116 and 117). A urine toxicology screen to exclude cocaine or amphetamine overdose is pertinent in a patient who appears clinically to have excessive sympathetic nervous system activity.

Diagnostic investigations for secondary hypertension should also be considered at the time of presentation. Urine collection of catecholamines, metanephrines, and VMAs also can be initiated if the suspicion of a pheochromocytoma exists. Persistent tachycardia and widened pulse pressure may alert a physician to send thyroid function tests. Captopril renography and measurement of plasma renin activity may be useful in a patient who has an abdominal

Figure 48.1 Effects of malignant or accelerated hypertension on the retina. **A.** The fundus shows marked hemorrhage and infarction. **B.** The fundus shows loss of integrity of the optic disc with papilledema. These findings on physical examination indicate acute target injury regardless of the level of blood pressure.

Figure 48.2 Aortogram in a young man who presented with malignant hypertension, seizures, and hematuria. The right renal artery shows an acute and spontaneous dissection that led to right renal ischemia/infarction and renin-dependent hypertension. Initially, blood pressure was controlled with intravenous enalaprilat and labetalol. This patient later underwent right nephrectomy and has been normotensive for 6 years postoperatively.

bruit, significant peripheral vascular disease, worsening renal function on an angiotensin-converting enzyme inhibitor, or severe flank pain, all of which may be signs of renovascular hypertension, including renal artery dissection (Figure 48.2). Unprovoked hypokalemia during the course of hospitalization should be evaluated by obtaining paired serum aldosterone and plasma renin activity measurements, though hyperaldosteronism only rarely presents with severe, accelerated hypertension.

Indications for Hospitalization

A spectrum of clinical manifestations warrants emergent treatment and hospitalization (Figure 48.3). Patients who present with severe elevations in blood pressure but who have no evidence of acute target organ damage and appear to be reliable usually do not require hospitalization; they can be managed as outpatients with careful and early follow-up (within 10 days after the initial presentation).

Initial Therapy

Hypertensive emergencies should be treated in an intensively monitored environment. In a patient with suspected hypertensive encephalopathy, therapy should be instituted immediately prior to any diagnostic testing other than an electrocardiogram. Placement of an arterial line is appropriate in individuals for whom continuous readings are

necessary. However, most patients can be managed with noninvasive blood pressure recorders or traditional sphygmomanometry. Ideal drug therapies are medications that have a rapid onset of action, are short-acting and easy to titrate, have a predictable dose-response curve with minimal side effects (in particular, they do not alter the patient's mental status), and do not induce significant reductions in cerebral, renal, or coronary blood flow.

Blood pressure reduction should be performed quickly but with caution so as not to alter cerebral blood flow too rapidly and cause deterioration of neurologic symptoms. *Normalization of blood pressure need not be achieved and should not be the aim of therapy for hypertensive urgency or emergency.* Cerebral autoregulation of blood flow in normotensive patients occurs between mean arterial pressures (MAPs) of 50–150 mm Hg (MAP = diastolic blood pressure + $1/3$ [systolic blood pressure – diastolic blood pressure]). If blood pressure falls below the lower limit of autoregulation (typically 25% below the pretreatment MAP), the brain extracts more oxygen from the circulation to compensate for the reduction in blood flow until a point may be reached at which ischemic damage ensues. The dangers of precipitously lowering the blood pressure include serious complications such as blindness, stroke, coma, or even death.

In elderly hypertensive patients and patients with cerebrovascular disease, adaptive changes in cerebral blood flow cause higher MAPs to become the lower limit of autoregulation (Figure 48.4). Hence, care should be taken to avoid marked reductions that dangerously reduce blood pressure below that lower-limit set point for autoregulation. Intravenous medication is recommended initially either by constant infusion or by repeated small injections to give a rapid pharmacologic onset and a controlled duration of action (Table 48.2). The general consensus is that *the blood pressure reduction for the first several hours should not be more than 20% of the resting MAP that is observed on admission.* During this time, neurologic status should be closely monitored; if it deteriorates, the rate of administration of the antihypertensive drug should be reduced to allow the MAP to recover. Although certain conditions of ongoing end-organ damage may demand a more rapid reduction in blood pressure (e.g., cardiac ischemia, aortic dissection, pulmonary edema, and hypertensive encephalopathy), the physician should be cognizant of the patient's neurologic status at all times.

Specific Drug Therapies

Sodium nitroprusside, a potent vasodilator and venodilator, is the time-tested drug for management of hypertensive emergencies, because of its high (80%) rate of efficacy. However, hypotension, reflex tachycardia, and thiocyanate toxicity are clinically significant adverse effects of this drug. Thiocyanate toxicity is more likely to occur in patients with renal insufficiency, prolonged use (>48 hours) of the

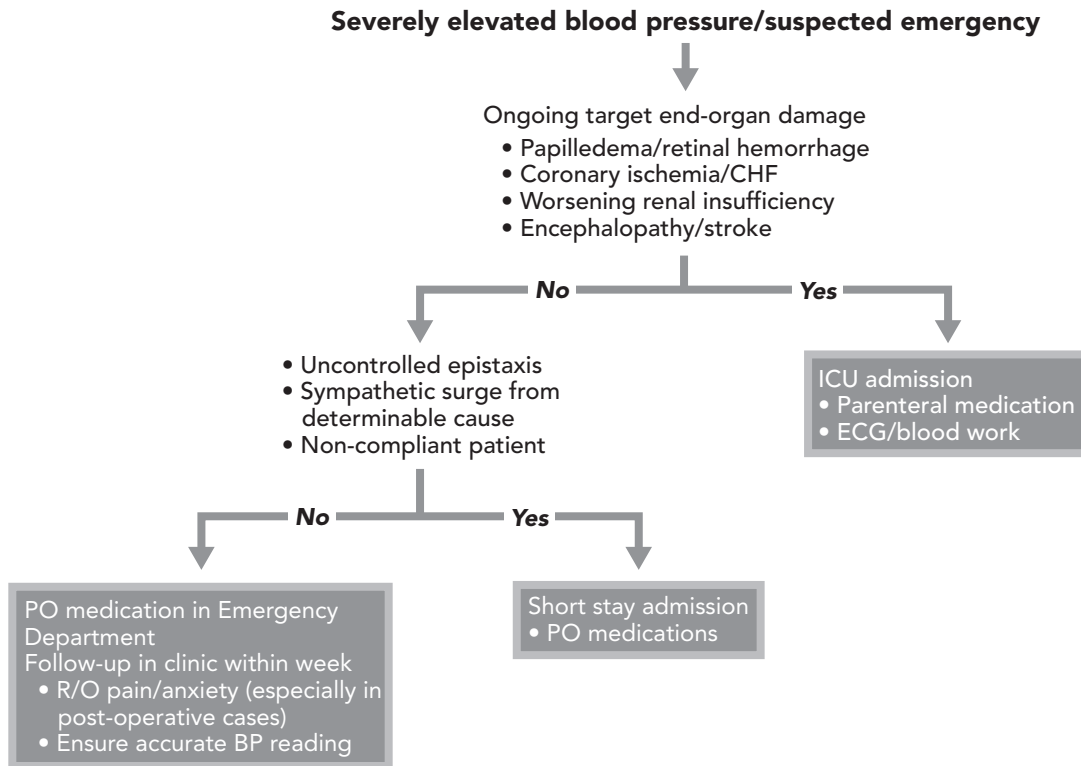

Figure 48.3 Triage of the severely hypertensive patient. The presence of severe and acute target organ injury requires admission to a critical care unit, laboratory evaluation, and immediate or nearly immediate blood pressure lowering with parenteral therapy. Severely hypertensive patients with symptoms who lack overt target organ injury should be placed in observation units until stable. Most other patients with severe hypertension can be managed with close follow-up in the ambulatory setting. *BP*, blood pressure; *CHF*, congestive heart failure; *ECG*, electrocardiogram; *ICU*, intensive care unit; *PO*, oral.

Figure 48.4 Autoregulation of cerebral blood flow. Cerebral blood flow is autoregulated as a protective mechanism. However, if systemic arterial pressure is accelerated to extremely high values, this autoregulatory process is lost and cerebral edema may occur. Loss of autoregulation in normotensive individuals occurs at lower levels of systemic mean arterial pressure than in hypertensive patients.

medication, and plasma thiocyanate levels exceeding 1.7 mmol/L (3). Manifestations of the toxicity include nausea, vomiting, headache, delirium, and psychosis. Infusion rates of sodium nitroprusside need to be started at 0.1–0.2 mcg/kg/min and meticulously monitored; maximal rates of infusion are 2.0 mcg/kg/min.

Fenoldopam is a newer intravenous dopaminergic agonist that dilates most vascular beds but has its greatest effects in the splanchnic and renal vessels. Thus, it is a potent renal and systemic vasodilator that lowers the MAP promptly and smoothly, comparable to the effects of sodium nitroprusside (4). Unlike sodium nitroprusside, fenoldopam does not cause as large an increase in heart rate, because of its limited action on α - and β -agonist receptors. In addition, fenoldopam is associated with a natriuresis that makes it useful for patients with heart failure or renal failure and that may obviate the need for a loop diuretic in some patients (5). Despite these small advantages, sodium nitroprusside remains the first line agent in most settings, in large part because it is substantially less expensive.

TABLE 48.2**PARENTERAL ANTIHYPERTENSIVE MEDICATIONS RECOMMENDED FOR HYPERTENSIVE EMERGENCIES**

Medication	Dosage	Mechanism of action	Onset-duration of action	Special indications	Cautions and contraindications
For general use					
Sodium nitroprusside (Nipride)	0.2–10 mcg/kg/min; increase at rate of 0.05 mcg/kg/min q15 min to meet BP goal	Arterial and venous vasodilator	1–2 min/10 min	Encephalopathy, stroke/bleed MI/heart failure/aortic dissection (with β -blockers)	Pregnancy; caution in renal failure due to thiocyanate toxicity; methemoglobinemia, muscle twitching, hypotension; delivery system must be light-resistant
Fenoldopam mesylate (Corlopam)	0.1–1.7 mcg/kg/min; increase at rate of 0.1 mcg/kg/min q20 min to meet BP goal	Dopamine (D1) receptor agonist—systemic and renal vasodilator	1–5 min/10 min	Renal insufficiency; postoperative and all other hypertensive emergencies	May increase intraocular pressure and should be used with caution in glaucoma; flushing
Labetalol hydrochloride IV (Normodyne, Trandate)	5–10 mg IV bolus q10 min or 0.5–2.0 mg/min; total dose: 300 mg/d	α - and β -receptor blocker; IV ratio: 7:1; oral ratio: 3:1	5–10 min/1.8–6 h	Hyperadrenergic syndromes: cardiac and cerebral events, eclampsia, MAO inhibitor—tyramine interaction	2nd-degree or greater heart block, bronchoconstriction, orthostatic hypotension; sick-sinus syndrome
For special situations					
Diltiazem (Cardiazem)	0.25 mg/kg over 2 min as a bolus; repeat in 15 min or 5–15 mg/h infusion	Calcium-channel blocker	2–5 min/12 h	Atrial fibrillation and supraventricular tachycardia	2nd-degree or greater heart block
Nitroglycerin IV	5–200 mcg/min	Venodilator: coronary arteries and veins	2–5 min/3–5 min	Unstable angina, MI	Methemoglobinemia headache; tachycardia; special delivery system due to drug binding to tubing; BP effects are variable
Furosemide (Lasix)	20–120 mg q6 hourly not to exceed 600 mg/d	Loop diuretic	15 min/6 h	Congestive heart failure/volume-overload states	Ototoxicity; prerenal azotemia
Enalaprilat (Vasotec)	0.625–1.25 mg q6–8 h	Angiotensin-converting enzyme inhibitor	30 min/4–6 h	Most useful in high renin states, e.g., renal artery stenosis	Bilateral renal-artery stenosis; hyperkalemia; contraindicated in pregnancy
Hydralazine hydrochloride (Apresoline)	IV: 5–20 mg slowly at 1 mg/min; IM: 10–50 mg	Vasodilator: Arterial > venous	IV: 10–15 min, IM: 20–30 min/IV: >1 h, IM: 4–6 h	Eclampsia, severe hypertension during pregnancy	Tachycardia, increase in dp/dt, increase in intracranial pressure; avoid in aortic dissection, central nervous system, or cardiovascular complications
Phentolamine (Regitine)	1–5 mg IV q5–15 minutes	Nonselective α -receptor blocker	2–5 min/30–120 min	Drug of choice in pheochromocytoma; MAO inhibitor—tyramine interaction	Tachycardia and increase in dp/dt; orthostatic hypotension
Nicardipine IV (Cardene)	Infusion at 2–4 mg/h and increase by 1–2.5 mg/h to maximum of 15 mg/h	Dihydropyridine calcium-channel blocker	10–15 min/short until 12 h or infusion, then >4 h	Cyclosporine-induced hypertension, similar spectrum to sodium nitroprusside	Increases intracranial pressure

BP, blood pressure; dp/dt, change in pressure per change in time; IM, intramuscular; IV, intravenous; MAO, monoamine oxidase; MI, myocardial infarction.

TABLE 48.3
ORGAN-SPECIFIC DISEASE AND THERAPY

End-organ damage	Incidence (%) (6)	Recommended treatment	Medications to be avoided
Cerebral infarction	24.5	No treatment (7), SNP, fenoldopam, labetalol	Clonidine and α -methyldopa (because of central nervous system depression)
Encephalopathy	16.3	SNP, fenoldopam, labetalol	Clonidine and α -methyldopa
Intracerebral/subarachnoid hemorrhage	4.5	No treatment (6), SNP, fenoldopam, labetalol	Clonidine and α -methyldopa
Myocardial ischemia/infarction	12.0	NTG, labetalol, SNP, fenoldopam	Hydralazine, diazoxide, minoxidil
Acute pulmonary edema	14.3	Fenoldopam, SNP with loop diuretic, NTG with loop diuretic	Hydralazine, diazoxide, minoxidil
Aortic dissection aortic valve and arch beyond aortic arch	2.0	Surgery SNP with β -blocker, labetalol	Hydralazine, diazoxide, minoxidil
Eclampsia	4.5	Labetalol, hydralazine, calcium channel blockers, diazoxide	Diuretics, β -blockers, trimethaphan, angiotensin-converting enzyme inhibitor
Acute renal failure	NA	Fenoldopam, labetalol, and SNP (with caution)	β -blocker (reduce glomerular filtration rate), trimethaphan
Keith–Wagner III/IV changes (Figure 48.1)	NA	Fenoldopam, SNP, labetalol, calcium-channel blockers	Clonidine, α -methyldopa, β -blockers
Microangiopathic hemolytic anemia	NA	Fenoldopam, SNP, labetalol, calcium-channel blockers	β -blockers

NA, not available; NTG, nitroglycerin; SNP, sodium nitroprusside.

Patients who present with specific causes of hypertensive urgencies and emergencies may benefit from specific types of medications (Table 48.3) (6, 7). *Labetalol*, an α - and β -blocker, is especially useful in patients with ischemic heart disease. Labetalol or pure β -blockers are also indicated to control or reverse the reflex tachycardia often induced by nitroprusside. Although *nitroglycerin* is not generally as effective as nitroprusside, it may be preferable in patients with unstable angina or myocardial infarction because it better maintains blood flow to ischemic myocardium.

Diuretics should be administered only if fluid overload is evident on examination. If diuretics are administered to hypertensive patients who are volume-depleted, they cause more harm (such as a precipitous drop in blood pressure) than benefit.

Nifedipine has an unreliable dose-response curve and is *not* recommended for urgent or emergent hypertension. The once-popular use of sublingual nifedipine, in particular, is dangerous and should be abandoned.

Indications for Early Consultation

A consultant is not always necessary unless there is failure to respond to initial therapy or an issue regarding the appropriate diagnostic evaluation. In some cases, cardiology, nephrology, or neurology consultation may be appropriate depending on the primary manifestations of target organ injury.

ISSUES DURING HOSPITALIZATION

As with many other medical emergencies, the initial therapy is of great importance. The patient should be kept fasting in view of possible pending procedures or because of suboptimal or wavering mental status. The patient should remain in the ICU for approximately 24–48 hours before transfer to a regular medical floor. The critical care pathway for each patient must be individualized according to the type of end-organ damage involved. For example, a patient

TABLE 48.4
WHAT TO THINK ABOUT IF THE PATIENT FAILS TO IMPROVE AS EXPECTED

Causes	Indicators	Tests	Treatment
Secondary HTN Pheochromocytoma	Flushing, palpitations, persistent tachycardia, episodic/severe elevations in blood pressure, worsening on β -blockers alone, significant improvement on α -blockers	24-h urine for catecholamines, magnetic resonance imaging of adrenal gland with “light bulb” effect on T2-weighted images	α -blockers, β -blockers if tachycardic, surgery
Renal-artery stenosis/dissection (Figure 48.2)	Abdominal bruit, flank pain; premorbid indicators: AODM, PVD, smoking Hypercholesterolemia	Plasma renin activity, captopril renal scan, renal arteriogram	Angiotensin-converting enzyme inhibitor, angioplasty, surgery
Hyperaldosteronism	Persistent/unprovoked hypokalemia	Plasma renin activity Serum and urine aldosterone	Medication: spironolactone, eplerenone, amiloride Surgery (if adenoma)
Use of drugs (e.g., cocaine)	Hyperthermia, mydriasis, agitation, chest pain, nasal mucosal injury/lesions	Urine toxicology screen	α - and β -blockers in combination
Problems with the delivery system	Ensure adequate dosing—errors commonly made with IV infusions Light-resistant system for sodium nitroprusside Special tubing for IV nitroglycerin	Check infusion concentrations and rates	Improve delivery system (Chapter 21)

AODM, adult-onset diabetes mellitus; BP, blood pressure; dp/dt , change in pressure per change in time; IM, intramuscular; IV, intravenous; MAO, monoamine oxidase; MI, myocardial infarction; PVD, peripheral vascular disease.

with myocardial ischemia or infarction follows a specific pathway that addresses blood pressure reduction in the face of ischemia and potential left-ventricular dysfunction. Failure to respond to common therapies should always alert the physician to the possibility of secondary forms of hypertension (Table 48.4).

Although blood pressure need not be normalized prior to discharge, there should be substantial improvement in blood pressure and reversal or stabilization of target organ damage. Inpatient education is essential, as most patients are either newly diagnosed or noncompliant. Emphasis should be placed on the fact that medications are likely to be required for the rest of the patient’s life, with grave danger of repeated cardiovascular or cerebrovascular insults if the patient is noncompliant. Detailed written instructions regarding discharge medications should be reviewed with the patient and family. Long-acting drugs with once- or twice-a-day dosing promote compliance.

Patient-directed home blood pressure monitoring using automated devices should be strongly considered. These devices facilitate the management of the hypertension and require the patient to take more responsibility for his or her care. If home monitoring is not an option (i.e., because of lack of patient motivation or resources), other mechanisms may be established to assist in blood pressure monitoring. Early follow-up (within 2–10 days) is recommended after discharge.

ASSESSMENT AND MANAGEMENT OF A PATIENT WITH “URGENT” HYPERTENSION DURING A HOSPITALIZATION

The initial evaluation of an urgently hypertensive patient already admitted to the hospital is similar to the evaluation for an outpatient. The most common in-hospital scenario is the postoperative patient. Severe hypertension can occur as the patient awakens and as the discontinuation of positive pressure ventilation permits a sudden increase in venous return. Preferred medications in the postoperative period include intravenous labetalol or enalaprilat in repeated scheduled bolus injections. Transdermal clonidine is also a practical option but takes 1–2 days before blood pressure is effectively lowered. Nifedipine capsules and hydralazine are not recommended. Analgesia should be a priority because excessive sympathetic nervous system activity associated with pain often increases blood pressure and heart rate.

Another type of urgent hypertension encountered in the hospital is seen in post-transplant patients receiving immunotherapy (high-dosage corticosteroids or cyclosporine) who develop elevations in the blood pressure secondary to their disease processes or treatment. Elevations in blood pressure may demand urgent attention, because of severe accompanying thrombocytopenia. Volume status should be evaluated, as fluid overload is common in these patients

and responds well to loop diuretics. Cyclosporine produces widespread vasoconstriction and severe hypertension that responds best to dihydropyridine calcium channel blockers (e.g., nifedipine, amlodipine, nicardipine). By comparison, verapamil and diltiazem increase cyclosporine levels and may precipitate hepatotoxicity and nephrotoxicity; they should not be used in this setting. If the patient is unable to take medication orally, intravenous nicardipine is preferred. Angiotensin-converting enzyme inhibitors typically produce a limited response because the renin-angiotensin system is already suppressed (9). Labetalol may be used alone or in combination with the dihydropyridines.

COST CONSIDERATIONS

A patient with a hypertensive emergency can incur a significant cost, primarily because of the ICU stay in the initial 24–48 hours. Of note, fenoldopam is 25–50 times more expensive than sodium nitroprusside or labetalol. Of course, the most cost-effective maneuver is prevention, which is best assured by patient education and adherence to chronic antihypertensive therapy.

KEY POINTS

- Hypertensive emergencies are diagnosed not on the absolute blood pressure value but by clinical evidence for acute target-organ damage.
- Hypertensive urgencies can be managed as an outpatient with vigilant follow-up.
- Treatment should be immediate and not be delayed while awaiting laboratory results.
- The goal of initial therapy is to reduce blood pressure by 20% of the original MAP and not necessarily to achieve a normal (<140/90 mm Hg) blood pressure rapidly.
- Fenoldopam, a parenteral dopamine-1 agonist, is as effective as sodium nitroprusside and induces less reduction in renal blood flow; however, it is much more costly.
- Short-acting nifedipine is not indicated or approved by the U.S. Food and Drug Administration for hypertensive

urgencies or emergencies and may cause excessive hypotension.

- Patient education regarding lifelong therapy and compliance should be started in the hospital, because of the significant morbidity and mortality rates associated with the disease.

Aortic Intramural Hematoma and Dissection

Lee Goldman

INTRODUCTION

Diseases of the aorta include intramural hematoma, aortic dissection, and aneurysms of the thoracic and abdominal aorta. Hematoma or dissection can involve the ascending aorta, aortic arch, or descending aorta. Because not all aortic hematomas or dissections result in aneurysmal dilatation of the aorta, the terms *aortic intramural hematoma and dissection* are preferred to “dissecting aneurysm”. Aneurysms of the thoracic and especially the abdominal aorta commonly occur in the absence of dissection; such aneurysms are discussed in Chapter 50. The key clinical challenges are to suspect aortic hematomas and dissection from the patient’s symptoms, to diagnose them expeditiously, and to treat the patient rapidly and appropriately.

AORTIC DISSECTION AND INTRAMURAL HEMATOMA

In *dissection of the aorta*, there is a sudden tearing of the intima of the aorta, with communication between the false and the true aortic lumens (Figure 49.1). The phasic aortic pressure waves then are delivered directly into the false lumen, tearing the media down the aorta, compromising arterial branches that arise from it, and creating ischemia of organs and tissues that these vessels supply. With external rupture of the adventitia, there is hemorrhage and, frequently, rapid death. *Intramural hematoma* is also a

potentially lethal condition because of the possibility of additional hemorrhage within the arterial wall, which is thought to be most commonly caused by rupture of the vasa vasorum. Although no intimal tear is initially present, the hematoma can extend to compromise distal vessels and the organs they supply. It can also rupture either into the lumen, hence becoming a more typical aortic dissection, or externally. In 10% of patients who die, only an intramural hematoma is found. These patients, who are increasingly diagnosed by noninvasive imaging, would be missed by angiography because they lack an intimal tear. The increasing recognition of intramural hematomas suggests that, in many patients with aortic dissection, formation of the hematoma is the initial event (i.e., it precedes tearing of the abnormal media and later rupture into the aortic lumen). In some patients, however, it is still possible that the initial event is an intimal tear.

The clinical picture is determined by the organs made ischemic by compromised blood vessels and by the place at which an aortic rupture occurs. *Proximal hematomas and dissections* involve the ascending aorta with or without distal dissection; *distal hematomas or dissections* are defined as those that do not involve the ascending aorta.

Because the driving force for dissection is the left-ventricular systolic pressure, the rate of rise of the aortic pressure (dP/dt) and the aortic systolic pressure itself are the two major determinants of progression. It is common for dissection to proceed and suddenly stop, only to begin again.

Issues at the Time of Admission

Clinical Presentation

Hematomas and dissection of the aorta are seen most commonly in the fifth through the seventh decades of life. They occur twice as often in men as in women, and most patients have a history of hypertension or are hypertensive. In younger patients, dissection usually is seen either with a connective tissue disorder, commonly Marfan's syndrome or Turner's syndrome, or in women in association with a pregnancy. Other disorders that predispose to aortic dissection include bicuspid aortic valve, coarctation of the aorta, and, to a much lesser degree, aortic stenosis.

The most common presenting symptom for intramural hematoma and dissection is *pain*, which occurs in about 90% of cases (1–3) (Table 49.1). The pain, which usually is described as sudden in onset and extremely severe, often is described as “tearing” or “ripping”. It usually occurs in or radiates into the regions in which the aorta is involved. The pain is frequently in the anterior precordium or substernal area and, less frequently, in the interscapular area, the epigastrium, and the lumbar region.

Figure 49.1 Angiogram in the left anterior oblique view, injection into the left ventricle. The catheter is passed through a patent foramen ovale into the left atrium and then into the left ventricle. The patient is a 62-year-old nurse with severe anterior chest pain. The angiogram shows a proximal dissection with the false lumen less opacified than the true lumen. Notice the radiolucent flap of the dissected aorta with contrast on both sides (*black arrowhead*); this finding is pathognomonic of aortic dissection. The total aortic diameter is normal, not aneurysmal, and the true lumen is compressed.

Frequently the pain mimics that of an acute myocardial infarction. Features that help to distinguish an aortic dissection are that the pain frequently begins abruptly at its maximum degree without the gradual build-up in severity seen with an acute myocardial infarction, and that the pain can start in one or more locations and move from one area to another as the aortic dissection progresses (Chapters 35 and 38). At times, the prominent symptom of dissection is that of a myocardial infarction (caused by occlusion of an arterial branch), abdominal or back pain (caused by splenic or renal artery occlusion), or arm or leg pain (caused by subclavian artery or femoral artery occlusion).

In the minority of patients in whom pain is not a prominent feature, *neurologic involvement* is common and may explain the absence of pain. A classic stroke can occur. Alternatively, the patient may present with syncope, which can be neurologic or can signify acute cardiac tamponade resulting from rupture of the ascending aorta into the pericardial sac (Chapters 44 and 46).

The final event is the *external rupture*. Because the proximal two-thirds of the ascending aorta is intrapericardial, there is no external compression on the adventitia; cardiac tamponade occurs rapidly and is usually fatal. The next most frequent site of rupture, the descending thoracic aorta, results in mediastinal hematoma or bleeding into the left pleural cavity causing a left pleural effusion. Rupture also can occur retroperitoneally or into the abdominal cavity.

On physical examination, the classic description is the patient with chest pain or back pain who is pale and sweaty, appears to be in shock, and sometimes has elevated blood pressure. In proximal dissection, aortic regurgitation occurs about half the time. Because the dissection spirals around the aorta and because some of the vessels are supplied from the false lumen, about 30% of patients have arterial pulse deficits. As the intramural hematoma progresses, the pressure in the false lumen can change abruptly, decreasing compression of the true lumen as the false lumen collapses; as a result, arterial pulses may be present at one time and absent at the next examination.

Younger patients with dissection are more likely to have Marfan's syndrome, a bicuspid aortic valve, or prior aortic surgery, and less likely to be hypertensive (4). Older patients are more likely to have hypertension, known atherosclerosis, and a prior aortic aneurysm (5).

Differential Diagnosis and Initial Evaluation

If aortic dissection is suspected clinically, immediate evaluation is required. In about 65% of patients, the chest radiograph is abnormal, with dilatation of the ascending aorta, dilatation of the aortic knob, or lateral bowing of the descending aorta (Figure 49.2). However, all these findings are relatively common in elderly patients without dissection because they can result from atherosclerosis with lengthening and uncoiling of the aorta. Overall, the finding of an enlarged aorta on the chest radiograph increases the

TABLE 49.1

likelihood of dissection two-fold, but the absence of enlargement does not exclude dissection.

With transesophageal echocardiography, it is possible to visualize the entire ascending aorta, part of the arch, and the entire descending thoracic aorta (Figure 49.3). CT with contrast, especially spiral CT, can picture the entire aorta from the origin to the iliac bifurcation. Magnetic resonance imaging (MRI) provides an excellent view of the entire aorta without the use of contrast (Figure 49.4). Whereas in classic dissection the key finding is the intimal flap, in intramural hematoma, the characteristic appearance is that of high signal intensity in the aortic wall (Figure 49.5). With MRI, however, the imaging time is longer and the patient is relatively inaccessible to treatment during imaging.

Because each of these techniques has about the same sensitivity and specificity (both about 95%) for dissection, if one study is negative and there is still strong suspicion that the patient has aortic dissection, a second imaging technique should be used. If, however, suspicion is low-to-moderate for aortic dissection, then a negative study is sufficient to exclude the diagnosis (Chapter 6). *Angiography* is

Figure 49.2 Chest radiograph, posteroanterior view. A 70-year-old man entered the hospital with tearing anterior chest pain. Notice the large aortic knob. The *open black arrow* indicates intimal calcification. The *small white arrow* indicates the outside wall of the aorta. The 6-mm thickness of the aortic wall between the arrows is consistent with blood in the false lumen of an aortic dissection.

Figure 49.3 Transesophageal echocardiogram, long axis view. *Small arrows* indicate aortic leaflets, the *large arrow* indicates intimal flap in the ascending aorta just above the sinus of Valsalva. A, left atrium; V, left ventricle.

Figure 49.4 Magnetic resonance imaging; horizontal section at the level of the ascending aorta and the right pulmonary artery as it passes posterior to the ascending aorta. The *large arrow* indicates dissected intimal flap in the ascending aorta; the *small arrow* indicates dissected intimal flap in the descending aorta. This patient had a proximal aortic dissection. r, right pulmonary artery.

Figure 49.5 An aortic intramural aortic hematoma. In the acute phase, MRI shows a high signal intensity suggestive of intramural hematoma. Top, sagittal view demonstrates the hematoma in the upper and middle third of the descending thoracic aorta; bottom, the intramural hematoma is seen as a crescent in the axial view. This particular hematoma, which was observed without surgical treatment, later progressed (over 4 years of follow-up) to localized dissection and formation of a pseudoaneurysm.

(Reprinted with permission from Evangelista A, Dominguez R, Sebastia C, et al. Long-term follow-up of aortic intramural hematoma: predictors of outcome. *Circulation* 2003;108:583–589).

not the gold standard because its sensitivity is too low for dissection and it is not good at detecting intramural hematoma.

Indications for Hospitalization

All patients with suspected acute or chronic aortic dissections, either proximal or distal, should be admitted to the hospital unless the diagnosis can be excluded effectively by an evaluation in the emergency department. It is critical that blood pressure be lowered aggressively and that the

patient be placed on β -blockers to eliminate reflex sympathetic stimulation while the diagnosis is being actively considered and until it has been excluded.

Indications for Initial Intensive Care Unit Admission

An ICU admission is indicated in patients with proximal aortic intramural hematomas or dissections if they cannot be taken immediately to the operating room from the emergency department. In patients with distal hematomas or dissections, ICU admission is required if there is ongoing pain, ischemia of vital organs, or other complications. In most hospitals, ICU care is indicated to monitor the intravenous medications or intra-arterial catheters required to achieve strict blood pressure control; in some hospitals, however, a step-down unit may suffice if blood pressure control has been achieved rapidly and if nursing capabilities are sufficient to monitor intravenous medications and blood pressure.

Treatment

While the diagnosis is being established, *all patients should be started on β -blockers and, if needed, vasodilators*, unless there is an absolute contraindication. Intravenous morphine should be given for pain relief. Labetolol, a combined α - and β -blocker, is an excellent first choice as an IV bolus of 5–10 mg followed by 0.5–2 mg/min. Alternatively, propranolol is administered intravenously in 0.5-mg increments at 1- to 5-minute intervals until target blood pressure of 100–110 mm Hg is reached or a total dose of 0.15 mg/kg of body weight has been given. Alternatively, metoprolol can be given intravenously as 5 mg every 5 minutes for 3 doses, then 25–50 mg 3 times per day orally. Intravenous esmolol has a rapid onset and offset of action; it must be

diluted to a concentration of no more than 10 mg/mL because of venous irritation. An initial intravenous loading dose of 0.5 mg/kg is given over 1 min, followed by an infusion of 0.05 mg/kg/min. The infusion rate can be increased every 4 minutes by 0.05 mg/kg/min, up to 0.3 mg/kg/min. If β -blockers alone do not reduce systolic blood pressure to 100–110 mm Hg, intravenous nitroprusside should be added to reduce blood pressure promptly, starting at 0.5 mcg/kg/min and increasing gradually up to 10 mcg/kg/min until the target blood pressure is achieved.

Patients with *proximal* aortic dissections have a high risk of early life-threatening complications (Table 49.2) and should undergo immediate operative repair unless there are absolute contraindications. Risk factors for death include age over 70 years, abrupt onset of pain, renal failure, abnormal electrocardiogram, a pulse deficit, or the presence of hypotension, pericardial tamponade, or shock (6). For *proximal intramural hematomas*, resorption without progression to clinical complications may occur in half to two-thirds of patients (7, 8). Although the likelihood of progressive dissection or other complications is lower than in patients with hematoma than in those who initially present with a frank dissection (particularly in patients with smaller hematomas and normal aortic dimensions) (9, 10), the 25%–50% risk of progression has led many experts to recommend early surgery. However, a strategy of serial follow-up imaging studies, with surgery reserved for those who progress, may be a reasonable alternative, especially in patients who are elderly or have comorbid conditions that increase the risk of surgery (11, 12). For *distal* hematomas or dissections, medical management is reasonable if there are no secondary complications and the aorta stabilizes without marked dilatation, especially if the patient has severe coronary artery disease; otherwise, surgical repair is indicated.

The goal of surgery for dissection is to eliminate the proximal intimal tear, at which most of the external

ruptures occur, and to close the false channel at this site. For ascending aortic dissections, surgery usually involves transection of the aorta at the proximal level of the dissection while on cardiopulmonary bypass, obliteration of the false lumen by suturing its inner and outer walls, and placement of a graft beyond the dissected aorta to the takeoff of the innominate artery (13, 14). If the aortic valve is prolapsed, it can be successfully resuspended by sewing the commissures to the proximal graft. Other patients may require a prosthetic valve or, if the dissection extends into the sinuses of Valsalva, a composite tube graft with an aortic valve and reimplantation of the coronary arteries. The likelihood of being alive without further events with medical management can be as high as 70% at 8 years for distal dissections (15), but is less than 50% at 5 years and only about 20% at 10 years for proximal dissection (16).

In the open surgical option for distal dissections, the aorta is transected proximal to the intimal tear, the false lumen is obliterated by suturing, and an interposed tube graft is placed. If the aortic dissection is chronic, then the interposed graft is sewed to the outer wall to allow the false lumen to be perfused in case important arteries might arise totally from the false lumen. Alternatively, endovascular exclusion and/or closure of the entry tear has been reported to have excellent results at 2–3 years for distal dissections in experienced centers (17, 18).

The surgical mortality rate in nonruptured aortic dissection is between 10% and 15%. By comparison, the in-hospital mortality rate after endovascular repair of distal dissections is reported to be about 4%.

Indications for Early Consultation

All patients with suspected or proven aortic intramural hematoma or dissection should have early consultation with a cardiologist to aid in diagnosis. As soon as there is strong supportive evidence from any testing modality, consultation with a cardiothoracic surgeon is mandatory. In hospitals without cardiothoracic surgery capabilities, arrangements should be made urgently to transfer the patient to a hospital with such capabilities as soon as the diagnosis is established.

Issues During the Course of Hospitalization

For aortic intramural hematomas or dissections that do not involve the ascending aorta or the aortic arch and are classified as distal dissections, outcomes are generally comparable for medical and surgical therapy. Surgical therapy can be reserved for patients with continued expansion of the aneurysm, uncontrolled pain, ongoing ischemia of organs supplied by compromised vessels, or saccular aneurysm formation. If observation is chosen for proximal intramural hematoma, observation and treatment in the hospital is similar as for distal dissections. Surgery is also recommended for patients with dissections resulting from Marfan syndrome, regardless of the location.

Some patients may be diagnosed as having “chronic” dissection of either the proximal or distal aorta. These patients, who are generally defined by being diagnosed more than 2 weeks after the presumed acute event, are usually reasonably stable at the time of diagnosis. For chronic proximal dissections, surgery is generally recommended if the patient has severe aortic regurgitation, a localized aneurysm, or symptoms related to compression of surrounding structures. For chronic distal dissections, symptoms or aneurysmal enlargement to >6.0 cm are indications for surgery.

During the hospital phase, *blood pressure control is critical*. The long-term goal should be to maintain ambulatory blood pressure at no more than 110 mm Hg, with an emphasis on β -blockers to reduce myocardial contractility. If β -blockers alone are insufficient, calcium channel blockers, which also decrease contractility, are recommended. Other medications utilized in patients with hypertension can be added as needed, with the exception that α -blockers should be avoided.

The reemergence of pain generally indicates ongoing dissection and the failure of medical therapy. In such situations, aggressive therapy similar to what is recommended at the time of admission must be instituted. Urgent surgery commonly is required.

Discharge Issues

Patients generally are ready for discharge after several days without pain and at least 1 day of desired blood pressure with oral medications. Plans must be made for careful outpatient follow-up to ensure strict blood pressure control. Usually a patient is followed by a cardiovascular specialist. Follow-up should include a chest radiograph every 3 months for the first year and a contrast CT scan or MRI every 6 months for the first 2 years and then annually thereafter. For distal dissections, progressive asymptomatic growth, especially with persistent blood flow in the false lumen, may be an indication for elective surgery (19). Blood pressure control should generally continue to emphasize β -blockers and calcium channel blockers, both of which have negative inotropic properties.

Of patients who survive hospitalization, about 80% survive for the next 5 years. Long-term complications include aortic regurgitation (in patients with proximal dissections), recurrent dissection, or formation of true or false aneurysms.

KEY POINTS

- Aortic dissection must be considered in any patient with acute chest pain, especially if it radiates to the back. Rapid evaluation includes assessment of any pulse or blood pressure deficits, a chest radiograph, and a sensitive diagnostic test (transesophageal echocardiography, CT, or MRI).

- Aortic dissection requires emergent blood pressure control and β -adrenergic blockade followed by emergent surgery for proximal dissections or complicated distal dissections and most proximal intramural hematomas; uncomplicated distal dissections and most chronic dissections and perhaps some proximal intramural hematomas can be managed medically.

Aortic Aneurysm

50

Frank A. Lederle

INTRODUCTION

Aortic aneurysm can develop anywhere along the course of the aorta, from the ascending aorta to the iliac bifurcation. The diameter of the aorta gradually decreases so that the descending thoracic aorta is only about two-thirds the size of the ascending aorta. The ascending and thoracic aorta have vessels called vasa vasora to nourish the aortic wall. As the thoracic aorta becomes the abdominal aorta, the vasa vasora diminish; nourishment of the abdominal aortic wall is mainly from the luminal blood. Because of the additive effect of transmitted pressure waves and waves reflected from the aortic bifurcation, systolic aortic pressure and thus the distending pressure of the aorta are higher in the abdominal aorta than more proximally. Aortic aneurysms are caused by the distending pressure on the aortic wall as well as the failure of material components of the wall.

Aortic aneurysms can be classified by their geometric shapes (fusiform [cylindrical] or saccular) and their extent (focal or diffuse). Aortic aneurysms can also be classified as false or true aneurysms. True aneurysms involve all three layers of the aortic wall; false aneurysms are contained aortic ruptures in which the wall of the aneurysm is formed by the aortic adventitia as well as adherent adjacent tissues (e.g., pleural and mediastinal).

Most aortic aneurysms result from an idiopathic degenerative process involving the elastin and collagen of the arterial media, probably related to matrix metalloproteinases released by macrophages (Table 50.1) (1). Aneurysms of the thoracic aorta also may be caused by connective tissue diseases, such as Marfan syndrome, or idiopathic aortitis, such as granulomatous aortitis and Takayasu's disease. Prior trauma also can cause a false aneurysm that usually occurs in the thoracic aorta just beyond the takeoff of the left subclavian artery. Syphilitic aortitis is now uncommon.

Ninety percent of abdominal aneurysms involve the infrarenal abdominal aorta, where an aortic diameter greater than 3.0 cm, as determined by ultrasound or computed tomography (CT), is abnormal. In the United States, aortic aneurysm result in 15,000 deaths per year, including those resulting from treatment, making it the 15th leading cause of death. Although thoracic and abdominal aortic aneurysms are indistinguishable on gross or microscopic pathology, thoracic aneurysms occur equally in men and women, whereas abdominal aortic aneurysms are four times more frequent in men than women. There are also genetic influences, as demonstrated by the six-fold increase in abdominal aortic aneurysms in first-degree relatives of patients with such aneurysms.

AORTIC ANEURYSM AND RUPTURE

Most aneurysms of the thoracic aorta, thoracoabdominal aorta, and abdominal aorta are totally asymptomatic until they rupture suddenly, at which time they are usually rapidly fatal. For aortic aneurysms at each of these locations, patients may present moribund, with refractory hypotension resulting from exsanguinating hemorrhage. Other patients may have pain and an incipient leak, which permits emergent surgery in a relatively stable patient. Still others are somewhere on a continuum between these two extremes. All patients with rupture require emergent evaluation, to confirm the diagnosis and determine the site of the leak, and emergent surgical repair. Surgery after rupture carries a 50% or greater mortality rate, whereas operation in the asymptomatic patient carries a low mortality rate.

By comparison, other patients may be diagnosed as having asymptomatic aortic aneurysms that either require serial follow-up evaluations or are large enough to mandate semi-elective surgery. These patients normally do not re-

Traumatic aneurysm
Dissection of the aorta

quire hospitalization or prolongation of an existing hospitalization, because most of the preoperative evaluation can be performed on an outpatient basis.

Non-traumatic aortic rupture is nearly always because of aneurysm. Dissection nearly always occurs in the thoracic aorta (Chapter 49). Thus, abdominal aortic aneurysms rupture, whereas thoracic aneurysms can either dissect or rupture with approximately equal frequency (2). The risk of dissection is increased by the presence of a thoracic aneurysm, but *about 80% of dissections occur in non-aneurysmal aortas*. Finally, about one-fourth of aortic dissections result in aneurysm, and chronic aortic dissection is the cause of about one-fifth of all thoracic aneurysms.

THORACIC AORTIC ANEURYSM

Thoracic aortic aneurysms can involve the aortic root (annuloaortic ectasia), the ascending aorta, the aortic arch, the descending aorta, and the thoracoabdominal aorta. The larger the aneurysm is, the higher the risk of leaking or rupture. Thoracic aneurysms are often detected in patients with a previously diagnosed abdominal aortic aneurysm.

Issues at the Time of Admission

Clinical Presentation

Although most thoracic aortic aneurysms are asymptomatic, ascending aortic aneurysms can cause signs or symptoms by their pressure on adjacent structures, such as the superior vena cava. Deep chest pain, described as throbbing or aching, is seen if there is erosion of ribs or vertebrae. Aneurysms of the aortic arch can involve the great vessels and cause ischemia of the organs they supply. Aneurysms of the aortic arch also can compress mediastinal

structures, the thoracic spine, or tracheobronchial structures and cause cough, dyspnea, or tracheal deviation. Pressure on the esophagus may cause dysphagia; stretch of the left recurrent laryngeal nerve may cause hoarseness. Aneurysms of descending aorta or thoracoabdominal aorta rarely compress any structures or cause symptoms until they rupture.

With rupture of a thoracic aneurysm, there may be massive cardiac tamponade (ascending aorta) or exsanguinating hemorrhage, usually into the left pleural cavity, depending on the site. Hemoptysis, sometimes intermittent over days or weeks, may occur if a descending aortic aneurysm is adherent to the lung and ruptures into it.

The physical examination is of little help in detecting thoracic aortic aneurysms unless they are very large or involve the aortic valve (causing aortic regurgitation). By the time a hemorrhagic pleural effusion can be detected by physical examination, the patient is usually *in extremis*.

Differential Diagnosis and Initial Evaluation

The differential diagnosis includes other causes of chest pain, hypertension, or thoracic mass. Aneurysms usually are suspected after examination of the chest radiograph: spherical aneurysms can deform the aortic silhouette, and cylindrical aneurysms can increase the mediastinal shadow and simulate a progressive uncoiling of the aorta.

With intimal calcification, which is very common in the elderly, it is possible to identify the lateral borders of the aorta and sometimes even the medial border. A calcified aortic aneurysm can be detected on the plain chest radiograph. The diagnosis of a thoracic aneurysm is usually confirmed by a spiral CT scan, MRI, transesophageal echocardiography, or aortogram.

Initial Therapy

Aneurysms that produce symptoms or are associated with bleeding should be treated emergently as impending rupture. The correct management of asymptomatic thoracic aneurysms is less clear. No randomized trials have compared early elective repair with surveillance, and data on natural history are limited. Nationwide, elective surgical treatment of thoracic aortic aneurysms carries a perioperative mortality rate of 20%–25% (3, 4), though centers that choose to publish their results tend to report much lower rates. The risks of dissection and rupture increase with the diameter of the aneurysm. A population-based study from Olmsted County, Minnesota, found a 5-year rupture risk of 0% for thoracic aneurysms smaller than 4.0 cm in diameter, 16% for those 4.0–6.0 cm, and 31% for those larger than 6.0 cm (5). The Yale prospective database of 721 patients with thoracic aortic aneurysm reported an annual rupture or dissection rate of 6.9% (2). Based on these natural history data, the Yale group has recommended elective repair of asymptomatic aneurysms larger than

6.5 cm in the descending thoracic aorta or 5.5 cm in the ascending aorta. However, these recommendations were based on a 9% operative mortality in their own series, or less than half the national average. The authors of the nationwide studies have recommended that these recommendations be re-evaluated (4). Others have recommended that elective repair be undertaken when the 1-year rupture risk exceeds the operative mortality (6). Using this criterion, there are insufficient data to recommend elective repair of thoracic aneurysms of any diameter. Better data, ideally from randomized trials, will be needed to resolve this issue.

Elective repair of thoracic aneurysms 5.5–6.5 cm may be justifiable for patients with *Marfan syndrome*. Marfan patients appear to have significantly higher rates of dissection or rupture, and significantly lower operative mortality rates (2). In one study of 675 Marfan patients who had aortic root replacement at a mean age of 34, one-year survival was 93% (7).

In Marfan patients with smaller aneurysms, close observation is indicated. β -blockers are now widely used in Marfan patients, though their benefit has not been proven (8).

Surgical Issues

Annuloaortic ectasia requires replacement of the ascending aorta with a graft that includes a prosthetic aortic valve and implantation of the coronary ostia into a site in the graft above the valve. Ascending aortic aneurysms require replacement of the aorta from just above the coronary ostia to just below the takeoff of the innominate artery. Operation for aneurysm of the transverse arch is the most difficult and hazardous because the brain must be perfused while the aorta is cross-clamped.

One serious potential surgical complication is spinal-cord injury and paralysis. Thoracoabdominal aneurysms are more difficult to treat, because both the thoracic and the abdominal cavities must be entered. The celiac, superior mesenteric, and renal arteries must be reimplanted in the graft.

Indications for Hospitalization and Early Consultation

Patients with leaking or ruptured thoracic aortic aneurysms usually go directly from the emergency department to the operating room. An asymptomatic thoracic aortic aneurysm may require further evaluation, but this evaluation usually does not need to occur emergently and does not require hospitalization. For patients with asymptomatic aneurysms, consultation with a cardiologist and often a vascular surgeon is indicated to guide evaluation and follow-up.

Issues During the Course of Hospitalization

Adequate blood pressure control may slow progression of the aneurysm in patients who are not initially managed surgically. β -blockers and vasodilators are commonly used for this purpose.

Discharge Issues

For patients with asymptomatic thoracic aortic aneurysms, the aneurysm itself should not affect discharge decisions other than by creating a need for appropriate follow-up. For smaller aneurysms, suitable follow-up should be arranged, usually at 6-month intervals for 1–2 years and annually thereafter, usually with a CT scan or MRI study.

ABDOMINAL AORTIC ANEURYSM

Issues at the Time of Admission

Clinical Presentation

Any patient who has abdominal or back pain and evidence of an abdominal aortic aneurysm by imaging study or abdominal palpation could be leaking or rupturing; such patients must be evaluated and treated emergently. Ruptured abdominal aortic aneurysms can be surprisingly difficult to diagnose. Most ruptures occur in previously undiagnosed abdominal aortic aneurysm, and delays and errors are common. Physicians can be misled by symptoms of dysfunction of the gastrointestinal or genitourinary tracts (due to mass effect and compromised circulation), leukocytosis, and preservation of blood pressure and hematocrit, all of which are characteristic of rupture of an abdominal aortic aneurysm. If retroperitoneal bleeding has been extensive, ecchymoses may appear in the skin of the flanks and the lateral abdominal wall. Abdominal aortic aneurysms sometimes can attach to viscera and rupture into the lumen of the gastrointestinal tract, especially the small intestine, resulting in an *aortoenteric fistula* and causing massive gastrointestinal bleeding. Occasionally, the bleeding can be intermittent and gradual, simulating a chronic lower gastrointestinal bleed. After initially successful abdominal aortic aneurysm surgery, a similar syndrome also is seen in patients who leak adjacent to the graft months or years later, often in association with a focal site of bacterial endarteritis.

In some patients, abdominal aortic aneurysms develop layers of mural thrombus that can result in distal embolization of either thrombus or atheromatous debris, especially after trauma from a catheter (Chapter 51). Patients can present with sudden pain or numbness in the foot or lower leg caused by peripheral ischemia or with hypertension, hematuria, or renal failure resulting from atheromatous embolization to the kidney. Livedo reticularis is often present. As with thoracic aneurysms,

patients with frank rupture can present with severe or refractory hypotension resulting from exsanguinating hemorrhage.

Differential Diagnosis and Initial Evaluation

Asymptomatic abdominal aortic aneurysms are often palpable, most commonly in men over age 50 who have smoked. In nonobese patients, it is usually possible to feel pulsation of the normal abdominal aorta. If the physician places both hands flat against the abdominal wall on either side of the palpable aorta and gently compresses the abdominal wall, the width of the abdominal aorta can be estimated.

Unfortunately, the ability to feel an abdominal aortic aneurysm is limited by the size of the abdomen. In one study of 200 patients ages 51–88, half of whom had abdominal aortic aneurysms, sensitivity of abdominal palpation by examiners unaware of the diagnosis was 91% when abdominal girth was less than 100 cm but only 53% when girth was 100 cm or greater (9). No abdominal aortic aneurysm of 5.0 cm or larger was missed when abdominal girth was less than 100 cm.

Aneurysms smaller than 4.0 cm in diameter rarely rupture. Aneurysms expand by an average of about 0.3 cm/y, but expansion is variable from year to year, even in an individual patient. For aneurysms of 4.0–5.5 cm in diameter that are followed by ultrasound surveillance, the annual rupture rate is about 1% per year; it is substantially higher for larger aneurysms.

A lateral abdominal radiograph may show intimal calcification, but abdominal ultrasound is the preferred test, with a specificity and positive predictive value approaching 100% (Figure 50.1). CT with or without contrast and MRI provide additional detail for preoperative evaluation.

Indications for Hospitalization

Any patient with a suspected leaking abdominal aortic aneurysm must be admitted emergently for evaluation. Commonly, such patients go directly from the emergency department to the surgical ICU or to the operating room. Patients with asymptomatic abdominal aortic aneurysms do not require hospitalization unless the aneurysm is sufficiently large to require surgery.

Initial Therapy

Patients with symptomatic abdominal aneurysms require immediate hospitalization, emergent diagnostic imaging, and immediate consultation with a vascular surgeon. Even as resuscitative efforts begin, patients with ruptured aortic aneurysms must be taken immediately to the operating room to control hemorrhage, exclude the aneurysm, and place a bypass graft. Currently, fluid resuscitation prior to repair of a ruptured abdominal aortic aneurysm is an area of controversy. Although fluids may reduce the adverse sequelae of shock, they may also cause clot disruption,

Figure 50.1 Abdominal aortic ultrasound showing a large abdominal aortic aneurysm 7.5 cm in diameter just distal to the takeoff of the renal arteries. The open arrow indicates mural thrombus. Small scale markers are 0.5 cm.

hemodilution, and coagulopathy. Although there are no studies that address this question directly, one large randomized trial of patients with stab wounds and shock found that preoperative fluid resuscitation significantly increased mortality (10). For preoperative management of patients with ruptured abdominal aortic aneurysm, resuscitation to a systolic pressure of 90 mm Hg is sometimes recommended as a compromise.

The mortality rate once the aneurysm has ruptured is very high. More than 50% of patients die before reaching the operating room, and operative mortality for open repair remains about 50%, resulting in an 80% overall mortality for ruptured abdominal aortic aneurysm (11). Endovascular repair is emerging as a potentially important therapy for ruptured abdominal aortic aneurysm, sometimes accompanied by drainage of the retroperitoneal hematoma. In two randomized trials, endovascular repair had a lower operative mortality and complication rate (12, 13), but long-term follow-up is not yet available.

Although repair of some type is usually attempted for ruptured abdominal aortic aneurysm because the alternative is certain death, the indications for elective repair of an unruptured abdominal aortic aneurysm must be carefully weighed against peri-operative risk, especially cardiac risk (Chapter 30). In the absence of any clinical or electrocardiographic evidence of coronary artery disease in an active

patient with good exercise capacity, surgery for abdominal aortic aneurysm is relatively safe, with low rates of morbidity and mortality from cardiac events. If there is evidence of coronary artery disease and the patient is stable and has good exercise tolerance (i.e., can climb two flights of stairs without difficulty), it is probably safe to proceed to surgery. If the patient is at high risk (i.e., has decreased left-ventricular systolic function, signs of heart failure, or myocardial ischemia at low levels of exercise), preoperative testing (Chapter 30) is indicated. Coronary revascularization is not recommended before abdominal aortic surgery unless the patient has severe coronary disease and would be a candidate for coronary revascularization independent of the need for the abdominal aortic surgery (14).

Various surgical and endovascular approaches to elective repair are associated with operative mortality rates of about 2%–5%. Surgery does not remove the aneurysm but rather involves the placement of a prosthesis to connect normal proximal and distal aortic lumens, either within the aneurysmal sac itself or adjacent to a ligated and excluded aneurysmal sac. Alternatively, a stent graft can be placed into the aneurysmal aorta via the femoral artery. Currently, these various approaches have reasonably similar success rates. The endovascular approach may ultimately be preferred in patients with severe cardiac or pulmonary disease, although experience with this technique varies from hospital to hospital, success rates are highly dependent on individual operators, and long-term outcomes are unknown.

Indications for Early Consultation

Any patient with suspected leaking from an abdominal aortic aneurysm requires emergent surgical consultation because of the need for emergent surgery. For patients with asymptomatic abdominal aortic aneurysms 5.5 cm or larger, surgical consultation should be obtained to consider elective surgery.

Issues During the Course of Hospitalization

If a leaking abdominal aortic aneurysm is suspected during the course of hospitalization, the approach is similar to the recommendations for a patient who is admitted with abdominal aortic aneurysm rupture. For patients with asymptomatic abdominal aortic aneurysms discovered during hospitalization, noninvasive testing with ultrasound, or rarely CT or MRI, should be obtained to determine the maximum diameter of the aneurysm.

Discharge Issues

For patients who do not undergo surgery, an asymptomatic aortic aneurysm usually does not prolong hospitalization unless it is large enough to warrant surgery. Two large randomized trials have evaluated immediate open surgical repair compared with imaging surveillance every 6 months

in good operative candidates with abdominal aortic aneurysms of 4.0–5.5 cm in diameter (15, 16). Both studies reported no survival benefit from immediate repair, thereby indicating that repair can be deferred until the AAA enlarges to ≥ 5.5 cm. In the Department of Veterans Affairs trial, the survival trend favored surveillance (versus immediate repair) regardless of age or the diameter of the aneurysm, despite a low 30-day operative mortality of 2%. These studies suggest that the surveillance strategy can reduce the number of elective abdominal aortic aneurysm repairs in this population by about 20%. The most likely reason that early repair was not beneficial in these trials was that the rate of rupture of abdominal aortic aneurysm in patients randomized to surveillance was less than 1% per year. In patients who are at high operative risk, elective repair may be further deferred until the abdominal aortic aneurysm enlarges to the point at which the risk of rupture is thought to warrant the risk of repair. However, patients at high operative risk may also be at especially high risk for rupture; in a series of 199 such patients in whom repair was not undertaken because of high operative risk or because they refused surgery, risk of rupture was 10% at one year for abdominal aortic aneurysms 5.5–6.9 cm and more than 30% at one year for abdominal aortic aneurysms ≥ 7.0 cm (17). β -blocker therapy does not slow the rate of growth of abdominal aortic aneurysms and should not be prescribed for this purpose (18).

KEY POINTS

- Most thoracic aortic aneurysms are asymptomatic unless they dissect, rupture, or compress adjacent structures; elective surgery (at centers of excellence) may be indicated for large thoracic aneurysms.
- A symptomatic abdominal aortic aneurysm requires emergent evaluation because such symptoms commonly indicate leaking and impending rupture.
- Elective surgical repair is indicated for abdominal aortic aneurysms at least 5.5 cm in diameter. For aneurysms smaller than 5.5 cm, surveillance ultrasonography is recommended, every 6 months for abdominal aortic aneurysms ≥ 4.0 cm, and every 1–2 years for smaller abdominal aortic aneurysms.
- Careful evaluation is required to assess operative risk prior to elective aortic aneurysm surgery.
- The choice of surgical technique depends on local expertise; endovascular stenting is a new and promising alternative to the open surgical approach, especially in patients with rupture or substantial comorbid cardiac or pulmonary disease.

Peripheral Arterial Disease

51

Eric P. Brass William R. Hiatt Mark R. Nehler

INTRODUCTION

Peripheral arterial disease (PAD) is an atherosclerotic disease associated with cardiovascular risk factors (particularly diabetes and smoking) and aging. Because the Western population is rapidly aging, an increase in hospitalized patients with PAD can be anticipated. PAD includes two overlapping but distinct pathophysiologic processes. Patients may present with clinical problems related to *chronic, atherosclerotic PAD*, including critical leg ischemia or ischemic ulcerations. Alternatively, patients may present with *acute arterial occlusion or insufficiency* as a result of embolic or thrombotic events in the arteries supplying the lower extremities. The majority of hospitalized patients with acute peripheral arterial problems are suffering sequelae of chronic PAD.

The major symptom of PAD is *intermittent claudication*. Claudication means to limp, but more specifically it refers to exercise-induced discomfort in the calf, thigh, or buttocks that is reliably brought on by a given level of exercise and relieved within 10 minutes of rest (Chapter 47). The pain should not begin at rest or with change in position. The pathophysiology of claudication is primarily a supply-demand mismatch, with inadequate oxygen delivery to meet the metabolic demand of exercising skeletal muscle.

The prevalence of PAD from a variety of population studies ranges from 7%–20% in individuals older than 55 years, although two-thirds of these patients may be asymptomatic and their disease unrecognized (1). In addition to involving the vessels in the lower extremity, atherosclerosis is a systemic disease. By clinical history, about 40%–60% of patients with PAD have had events indicating the presence of concomitant coronary disease; however, by angiographic

studies, 90% have concomitant, significant coronary disease and as many as 80% have significant carotid artery disease. Given these associations, an ankle-brachial index below 0.90 at rest (ABI) (see Chapter 47) has been shown to be a strong, independent predictor of cardiovascular death. A number of epidemiologic studies have shown an approximate 4%–5% rate of myocardial infarction, stroke, or vascular mortality per year in patients with claudication. Moreover patients with critical leg ischemia have an annual mortality of 20%, with 80% of these deaths due to vascular causes. Thus, inpatient treatment goals for this disorder are primarily to relieve symptoms and preserve the lower extremity, as well as to ensure that the greatly increased risk of cardio- and neurovascular injury and death in these patients is subsequently addressed.

The prevalence of intermittent claudication is lower than that of PAD, as defined by ABI measurements. Based on a variety of trials, the prevalence of claudication is $\leq 1\%$ in individuals younger than 50 years, 3%–5% in 50- to 59-year-olds, 5%–10% in 60- to 69-year-olds, and $\geq 10\%$ in those older than 70 years. Males are overrepresented in the claudication population, with a male:female ratio between 1.5:1 and 2.5:1. However, the gender ratio is approximately 1:1 when PAD is defined as the presence of an abnormal ABI. Natural-history studies of patients with claudication reveal that 75% of individuals have stable symptoms if followed over 5 years, and only 25% clinically worsen; only 5% require revascularization, and about 2%–4% will have amputations over the same 5-year period. Thus, most patients with claudication have a stable natural history and can be managed as outpatients with medical therapies. Progression of disease is more likely in patients who continue to smoke or who have diabetes; for example, PAD patients with diabetes are

2–10 times more likely to progress to amputation than are PAD patients without diabetes.

Critical leg ischemia is the most severe manifestation of PAD. Patients with critical leg ischemia by definition have one or more hemodynamically significant occlusive lesions that reduce blood flow to the extremity at rest. This severe compromise of limb blood flow results in the clinical manifestations of either ischemic rest pain, ischemic ulceration, or gangrene principally affecting the distal ankle and foot. The pathophysiology of critical leg ischemia is severe blood-oxygen supply-demand mismatch manifest in the resting state, principally involving the skin of the distal lower extremity. Ischemic rest pain typically occurs at night with the patient supine. The pain progressively becomes more severe and is relieved upon dangling the foot to augment distal blood flow. Ischemic ulcerations, which principally affect the toes and distal forefoot or heel, are usually the result of minor trauma in a limb with a compromised circulation. Ischemic ulcers have dark necrotic centers and are painful, similar to the ischemic pain experienced in the remainder of the foot. As ischemic ulceration progresses, it leads to gangrene, and ultimately loss of the extremity. Several studies have reported an incidence of critical leg ischemia of approximately 500–1,000 new cases per million adults per year, with an estimated prevalence between 500,000 and 1,000,000 in the United States. Seventy-five percent of those affected with critical leg ischemia are older than 60 years. Patients with critical leg ischemia have a poor natural history regarding both limb and life. Without revascularization, the amputation rate at 3-month follow-up is about 12%, and it may be as high as 35% at 6 months. The annual mortality rate is approximately 20% per year (2).

Importantly, some patients with acute arterial insufficiency are experiencing an embolic or thrombotic occlusion in an otherwise normal arterial circulation (Table 51.1) rather than as a complication of chronic, occlusive PAD. These patients without chronic arterial insufficiency have fewer collateral vessels, are less able to tolerate acute severe ischemia, and are more likely to require amputation than patients with chronic, occlusive PAD in whom collateral formation is better established. Several studies have demonstrated that among patients with acute onset of critical leg ischemia symptoms and no history of PAD, more than 50% require amputation.

Patients with acute arterial insufficiency or severe, symptomatic chronic PAD should be admitted to the hospital for possible revascularization procedures in an attempt to relieve claudication or ischemic rest pain, to promote wound healing, and to prevent amputation. These interventions also are designed to prevent limb loss and to improve the functional status of the patient. Since these patients are at high risk for cardiovascular events in the perioperative period, physicians must consider the appropriate cardiac evaluation and therapy needed during the perioperative course (Chapters 30 and 31).

TABLE 51.1**CAUSES OF PERIPHERAL ARTERIAL INSUFFICIENCY****Chronic arterial occlusive disease**

Atherosclerosis
Buerger's disease (thromboangiitis obliterans)
Arteritis
 Giant-cell arteritis
 Takayasu's arteritis
 Fibromuscular dysplasia

Embolic

Cardiac origin
 Left-ventricular thrombus (from underlying myocardial infarction or cardiomyopathy)
 Left-atrial thrombus
 Mitral or aortic-valve thrombus (from infectious endocarditis [vegetation] or marantic endocarditis)
 Prosthetic-valve thrombus or vegetation
Paradoxical embolism of venous clot via a right-to-left shunt, principally an atrial septal defect or patent foramen ovale
Noncardiac atheroembolism from proximal aneurysm or atherosclerosis

In situ arterial thrombosis

Postprocedure/pseudoaneurysm
Hypercoagulable states
Heparin-induced thrombocytopenia

Other

Trauma
Aneurysm
Cyst
Vasoconstrictor drugs
 Cocaine
 Ergots
 Cyclosporine
Radiation

ACUTE LIMB ISCHEMIA**Issues at the Time of Presentation****Clinical Presentation**

The pain in acute limb ischemia is usually of sudden onset, but occasionally it may develop gradually over several hours, depending on the location and extent of the arterial occlusion. This pain is unrelenting, diffuse foot pain, often extending above the ankle, and is not affected by dependent position of the limb. Alert patients are in extreme discomfort, so the diagnosis is usually not subtle. The patient complains of paresthesias, numbness, and, as symptoms progress, weakness and paralysis in the affected limb. A history of prior revascularization procedures, antecedent claudication, diabetes, tobacco use, cardiac disease,

arrhythmias, or chronic anticoagulation therapy may be helpful in defining the etiology.

Acute arterial insufficiency not related to PAD is frequently the result of *cardiac emboli, atheroembolism, or in situ arterial thrombosis*, with rare additional causes (Table 51.1). The most common presentation of acute ischemia in patients with known PAD is *occlusion of an existing bypass graft*. These patients present with either rest pain or increasing claudication, depending on the degree of the resulting ischemia.

Cardiac embolism most commonly is encountered in patients who have mural thrombus of the ventricle as a complication of prior myocardial infarction or cardiomyopathy, atrial thrombosis as a complication of mitral valve disease or atrial fibrillation or flutter, or valvular thrombus or vegetation. The most frequent sites of hemodynamically significant lower extremity embolization involve the aortic and femoral bifurcations. Patients may suffer severe ischemia caused by a lack of existing collateral circulation at the time of occlusion.
