Virtually all patients become severely neutropenic following transplant. The duration of neutropenia is generally from 7–21 days, depending on the source of stem cells, whether methotrexate is used to prevent GVHD, and whether hematopoietic growth factors are used. Peripheral blood stem cells generally engraft most quickly, often by posttransplant day 10, whereas cells from cord blood take the longest, on average 25 days or more. Methotrexate delays engraftment by 3–5 days, and the use of

hematopoietic growth factors accelerates engraftment by 4–6 days.

To reduce the risk for infection during the neutropenic period, patients are usually treated in some sort of protected environment, with either laminar air flow isolation or HEPA (high-efficiency particulate air) filtering. Careful hand washing and avoidance of contact with anyone having a communicable disease are absolutely necessary. Because the risk for bacterial infection is so great, most centers initiate antibiotic therapy once the granulocyte count falls below 500/ μ L. Fluconazole prophylaxis at a dose of 200–400 mg/d reduces the risk for candidal infections. In patients who are seropositive for *Herpes simplex virus*, severe local or disseminated disease can develop early after transplant, but this can be prevented in most patients by the use of acyclovir prophylaxis (either 250 mg/m² intravenously every 12 hours or 500 mg/m² orally twice daily). Despite the use of protected environments and various prophylactic regimens, most patients become febrile while neutropenic. See Chapter 63 for a complete discussion of the approach to this problem.

Thrombocytopenia

Platelet transfusions are routinely used to prevent bleeding in severely thrombocytopenic patients. In general, platelets

Figure 96.1 Major syndromes complicating marrow transplantation. An approximate time frame for some of the major complications occurring during the first year after transplant. CMV, cytomegalovirus; GVHD, graft-versus-host disease; HSV, *Herpes simplex virus*; VOD, veno-occlusive disease of the liver; VZV, varicella-zoster virus.

are transfused once the platelet count drops below 20,000/ μL , but a lower threshold of 10,000/ μL can be used for clinically stable afebrile patients without evidence of hemorrhage (Chapters 93 and 98). Attention must be paid to the cytomegalovirus (CMV) serologic status of the patient (see the “Infection” section later in this chapter). Platelets should be irradiated with 2,500 cGy before infusion to prevent accidental engraftment and the development of transfusion-induced GVHD.

Mucositis

Oropharyngeal mucositis is an almost invariable result of most preparative regimens and may range from mild to severe. The first signs of mucositis appear within the first week after completion of the preparative regimen and usually peak at about 2 weeks. Intensive management of mucositis can significantly lessen symptoms. Oral rinsing with 0.9% saline solution every hour while the patient is awake helps keep tissue clean and debrided. If mucous membranes are intact, topical analgesics like viscous lidocaine or a mixture of dicyclomine HCl and diphenhydramine may relieve local symptoms. Systemic analgesics, including opioids, are frequently needed to control the pain associated with mucositis.

Veno-Occlusive Disease of the Liver

The intensive cytoreductive chemotherapy and radiotherapy comprising the transplant preparative regimen can occasionally result in a syndrome of liver toxicity termed *veno-occlusive disease* (VOD), also sometimes called sinusoidal obstruction syndrome (SOS). VOD is characterized by tender hepatomegaly, weight gain, and jaundice. The first signs of VOD usually appear during the first 21 days after transplant. The overall incidence of VOD ranges from 10%–25% and is influenced by a number of factors. VOD is more commonly seen in patients with preexisting liver disease, those with fever and infection at the time they receive the preparative regimen, and in patients who are treated with more intensive preparative regimens. Although development of tender hepatomegaly with weight gain and jaundice during the first 3 weeks after transplant is usually secondary to VOD, occasionally hepatic infiltration by fungus or tumor, congestion resulting from right ventricular failure, or cholestatic jaundice secondary to cyclosporine toxicity or GVHD can contribute to the picture. The only way to differentiate these entities with certainty is by liver biopsy. Because of the risk for bleeding during the early posttransplant period, biopsy is usually performed via a transvenous approach. VOD is more likely to be severe if the onset is early (before posttransplant day five) and accompanied by a rapid rise in bilirubin levels and rapid weight gain.

The management of VOD requires careful attention to supportive care in addition to consideration of specific

therapies. The primary objective of supportive care is to minimize fluid retention while maintaining renal perfusion. Careful monitoring of fluid and electrolyte balance is critical. If volume overload develops, the daily intake of sodium and fluids should be restricted, and attempts to increase sodium excretion by the use of diuretics should be carefully initiated. However, diuretics can deplete intravascular volume and reduce renal blood flow, which should be avoided. If diuresis is unsuccessful and the patient shows signs of severe volume excess (e.g., tense ascites, pleural effusions, hypoxemia), paracentesis of ascitic fluid, hemodialysis, or hemofiltration should be considered. Patients with severe VOD have increased platelet sequestration and are at an increased risk for bleeding complications. Efforts should be made to maintain platelet counts at higher levels, although this can be difficult.

No specific therapies have been unambiguously demonstrated to ameliorate the course of VOD, but several therapies have shown promise in preliminary studies. A combination of tissue plasminogen activator and heparin has been used, because microthrombi can be found in the walls of the central veins of the liver in VOD. Approximately 30% of patients with mild-to-moderate VOD appear to respond to tissue plasminogen activator and heparin, but this therapy increases the risk for severe bleeding. The dose of tissue plasminogen activator is 20 mg infused over 4 hours on each of 4 consecutive days. The activated partial thromboplastin time is generally kept at or just above the upper limit of normal by adjusting the heparin dose. Defibrotide is an experimental drug that, in an uncontrolled study, was associated with responses in 30%–40% of patients with moderate-to-severe VOD (8). Nephrotoxic and hepatotoxic drugs should be avoided in patients with VOD, and the pharmacology of drugs normally metabolized by the liver may be altered in these patients.

INTERMEDIATE COMPLICATIONS (DAYS 14 TO 80 AFTER TRANSPLANT)

Graft Failure

Although complete and sustained engraftment is seen in the large majority of transplant patients, marrow function occasionally does not return, nor is it lost after temporary engraftment. Graft failure occurring after autologous transplantation may be related to stem cell damage that occurred before stem cell collections, during the storage process, or after transplantation. A correlation has been found between poor graft function after autologous transplantation and prior exposure to extensive chemotherapy before marrow storage. Poor graft function has also been seen in recipients of highly purified stem cells. Exposure after transplant to potential marrow toxins, such as ganciclovir, and infection with CMV or human herpesvirus six have also been associated with graft failure.

Similarly, graft failure after allogeneic transplantation can be caused by exposure to marrow toxins or viral infections, but it may also be the result of graft rejection when host immune cells react against the new marrow graft. Graft rejection is more commonly seen in recipients of T-cell-depleted marrow, patients who receive HLA-mismatched or unrelated grafts, and those in whom less intensive preparative regimens are used. The approach to treating graft failure depends on its most likely cause. A reasonable first step in patients with poor graft function is to remove all potential myelosuppressive agents. The addition of a myeloid growth factor, such as GM-CSF, results in increased granulocytes in 40%–50% of patients. Immunologically-mediated graft rejection is demonstrated by the presence of a severely hypoplastic marrow and circulating host-derived lymphocytes in the peripheral blood of the patient. Occasional patients may recover host hematopoiesis with prolonged support. More often, however, patients remain severely hypoplastic, and it is necessary to consider a second transplant. Recent studies have shown that second grafts can be successful in the majority of patients when a combination of steroids and an anti-CD3 monoclonal antibody is used before the second marrow infusion.

Acute Graft-versus-Host Disease

Graft-versus-host disease results when allogeneic T-cells transfused with the graft, or developing from it, react with major or minor histocompatibility antigens on the genetically different host. Acute GVHD usually develops between days 14 and 28 after transplant and most often involves the skin, liver, and gastrointestinal tract. The skin rash is classically an erythematous maculopapular rash on the arms, legs, and trunk and involves the palms and soles. Liver disease is characterized by increases in bilirubin, transaminases, and alkaline phosphatase, but the weight gain and tender hepatomegaly generally associated with VOD are not usually seen. Gastrointestinal disease most commonly presents with diarrhea and abdominal pain, but anorexia and upper abdominal discomfort may predominate. Because the therapy of GVHD involves systemic immunosuppression, and because other diseases can mimic GVHD, a biopsy for definite diagnosis should be performed if possible. Pathologic features include lymphocytic and

monocytic infiltration into perivascular spaces in the dermis and epidermal junction of the skin, into the base of the intestinal crypts in the small or large bowel, and into the periportal areas of the liver. Acute GVHD is usually staged and graded according to the Seattle criteria (Table 96.2). Most clinicians withhold therapy until grade 2 or higher acute GVHD develops. If the patient is on cyclosporine or tacrolimus, it is customary to continue that drug and add another immunosuppressive agent, usually 1 or 2 mg of prednisone per kilogram daily. Prednisone is normally continued for 2 weeks and then slowly tapered in responding patients. Other immunosuppressive agents that can be used instead of prednisone or in patients who fail to respond to prednisone include antithymocyte globulin, monoclonal antibodies against T-cells, mycophenolate mofetil or rapamycin.

Patients with significant gastrointestinal symptoms are generally given nothing by mouth until symptoms abate and then are carefully allowed to resume eating. Rash associated with GVHD can lead to significant skin breakdown. Cleansing excoriated areas and applying nystatin/polymyxin powders to skin folds may help. Aquaphor ointment or emollients can be used for flat surfaces or extremities. Severe rashes with bullae and desquamation should be treated like burns.

Infection

Infections in the neutropenic patient are considered above (see Early Complications). Even after engraftment, transplant patients remain severely immunosuppressed for months, and infectious complications are frequent (Chapter 63). The risk for bacterial infection diminishes after granulocyte recovery. Thus, patients are not normally kept on prophylactic systemic antibiotics once granulocyte counts recover to 500/ μ L. However, a wide variety of bacterial infections is seen after engraftment, and any fever in the posttransplant patient requires intensive evaluation. Gram-positive infections associated with indwelling catheters are common, but a wide array of other organisms can also cause infection. The incidence of candidal infections can be lessened by the use of prophylactic fluconazole (200–400 mg/d through day 75) (9). With the use of fluconazole, aspergillosis has emerged as the most common

TABLE 96.2

CLINICAL STAGING OF ACUTE GRAFT-VERSUS-HOST DISEASE

Stage	Skin	Liver	Gut
I	Maculopapular rash <25% body surface	Bilirubin 2–3 mg/dL	Diarrhea 500–1,000 mL/d
II	Maculopapular rash 25–50% body surface	Bilirubin 3–6 mg/dL	Diarrhea 1,000–1,500 mL/d
III	Generalized erythroderma	Bilirubin 6–15 mg/dL	Diarrhea >1,500 mL/d
IV	Desquamation and bullae	Bilirubin >15 mg/dL	Pain and ileus

fungal infection in the posttransplant patient. *Aspergillus* infections are often fatal, and successful treatment, when it occurs, requires that infection be diagnosed while still relatively localized, so that it can be controlled with antifungals and, if possible, surgical excision. The preferred initial therapy of documented *Aspergillus* infection includes voriconazole plus caspofungin (10).

In the past, CMV infections involving the lungs and gastrointestinal tract were frequent and led to death in 10%–15% of allogeneic transplant patients. Currently, if the donor and recipient are CMV-seronegative at the time of transplant, CMV infections can be entirely prevented by avoiding exposure to blood products from CMV-seropositive donors. In patients who are CMV-seropositive at the outset of transplant, the incidence of CMV infection can be substantially reduced with the use of *prophylactic ganciclovir* (11). One strategy is to use ganciclovir prophylaxis in all seropositive patients beginning at the time of engraftment and continuing until day 100. Although ganciclovir is highly effective in preventing CMV disease when used this way, it is also associated with significant marrow suppression. In some patients, severe granulocytopenia and life-threatening infection can result. Other centers monitor patients for the development of CMV antigenemia and begin ganciclovir only when a positive result is observed. Ganciclovir prophylaxis can prevent CMV disease, but it also delays the recovery of immune responses to CMV. Thus, with ganciclovir prophylaxis, late CMV infections (after day 100) are occasionally seen in patients once prophylaxis is stopped. Foscarnet is effective for some patients in whom CMV antigenemia or infection develops despite the use of ganciclovir, or for patients who cannot tolerate the drug.

Pneumocystis jirovecii (formerly *P. carinii*) pneumonia, previously seen in 5%–10% of transplant patients, can be prevented by treatment with oral trimethoprim-sulfamethoxazole for one week before transplant and resumption of the treatment once engraftment has occurred. The usual dose is one double-strength tablet orally twice daily 2 days a week. Treatment is usually continued as long as patients are on immunosuppressive medications. If allergy to trimethoprim-sulfamethoxazole develops in a patient, desensitization is a reasonable course. Dapsone is an alternative, but must be avoided in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency.

Interstitial Pneumonia

Pneumonias that develop after transplant are frequently caused by bacterial, fungal, or viral organisms. In 5%–10% of cases, however, no infectious cause can be found, and biopsy reveals diffuse cellular damage with or without an additional interstitial component. This type of pneumonia, termed *idiopathic interstitial pneumonia*, is thought to be the result of direct toxicity of the preparative regimen to

the lung, although evidence for a role of soluble cytokines is growing. Many infectious causes of posttransplant pneumonias can be identified by bronchoalveolar lavage. If no organism is found and idiopathic pneumonia is diagnosed, therapy with high-dose glucocorticoids is often tried, although no randomized trials have validated this approach.

LATE TOXICITIES (BEYOND DAY 80 AFTER TRANSPLANT)

Late Infections

Even more than 3 months after transplant, patients are still at risk for the development of significant, life-threatening infections. This risk is considerably less after autologous than after allogeneic transplantation, and it is increased in patients on immunosuppressive therapy for chronic GVHD. A wide variety of bacterial, viral, and fungal diseases have been reported in the late posttransplant period. Because the risk for bacterial infection is so high in patients with chronic GVHD, many centers place such patients on prophylaxis with trimethoprim-sulfamethoxazole, penicillin, or both. Herpes zoster is common; it usually presents as localized disease, but subsequent dissemination is noted in about one-third of infected patients. The case fatality rate of disseminated herpes zoster is high. Thus, some centers place all patients on acyclovir prophylaxis for one year to prevent reactivation. At a minimum, all patients in whom dermatomal disease develops within the first year of transplant should be treated with acyclovir to prevent dissemination. As discussed above, CMV infections developing after posttransplant day 100 are becoming more common. Patients typically present with fever, leukopenia, or interstitial pneumonia. Treatment is with ganciclovir and CMV-specific immunoglobulin, if available.

Chronic Graft-versus-Host Disease

Manifestations of the graft-versus-host reaction that occur more than three months after transplantation are termed *chronic GVHD*. Chronic GVHD differs markedly from the acute form in its manifestations and tempo. Chronic GVHD resembles a collagen vascular disease, with skin involvement (malar erythema, sclerodermatous changes, and cutaneous ulcers), alopecia, sicca syndrome, polyserositis, and liver dysfunction. Chronic GVHD develops in 20%–40% of matched sibling transplants, and it is more common in patients who have had a prior episode of acute GVHD, in older patients, and in recipients of mismatched or unrelated transplants. Prednisone, cyclosporine, or the two in combination are the usual treatments. Thalidomide and azathioprine have also been reported to be useful.

Immunosuppressive therapy is usually required for prolonged periods. Patients are generally treated for 9 months, after which the immunosuppression is gradually tapered if their chronic GVHD is in remission. In most patients, chronic GVHD eventually resolves and immunosuppression can be entirely withdrawn, but this may require 1–3 years of treatment. If corticosteroids are used as treatment, an alternate-day schedule after initial remission may help avoid late toxicities.

Second Malignancies

Survivors of marrow transplantation are at increased risk for the development of second malignancies. Patients who have been transplanted with T-cell-depleted marrow or who receive multiple cycles of immunosuppressive therapy to treat GVHD are at increased risk for the development of an aggressive lymphoproliferative disease associated with the Epstein-Barr virus. This syndrome often begins as a polyclonal disorder but evolves into an aggressive monoclonal B-cell malignancy. Infusion of Epstein-Barr virus-specific donor T cells can reverse the disease in some cases. Rituximab may also be effective.

A small increase in the incidence of solid tumors has been documented after marrow transplantation. At 10 years, the cumulative incidence is 2.9%, with a higher incidence seen in patients with chronic GVHD and those who have received extensive radiation. An incidence of myelodysplasia approaching 10% has been reported following autologous transplantation for malignant lymphomas. Whether this is caused directly by the transplant or is a long-term effect of previous chemotherapy before transplantation is unknown.

Relapse After Transplant

The risk for recurrence of malignancy is substantial after transplant, particularly when transplantation is performed for relapsed or refractory disease rather than for disease at an earlier stage. Management of posttransplant relapse is influenced by the transplant setting. Patients who relapse after autologous transplantation may respond to subsequent chemotherapy, and occasionally these responses can be complete and prolonged. Additional options are available to the patient who relapses following allogeneic transplantation, including discontinuation of immunosuppressive therapy and infusion of viable donor lymphocytes.

KEY POINTS

- Marrow transplantation, particularly allogeneic transplantation, is a complex undertaking and is best carried out at centers specializing in the procedure.

- It takes on average at least three months to identify a matched unrelated donor and schedule a transplant, which means that physicians and patients considering the procedure must provide the transplant center with sufficient lead time.
- Marrow transplantation is widely applicable in the treatment of hematologic malignancies and other chemotherapy-responsive tumors, but it has little role in the treatment of tumors completely refractory to standard-dose therapy.
- With appropriate prophylactic measures, most cases of early posttransplant cytomegalovirus and *Candida albicans* infection can be prevented.
- *Pneumocystis jirovecii* infection can be prevented with oral trimethoprim-sulfamethoxazole prophylaxis.
- Immunosuppression is profound in early posttransplant patients, and any infection can be lethal. Even after engraftment, patients are at substantial risk for the development of severe and life-threatening infection. Thus, patients must be followed closely and any potential infection pursued vigorously.
- Determining the cause of early posttransplant liver dysfunction is often difficult. A transvenous liver biopsy is often helpful in such patients and can usually be performed safely, even in patients requiring platelet support.
- Treatment of chronic graft-versus-host disease may require prolonged immunosuppressive therapy with cyclosporine and prednisone. Such patients are at high risk for a number of complications, including infections, aseptic necrosis, and cataracts.
- Posttransplant relapse can be treated successfully in some cases with further chemotherapy, a second transplant, or donor lymphocyte infusions.

Sickle Cell Disease

97

Martin H. Steinberg *Harrison W. Farber*

INTRODUCTION

Sickle cell disease results from a mutation in the gene for β -globin, a subunit of adult hemoglobin (HbA). A point mutation in codon six of this gene encodes the synthesis of the sickle β -globin chain (β^s), which contains a valine residue in place of the glutamic acid normally found at this position. Sickle hemoglobin (HbS, $\alpha_2\beta_2^s$) has the unique property of polymerizing when deoxygenated. Sufficient HbS polymer within the erythrocyte evokes the cellular injury responsible for the phenotype of sickle cell disease (1).

Sickle cell disease is a phenotype with distinctive clinical and hematologic features, in which at least half the hemoglobin present is HbS. *Sickle cell trait*, the heterozygous carrier of an HbS gene, is present in about 8% of African-Americans. It is not considered a type of sickle cell disease because it is clinically benign. Among the common genotypes of sickle cell disease are homozygosity for the HbS mutation (*sickle cell anemia*), compound heterozygosity for HbS and HbC (*HbSC disease*), and compound heterozygosity for HbS and β -thalassemia (HbS- β -thalassemia) (Table 97.1). Whenever possible, a diagnosis of sickle cell disease should be assigned by the genotype of the patient because this designation allows the best assessment of prognosis. Accurate genetic counseling—an important aspect of patient management—is possible only when the genotypic diagnosis is known.

Pathophysiology

Sickle hemoglobin has the property of polymerizing when deoxygenated. The *vaso-occlusive features of sickle cell disease are unique among the hemolytic anemias*. Sickle cells cause vascular injury, occluding small and sometimes large blood

vessels. No single mechanism explains sickle vaso-occlusion (Figure 97.1). Hemolysis is the other cardinal feature of sickle cell disease, but it causes fewer problems than the myriad vaso-occlusive events.

Erythrocyte heterogeneity in sickle cell anemia is dependent on the cellular content of fetal hemoglobin (HbF). Vaso-occlusion is initiated and sustained by interactions among sickle cells, endothelial cells, leukocytes, and plasma proteins. Sickle erythrocytes alone do not initiate vaso-occlusive disease. Activated neutrophils liberate harmful cytokines and interact with sickle and endothelial cells. Activated platelets release thrombospondin, which promotes adherence of sickle erythrocytes to endothelium. Young reticulocytes contain additional adhesive ligands that facilitate erythrocyte endothelium interactions.

Diagnosis

Diagnosing sickle cell disease is not difficult. Examining the parents or siblings of affected patients is the least costly way of establishing the genotype, and this can be accomplished with simple combinations of blood cell counts and quantitative studies of hemoglobin fractions (Table 97.1). Sickled cells are nearly always seen in sickle cell anemia and HbS- β^0 -thalassemia, but are less common in other forms of sickle cell disease. Their presence does not help diagnose acute complications like painful episodes. In untreated adults with sickle cell anemia, HbS nearly always forms more than 80% of the hemolysate. Sickle cell anemia and HbS- β^0 -thalassemia are very much alike hematologically and clinically, and the distinction between them requires genetic testing and cannot be made from hemoglobin studies or blood cell counts alone.

TABLE 97.1**LABORATORY DIFFERENTIATION OF SICKLE HEMOGLOBINOPATHIES**

Diagnosis	Hemoglobin (g/dL)	Reticulocytes (%)	MCV (fl)	HbS (%)	HbA ₂ (%)	HbF (%)
Sickle cell anemia	6–9	10	85–95	>90	2–3	7
HbSC disease	8–12	4	70–85	50	2–3	3
HbS-β ⁰ thalassemia	7–10	10	65–75	>90	4–6	8
HbS-β ⁺ thalassemia	10–12	2	60–70	70	4–6	2
Sickle cell trait	13–16	1	80–90	35	2–3	<1

These are average laboratory values in adults with stable disease. They may vary considerably in individual patients and also be affected by acute disease complications.

HbA₂, minor fraction of adult hemoglobin; HbF, fetal hemoglobin; HbS, sickle cell hemoglobin; HbSC, sickle cell hemoglobin C disease; MCV, mean corpuscular volume.

Clinical Features

Sickle cell anemia is present in 1 in 600 African-Americans, and the prevalence of sickle cell disease is about 1 in 300. Sickle cell disease is associated with acute, recurrent, and chronic complications, the most common of which are shown in Table 97.2. Vaso-occlusive disease can occur almost anywhere blood flows and is responsible for the unique features and the most severe complications of this disorder. Hemolysis, which is constantly present, explains why the temporary interruption of erythropoiesis can cause the rapid development of severe anemia (the so-

called “aplastic crisis”), and why gallstones form in most patients.

Adults with sickle cell anemia or HbS-β⁰-thalassemia are most frequently hospitalized for the treatment of severe painful episodes and acute chest syndrome, and for surgical procedures. Patients with HbSC disease and with HbS-β⁺-thalassemia require hospitalization about half as often as those with sickle cell anemia and on average live about 20 years longer. Nevertheless, with the promising results of hydroxyurea treatment in patients with sickle cell anemia (see the section on “Discharge Issues” later in this chapter), patients with HbSC disease are beginning to

Figure 97.1 Pathophysiology of sickle cell disease. With deoxygenation, sickle hemoglobin polymerizes and eventually causes cell sickling and damage to the membrane. Red cells are heterogeneous, with a spectrum of densities, membrane injury, and fetal hemoglobin. Some cells adhere to the endothelium to cause vaso-occlusion.

TABLE 97.2
CLINICAL FEATURES OF SICKLE CELL DISEASE

Features	
Vaso-occlusive complications	
Painful episodes	>70% of patients affected; very frequent in some, rare in others
Stroke	~10% in childhood; two to three times more patients with "silent" MRI defects and cognitive impairment
Acute chest syndrome	50% of all patients; more common in children, more severe in adults
Priapism	10–40% of male patients; severe cases cause impotence
Hepatopathy	<2%; many causes; extreme bilirubin elevations
Splenic sequestration	Children <6 y; often preceded by infection
Spontaneous abortion	~6% in sickle cell anemia; much less in HbSC disease
Leg ulcers	~20% of adult sickle cell anemia; rare in HbSC disease
Osteonecrosis	10–15% of adults with sickle cell anemia and HbSC disease
Proliferative retinopathy	Rare in sickle cell anemia; 50% adults with HbSC disease
Renal insufficiency	5–20% of adults; severe anemia often present
Complications of hemolysis	
Anemia	PCV 15–30 in sickle cell anemia; greater in HbSC disease
Cholelithiasis	Present in most adults; often asymptomatic
Acute aplastic episodes	May be caused by parvovirus B19; rapidly occurring severe anemia
Infectious complications	
<i>Streptococcus pneumoniae</i> sepsis	10% of children <5 y with sickle cell anemia
Osteomyelitis	<i>Salmonella</i> spp. and <i>Staphylococcus aureus</i> are usual agents
<i>Escherichia coli</i>	In adults, usually initiated by UTI urinary sepsis
<i>Chlamydia</i>	May cause acute chest syndrome

HbSC, sickle cell hemoglobin C disease; MRI, magnetic resonance imaging; PCV, packed cell volume; UTI, urinary tract infection.

From Steinberg MH. Drug therapy: management of sickle cell disease. *N Engl J Med* 1999;340:1021–1030, with permission.

represent an increasing proportion of sickle cell disease patients who need hospital care.

PAINFUL EPISODES AND PRIAPISM

Issues at the Time of Admission

Acute painful episodes are the main cause of hospitalization in sickle cell disease. Although these are generally believed to be caused by vaso-occlusion by sickle erythrocytes, some authorities believe that they have a neurovascular basis, as blood is shunted away from involved regions. Whatever the physiology, the episodes are characterized by bouts of excruciating pain in the chest, back, abdomen, or extremities. Painful episodes often involve multiple areas simultaneously, symmetrically affect

the extremities, and might last days or even weeks. Sickle cell pain is notorious for severity surpassing that of post-surgical pain and the pain of trauma. Some patients never describe a painful episode, whereas others seem to have them continuously. These discrete attacks of pain must be separated from the more chronic pain of osteoporosis and osteomalacia that usually affects the spine, the pain associated with osteonecrosis of the hips and shoulders, and the milder aches, pains, and soreness that frequently are present between severe episodes.

On average, patients with sickle cell anemia and HbS- β^0 -thalassemia have twice as many episodes of pain yearly as do persons with HbSC disease and HbS- β^+ -thalassemia. Clearly, some patients are more predisposed to painful episodes than others. Whereas about 5% of patients account for more than 30% of the crises, nearly 40% of patients with sickle cell anemia do not have a single

episode of pain in a given year. Rates of pain are highest during the third and fourth decades of life (1). The rate of pain varies directly with the packed cell volume (PCV) and inversely with the HbF level. As the pain of a crisis intensifies, there is also a small decrease in PCV and a rise in reticulocytes, but this is insufficient to be diagnostically useful in an individual patient. Unfortunately, *no useful laboratory test can determine whether a vaso-occlusive pain crisis is occurring, and the history remains the best clue.*

Frequent episodes of pain portend increased mortality in adults. Patients with the highest PCVs and leukocyte counts and the lowest HbF levels are at the greatest risk. Often, death in adults is unexpected and occurs in the midst of an acute event—most often a pain episode—as a result of cardiovascular collapse. In the United States, the median age of death is about 45 years in sickle cell anemia and about 65 years in HbSC disease.

Painful episodes are often stereotypical, affecting each patient in the same manner from episode to episode. Patients usually know if the pain they are experiencing is different from their typical painful episode, and physicians should heed what patients say about the need for hospitalization or the likelihood that their pain can be explained by something other than a “pain crisis.”

The pain of acute cholecystitis, splenic sequestration crisis, splenic infarction, and right upper quadrant syndrome can sometimes be mistaken for uncomplicated pain episodes. In splenic sequestration and right upper quadrant syndrome, the spleen and liver can be distended by blood that accumulates as the vasculature of these organs dilates. Usually, in splenic sequestration crisis, the hemoglobin concentration falls rapidly, whereas in right upper quadrant syndrome, parameters of liver function become grossly abnormal. Neither acute, severe anemia nor newly deranged liver functions are typical features of a painful episode. Acute painful episodes are often the heralding events in acute chest syndrome, discussed below. Occasionally, pain episodes end with multiple organ failure. No data allow one to foretell whether a “usual” pain episode will have a morbid or mortal outcome.

It has been estimated that nearly 40% of adult men with sickle cell anemia have had at least one episode of *priapism*. Recurrent attacks of priapism can last for several hours with tolerable discomfort and be self-limited. These episodes, which have been termed stuttering priapism, usually have a nocturnal onset. Erectile function is mostly preserved between these attacks, which can recur for years and number in the dozens. Major episodes of priapism often (not always) follow a history of stuttering attacks, last for days, and can be excruciatingly painful. They usually destroy sexual function by causing irreversible damage to the corporal bodies. Priapism has been considered one manifestation of severe vascular disease and has been associated with an increased chance of cerebrovascular accidents.

Indications for Hospitalization

Patients are generally quite “savvy” about the management of painful episodes. They know when the event is sufficiently minor that they can be cared for at home with rest, oral fluids, local measures such as heating pads, and oral analgesics. When the pain is beyond home treatment, patients will, depending on the resources available, visit a physician’s office, a medical clinic, day hospitals that focus on the treatment of acute sickle cell pain episodes, or the emergency department. From these venues, after the duration and severity of pain and the history of response to pain treatment have been assessed, the decision regarding hospitalization can be made. It is important to consider whether or not complicating factors are present, such as excessive tachycardia, hypotension, temperature above 101°F, marked leukocytosis, a fall in hemoglobin level, reduced O₂ saturation, or evidence of pneumonia on examination or chest radiography. The presence of any of these factors argues for early admission.

If the pain episode appears to be uncomplicated, and if, after treatment in the emergency department or day hospital, pain has not diminished to the point at which the patient feels that it is manageable at home, hospitalization is warranted. Because of the pressures of their jobs and family life, the chronicity of their illness, or adverse experiences with pain management in the hospital, many patients are reluctant to be hospitalized. Conversely, some patients—a small minority—actively seek hospitalization because of their inability to cope psychologically with pain or because they are seeking opiates. It cannot be overemphasized that *this latter class of patients comprises only a small percentage of the population with sickle cell anemia*, although they may be responsible for a disproportionate amount of the monetary and medical resources expended on this disease.

Indications for Initial Intensive Care Unit Admission

Respiratory distress, reduced O₂ saturation, high-grade fever, rising serum creatinine, falling PCV and platelet count, and circulatory instability all suggest that acute chest syndrome may be present or multiple organ failure is developing. These findings should prompt consideration of ICU admission.

Initial Approach

A close and mutually satisfactory relationship between the patient and the treating physician is a major adjunct to the successful management of an acute painful episode. This provides the patient with confidence that his or her history of prior painful events and their effective treatment has been considered in the formulation of a treatment plan. Reliance on a succession of skeptical physicians as primary

caregivers can compromise effective treatment. Most pain episodes do not have an identifiable precipitating cause, but this does not mean that one should not be diligently sought. Painful episodes are sometimes triggered by an infection, extremes of temperature, or physical and emotional stress. Pneumonia is the most prevalent infection associated with acute pain episodes and is caused by the organisms responsible for community-acquired pneumonia (Chapter 65).

More commonly, painful episodes begin with little warning. Physical examination is usually not helpful for determining if an acute pain episode is in progress, but sometimes localized swelling and pain are noted over an involved bone. A chest radiograph should be obtained in most patients sufficiently ill to be hospitalized to exclude acute chest syndrome or pneumonia. Most patients with sickle cell anemia have a leukocyte count between 12,000 and 14,000/ μL in their basal state, so that mild leukocytosis does not signify infection. Elevation beyond the baseline may be a clue to an infectious process but also occurs with acute chest syndrome and severe painful episodes. Low-grade fever can accompany the acute painful episode, but higher elevations may point to infection or extensive tissue damage.

Table 97.3 outlines one approach to the treatment of painful events in sickle cell anemia. Administration of opiate analgesics in sufficient doses and frequency is the foundation of treatment. The choice of drug and the dose can be

guided by the history of previous pain episodes. For severe pain, parenteral opiates are required. They must be given at frequent fixed intervals, not “as needed,” until the pain has diminished, at which time they can be tapered, then stopped, and oral analgesics substituted (1) (Table 97.3). Breakthrough pain can be managed by giving one-half to one-fourth of the maintenance dose. Nonsteroidal anti-inflammatory agents and other adjuvant drugs like hydroxyzine are useful in some patients. The use of pain measurement scales and frequent reassessment of pain, at 2- to 3-hour intervals if possible, help guide the intensity of treatment. Some patients prefer patient-controlled analgesia. (For further information on the general principles of pain management, see Chapter 18.)

The conundrum of managing priapism lies in determining when “conservative” treatment should be stopped and operative intervention initiated, a challenge made greater because of the lack of controlled clinical trials of any acute treatment modality (2). Pain should be relieved in the same manner as pain affecting other areas, and adequate fluids provided. If the episode differs from prior episodes of stuttering priapism according to the patient’s history and physician’s experience, aspiration and irrigation should be performed within a 12-hour window after the onset of erection. Simple or exchange transfusions may also be useful. Invasive treatment for priapism in sickle cell anemia is designed to evacuate stagnant blood within the corpora cavernosa

TABLE 97.3

MANAGEMENT OF ACUTE PAIN IN SICKLE CELL DISEASE

Treat cause if one is identified; begin analgesic treatment promptly.

Liberal fluid replacement, 3–4 L daily in adults

Orally, if possible.

Intravenously, if needed. Use 0.5 N saline solution.

Analgesics for acute pain

Morphine, hydromorphone (Dilaudid) or, if necessary, meperidine (Demerol), parenterally, at *full therapeutic doses*, at intervals of 2–4 h to relieve pain. Additional smaller doses for “breakthrough” pain. Reassess pain frequently.

Do not order as needed (prn) medication.

Consider use of adjunctive drugs like hydroxyzine, diphenhydramine, or promethazine, and nonsteroidal antiinflammatory drugs.

Consider patient-controlled analgesia if more frequent dosing is needed. Use pain scales (digital analog or 0–10, absent to worst possible [Chapter 18]) to gauge treatment effects and determine doses.

Analgesics for mild–moderate pain

Fentanyl patches for prolonged moderate–severe pain

Acetaminophen with codeine for mild–moderate pain not requiring physician visit

Nonsteroidal antiinflammatory agents for pain of osteonecrosis if not contraindicated because of renal disease or severe liver disease

Modified from Ballas SK. Neurobiology and treatment of pain. In Embury SH, Hebbel RP, Mohandas N, et al., eds. *Sickle Cell Disease: Basic Principles and Clinical Practice*. New York: Raven Press, 1997:745–772.

and prevent immediate recurrence of corporal expansion. While the simplest surgical procedure is aspiration of the corporal bodies with irrigation, aspiration of blood is usually difficult after a major episode of priapism has lasted for 24–48 hours. Operative intervention can be considered if detumescence is not achieved with aspiration and irrigation. When surgery is chosen, a Winter shunt between the glans penis and corpora cavernosa should be placed within 24 hours. This plan requires crucial decisions within 12 hours of the onset of priapism, and, because patients are often reluctant to visit the emergency department or clinic based on their experience with self-limited priapism, time for observation may be lacking. Urologists conversant with the management of priapism should be consulted when the patient with a severe episode is first seen.

Indications for Early Consultation

Patients who have very frequent pain episodes are the most difficult to manage. Early and continued consultations with therapists, psychiatrists, and experts in pain management may decrease their rate of hospitalization and emergency department visits, but the general effectiveness of this adjunctive treatment has not been critically evaluated. Priapism has a tendency to recur, until erectile function is lost. Efforts should be made to interrupt the episodes of stuttering priapism that presage a major event. However, the options available are imperfect and untested. These include pseudoephedrine, leuprolide, stilbesterol, and prophylactic transfusion. Penile prostheses may help some impotent patients.

Issues During the Course of Hospitalization

Painful episodes resolve with time, but their length varies considerably between patients and from episode to episode. On average, pain diminishes to the point at which oral analgesics are sufficient and discharge can be contemplated in 4–7 days, but persistence of pain far beyond this interval is common. In unusually prolonged pain episodes, the question of whether pain persists because of “organic” reasons versus psychological factors is often raised. With laboratory tests indicative of a painful episode lacking, this distinction is often impossible to resolve. Because acute painful episodes can be the sign of more ominous events, such as acute chest syndrome, the search for signs and symptoms of lung involvement must be vigilant.

Discharge Issues

Discharge is possible when pain has receded to the point at which it can be managed at home with oral analgesics and rest. Unless events during hospitalization warrant, such as deterioration in renal or liver function or a fall in PCV, a special clinic appointment for follow-up is not necessary. A

telephone call will suffice, and regularly scheduled outpatient appointments can be kept. Perhaps because of the fluctuation in erythrocyte populations during the evolution of painful episodes, recurrence within weeks of an apparent resolution sometimes happens. This does not signify a treatment failure.

Now that an effective approach for the prevention of painful episodes is available, initiation of this therapy in selected hospitalized patients who qualify for this type of treatment should be considered (3). In adults with a history of several pain episodes yearly, *hydroxyurea* reduces by nearly half the incidence of pain crisis, acute chest syndrome, hospitalization, and blood transfusion. Treatment is also associated with a substantial reduction in mortality (4).

Hydroxyurea should be reserved for patients who average one or two pain episodes per year that require sustained treatment with parenteral opiates, who have had severe episodes of acute chest syndrome, or who have other severe vaso-occlusive events (Table 97.4). These patients must also be willing and able to comply with the treatment regimen. Therapy is initiated with 500 mg of hydroxyurea daily (10–15 mg/kg). Dose titration and continued monitoring of patients is carried out in the office or clinic.

Patients should be explicitly counseled regarding the following: responses differ among individuals; many months may be needed to find the best dose of the drug; medication must be taken exactly as directed, with frequent blood tests performed; and long-term toxicities and effects of treatment are unknown. It is not yet established if hydroxyurea is mutagenic, carcinogenic, or leukemogenic. Also unknown is whether hydroxyurea will prevent organ damage, or restore function to already injured organs. Finally, whether hydroxyurea can affect the course of HbSC disease is unknown.

ACUTE CHEST SYNDROME

Issues at the Time of Admission

Acute chest syndrome (ACS) is the most common form of acute pulmonary disease in patients with sickle cell disease. It occurs in almost one-half of all sickle cell patients (1). ACS is most common but less severe in children and, after the painful episode, is the second most frequent cause of hospitalization in sickle cell anemia. It is the most frequently reported cause of death in adults and is a risk factor for early mortality, particularly since recurrent events can end in chronic sickle cell lung disease characterized by pulmonary hypertension (see the section on “Pulmonary Hypertension” later in this chapter), cor pulmonale and eventual death. ACS is defined as the presence of the following signs and symptoms in a patient with sickle cell disease: (1) presence of a new pulmonary infiltrate, involving at least one complete lung segment (not atelectasis); (2)

TABLE 97.4
USE OF HYDROXYUREA IN SICKLE CELL ANEMIA

Indication for treatment

Adolescents or adults with frequent pain episodes, history of acute chest syndrome, other severe vaso-occlusive complications, severe symptomatic anemia

Baseline evaluation

Blood counts, red cell indices, HbF, serum chemistries, pregnancy test, willingness to adhere to all recommendations for treatment, absence of chronic transfusion program

Initiation of treatment

Hydroxyurea 500 mg (10–15 mg/kg) each morning for 6–8 wk, CBC q2wk

Treatment end points

Less pain, increase in HbF (or MCV), increased hemoglobin level if severely anemic, acceptable myelotoxicity (granulocytes $>2,000/\mu\text{L}$, platelets $>80,000/\mu\text{L}$)

Special caution should be exercised in patients with compromised renal or hepatic function or who are habituated to opiates. Contraception should be practiced by both men and women because the effects of hydroxyurea on pregnancy are not known. Granulocyte count should be $>2,000/\mu\text{L}$, platelet count $>80,000/\mu\text{L}$. A fall in hemoglobin level and absolute reticulocyte count should be carefully evaluated (in most patients who respond, the hemoglobin level increases slightly).

CBC, complete blood count; HbF, fetal hemoglobin; MCV, mean corpuscular volume.

From Steinberg MH. Drug therapy: management of sickle cell disease. *N Engl J Med* 1999;340:1021–1030, with permission.

chest pain; (3) temperature $>38.5^{\circ}\text{C}$; (4) tachypnea, wheezing, or cough; and (5) hypoxemia. On examination, there may be splinting, signs of pulmonary consolidation, or scattered rales. Chest findings can change rapidly and dramatically, which highlights the need for continual reassessment.

The principal causes of ACS remain unclear. However, probable etiologic factors include: (1) Macrovascular or microvascular infarction within the pulmonary vasculature, most likely due to *in-situ* thrombosis; (2) pulmonary fat embolism, a result of bone marrow necrosis. Lipid-laden macrophages are found in 50%–60% of children and adults with ACS. Patients with fat emboli are more likely to complain of bone pain and may develop neurologic symptoms, a finding not seen in ACS without fat emboli; (3) rib and sternal infarctions, leading to hypoventilation. Splinting due to local pain results in atelectasis and hypoxemia, which furthers the development of ACS; (4) although bacterial pneumonia was once thought to be responsible for ACS in 50% of children, more recent culture-based studies have failed to demonstrate its role as a major etiologic factor in children or adults. Pulmonary edema may also contribute, either secondary to excessive hydration or to changes in pulmonary vascular permeability due to opioids. In a study of 671 episodes of ACS in 538 patients with sickle cell disease,

the following causes of ACS were identified: pulmonary infarction, 16%; fat embolism (with or without infection), 9%; *Chlamydia pneumoniae* infection, 7%; *Mycoplasma pneumoniae* infection, 7%; viral infection, 6%; mixed infection, 4%; other pathogens, 1%; unknown cause, 46% (5).

Differentiating among the various infectious and non-infectious causes of acute chest syndrome is difficult. However, with our current state of knowledge, this sorting probably does not change the course of treatment. No current laboratory or radiographic finding permits the differentiation of ACS from other acute pulmonary manifestations of sickle cell disease, including pneumonia and infarction.

Sputum and blood cultures should be obtained. General measures that improve symptoms in many patients include optimal hydration, administration of oxygen to maintain a PaO_2 of 70–100 mm Hg, incentive spirometry, and the use of bronchodilators. Pain usually accompanies acute chest syndrome and must be treated. However, excessive opiate use can suppress respiration and should be avoided. Although microbiologic data are rarely diagnostic, antibiotic regimens that include coverage for community-acquired and atypical organisms should be employed (Chapter 65). Exchange transfusion is recommended in the setting of progressive infiltrates and hypoxemia

refractory to conventional therapy. Reduction of the HbS level to below 30% can lead to marked improvement in the majority of cases. These recommendations are based on observations that transfusions rapidly reverse hypoxia in some patients. However, no controlled clinical studies have documented the value of transfusion or have compared exchange transfusions with simple transfusions (6).

Indications for Initial Intensive Care Unit Admission

Hypoxia with respiratory distress, high-grade fever, circulatory instability, and acute respiratory distress syndrome (ARDS) are all adverse prognostic findings that should prompt consideration of ICU admission.

Issues During the Course of Hospitalization and at Discharge

Hypoxic patients should be closely monitored with frequent blood gas measurements (see Chapter 24 for management of respiratory failure). Serial assessments of blood cell counts and changes in chest radiograph, especially in the first few days of the episode, can be useful prognostically and suggest whether ICU transfer is advisable. It may take weeks for all signs of acute chest syndrome to resolve and hospitalization can last 1–2 weeks, depending on the cause and severity of the episode.

One or more documented episodes of acute chest syndrome may be an indication for initiating treatment with hydroxyurea. The rationale for this suggestion is the observation that acute chest syndrome tends to be a recurrent event that is associated with increased morbidity and early mortality in adults. Hydroxyurea can reduce by 50% the incidence of this complication.

Multiple acute chest episodes presage a poor prognosis. Sometimes, consideration of bone marrow transplantation in this situation is warranted (Chapter 96). Children below the age of 16 with an HLA-matched donor are presently the best candidates, but only 1% of sickle cell anemia patients meet these requirements. Of the approximately 200 patients who have undergone transplantation, more than 90% survived, 70%–85% had prolonged event-free survival, and 15% suffered graft rejection. Whether or not transplantation can reverse established organ damage has not been determined, but early reports suggest some improvement in chronic lung disease.

PULMONARY HYPERTENSION

Using echocardiography as the diagnostic tool, the estimated incidence of pulmonary hypertension in sickle cell anemia has been found to be between 8% and 30%. In a recent catheterization study of 34 adult patients with

sickle cell disease, 20 patients (59%) were diagnosed with pulmonary hypertension (average mean pulmonary artery pressure 36 mm Hg). Several of these patients had elevated pulmonary capillary wedge pressures consistent with left ventricular diastolic dysfunction. Mean pulmonary artery pressure was inversely related to survival. Each increase of 10 mmHg in mean pulmonary artery pressure was associated with a 1.7-fold increase in the rate of death (7). Chapter 59 reviews the diagnosis and management of pulmonary hypertension.

BLOOD TRANSFUSIONS

Transfusions play a vital role in the treatment of some complications of sickle cell anemia, and there are singular considerations and discrete indications for their use (Table 97.5). Transfusions are not needed for the usual anemia or painful episode. Except for aplastic crises and precipitous falls in PCV that occasionally occur during acute events like chest syndrome or sepsis, the PCV remains quite constant over time. Some patients can be

TABLE 97.5
TRANSFUSIONS IN SICKLE CELL DISEASE

Indicated

Symptomatic acute anemic episodes
Severe symptomatic chronic anemia—for example, with renal failure
Prevention of first stroke and recurrent strokes in childhood
Acute chest syndrome with hypoxia^a
Surgery with general anesthesia or eye surgery^b

Perhaps useful

Complicated obstetric problems
Severe right upper quadrant syndrome with extreme hyperbilirubinemia
Refractory leg ulcers
Refractory and protracted painful episodes
Acute severe priapism, when given early in episode

Probably not indicated

Raising the customary hemoglobin level
Uncomplicated painful episode
Uncomplicated pregnancies
Minor surgery with local anesthesia

^a Controlled studies of exchange versus simple transfusions in acute chest syndrome are lacking.

^b Exchange transfusion appeared to increase the incidence of transfusion-related complications like allo-immunization. When possible, leukocyte-depleted, phenotypically matched packed red cells should be transfused.

From Steinberg MH. Drug therapy: management of sickle cell disease. *N Engl J Med* 1999;340:1021–1030, with permission.

active and symptom-free with PCVs of 16%–20%. Sudden severe anemia, which occurs in children when blood is sequestered in an enlarged spleen or when parvovirus B19 infection causes transient aplastic crisis, often requires urgent blood replacement. Symptomatic anemia occasionally accompanies renal failure, and some of these patients may require transfusion. Alternatively, the judicious use of erythropoietin can sometimes restore hemoglobin levels to pre-renal failure levels.

Recent clinical trials have evaluated the efficacy of transfusion in preventing some of the complications of sickle cell disease (8, 9). Measuring the velocity of cerebral blood by trans-cranial Doppler flow studies and placing individuals at high risk for stroke on prophylactic transfusions reduces the likelihood of an initial stroke (10). Long-term transfusion reduces the recurrence of stroke in children with sickle cell anemia with a prior stroke. The aim of exchange transfusion is to rapidly reduce the HbS level to less than 30% and maintain this level for 3–5 years. Stopping transfusions—even after many years—is often followed by recurrent stroke. Reducing the frequency of transfusion and permitting the HbS level to rise to 50% after four years of more intensive transfusion appears safe.

When general anesthesia is used, preoperative transfusion to a PCV of about 30% prevents postoperative complications as effectively as aggressive exchange transfusion, and is associated with half as many transfusion-related complications (5). Routine intrapartum transfusions are not indicated (8).

Among the general complications of transfusion, *allo-immunization* stands out as a special hazard for patients with sickle cell disease. Because of antigenic differences between the erythrocytes of a predominantly Caucasian blood donor pool and the African-American recipients, 20%–30% of patients with sickle cell anemia who undergo transfusion become allo-immunized. Therefore, red cells phenotypically matched for the antigenic determinants most often eliciting an immune response and depleted of leukocytes are the preferred transfusion product. Another consequence of repetitive transfusion is *iron storage disease*. When transfusions are utilized continually, iron chelation therapy should be planned. Presently, this can be accomplished only with desferrioxamine, given by prolonged subcutaneous or intravenous infusion 8–12 hours nightly, 5–6 days weekly, at doses of 2–6 g daily.

COST CONSIDERATIONS AND RESOURCE USE

Each hospital admission for treatment of a painful episode may last between 5 and 11 days and is associated with charges of \$4,000–\$16,500. Emergency department charges for treating the pain of sickle cell disease vary between \$400 and \$600. Treating acute chest syndrome is

usually far more expensive. Treating patients with hydroxyurea appears to be associated with a reduction in medical costs (11). Regular clinic attendance has also been shown to reduce the health care costs of sickle cell disease.

KEY POINTS

- Frequent painful episodes and acute chest syndrome portend a poor, sometimes fatal, prognosis. Hydroxyurea reduces morbidity and mortality in these patients.
- Large amounts of opiates may be needed to relieve pain during an acute painful episode.
- Acute chest syndrome may develop in the course of a painful episode, even if it was not apparent on first presentation.
- Blood transfusions are indicated in acute chest syndrome with hypoxia.
- Blood transfusions are not indicated in uncomplicated pain episodes or to treat the usual level of anemia.
- Severe priapism must be evaluated early in its course and the decision made within 24 hours to move from conservative to invasive therapy.

Hemorrhagic and Thrombotic Disorders

98

Julie Hambleton Marc Shuman

INTRODUCTION

The hemostatic system is a finely balanced network of coagulation factors and endothelial and platelet components. Its normal function is either to rapidly arrest the bleeding associated with trauma or to terminate this process to prevent excessive clotting. Abnormalities in any of these components can lead to pathologic bleeding or thrombosis. The following general overview of hemorrhagic and thrombotic disorders includes a summary of our approach to evaluating and treating hospitalized patients with disorders of bleeding or thrombosis.

Pathologic Bleeding Caused by Platelet and Coagulation Disorders

A fundamental issue in patients presenting with a bleeding diathesis is to determine whether the bleeding is entirely the consequence of a structural problem, or whether a significant primary platelet or coagulation defect is present. This distinction is not always clear, and it may be necessary to exclude the latter possibilities by laboratory testing. Bleeding caused by a coagulation or platelet disorder frequently occurs at sites where a structural abnormality is present, such as one caused by peptic ulcer disease, a recent surgical procedure, or a traumatic injury.

When evaluating for a possible bleeding disorder, the patient's history may suggest whether a bleeding diathesis is congenital or acquired and, if the latter, the most likely category into which it falls. Moreover, careful physical examination may reveal signs that indicate a platelet or vascular defect vs. a coagulation defect. Based on this information, it frequently can be determined whether bleeding is secondary to a platelet or a coagulation disorder (Table 98.1).

The following historical information is useful in narrowing the diagnostic possibilities:

1. *Timing of the first manifestation of bleeding.* In severe hereditary bleeding disorders, the onset is frequently at birth or at the time of male circumcision. In milder congenital disorders, abnormal bleeding may present (as epistaxis) later in childhood when a child becomes more physically active, or at menarche in affected girls.
2. *Frequency and duration of bleeding.* A history of bleeding on some occasions but not others does not exclude the diagnosis of a primary bleeding disorder. Patients with mild von Willebrand disease or factor XI deficiency, for example, may have this type of history.
3. *Events frequently complicated by bleeding.* These include menorrhagia or postpartum bleeding in von Willebrand disease.
4. *Location of bleeding.* In platelet disorders, epistaxis, cutaneous bleeding, and excessive menstrual bleeding are common. In hemophilia, joint bleeding is typical.
5. *Medications.* See Table 98.2 for a list of drugs that alter platelet activity or coagulation.
6. *Family history.* Most coagulation and platelet disorders are autosomal recessive; the inheritance pattern of von Willebrand disease is autosomal dominant, and hemophilia A and B (Factor VIII and IX deficiency, respectively) are X-linked recessive disorders.

Examination findings provide important clues to the nature of bleeding disorders. In platelet abnormalities or vascular defects, hemorrhage is usually mucosal or cutaneous. Bleeding secondary to a clotting factor deficiency is often intramuscular or intra-articular. The presence of petechiae indicates a platelet or vascular defect rather than deficiencies of clotting factors. Quantitative platelet disorders are associated with petechiae only when the platelet count is

TABLE 98.1**DISTINGUISHING PLATELET-TYPE BLEEDING DISORDERS FROM COAGULATION DISORDERS**

profoundly low. Purpura is found more commonly in platelet than in clotting factor disorders. Punctate telangiectases on the tongue, nasal mucosa, lips, or fingertips are diagnostic of hereditary hemorrhagic telangiectasia.

Laboratory evaluation is used to elucidate the underlying defect suggested by history and examination. Figure 98.1 provides a general algorithm for the evaluation of possible bleeding disorders. The platelet count can be obtained either by automated techniques or by estimating the number in the peripheral blood smear, a useful method for rapidly detecting low platelet counts. Normally, 3–10 platelets per high-power (oil immersion) field appear on the peripheral smear. The *bleeding time* is a crude measure of platelet function and is prolonged when the platelet count is below 90,000/ μ L or when a functional platelet abnormality is present. The platelet function analyzer (PFA-100®) is another tool available in some laboratories and may detect the presence of abnormal platelet function. While both the bleeding time and PFA-100® have varying sensitivities for platelet disorders and neither are predictive of surgical bleeding, the PFA-100 may

be the more sensitive assay. Platelet aggregometry measures temporal, semiquantitative, and qualitative parameters of platelet aggregation *in vitro*. This technique is of greatest value in diagnosing congenital qualitative platelet disorders.

The two most useful and commonly performed tests to assess the integrity of the coagulation system are the prothrombin time (PT) and activated partial thromboplastin time (aPTT). Whenever results of these tests are abnormal, they should be repeated on a fresh blood sample to be certain that the abnormality is not artifactual. The PT reflects the combined activity of clotting factors II, V, VII, and X and fibrinogen. The aPTT measures the combined activity of factors II, V, VIII, IX, X, XI, and XII and fibrinogen.

Other laboratory tests useful in pinpointing the diagnosis in coagulation disorders include the following:

1. *Fibrinogen* (quantitative). Decreased fibrinogen is seen most commonly in severe liver disease and disseminated intravascular coagulation (DIC). Heparin in the plasma sample may cause a falsely low value as a result of incomplete clotting.

TABLE 98.2
DRUGS THAT MAY ALTER HEMOSTASIS

Drugs reported to cause thrombocytopenia

Immune mechanisms proposed^a

Quinine/quinidine	Ranitidine
Sulfa compounds	Cimetidine
Ampicillin	Danazol
Penicillin	Procainamide
Thiazide diuretics	Carbamazepine
Furosemide	Acetaminophen
Chlorthalidone	Phenylbutazone
Phenytoin	Aminosalicylate
α -Methyldopa	Rifampin
Heparin	Acetazolamide
Digitalis derivatives	Anazole
Aspirin	Arsenicals
Valproic acid	

Nonimmune mechanisms (hemolytic-uremic syndrome)

Mitomycin C	Cyclosporine
Cisplatin	Ticlopidine

Mechanisms undefined

Gold compounds
Indomethacin

Drugs that alter platelet function

Primary antiplatelet agents

Aspirin	Sulfapyrazone
Dextran	Ticlopidine/clopidogrel
Dipyridamole	Glycoprotein IIb/IIIa inhibitors

Drugs in which inhibition of platelet function is associated with prolongation of the bleeding time

Nonsteroidal antiinflammatory agents
β -lactam antibiotics
ϵ -Aminocaproic acid (>24 g/d)
Heparin
Plasminogen activators (streptokinase, urokinase, tissue plasminogen activator)

Drugs that affect coagulation factors

Induction of antibodies inhibiting function

Lupus anticoagulant ^b	Factor V antibodies
Phenothiazines	Aminoglycosides
Procainamide	Factor XIII antibodies
Factor VIII antibodies	Isoniazid
Penicillin	

Inhibitors of synthesis of vitamin K-dependent clotting factors (Factors II, VII, IX, X, proteins C and S)

Coumarin compounds
Moxalactam

Inhibitor of fibrinogen synthesis

L-asparaginase ^c

^a List is limited to drugs for which there are multiple reports and *in vitro* or *in vivo* evidence of antiplatelet antibodies.

^b Does not cause bleeding.

^c May cause thrombosis.

2. *Specific factor assays.* Factor assays are performed by determining the extent to which the patient's plasma corrects the clotting time of plasma known to be deficient only in one particular clotting factor.
3. *Mixing tests* are used to detect inhibitors of clotting. When a plasma sample with a deficiency of one of the coagulation factors is mixed with an equal volume of normal plasma, the PT or aPTT is normalized. Conversely, if an inhibitor is present in the patient's plasma, the PT or aPTT will still be prolonged.
4. *Tests for fibrin degradation products.* Most tests measure plasmin degradation products of fibrin(ogen) by

means of an antibody against fibrin. Fibrin degradation products are elevated in DIC and in liver and kidney failure, organs in which large and small fragments are cleared, respectively. Fibrin degradation products are also increased after major surgery and trauma. In the D-dimer test for intravascular clotting and fibrinolysis, a plasmin cleavage product of cross-linked fibrin, D, is measured. D-dimer is elevated in DIC, and venous thromboembolic disease, and after major surgery.

5. *Thrombin time* measures the ability of fibrin to form a clot. It is abnormal in the presence of a dysfibrinogenemia or heparin.

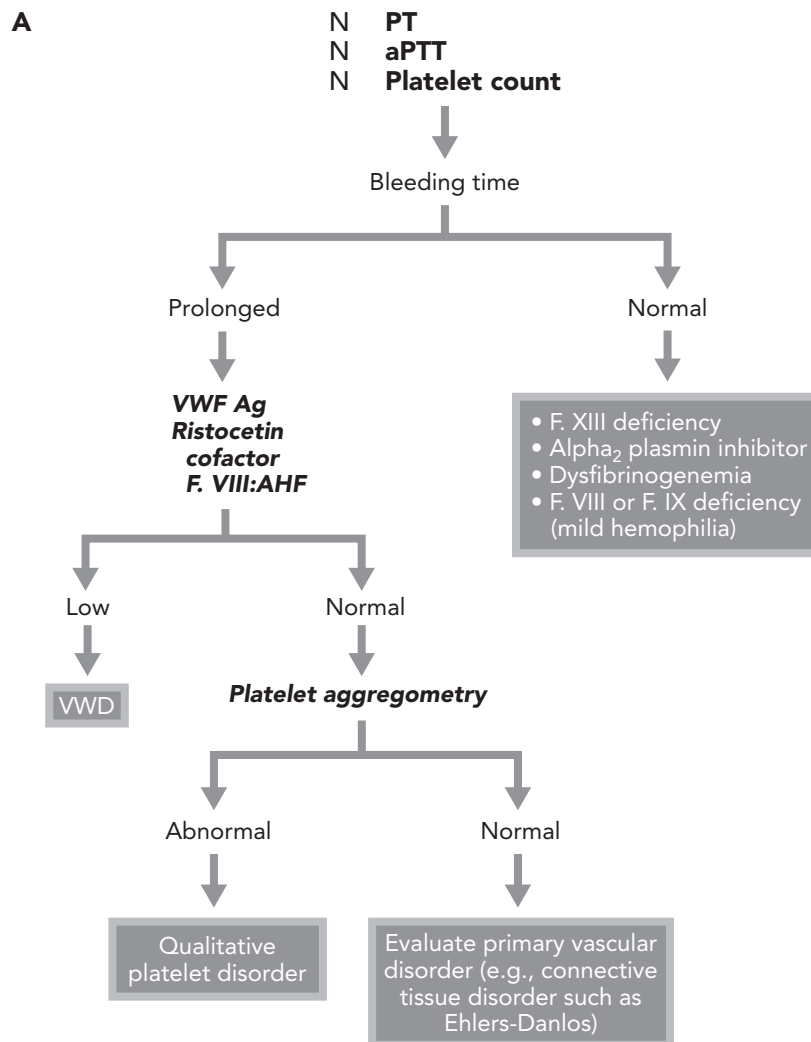

Figure 98.1A A–E: Laboratory evaluation of clinical bleeding disorders. A, abnormal; AHF, antihemophilic factor; aPTT, activated partial thromboplastin time; DIC, disseminated intravascular coagulation; FSP, fibrin split products; N, normal; PT, prothrombin time; RVV, Russell viper venom test; VWD, von Willebrand disease; VWF, von Willebrand factor. ^aAssumes patient is not receiving heparin. Consider checking aPTT on Hepasorb to rule out heparin effect if unsure. ^bSupratherapeutic heparin or warfarin effect can result in elevations of both PT and aPTT.

Typical charges for the laboratory tests used in evaluating patients with disorders of bleeding (or clotting) are shown in Table 98.3.

Thrombotic Disorders

Acute venous thromboembolic (VTE) disease is diagnosed annually in approximately 250,000 patients; the major morbidity relates to recurrent disease, pulmonary embolism, and post-phlebotic syndrome. These patients and patients with thrombosis in an unusual location present some of the greatest medical challenges for treating physicians. When evaluating the patient presenting with thrombosis, it is necessary to define the nature and extent of thromboembolic disease

by addressing the following issues:

- Does the disease involve the arterial or venous vasculature?
- Is the clot located in the cerebral, peripheral, mesenteric, renal, or cardiopulmonary vessels?
- Is there an underlying risk factor for thrombosis?
- Should the patient undergo additional evaluation?
- What type of anticoagulant should be used, and what is the optimal duration of therapy?

These questions will guide the treating physician in evaluating and treating the patient, and help determine if further hematologic consultation should be obtained.

The definition of *hypercoagulability* (also referred to as *thrombophilia*) is a clinical one (Table 98.4). No screening

test exists that identifies which patients have an underlying cause for their tendency to clot. In general, the hospital physician should try to determine whether the patient has elements of a primary or secondary form of thrombophilia (Table 98.5). It is important to distinguish whether the acute thrombosis arose in the arterial or venous vasculature, as the differential diagnosis differs for these two events.

The inherited disorders of thrombophilia pertain to either quantitative or qualitative abnormalities of the natural anticoagulant system. Deficiencies in the natural anticoagulants antithrombin (AT), protein C, and protein S account

TABLE 98.4
GENERAL CLINICAL FEATURES OF HYPERCOAGULABILITY

- Positive family history
- Recurrent thromboses
- Idiopathic thrombosis on trivial provocation, especially in a patient under age 65
- Unusual site of thrombosis (i.e., visceral, cerebral, axillary, or cutaneous vessels)
- Recurrent thrombosis despite adequate anticoagulation

TABLE 98.5
CAUSES OF THROMBOEMBOLIC DISEASE

Primary (inherited)

Deficiencies of natural inhibitors or qualitative abnormalities of the clotting cascade

- Antithrombin deficiency
- Protein C deficiency
- Protein S deficiency
- Factor V Leiden mutation
- Prothrombin 20210
- Hyperhomocysteinemia

Qualitative abnormalities of fibrinogen

- Dysfibrinogenemia

Defects in the fibrinolytic system with impaired clot lysis

Secondary (acquired)

Abnormalities of coagulation and fibrinolysis

- Disseminated intravascular coagulation
- Malignancy
- Pregnancy, estrogen use
- Nephrotic syndrome
- Inflammatory bowel disease
- Lupus anticoagulant
- Anti-phospholipid antibody syndrome

Abnormalities of platelets

- Myeloproliferative disorders: essential thrombocytosis, polycythemia rubra vera
- Paroxysmal nocturnal hemoglobinuria
- Heparin-induced thrombocytopenia

Abnormalities of blood vessels and rheology

- Venous stasis—congestive heart failure, immobilization, obesity, age, postoperative state
- Artificial surfaces (grafts)
- Vasculitis
- Hyperviscosity syndromes (Waldenström's, leukostasis)
- Thrombotic thrombocytopenic purpura

for only 15% of selected patients with juvenile or recurrent thrombosis and 5%–10% of unselected cases of acute venous thrombosis. Factor V Leiden mutation, hyperhomocysteinemia, and the prothrombin 20210 polymorphism account for a greater number of hypercoagulable patients (1).

An approach to the laboratory workup of patients suspected of having hypercoagulable blood is shown in Table 98.6. Note that certain tests can be interpreted only while patients are off anticoagulant medications.

Antithrombin Deficiency

Antithrombin inactivates thrombin and factors Xa, IXa, XIa, and XIIa. Its anticoagulant activity is enhanced by the presence of heparin, which forms a ternary complex with AT and the procoagulant factors. A deficiency of this natural anticoagulant results in recurrent VTE.

The inheritance pattern of AT deficiency is autosomal dominant. The frequency of symptomatic AT deficiency in

^b Either send before anticoagulation is initiated or send after a treatment course is completed. If an abnormal test result will lead to lifelong therapy, consider repeating test before acting on one abnormal result.

^c Although the lupus anticoagulant is not a “primary” hypercoagulable state, a test for it should be included in the workup of a patient with an idiopathic thromboembolism because of its high rate of recurrent venous and arterial thromboembolic disease.

the general population has been estimated to be between 1 in 2,000 and 1 in 5,000. In unselected patients with a history of VTE, the frequency is 1.1%; in selected patients with histories of recurrent VTE or a familial history, the frequency is approximately 2.4%. The majority of affected persons are heterozygotes with AT levels between 40%–70% of normal. Of the three types of AT deficiency, the majority is either type I or II and can be diagnosed by determining the functional AT level.

Deficiency of Proteins C and S

Proteins C and S are vitamin K-dependent glycoproteins that are involved in the inactivation of activated factors V and VIII. Protein C is slowly activated by thrombin to form activated protein C (APC). This activation is enhanced by the formation of complexes with thrombin and the endothelial receptor thrombomodulin. Protein S in and of itself has no intrinsic anticoagulant activity. Instead, it enhances the affinity of APC for negatively charged phospholipids, such as the platelet surface, by forming a membrane-bound APC–protein S complex that renders factors Va and VIIIa more easily accessible to APC-mediated cleavage.

Deficiencies in protein C and protein S are transmitted as autosomal dominant traits. Homozygous protein C deficiency is associated with neonatal purpura fulminans and warfarin-induced skin necrosis. The frequency of protein C and protein S deficiencies is 2.2%–3.2% in unselected pa-

tients with venous thrombosis and 3% to 3.8% in selected patients.

Factor V Leiden Mutation

The factor V Leiden mutation is represented by a single adenine-to-guanine point mutation in the gene encoding coagulation factor V. This results in the replacement of arginine by glutamine at a key proteolytic site on the activated factor V protein, such that the molecule cannot be cleaved by activated protein C—hence the so-called “APC resistance.” Factor V clotting activity is normal in coagulation assays. Rather, factor V is resistant to inactivation *in vivo*. The factor V Leiden mutation is found in 2%–5% of the asymptomatic Caucasian population, and it accounts for approximately 40% of patients presenting with idiopathic VTE disease. It has also been associated with increased risks for recurrent venous thromboembolism, for venous thrombosis during use of oral contraceptives and pregnancy, and for thrombosis in the presence of other genetic and acquired abnormalities of anticoagulation, such as protein C and S deficiencies (2).

Prothrombin 20210

A polymorphism in the 3′-untranslated region of the prothrombin (factor II) gene is associated with mild increases in plasma prothrombin levels and in the risk for venous thrombosis. The factor II 20210A polymorphism may be found in 18% of selected patients with a personal and family history of venous thrombosis, in 6.2% of unselected consecutive patients presenting with their first idiopathic deep venous thrombosis, and in 2.3% of normal controls. Carriers of the 20210A allele have a 2.8-fold increased risk for VTE.

The clinical manifestations in patients with protein C, protein S, AT deficiencies, or the Leiden and prothrombin mutations are very similar. More than 90% of patients present with venous thrombosis of the lower extremity, with or without accompanying pulmonary embolus. A minority of patients (generally 5%) present with venous thrombosis in an unusual location, such as the sagittal sinus or mesenteric vessels. Rarely are these disorders associated with arterial thrombosis. VTE develops in 60%–80% of people heterozygous for AT, protein C, or protein S deficiency, typically before the age 40–45. About 50% of patients have recurrent disease. People with the Leiden and prothrombin mutations have a lesser tendency for thrombosis, and the first episode of thrombosis often occurs at a more advanced age. However, the concomitant occurrence of the factor V Leiden or prothrombin mutation and AT, protein C, or protein S deficiency greatly enhances a person’s risk for thrombosis.

About 50% of patients with these thrombophilic defects have no inciting event as the cause of their deep venous thrombosis. In the remaining patients, thrombosis may be associated with minor trauma, pregnancy, use of oral

contraceptives, recent surgery, or immobilization. The frequency of thrombosis during pregnancy and the peripartum period has been thought to be quite high (31% and 44%, respectively, for AT deficiency; 10% and 19%, respectively, for protein C and protein S deficiency; 28% for the Leiden mutation), although recent studies suggest a lower risk. Administration of estrogen to a woman with the factor V Leiden or Prothrombin mutation will increase her risk of developing cerebral vein thrombosis, and recurrent fetal loss has been associated with the presence of these genetic thrombophilic defects. The frequency of postoperative thrombosis has been shown to be high in patients with AT, protein C, or protein S deficiencies: 21% in patients undergoing abdominal surgery and 37% in patients undergoing high-risk orthopedic or cancer surgery. Patients with factor V Leiden mutation do not have an increased risk for thrombosis after joint replacement surgery if treated with appropriate anticoagulant prophylaxis.

Hyperhomocysteinemia

The early descriptions of hyperhomocysteinemia involved patients with homozygous mutations in genes encoding for enzymes of homocysteine metabolism. The classic disorder of hyperhomocysteinemia is associated with a mutation in cystathionine β -synthase that leads to fasting plasma homocysteine concentrations as high as 100–400 mmol/L (normal, <16 mmol/L). The clinical manifestations of this disorder include mental retardation, ectopic lens, skeletal abnormalities, premature arterial disease, and venous thrombosis. Severe elevations in plasma homocysteine are also associated with homozygous defects of the methylenetetrahydrofolate reductase (MTHFR) gene or of various enzymes that participate in the vitamin B₁₂ cycle. However, these mutations are uncommon.

More common forms of hyperhomocysteinemia are subtle in presentation and may be caused by less severe defects in genes encoding for enzymes or by inadequate status of vitamins involved in homocysteine metabolism. Inadequate folate, vitamin B₁₂, or pyridoxine may result in a substantial increase in plasma homocysteine concentration. When present in the homozygous state, a common thermolabile polymorphism of the MTHFR gene has been found to be associated with elevated homocysteine levels in the setting of folate deficiency.

Mild (16–24 mmol/L) and moderate (25–100 mmol/L) hyperhomocysteinemia has been shown to be an independent risk factor for stroke, myocardial infarction, peripheral arterial disease, and extracranial carotid artery stenosis. It has also been shown to be a risk factor for VTE disease, and it augments the risk for VTE associated with oral contraceptive use, pregnancy, trauma and surgery, immobilization, and inherited disorders of thrombophilia, most notably factor V Leiden mutation and presence of lupus anticoagulant.

As the evaluation of inherited causes of hypercoagulability is both complex and expensive (Table 98.3), it is

generally best directed by a hematologist or by a specialist knowledgeable in this area.

ISSUES IN THE HOSPITALIZED PATIENT

Approach to the Bleeding Patient

Thrombocytopenia

The most common causes of abnormal bleeding in hospitalized patients are acquired thrombocytopenia, an acquired qualitative platelet defect (e.g., associated with aspirin use), or the presence of a structural lesion. Thrombocytopenia can be caused by disturbances in production, distribution, or destruction (Figure 98.2). With splenic enlargement, platelet

pooling increases, which can cause thrombocytopenia. Platelet counts below 30,000–50,000/ μL are unusual. Hypoplasia of hematopoietic stem cells can cause thrombocytopenia. Causes of hypoplasia include decreased numbers of megakaryoblasts following injury of the bone marrow by drugs, chemicals, or radiation, and replacement of bone marrow by abnormal tissue, most commonly cancer. Examination of the bone marrow reveals decreased numbers of megakaryocytes and either an overall decrease in cellularity or infiltration by abnormal cells.

Decreased production of platelets may also be a consequence of abnormal maturation of megakaryocytes. Deficiencies of either vitamin B₁₂ or folate can cause ineffective thrombocytopoiesis leading to thrombocytopenia (Chapter 89). Similarly, abnormal platelet production is common in hematopoietic dysplasias. In both disorders, megakary-

Initial evaluation

ocytes are usually increased. In hematopoietic dysplasia, megakaryocytes may be abnormal in appearance.

Increased peripheral destruction or decreased production of platelets as consequences of drug therapy are probably the most common causes of thrombocytopenia in hospitalized patients. The etiology of drug-induced thrombocytopenia is typically destruction of platelets by drug-induced antibodies (Table 98.2). More than 50 drugs have been reported to cause immune thrombocytopenia, but conclusive confirmation is rare (3, 4). In most instances, the drug must be present to cause antibody binding and thrombocytopenia, and the platelet count returns to normal within a few days after discontinuation. Glucocorticoids do not accelerate recovery. Platelet antibody tests, with and without the putative offending agent, are useful in determining the cause of thrombocytopenia, but they cannot be performed until the drug clears from the plasma. In addition, a drug metabolite, rather than the parent compound, may be responsible for antibody formation. Unless the metabolite is specifically tested, a negative result will be obtained.

Heparin therapy is associated with a transient decline in the platelet count that often resolves spontaneously despite continuation of the drug. This early thrombocytopenia (within five days of initial therapy) may be seen in more than 9% of patients. A more worrisome association of thrombocytopenia with heparin occurs after 5–10 days of initial heparin therapy. In 3%–5% of patients receiving unfractionated heparin therapy, platelet counts fall by more than 50%, or patients become frankly thrombocytopenic. This *heparin-induced thrombocytopenia* is mediated by the induction of an IgG antibody that binds the heparin-platelet factor 4 complex, which in turn binds the Fc receptor of an adjacent platelet, causing platelet aggregation and clearance. Heparin-induced thrombocytopenia is seen with both full-dose unfractionated heparin and low-dose therapy, and it occurs with the low-molecular-weight heparins, but to a lesser extent. Heparin-induced thrombocytopenia does not result in abnormal bleeding. Rather, in a subset of patients, arterial or venous thrombosis may ensue, posing a therapeutic challenge (see later in this chapter).

Idiopathic thrombocytopenic purpura (ITP) is an autoimmune bleeding disorder characterized by the development of antibodies to one's own platelets, which are then destroyed by phagocytosis in the spleen and liver. In adults, the onset is usually gradual, lacks a preceding illness, and runs a chronic course. In a small percentage of adult cases, the disease has an acute onset. Ninety percent of adults with ITP are under age 40, and the ratio of women to men is between 3:1 and 4:1. Petechiae, ecchymoses, and epistaxis develop, and menorrhagia may develop in women. Death from hemorrhage occurs in about 5% of patients with chronic ITP. Cerebral bleeding occurs in approximately 1% of cases. The diagnosis of ITP depends on excluding underlying systemic disorders that result in increased peripheral destruction or decreased production of

platelets. On physical examination, the spleen is not enlarged. In ITP, the hemoglobin level is normal unless the patient has significant bleeding. Peripheral blood smears reveal normochromic, normocytic red blood cells. The value of antiplatelet antibody assays in diagnosing ITP is uncertain. In most cases of ITP, the diagnosis is clear, making it unnecessary to confirm the presence of antiplatelet antibodies. In complex cases, the antibody test may be helpful. If the clinical evaluation and blood tests do not identify any systemic disorder causing the thrombocytopenia, the bone marrow should be examined. In ITP, the marrow is normal, although megakaryocytes may be increased in number.

Patients with ITP and platelet counts below 20,000/ μ L are usually symptomatic and require treatment. Initially, bleeding associated with ITP is treated with prednisone or a similar corticosteroid at a dose of 1–2 mg/kg daily. In 80%–90% of patients, the platelet count rises to hemostatic levels within 2–3 weeks. Failure to respond to steroids is indicated by a platelet count below 50,000/ μ L after 4 weeks of treatment. A subnormal platelet count after 6 weeks of treatment also indicates steroid failure. Once the platelet count has reached its apex and is stable, steroids are tapered slowly. However, when the dose of prednisone is tapered, most patients (>90%) exhibit a recurrence of thrombocytopenia. Thus, the primary benefit of prednisone is in the acute management of bleeding.

Another effective approach to managing patients with ITP who are actively bleeding or for whom major surgery is necessary is the use of *intravenous gamma globulin*. IgG concentrate raises the platelet count within 3–5 days in most patients and is the most rapidly active agent. Unfortunately, the therapeutic effect is usually transient, with the platelet count falling to baseline levels during the next month. The dosage is 1 g/kg daily for two successive days. In 80% of patients, subsequent platelet counts rise above 50,000/ μ L. A slightly less expensive alternative is anti-Rh antibody (Winrho), which may be effective in Rh-positive patients with intact spleens (5).

Given the lack of a sustained remission in most patients with severe ITP treated with steroids or IgG, a more definitive approach is often necessary. *Splenectomy* improves the platelet count in 70% of patients with ITP and induces a sustained remission in approximately 60%, but no tests reliably predict which patients will respond. The platelet count rises within a few days after splenectomy, or at most in 1–2 weeks. A more recent approach to treating patients with ITP is the use of *Rituximab* (Rituxan®), an anti-CD20 antibody. CD-20 is present on the surface of B lymphocytes. Immunotherapy with an anti-CD20 antibody has resulted in clinical remissions of a number of malignant and benign lymphoproliferative disorders, including ITP.

The management of ITP in pregnancy is complicated by the additional risk for the development of thrombocytopenia in the fetus, secondary to maternal antibodies. Intraventricular hemorrhage, gastrointestinal bleeding,

and death have been reported in such newborns. When ITP first develops during pregnancy, the risk for serious bleeding in the newborn is negligible. Conversely, neonates born to women with a history of ITP preceding pregnancy have a 20% risk for severe thrombocytopenia. In addition to treating the underlying ITP, some experts recommend cesarean delivery in this situation to decrease the risk for intracranial bleeding in the newborn, although this is controversial.

Antibodies directed against platelets may occur in several disorders other than ITP. Antibody-mediated destruction of platelets occurs in lymphoproliferative disorders, such as chronic lymphocytic leukemia and lymphoma. Generally, thrombocytopenia improves with treatment of the underlying malignancy. The platelet count improves with immunosuppressive therapy such as prednisone. Immune thrombocytopenia is also common in systemic lupus erythematosus (Chapter 112). The platelet count is usually mildly-to-moderately decreased. Other manifestations of the disease are present in most cases. Immune thrombocytopenia occurs less commonly in other systemic autoimmune disorders. Thrombocytopenia associated with antiplatelet antibodies has been reported in patients with infectious mononucleosis, HIV infection, and cytomegalovirus infection. In the case of infectious mononucleosis and cytomegalovirus infection, thrombocytopenia is usually self-limited, with recovery in 3–4 weeks. In patients with severe thrombocytopenia and bleeding, a short course of glucocorticoids may help raise the platelet count.

When packed erythrocytes or non-fresh whole blood is transfused to replace lost blood, thrombocytopenia may ensue (Chapter 91). Approximately 35%–40% of platelets remain in the circulation after replacement of 1 blood volume; microvascular bleeding from thrombocytopenia occurs rarely after replacement of 1–2 volumes. Platelets should be transfused only when thrombocytopenia and bleeding are present. Finally, microangiopathies associated with an increased consumption of platelets (as in DIC) are often the cause of thrombocytopenia in hospitalized patients (see later in this chapter).

Qualitative Disorders of Platelet Function

Drugs that inhibit platelet function include nonsteroidal anti-inflammatory agents, which inhibit platelet function by blocking platelet synthesis of prostaglandins. Aspirin permanently impairs platelet function. One aspirin tablet is sufficient to cause this effect. Fortunately, in most people, this does not result in excessive bleeding, but in patients with von Willebrand disease or with severe coagulation factor deficiency, serious bleeding can result. Therefore, aspirin is contraindicated in these disorders. High doses of β -lactam antibiotics induce an abnormality in platelet function that persists for 2–3 days after the drug is discontinued. The mechanism is unclear. The

bleeding time is prolonged, and patients may have increased bleeding.

Platelets function abnormally in patients with renal failure. The uremic metabolites responsible for this dysfunction are uncertain. Thrombocytopenia is uncommon and usually mild, and it may be a consequence of the underlying cause of renal disease. Uremic bleeding is usually mucocutaneous and reflects abnormal platelet or vascular hemostasis. The bleeding time is commonly prolonged, but other causes of prolongation must be excluded. Hematocrits of $<24\%$ also prolong the bleeding time in uremia. Transfusion of packed red blood cells to elevate the hematocrit above 26% improves the bleeding time, and is thus a reasonable therapeutic approach for patients with acute bleeding or whose risk for bleeding is high. Administration of recombinant erythropoietin to raise the hematocrit above 26% is also effective as prophylaxis against bleeding before elective surgery or in cases of chronic blood loss.

When abnormal bleeding develops in a uremic patient, one must evaluate the possibilities of a structural lesion and other hemostatic abnormalities. Platelet abnormalities are seldom the sole cause. When the hemostatic defect of renal failure is believed to be a significant contributing factor to bleeding, the patient should undergo dialysis (Chapter 101). Both peritoneal dialysis and hemodialysis usually reverse the hemostatic defect. If the bleeding time remains prolonged and the patient is bleeding, other agents can be tried. In order of preference, these are low-dose conjugated estrogens, 1-deamino-8-D-arginine vasopressin (DDAVP), and cryoprecipitate. Their efficacy, however, has not been firmly established. Platelet transfusion usually has no benefit.

Platelet function is sometimes abnormal in liver disease, but the extent to which this contributes to bleeding is unclear. The bleeding time may be prolonged in moderately severe liver disease when the platelet count is $<90,000/\mu\text{L}$. DDAVP has been reported to improve the bleeding time in these circumstances. More commonly in hepatic failure, a bleeding diathesis is secondary to deficiencies of coagulation factors (Chapters 82 and 83).

The inherited disorders of platelet function are found in a minority of hospitalized patients, but the presence of these disorders should be suspected in those patients with a supportive history of bleeding. Patients may provide a lifelong history of easy bruising, epistaxis, and prolonged oozing after venipuncture, dental extractions, and menses. These disorders often are characterized by a prolonged bleeding time and by platelets that fail to aggregate normally when stimulated with specific agonists, the particular pattern depending on which disorder is present. The platelet count is normal in most of these disorders.

The most common congenital bleeding disorder is *von Willebrand disease*. An autosomal dominant disorder, it is characterized by a deficiency of von Willebrand factor, which is necessary for the adhesion of platelets to connective

tive tissue. Because von Willebrand factor is a carrier protein for factor VIII, patients with von Willebrand disease can be deficient in both activities. In most patients, *von Willebrand disease causes a platelet-like bleeding diathesis*. The manifestations of disease differ from those of hemophilia in that bleeding is predominantly confined to the skin and mucous membranes; hemarthrosis is rare.

There are three general types of von Willebrand disease, based on whether the defect is quantitative (type I, the most common, and type III) or qualitative (type II). Measurement of the bleeding time is often the first screening test employed, but the bleeding time may be normal in some patients. A specific assay of von Willebrand factor is the measurement of the response of platelets to ristocetin. In the presence of ristocetin and von Willebrand factor, platelets agglutinate. Deficiency of factor VIII/von Willebrand factor can be quantified by measuring the extent of platelet agglutination in response to a standard concentration of ristocetin. The level of von Willebrand factor in plasma is also measured by immunologic techniques. However, the diagnosis of von Willebrand disease can be exceptionally difficult because the concentrations of von Willebrand factor and factor VIII in persons with and without von Willebrand disease can fluctuate considerably. Factors known to increase the concentrations of von Willebrand factor and factor VIII are stress, pregnancy, use of oral contraceptives, and estrogen replacement therapy in postmenopausal women.

Most types of von Willebrand disease are treated with administration of DDAVP, which is thought to increase endothelial cell release of stored von Willebrand factor. For those patients with severe quantitative defects of von Willebrand factor and qualitative defects, infusion of factor VIII concentrates enriched with von Willebrand factor may be necessary (6).

Treatment of Bleeding Patients with Platelet Disorders

The Role of Platelet Transfusions

When serious bleeding complicates thrombocytopenia, platelet transfusions are effective only if the cause is decreased production. Thrombocytopenia secondary to increased peripheral destruction or sequestration is usually refractory to platelet transfusion. Bleeding secondary to qualitative platelet disorders ordinarily responds to platelet transfusions, except when the bleeding diathesis is a consequence of uremia or hepatic failure or when an offending drug persists in the circulation. For patients with congenital platelet disorders, platelets must be transfused judiciously because repeated transfusions stimulate the production of allo-antibodies. Eventually, it may become impossible to raise the platelet count through transfusion. Accordingly, platelet transfusions should be reserved for serious bleeding or in preparation for surgery in patients with moderately severe platelet defects.

TABLE 98.7
RISK FOR BLEEDING IN PATIENTS WITH THROMBOCYTOPENIA, ACCORDING TO PLATELET COUNT^a

Platelet count (#/ μ L)	Usual clinical consequences
>100,000	No abnormal bleeding, even with major surgery.
50,000–100,000	Patients may bleed longer than normal with severe trauma.
20,000–50,000	Bleeding occurs with minor trauma, but spontaneous bleeding is unusual.
<20,000	Patients may have spontaneous bleeding.
<10,000	Patients are at high risk for severe bleeding.

^aAssumes normal platelet function.

The consequences of thrombocytopenia are entirely hemostatic. The risk for bleeding varies according to the platelet count (Table 98.7) (7).

Platelet transfusions are indicated for patients who are bleeding actively and have either a platelet count below 50,000/ μ L or a qualitative platelet abnormality manifested by a prolonged bleeding time. Platelet transfusions may also be indicated prophylactically before surgery or other invasive procedures. Before surgery, platelet counts should be above 50,000/ μ L in most cases, and above 90,000/ μ L for procedures such as neurosurgery or ophthalmologic surgery, in which any abnormal bleeding may cause excessive morbidity. For invasive procedures, such as kidney or liver biopsies, a platelet count above 50,000/ μ L is probably sufficient, provided platelet function is normal.

For patients who require platelet transfusions continually, platelets should be obtained from a single donor for each transfusion (generally 6–7 units) to reduce the risk for formation of multiple allo-antibodies (see later in this chapter). In a 70-kg patient, one unit of platelets usually raises the platelet count by approximately 10,000/ μ L. The count should be repeated 10–60 minutes after transfusion to assess the compatibility of the transfused platelets and to determine whether the desired count has been achieved. In actively bleeding patients, the platelet count should be maintained above 50,000/ μ L.

Allo-antibodies Against Platelets

In approximately 50%–60% of patients who become refractory to random donor platelets, anti-HLA (human leukocyte antigen) antibodies appear to be responsible. If this occurs, platelet cross-matching to find compatible donors is performed. Usually, a panel of platelets from 20–30 donors is tested. If a satisfactory response is not achieved with cross-matched platelets, HLA-compatible platelets are used because HLA antigens are the most

important in determining allo-immunization. Antibodies against platelet-specific antigens probably represent fewer than 1% of allo-immunization problems. Cross-matched platelets are available immediately, whereas HLA-compatible platelets usually are not available for 24 hours. With cross-matching, a number of compatible units may be identified with one test, but HLA testing is performed one donor at a time. The two platelet products are equally effective. Only 50% of refractory patients are refractory on the basis of allo-immunization.

Eventually, it may become impossible to raise the platelet count through transfusion. Accordingly, platelet transfusions should be reserved for serious bleeding or in preparation for surgery in patients with moderately severe platelet defects. When patients are refractory to platelet transfusion, consultation with a hematologist (if not already obtained) should be requested.

Platelet Growth Factors

Recently, it was discovered that recombinant forms of the cytokine interleukin 11 (IL-11, also called Neumega) and the growth factor thrombopoietin have the ability to raise the platelet count in patients with bone marrow failure and thrombocytopenia secondary to chemotherapy. IL-11 has been approved for use by the U.S. Food and Drug Administration, and recombinant forms of thrombopoietin are in clinical trials. Because these agents work by stimulating platelet production, their utility in disorders characterized by platelet destruction is uncertain.

Coagulation Disorders Associated with Bleeding

Hospitalized patients may also have a known or previously undiagnosed coagulation disorder as a cause of their bleeding. With few exceptions, a clinically significant coagulation disorder will present with elevations in the PT, aPTT, or both (Figure 98.1).

In descending order of frequency, the differential diagnosis of isolated prolongation of the PT includes the following:

1. Early liver disease
2. Vitamin K deficiency
3. Early warfarin therapy
4. Factor VII deficiency in the early stage of any disorder in which multiple coagulation factors are depleted (e.g., DIC)

Sole prolongation of the PT without prolongation of the aPTT occurs when the coagulation disorder involves only factor VII. Any process that diminishes all coagulation factors will initially be manifested as an isolated prolongation of the PT, because factor VII has the shortest plasma half-life and becomes depleted first. Therefore, in early or mild liver disease, the PT is often prolonged (with a normal aPTT). However, as the disease progresses, eventually all coagulation factors are depleted, accompanied by prolon-

gations in both the PT and aPTT. Similarly, though vitamin K deficiency and warfarin can ultimately prolong both the PT and the aPTT, early vitamin K deficiency or early warfarin (Coumadin) therapy is generally associated with an isolated prolongation of the PT. Disorders such as DIC or dilutional coagulopathy (in which all coagulation factors are depleted) can also present in their early stages as an isolated prolongation of the PT.

Factors II, V, VII, VIII, IX, X, and XIII, fibrinogen, and probably factor XI are all synthesized in the liver. Moderately severe liver disease can lead to a deficiency of any combination of these factors and produce a bleeding diathesis. Liver disease can also increase a patient's risk for bleeding by causing thrombocytopenia secondary to congestive splenomegaly and increasing baseline fibrinolysis. Correction of the hemostatic defects in patients with liver failure and acute bleeding is difficult. Because of the short half-life of factor VII (6 hours), correction of the PT by transfusion of plasma is transient. With severe clotting factor deficiency, volume limitations necessitate the use of factor II/VII/IX/X concentrates (prothrombin complex) in addition to plasma. Hypofibrinogenemia is usually present in end-stage liver disease. When the fibrinogen level is <100 mg/dL, patients can be treated with cryoprecipitate. When significant thrombocytopenia secondary to portal hypertension is present, platelet transfusion is frequently ineffective because of splenic sequestration. Consequently, one can often improve but not completely correct the hemostatic defects associated with end-stage liver disease.

Vitamin K is required for calcium-dependent activation of factors II, VII, IX, and X. Consequently, vitamin K deficiency is associated with decreased activity of these factors and a hemorrhagic tendency. Vitamin K deficiency and consequent abnormalities in coagulation are not unusual in severely ill, hospitalized patients. Antibiotics that eliminate the intestinal bacteria that synthesize vitamin K are commonly used, and patients frequently have an inadequate dietary intake of vitamin K. Vitamin K deficiency as a cause of abnormal clotting is diagnosed empirically by assessing the results of administering vitamin K. Improvement of the PT should be seen within 6 hours, with total correction within 24 hours, if vitamin K deficiency was the culprit.

Severe bleeding can develop in patients given warfarin for anticoagulation, whether the international normalized ratio (INR) is in the target therapeutic range or excessively prolonged. When the INR is in a therapeutic range, the aPTT may be mildly prolonged or normal. A localized cause of bleeding should be sought under these circumstances. Depending on the severity of bleeding, patients can be treated with plasma replacement, or, in severe cases, prothrombin complex concentrates, recombinant activated factor VII (rFVIIa, Novo7®), and fresh frozen plasma. Vitamin K should also be administered in those patients with marked prolongation of the INR and major bleeding (8). The most common causes of an isolated elevation of the aPTT in a

hospitalized patient are the presence of lupus anticoagulant, which is not associated with a bleeding diathesis, and unfractionated heparin therapy. Deficiencies of the factors that comprise the aPTT pathway and inhibitors of these factors are seen much less frequently, but they must be considered if the patient's bleeding is to be treated appropriately. Systemic administration of unfractionated heparin results in an elevated aPTT, or the aPTT can be increased artifactually when blood samples are drawn through intravenous lines containing heparin. Patients with the lupus anticoagulant and a prolonged aPTT are at increased risk for thrombosis. The remaining causes of an isolated, prolonged aPTT are relatively rare; they include hemophilia, other factor deficiencies, and inhibitors of clotting factors.

Patients in whom severe bleeding occurs while they are taking heparin usually have an underlying cause, such as a postoperative wound or a structural lesion (e.g., peptic ulcer, colonic polyp, recent trauma). Stopping the heparin is usually sufficient to stop the bleeding because heparin has a short half-life (about 1.5 hours). When life-threatening bleeding occurs and the aPTT is significantly prolonged by heparin, intravenous *protamine sulfate* can be given to reverse the effects of heparin. The amount given should be equivalent to the estimated dose of heparin given, with the short half-life of heparin taken into account (1 mg of protamine sulfate for approximately 90 units of heparin). If, for example, major bleeding occurs half an hour after a heparin bolus, the amount of protamine sulfate given should be equivalent to one-half the initial heparin dose. Protamine sulfate must administered cautiously—slowly over 10 minutes—as it can be associated with anaphylactic reactions. The anticoagulant effect of low-molecular-weight heparin is only partially neutralized by protamine sulfate.

The PT and aPTT are most likely to be prolonged together in clinical situations in which multiple clotting factors are diminished or altered in production (i.e., liver disease, vitamin K deficiency, warfarin therapy) or depleted through dilution or generalized consumption.

Hypercoagulability in the Hospitalized Patient

Secondary Thrombophilia

In the majority of patients admitted to the hospital with an idiopathic VTE event, an underlying cause is not diagnosed, and they are successfully treated with a standard regimen of heparin followed by warfarin. However, a minority of patients admitted to the hospital with thrombosis, and many patients in whom thrombosis develops while they are in the hospital, will be refractory to conventional treatment. Cancer patients with VTE, patients with chronic inflammatory bowel disease or a central line, patients undergoing revascularization procedures, and patients who have undergone transplantation of a solid organ are all at risk for the development of refractory thrombosis syndromes.

Hospitalized patients with thrombosis who have accompanying thrombocytopenia or coagulopathy are especially challenging. Anticoagulation in these patients must be approached with great caution.

The most common cause of hypercoagulability in hospitalized patients is secondary thrombosis associated with the postoperative state, prolonged immobilization, advanced age, or cancer. Thrombosis occurs after joint replacement surgery in more than 40%–60% of patients who do not receive prophylactic anticoagulation, and in approximately 30% of patients who do (5). Additionally, trauma, major abdominal surgery, and postoperative complications such as pneumonia, which prolong bed rest and immobilization, increase the risk for thrombosis.

The association of *thrombosis with cancer* is well documented, with or without accompanying DIC. In large series evaluating patients with deep venous thrombosis and pulmonary embolism (DVT/PE), more than 20% of patients had underlying cancer (9). In a cohort study of patients presenting with DVT/PE, the standardized incidence ratio for all types of cancer was 3 during the first 6 months of follow-up; at one year after the thrombotic event, it declined to one (10). The extent of an evaluation for cancer that should be performed in a patient presenting with DVT/PE is controversial, in that there is no evidence that early detection in this situation improves outcome. A reasonable approach would include a thorough physical examination, including breast and gynecologic examinations in a woman and a prostate examination in a man. Laboratory studies should determine the following: hematocrit, platelet count, PT, aPTT, fibrinogen level, and (in a man) possibly prostate-specific antigen level. Standard cancer screening techniques (such as colonoscopy or fecal occult blood testing and mammography) are appropriate, and chest radiography is also reasonable in this setting. Cancer patients with VTE are often refractory to warfarin treatment when it is given to achieve a standard target INR range of 2–3. Oftentimes, the thrombophilic disorder of these patients is best controlled by warfarin with an INR of 3–4 or with long-term low-molecular-weight heparin therapy, regardless of whether DIC complicates the picture (Chapter 52).

Heparin-induced thrombocytopenia should be considered in patients receiving heparin therapy when frank thrombocytopenia or a decrement of the platelet count by 50% occur. As discussed above, the exposure to heparin may not always be via a therapeutic heparin infusion. Patients with heparin-induced thrombocytopenia do not bleed; rather, they are at risk for the development of either arterial or venous thrombosis. These patients pose a great challenge because they cannot be treated with heparin (*either unfractionated or low-molecular-weight heparin*), and warfarin should not be used acutely as the sole anticoagulant. A hematology consultant should aid the treating physician in obtaining one of the newer thrombin inhibitor agents or heparinoids to treat these patients during episodes of acute thrombosis (11).

Central venous catheter-associated thrombosis is not uncommon, but it is often overlooked because of its initially subtle presentation. Neurology patients needing intermittent plasmapheresis, cancer patients receiving chemotherapy, patients with gastrointestinal disease who need nutrition or hydration, or patients with poor venous access often acquire some form of a central venous catheter while hospitalized. Central venous catheter-associated thrombosis may occur in 6%–60% of patients. The great variability in defining this complication is reflected in the broad range of definitions used in various clinical studies. The placement of central venous catheters is responsible for up to 60% of cases of superior vena cava syndrome in some series. The most common presentations of central venous catheter-associated thrombosis include a swollen, painful arm; facial swelling; breast swelling; overt superior vena cava syndrome (Chapter 92); evidence of an inferior vena caval clot associated with placement of a femoral vein line; or pulmonary embolus.

If these symptoms develop acutely while the patient is in the hospital and are severe, thrombolytic therapy, such as with tissue plasminogen activator (tPA), can be successfully administered (12), although rigorous studies proving its effectiveness are limited. Thrombolytic therapy should be administered in the ICU to allow close monitoring of laboratory test results and bleeding complications. Heparin therapy can be used concomitantly with and continued after the completion of the thrombolytic therapy. Bleeding commonly complicates the use of thrombolytic therapy in this setting. It typically manifests at the site of a large-bore venous catheter or any arterial puncture site, so caution should be exercised. Patients can then be treated for several months with warfarin (Chapter 52).

In very ill or medically complicated patients with significant pulmonary embolism, an inferior vena cava filter is often placed (Chapters 52 and 53). The presence of an inferior vena cava filter decreases the risk for subsequent pulmonary embolus acutely if the origin of the new clot is distal to the existing filter. However, placement of an inferior vena cava filter may be associated with recurrent VTE if the patient is not maintained on long-term anticoagulation (13).

Microangiopathies

The thrombotic microangiopathies are hematologic emergencies associated with abnormal clotting. They are characterized by the presence of microangiopathic hemolytic anemia, thrombocytopenia, microvascular thrombosis, and multiple organ dysfunction. Diagnosis of the microangiopathies is crucial to avoid the morbidity and mortality associated with these disorders.

Disseminated intravascular coagulation represents an imbalance of the clotting and fibrinolytic systems and is characterized by either clinical bleeding or clotting, thrombocytopenia, hypofibrinogenemia, and coagulopathy. It

may be associated with an acute presentation of sepsis and clinical bleeding, or a subtle presentation with DVT or migrating thrombophlebitis. The classic *Trousseau's syndrome* is the syndrome of hypercoagulability associated with cancer, especially of the adenomucinous type, with or without DIC. In “well-compensated DIC”, the patient presents with DIC characterized by a low-to-normal platelet count and a normal PT and aPTT. Once suspected, the diagnosis of DIC is confirmed by a review of the blood smear, which demonstrates the presence of schistocytes, and by laboratory findings of a low fibrinogen level and a positive D-dimer test result.

Patients with DIC and thrombosis can be treated both acutely and on a long-term basis with standard heparin therapy, although this is controversial. The patient with DIC who presents with bleeding presents a greater therapeutic challenge. Treatment of the underlying disorder is paramount, but not always feasible or successful. Patients can be supported with low-dose unfractionated heparin (300–500 units/h) in an attempt to control the consumptive thrombotic process. Platelet and cryoprecipitate transfusions may be necessary to treat the profound thrombocytopenia and hypofibrinogenemia, respectively. An antifibrinolytic agent (e.g., Amicar) is generally contraindicated unless the patient has excessive bleeding, in which case an antifibrinolytic agent may be a necessary addition to the heparin therapy. These complicated clinical scenarios are best handled with the active input of a hematologist who specializes in the clinical care of patients with coagulopathies.

Thrombotic thrombocytopenic purpura and *hemolytic uremic syndrome* are also thrombotic microangiopathies with overlapping clinical components. Hemolytic uremic syndrome is more common in children than in adults and is typically associated with a gastrointestinal illness caused by enterotoxigenic Gram-negative bacteria. Thrombotic thrombocytopenic purpura has been found to be an autoimmune disorder marked by the presence of an antibody directed against a metalloprotease responsible for cleaving large molecular weight forms of circulating von Willebrand factor (VWF). The TTP antibody inhibits the function of this protease, thereby inhibiting additional processing of VWF. The result is the presence of large multimeric forms of VWF in circulation, which are highly thrombogenic, leading to the widespread deposition of platelet microthrombi.

The classic presentation of thrombotic thrombocytopenic purpura includes the “pentad” of thrombocytopenia, microangiopathic hemolytic anemia, renal dysfunction, neurologic deficit, and fever. Hemolytic uremic syndrome, on the other hand, is characterized by only thrombocytopenia, anemia, and renal dysfunction. The clinical manifestations and systemic involvement of thrombotic thrombocytopenic purpura vary greatly, but the most consistent abnormalities include hemolytic ane-

mia, with hematocrits in the 21%–26% range, and consumptive thrombocytopenia, with platelet counts in the range of 20,000–40,000/ μ L. In one review, only 34% of patients with the clinical diagnosis of thrombotic thrombocytopenic purpura had the classic pentad. Ninety-eight percent of patients had an elevated lactate dehydrogenase level, with a median value of 1,208 units/L (14).

The diagnosis of thrombotic thrombocytopenic purpura is crucial because untreated TTP is associated with a 90% mortality rate. Thrombosis of the microvasculature may involve the myocardial, cerebral, renal, or mesenteric vessels, resulting in marked dysfunction of the affected organs. Once the diagnosis is suspected, a hematologist should be consulted immediately to confirm the diagnosis and institute therapy. The mainstay of therapy is plasmapheresis, which is associated with a 56%–80% response rate. Salvage therapy for those patients refractory to plasmapheresis includes splenectomy, steroid therapy, and rituximab (15).

KEY POINTS

- Proper use and interpretation of screening tests—prothrombin time, activated partial thromboplastin time, and platelet count—will usually be sufficient to determine whether a patient has a bleeding disorder and to define it. A normal prothrombin time means that the patient does not have liver disease as a cause of bleeding; a normal bleeding time means that uremia-associated hemostatic abnormalities are not the cause of bleeding.
- Most causes of abnormal bleeding are acquired: drug-induced thrombocytopenia, sepsis, poor vitamin K intake, administration of antibiotics in the intensive care unit, anticoagulants, and liver and renal failure.
- Blood products should be used judiciously in patients with abnormal laboratory results. If the patient is not bleeding, or is bleeding with mild laboratory abnormalities, transfusion of fresh frozen plasma, platelets, or both is not likely to be indicated.
- A careful drug history is critical in evaluating thrombocytopenia in hospitalized patients. The diagnosis of thrombophilia, whether of primary or secondary cause, is often a clinical one that may affect the intensity and duration of anticoagulant therapy.
- Hypercoagulability in the hospitalized patient can result from the presence of an underlying disease, especially cancer, and the presence of central venous access catheters.
- Thrombophilia caused by heparin therapy or microangiopathies is rare but constitutes a medical emergency that necessitates consultation with a coagulation specialist.

Signs, Symptoms, and Laboratory Abnormalities in Renal Disease

Rudolph A. Rodriguez *Burl R. Don*

TOPICS COVERED IN CHAPTER

- Urinalysis 995
- Oliguria and Anuria 998
- Edema 1001
- Elevated BUN and Creatinine 1003

INTRODUCTION

The clinical presentation of renal disease varies from signs and symptoms caused directly by the kidney (hematuria, proteinuria, flank pain) to those caused by the systemic effects of kidney disease (hypertension, edema). However, many patients are asymptomatic despite significant renal disease. After the presence of significant renal disease is recognized, the primary goal of the history, physical examination, and laboratory assessment is to make a correct diagnosis of the cause. The proper interpretation of the urinalysis and diagnosis of the cause of oliguria, increasing blood urea nitrogen (BUN) and creatinine levels, or edema help guide therapy and predict prognosis.

RENAL SIGNS, SYMPTOMS, AND LABORATORY ABNORMALITIES

Urinalysis

Interpretation at Time of Admission

In deciding whether to hospitalize a patient, the urinalysis can serve as an invaluable tool in the initial evaluation. This is true regardless of whether the patient has renal disease or not. The urine dipstick provides a battery of tests, which can provide clues to liver disease, volume status, diabetic control, urinary tract infection or stones, acid-base derangements, multiple myeloma, and rhabdomyolysis. The urinalysis also serves as the first and most important diagnostic test in any patient with acute or chronic renal disease. There are no abnormalities of the urinalysis that in isolation would necessitate hospitalization, but abnormalities may support a diagnosis that requires hospitalization. Early attention to the urinalysis may expedite appropriate hospitalization, consultations, and treatment.

Specific Gravity

One of the common diagnostic dilemmas faced at the time of admission is determining fluid status. The urine specific gravity is a useful adjunct to the history and physical examination in indicating volume status and, more importantly, the *effective circulating volume*. Urine osmolality is an accurate reflection of antidiuretic hormone secretion. Urine osmolality ranges from a low of 50–100 mOsm/L in the absence of antidiuretic hormone, to 900–1200 mOsm/L in the presence of maximum arginine vasopressin (AVP) effect if there is normal renal function. Urine specific gravity correlates well with urine osmolality, and specific gravity increases by 0.001 for every increase in urine osmolality of 35–40 mOsm/L. Urine that is iso-osmolar with plasma has a urine osmolality of 280 mOsm/kg or a specific gravity of 1.008. However, osmolality is a measure of particles in solution, and specific gravity is a measure of the number of particles and weight expressed as weight compared with water. These differences may lead to situations in which specific gravity and urine osmolality do not correlate, such as if there are large amounts of large particles in the urine (e.g., contrast media, heavy proteinuria, glucosuria). This leads to a very high specific gravity (1.030–1.050); the urine osmolality may be much lower.

Urine pH

The urine pH is useful in evaluating patients with an anion-gap metabolic acidosis (Chapter 105) or monitoring the response to intravenous bicarbonate therapy. If alkali therapy is used to prevent acute renal failure from rhabdomyolysis or uric acid or sulfadiazine stone disease, the urine pH should be kept above 6.5–7.0. The urine pH loses its diagnostic value if the urine is infected with urease-producing bacteria such as *Proteus* or *Klebsiella* organisms, which raise the urine pH.

Leukocyte Esterase and Nitrites

Leukocyte esterase is released from neutrophils and normally is not found in urine. The urine leukocyte esterase test screens for more than 10 leukocytes per high-power field. Nitrate is reduced to nitrite by the enterobacteriaceae family of Gram-negative bacteria, which includes many of the common urinary pathogens. The urine nitrite test predicts the presence of more than 10^5 colonies of these bacteria. However, urinary tract infections caused by Gram-positive bacteria is missed by the nitrite test. Both tests have a sensitivity of 90% and a specificity of 75%, with a negative predictive value of 99%. The decision to admit the patient with pyelonephritis usually is made on clinical grounds (Chapter 68), but the presence of urinary tract infection is supported by these screening tests, along with urine microscopy and culture.

Occult Blood

Most commercially available urine dipsticks test for occult blood. This test is very sensitive in detecting more than three

red cells per high power field, with a sensitivity of 80%–95% and specificity of more than 95%–99%. The presence of red cells should be confirmed with microscopy. On most occasions occult blood correlates with the red cells, but the occult-blood test also is positive in the presence of free hemoglobin or myoglobin. The presence of significant occult blood in the absence of red cells should raise the suspicion of rhabdomyolysis or massive intravascular hemolysis (1).

Ketones

In a patient with hyperglycemia and a high anion-gap metabolic acidosis, the diagnosis of diabetic ketoacidosis can be confirmed quickly with the urine dipstick, which confirms the presence of ketones. The urine dipstick detects the presence of acetoacetic acid and acetone but does not detect β -hydroxybutyric acid.

Bilirubin/Urobilinogen

Unconjugated bilirubin is protein-bound, water-insoluble, and not usually found in the urine. Thus, the urine dipstick test for bilirubin is negative if there is hemolytic anemia. Conjugated bilirubin is water-soluble and is detected readily by urine dipstick in clinical conditions such as biliary obstruction. Urine suspected of containing bilirubin should be tested quickly, because bilirubin breaks down quickly after exposure to light.

Intestinal bacteria convert bilirubin to urobilinogen, which is reabsorbed and may appear in the urine. Most conditions that cause increased bilirubin therefore also increase urinary urobilinogen levels. An important exception is biliary obstruction, which may prevent the entry of bilirubin into the intestine. Thus, patients with biliary obstruction may have a urine dipstick test that is positive for urine bilirubin but negative for urobilinogen.

Protein

The urine dipstick for protein detects urinary albumin. The test becomes positive if total albumin excretion is more than 300–500 mg/d. The result usually is reported from trace to “4+” protein, which corresponds to a range of between 15–30 and 500 mg/dL. Thus, the test result is a concentration that is influenced by both the total daily albumin excretion and the urine volume. The urine dipstick is not a sensitive test for proteinuria. In diabetic patients, a positive urine dipstick probably reflects macroalbuminuria and significant renal injury. The urine dipstick also is negative in patients excreting immunoglobulin light chains because of multiple myeloma. However, the sulfosalicylic acid test detects all urinary protein; this test should be performed in elderly patients presenting with unexplained renal failure, a negative urine sediment, and a negative dipstick test for protein.

Urine Microscopy

In the evaluation of renal disease, urine microscopy is the most important component of the urinalysis. The history

and physical examination along with dipstick and microscopy results narrow the differential diagnosis, guide further evaluation, and help with decisions about need for urgent treatment (Figure 99.1). The urine is examined under low power (10x) and high power (40x) for the presence of cells, casts, and crystals. Polarizing light is valuable in identifying crystals and lipids in the urine, and phase-contrast microscopy is useful in providing more detail of red-cell morphology.

In addition to noting the numbers per high-power field of the three cell types, the *red cell morphology* should be described as dysmorphic if acanthocytes are seen; dysmorphic

red cells are characteristic markers for glomerular bleeding (2). They are best seen under phase-contrast microscopy. Significant acanthocyturia (defined as $\geq 5\%$ of the excreted red cells) has a sensitivity of only 52% but a specificity of 98% for glomerular bleeding. Urine sometimes reveals lipid droplets, an abnormal finding that is diagnostic of glomerular disease.

The presence of *cellular casts* is extremely helpful in the evaluation of renal disease. Hyaline and granular casts are not abnormal findings in the urine sediment. However, *red cell casts* are virtually diagnostic of glomerulonephritis, with a specificity of 97% but a sensitivity of less than 25%

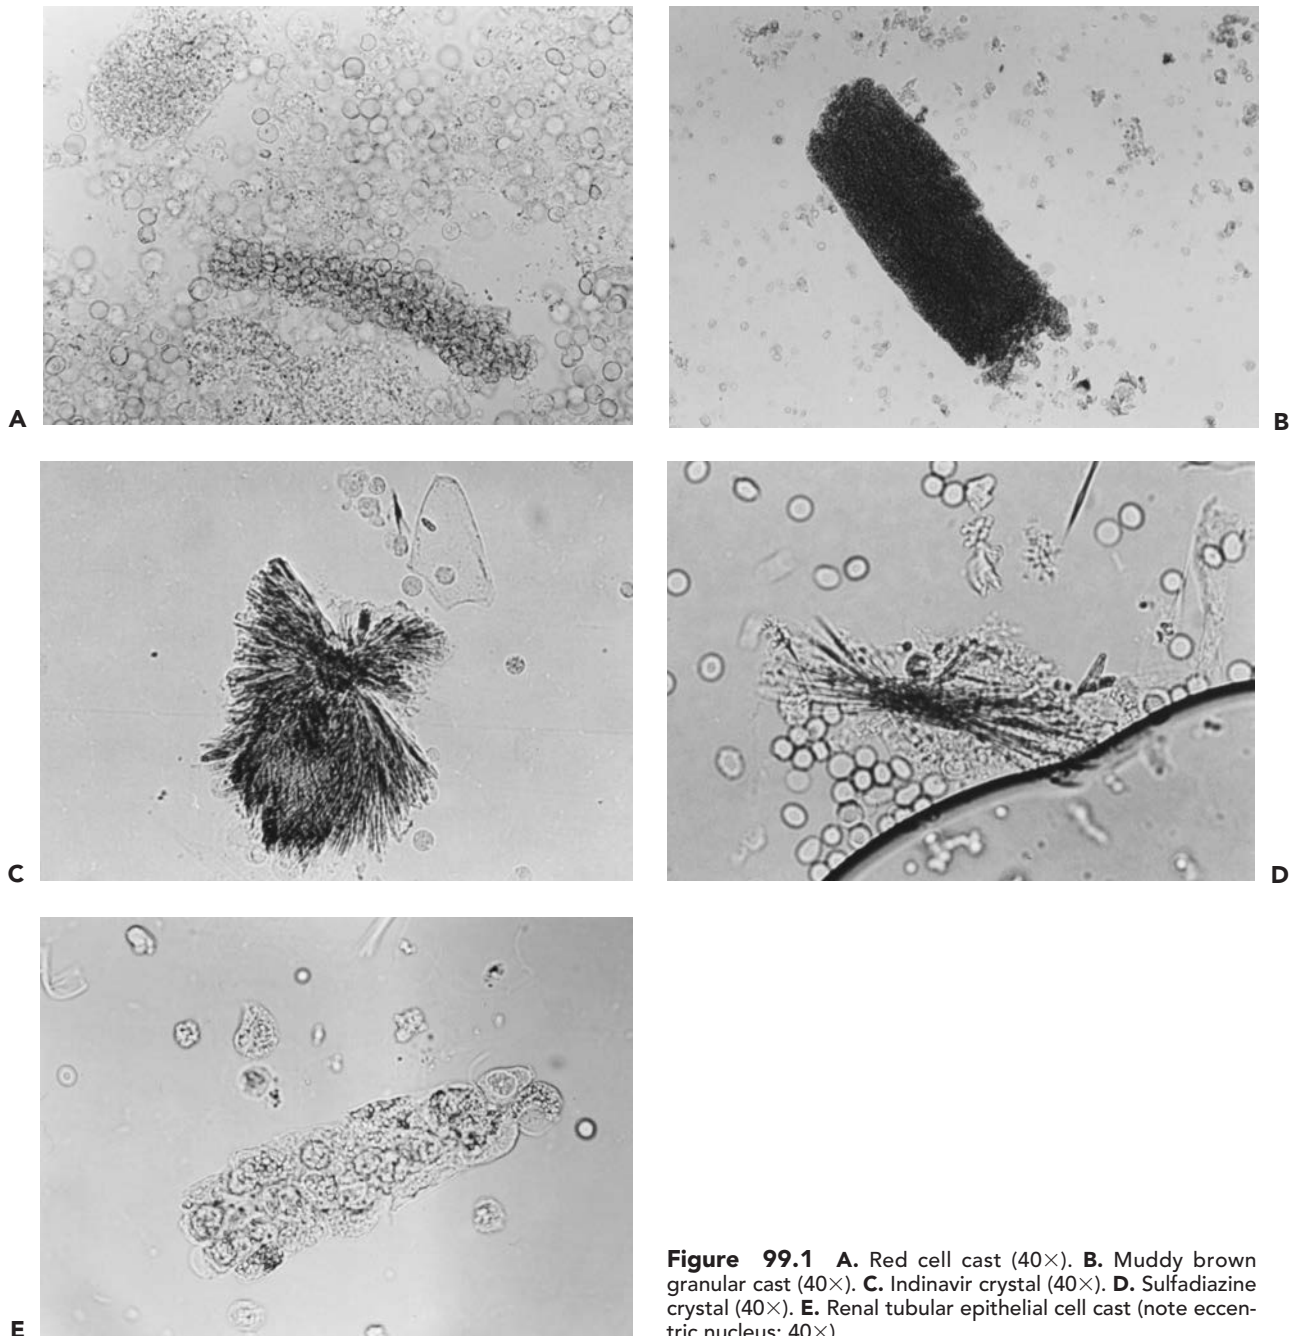

Figure 99.1 A. Red cell cast (40 \times). B. Muddy brown granular cast (40 \times). C. Indinavir crystal (40 \times). D. Sulfadiazine crystal (40 \times). E. Renal tubular epithelial cell cast (note eccentric nucleus; 40 \times).

(Figure 99.1A). In the absence of dysmorphic red cells or red cell casts, it is difficult to distinguish urologic from glomerular bleeding. More than 500 mg/d of proteinuria, “cola”-colored urine, and the absence of blood clots are all consistent with glomerular bleeding. The presence of red cells in the urine does not significantly increase urine protein concentration. Thus, significant proteinuria seen on the dipstick test should not be attributed to the presence of red cells. *White cell casts* indicate the presence of renal interstitial inflammation as seen in pyelonephritis or interstitial nephritis. The presence of white cell casts also helps differentiate pyelonephritis from cystitis.

The presence of muddy brown granular casts, free renal tubular cells, and renal tubular epithelial cell casts in the urine is indicative of tubular damage, and these findings support the diagnosis of *acute tubular necrosis* in a patient with acute renal failure (Figure 99.1 B, E). However, absence of these urinary findings does not exclude the diagnosis of acute tubular necrosis. Muddy brown granular casts and renal tubular cells also can be seen in patients with hyperbilirubinemia, normal renal function, and no tubular damage.

The presence of *crystalluria* is useful in the evaluation of renal disease in certain clinical situations. Many drugs can crystallize in the urine and can cause acute renal failure from bilateral ureteral drug stones or from intratubular crystal obstruction, nephrolithiasis, and dysuria. These drugs are used commonly in HIV-infected patients and include sulfadiazine, indinavir, and intravenous acyclovir (Figure 99.1 C, D). Some patients with normal renal function may have drug-induced crystalluria, which is not an abnormal finding. All patients with crystalluria and renal failure should be evaluated with a renal ultrasound study to exclude urinary tract obstruction. *Uric acid nephropathy* is the presence of acute renal failure caused by renal tubular obstruction by urate and uric acid crystals. The urine sediment may be normal but occasionally has amorphous material containing uric acid crystals, which appear as rhomboidal crystals or as microcrystallites. Crystalluria also is seen in ethylene glycol (automobile antifreeze) intoxication. In this case, the urinalysis typically reveals mild proteinuria, microscopic hematuria, pyuria, and calcium oxalate crystals.

Urinalysis Obtained During Hospitalization

The urinalysis is used in the same manner during hospitalization as at the time of admission. The main diagnostic dilemma in hospitalized patients is diagnosing the cause of acute renal failure (Chapter 100). The diagnosis of acute tubular necrosis can be confirmed with a urinalysis showing the presence of muddy brown granular casts and renal tubular cells. Allergic acute interstitial nephritis resulting from drugs given during the hospitalization should be suspected in patients developing acute renal failure; the presentation may include pyuria, white cell casts, fever, rash, and occasionally eosinophiluria. Glomerular diseases usu-

ally are present at the time of hospital admission and rarely develop *de novo* during hospitalization.

Oliguria and Anuria

Presenting at the Time of Admission

Description and Differential Diagnosis

The presence of oliguria or anuria is an important sign of impaired renal function that requires immediate evaluation, because early identification and treatment of potentially reversible causes of oliguria may restore normal renal function or prevent more prolonged renal dysfunction (3). The patient may relate a history of diminished or absent urine output over a variable period of time prior to admission. *Oliguria* usually is defined as a urine output of less than 20 mL/h, or 400–500 mL per 24 hours. This definition is based on the fact that an adult ingesting a normal diet is obliged to excrete approximately 600 mOsm of solute per day; because the urine can be maximally concentrated to 1200 mOsm/L, the minimum amount of urine needed to excrete this solute load is 0.5 L. Thus, any urine amount less than this results in the retention of solutes, including nitrogenous waste products. A subset of patients with oliguria may have negligible-to-absent urine output. This condition is referred to as *anuria*, defined as a urine output of less than 50 mL per 24 hours. The differential diagnosis for anuria is limited and includes urinary tract obstruction (the most common cause), renal cortical necrosis, necrotizing rapidly progressive glomerulonephritis, aortic aneurysm, and bilateral renal artery occlusion (4).

Oliguria is categorized as prerenal, renal, intrinsic (parenchymal) or postrenal (obstructive). The list of prerenal causes of oliguria includes conditions that result in decreased absolute intravascular volume or decreased effective circulating volume. Prerenal causes also include the use of drugs such as nonsteroidal anti-inflammatory drugs and angiotensin-converting enzyme (ACE) inhibitors that disrupt normal renal hemodynamics. The common denominator that underlies the prerenal causes of oliguria is decreased renal blood flow to normal, undamaged kidneys, resulting in decreased glomerular filtration rate (GFR) and subsequent reduction in urine output. Prompt restoration of renal blood flow in patients with prerenal oliguria usually results in rapid improvement in GFR and urine output.

Renal or intrinsic causes of oliguria result from damage to specific areas of the renal parenchyma resulting in decreased GFR. The renal causes can be subdivided based on the anatomic location of the renal lesion: tubular (most commonly, acute tubular necrosis), interstitial (acute interstitial nephritis), or glomerular (acute glomerulonephritis). Many of the prerenal causes of oliguria lead to ischemic injury to the tubules if not corrected. Thus, there is a continuum from prerenal events to intrinsic renal damage in the untreated patient. Moreover, patients frequently

have both prerenal (volume depletion) and intrinsic renal (acute tubular necrosis) components to their decreased GFR and consequent oliguria.

Obstruction of the urinary tract sufficient to result in oliguria can occur anywhere along the urinary tract, from the renal pelvis to the urethral meatus, and can result from a wide spectrum of causes including neoplasms, strictures, stones, retroperitoneal fibrosis, blood clots, and prostatic disorders (Chapter 103). Urinary tract obstruction can be divided into upper or lower urinary tract (bladder outlet) causes. In order to cause oliguria, upper urinary tract obstruction must involve both kidneys or a solitary kidney. Lower urinary tract obstruction resulting from prostatic disease is probably the most common cause of oliguria or anuria in patients presenting to the hospital emergency department.

Evaluation

Oliguria requires prompt evaluation to identify the presence of either prerenal or postrenal (obstructive) causes that can be reversed quickly. Early identification and treatment of prerenal causes may prevent or attenuate renal tubular injury and a prolonged course of acute renal failure. Early detection and relief of urinary tract obstruction may prevent or minimize permanent renal damage and hasten recovery of viable renal function.

The initial assessment of a patient with oliguria begins with characterization of the intravascular volume status. This involves obtaining a history, performing a careful physical examination, and, if necessary, invasive hemodynamic monitoring. True volume depletion usually is readily apparent in patients presenting with a history of fluid or blood loss and the physical signs and symptoms of hypovolemia. It is more difficult to assess the effective circulating volume in patients with obvious extracellular volume overload, such as those with congestive heart failure or cirrhosis. In these situations, invasive hemodynamic monitoring, including a pulmonary artery catheter, may be necessary to provide insight into the effective circulating volume and the cardiac output. In addition, patients who develop oliguria after the initiation of ACE inhibitors should be evaluated for renal artery stenosis.

Urinary tract obstruction always should be considered early in the evaluation of a patient with oliguria, especially in patients without evidence of volume depletion. The patient may present with symptoms and signs of obstruction, including difficulty initiating or maintaining urinary flow, dysuria, and suprapubic or back pain. A history of alternating episodes of polyuria and oliguria is also suggestive of possible urinary tract obstruction. Physical examination should include an abdominal examination, a digital rectal examination in men to evaluate the prostate, and a bimanual pelvic examination in women to detect possible causes of lower-tract obstruction. A bladder catheter should be placed after a spontaneous urinary void to measure the postvoid residual urine volume. As part of the assessment of oliguria, a renal ultrasound should be performed to

evaluate for evidence of hydronephrosis. Renal ultrasonography has a greater than 90% sensitivity and a 74%–92% specificity for detection of urinary tract obstruction. It may be falsely negative in the setting of conditions in which the calyces do not dilate despite the presence of obstruction. Such conditions include retroperitoneal malignancies, retroperitoneal fibrosis, volume depletion, and very early urinary tract obstruction. If urinary tract obstruction still is suspected despite lack of demonstrable hydronephrosis on ultrasound, a retrograde pyelogram should be performed.

The *urinalysis* is the first and most important laboratory test to be performed in the initial evaluation of the patient with oliguria. Prerenal causes of oliguria usually are associated with a bland urinary sediment, whereas intrinsic renal causes of oliguria usually result in abnormal sediment. Measurement of *serum BUN and creatinine* levels also are performed as part of the laboratory evaluation. Oliguria resulting from prerenal causes (and occasionally with obstructive causes) is usually associated with a BUN-to-creatinine ratio of greater than 20:1 because of enhanced urea reabsorption by the kidney. Oliguria caused by intrinsic renal disease is usually associated with a ratio less than 20:1. However, this ratio can be affected by other conditions. For example, increased catabolism or blood in the gastrointestinal tract augment urea production and increase the ratio, whereas a low-protein diet or liver disease reduce urea production and decrease the ratio.

Evaluation of *urinary sodium and water excretion* can be a helpful guide in the evaluation of a patient with oliguria, and serve as an indicator of the functional integrity of the renal tubules (Table 99.1). Patients with prerenal causes of oliguria intensely reabsorb sodium and water to maintain intravascular volume. Thus, in prerenal oliguria, the urinary sodium concentration and the fractional excretion of sodium ($[\text{urine/plasma Na}] \times [\text{urine/plasma creatinine}] \times 100$) are low, and the ratio of urine to plasma osmolality and creatinine is greater than 1. In the setting of intrinsic renal causes of oliguria, tubular function is impaired. The pattern of urinary indices in this setting reflects these defects, as manifested by high urinary sodium concentration and fractional excretion of sodium and urine osmolality that is equal or less than plasma osmolality. Similar urinary indices have been noted in acute interstitial nephritis. Not all intrinsic renal causes of oliguria show this pattern of urinary indices, however. For example, in acute glomerulonephritis, contrast- and myoglobin-induced acute tubular necrosis, and early urinary tract obstruction, the urinary indices may have a prerenal pattern. This probably results from intense renal vasoconstriction in the early stages of these disorders, which leads to avid sodium retention. In addition, the use of diuretics or dopamine and the presence of solutes in the urine such as glucose increase the urinary excretion of sodium. A recent study suggested that the fractional excretion of urea ($[\text{urine/plasma urea}] \times [\text{urine/plasma creatinine}] \times 100$) can help distinguish between prerenal azotemia versus acute tubular necrosis, especially when

TABLE 99.1**DIFFERENTIAL DIAGNOSIS OF OLIGURIA: URINALYSIS, WATER, AND SODIUM METABOLISM**

Diagnosis	Urinalysis	Water Metabolism	Sodium handling	
		Urine/plasma osmolality	Urine Na, mEq/L	Fractional excretion of Na (%)
Prerenal	Normal, or hyaline casts	≥ 1	< 20	< 1
Intrarenal				
• Tubular necrosis	Granular and epithelial cell casts	≤ 1	> 20	≥ 1
• Interstitial nephritis	Pyuria, hematuria, mild proteinuria, granular and epithelial cell casts, eosinophils	≤ 1	> 20	≥ 1
• Glomerulonephritis	Hematuria, marked proteinuria, red blood cell casts, granular casts	≥ 1	< 20	< 1
• Vascular disorders	Normal or hematuria, mild proteinuria	≥ 1	< 20	< 1
Postrenal	Normal or hematuria, granular casts, pyuria	≤ 1	Early, < 20 Late, > 20	Early, < 1 Late, > 1

Na, sodium.

diuretics have been administered (5). A low fractional excretion of urea ($< 35\%$) was found to be more sensitive and specific of an index of prerenal azotemia than was a low fractional excretion of sodium. Interpretation of the urinary indices should be done with caution. The diagnosis of the cause of oliguria should be based primarily on a thorough history and physical examination; the urinalysis and urinary indices should serve only as confirmatory data.

Management

Patients found to have true volume depletion should be hydrated with appropriate volume therapy (crystalloid, colloid, or blood products) to reestablish euolemia (Chapter 25). In addition, drugs that cause volume depletion (diuretics), disrupt renal hemodynamics (ACE inhibitors, nonsteroidal anti-inflammatory drugs), or decrease vascular resistance (antihypertensive agents) should be discontinued. Lower urinary tract obstruction usually is relieved by placement of a bladder catheter, whereas upper-tract obstruction requires urologic or interventional radiologic intervention. Following relief of urinary tract obstruction, there can be a substantial postobstructive diuresis (often 500–1000 mL/h) resulting from excretion of the retained excess sodium and water and impaired tubular reabsorptive function. Patients with a brisk postobstructive diuresis may need intravenous fluids to avoid hypovolemia (Chapter 103).

Oliguria and azotemia caused by disorders associated with decreases in effective circulating volume such as congestive heart failure or cirrhosis can be therapeutic challenges, because the treatment must be directed at improving cardiac or hepatic function in patients with chronic

irreversible damage of these organs (Chapters 39 and 83). The management of oliguria resulting from intrinsic renal disorders is discussed in Chapter 100.

Presenting During Hospitalization

Oliguria that develops in a hospitalized patient frequently is caused by multiple hemodynamic and nephrotoxic insults endured during the hospitalization (Chapter 100) (6, 7). This often is seen in the severely ill patient in the ICU with multi-organ system failure. Such insults include septicemia, volume contraction, surgery and anesthesia, nephrotoxic drugs, and radiocontrast agents. The majority of cases of oliguria in hospitalized patients are caused by iatrogenic factors. Classifying the cause of oliguria using the prerenal, intrinsic renal, and obstructive classes outlined previously is helpful in the hospitalized patient. Prerenal factors account for 30%–60% of the cases of oliguria. The major intrinsic renal cause for oliguria is acute tubular necrosis resulting from the various hemodynamic and nephrotoxic insults noted previously. Although acute interstitial nephritis resulting from administered drugs is a frequent cause of acute decrease in GFR in the hospitalized patient, this lesion usually does not cause oliguria. Urinary tract obstruction is encountered much less frequently in hospital-acquired oliguria, but patients with bladder catheters should be evaluated for possible occlusion of the catheter.

In evaluating a patient with acute oliguria, it is helpful to review the hemodynamic flow sheet for evidence of hypotension, especially hypotension during a perioperative period. In addition, the temporal relationship between the

onset of oliguria and the use of drugs that are potentially nephrotoxic or alter renal hemodynamics should be noted. The physical examination and changes in body weight should help determine the patient's volume status. If there is uncertainty as to the volume status, invasive hemodynamic monitoring should be considered. The evaluation of oliguria should include the performance of a urinalysis and, if necessary, obtaining urinary indices.

The management of acute oliguria in the hospitalized patient follows the same approach as for the patient in whom it presents at admission. Drugs that are nephrotoxic or negatively alter renal hemodynamics should be discontinued.

Edema

Presenting at the Time of Admission

Description and Differential Diagnosis

Edema is defined as a palpable swelling produced by expansion of the interstitial fluid volume and results because the amount of fluid filtered exceeds the amount returned in the lymphatics. The differential diagnosis can be divided into four groups by primary mechanisms (8) (Table 99.2): (a) in-

TABLE 99.2
MAJOR CAUSES OF EDEMA, BY PRIMARY MECHANISM

Generalized	Localized
Increased capillary hydrostatic pressure	Increased capillary hydrostatic pressure
Heart failure Cirrhosis Renal sodium retention Pregnancy/premenstrual Idiopathic edema	Venous obstruction (e.g., deep venous thrombosis)
Hypoalbuminemia	
Nephrotic syndrome (protein loss) Liver disease (reduced synthesis)	
Increased capillary permeability	Increased capillary permeability
Burns, sepsis, allergic reactions Trauma	Infection
Lymphatic obstruction or increased interstitial oncotic pressure	Lymphatic obstruction or increased pressure
Hypothyroidism	Malignant nodal involvement

creased capillary hydrostatic pressure, which is responsible for edema formation in heart failure, cirrhosis, and sodium retention caused by renal disease or drugs, pregnancy, or idiopathic edema; (b) hypoalbuminemia caused by protein loss or reduced synthesis, as occurs in nephrotic syndrome and liver disease, respectively; (c) increased capillary permeability caused by burns, sepsis, allergic reactions, trauma, or the adult respiratory distress syndrome; and (d) lymphatic obstruction or increased interstitial oncotic pressure, exemplified by lymph node enlargement or with hypothyroidism.

Evaluation

The first step in the evaluation of the patient with edema is to characterize the edema as localized or generalized (Table 99.2). Generalized edema reflects a widespread increase in extracellular fluid, and the location of edema reflects dependent forces. *Anasarca* is severe generalized edema that can be detected in virtually all body parts. Localized edema results from the local disturbance of the balance between fluid filtration and reabsorption. The differential diagnosis of localized edema includes inflammation, lymphatic obstruction, venous obstruction, and thrombophlebitis. Localized edema is easily differentiated from generalized edema by asymmetry and other associated findings such as redness, warmth, and pain. Cellulitis, lymphatic obstruction caused by tumor involvement of lymph nodes, and deep venous thrombosis all are causes of localized edema that usually require immediate attention and may require hospitalization.

Even in the absence of structural renal disease or renal insufficiency, the common derangement among the major causes of *generalized edema* is abnormal sodium retention by the kidney. In the patient with generalized edema, the goal is to identify the responsible disease process. The history, physical examination, and laboratory results should help the clinician differentiate among edema caused by congestive heart failure, cirrhosis, or renal diseases such as nephrotic syndrome, acute glomerulonephritis, or chronic renal insufficiency. Identifying patients with pulmonary edema is important independent of the cause of the generalized edema, because these patients need immediate attention and may require hospitalization (Chapter 39). Pulmonary edema is more likely to accompany congestive heart failure than cirrhosis or nephrotic syndrome. Isolated right ventricular dysfunction may present with peripheral edema, ascites, and edema of the abdominal wall without pulmonary edema. It may be confused with cirrhosis because of consequent liver dysfunction from hepatic congestion. However, right ventricular dysfunction causes elevation of the jugular venous pressure, while cirrhosis usually does not. Patients with generalized edema caused by hepatic cirrhosis are also more likely to give a history of developing ascites prior to developing peripheral edema.

Periorbital and peripheral edema (and at times ascites) characterize generalized edema resulting from nephrotic

syndrome. Although the early stage of renal disease is usually asymptomatic, the history may provide some clues. A history of frothy urine, which is caused by proteinuria, may help delineate the time course of the nephrotic syndrome. Patients with chronic renal insufficiency may complain of nocturia and frequency because of the inability to concentrate their urine. Significant glomerular hematuria leads to a history of "cola"-colored urine. The presence of renal disease may be confirmed by elevated serum BUN and creatinine levels, or a urinalysis showing proteinuria with or without hematuria. Patients with nephrotic syndrome and normal renal function usually do not present with signs of true intravascular volume expansion. However, patients with severe chronic renal insufficiency, acute renal failure, diabetic nephropathy, or acute glomerulonephritis may have renal sodium retention leading to true intravascular volume expansion and pulmonary edema.

The cause of localized and generalized edema should be diagnosed quickly on presentation, aided by the history, examination, and minimal tests. Patients who may require hospital admission include those with the combination of generalized edema and pulmonary edema, those with localized edema caused by deep venous thrombosis or cellulitis, and possibly those with unexplained venous obstruction (who may have an undiagnosed malignancy). Patients with generalized edema caused by nephrotic syndrome or cirrhosis but with no pulmonary edema rarely require hospital admission because of edema. However, even these patients may require hospitalization for control of the edema if they fail to respond to outpatient treatment with diuretics or develop other edema-related complications, such as skin breakdown and cellulitis.

Patients with no evident cardiac, renal, or hepatic cause of edema may have idiopathic edema, a diagnosis of exclusion that most often occurs in young, menstruating women. The etiology is not well understood. Idiopathic edema should not be confused with premenstrual edema, which resolves shortly after the onset of menses.

Management

The treatment of localized edema is directed at the underlying cause (9) (Chapters 39, 52, 69, and 83). Patients with localized edema usually become volume-depleted if diuretics are used to treat the edema. However, patients with generalized edema and pulmonary edema require immediate therapy. If cardiac disease is present, the initial treatment of the edema should include treatment of the underlying cardiac disease that precipitated pulmonary edema (e.g., ischemia, infarction, arrhythmia). The mainstay of treatment of generalized edema accompanied by pulmonary edema is loop diuretics (10), the use of which should be guided by a few basic principles. The pharmacologic properties of all loop diuretics are very similar; thus, patients who do not respond to adequate doses of one loop diuretic probably will not respond to another. All commonly used loop diuretics are highly protein-bound, and hypoalbuminemia leads to a

larger extravascular space and slower diuretic delivery to the kidney. Being protein-bound, diuretics do not enter the tubular fluid by glomerular filtration but by proximal tubule secretion. In addition, patients with significant proteinuria have filtered albumin, which can inactivate some of the diuretic in the nephron.

The first step in using loop diuretics is to determine the threshold dose. If a patient does not respond to the starting dose, the dose should be doubled until adequate natriuresis is achieved. Increasing the frequency of administration of the diuretic before the threshold dose is achieved does not lead to an improved natriuresis. The maximum effective dose of intravenous furosemide in patients with moderate renal insufficiency is 80–160 mg; severe renal insufficiency, 160–200 mg; nephrotic syndrome, 80–120 mg; cirrhosis, 40 mg; and congestive heart failure, 40–80 mg. The dose should be doubled when converting from intravenous to oral administration.

Ineffective natriuresis may occur for many reasons. Patients on a high sodium intake have an inadequate net natriuresis, and all patients started on diuretics for generalized edema should be placed on a low sodium diet (less than 100 mEq/d). Poor absorption of furosemide also should be considered. Patients with severe congestive heart failure may be prone to slower absorption and low bioavailability because of poor intestinal perfusion. Bumetanide or torsemide both have better bioavailability than furosemide and should be tried if oral doses of furosemide are not effective in patients with heart failure. If patients do not respond to maximal doses of loop diuretics, the addition of a thiazide diuretic usually increases natriuresis by blocking sodium absorption at a different nephron site. Spironolactone is usually a weak diuretic, but in patients with cirrhosis, it can be more effective than furosemide.

In the absence of cirrhosis, there is no limit to the rate of fluid removal in patients with generalized edema and pulmonary edema. Two to three liters per day can be removed safely in most patients. Rapidity of fluid removal is assured by maintaining an adequate effective circulating volume. The BUN and creatinine levels can serve as a monitor of this. The main exception to the safety of rapid fluid removal occurs in patients with cirrhosis and ascites, who do not have peripheral edema, and in whom diuresis should be slower (Chapter 83).

The main adverse reactions to diuretics include allergic reactions, ototoxicity, and fluid and electrolyte abnormalities. Ototoxicity is mostly associated with high doses of loop diuretics given in combination with other ototoxic drugs such as aminoglycosides. Most cases of deafness caused by loop diuretics are transient in nature. Continuous intravenous infusion of a loop diuretic may help minimize the risk of ototoxicity in hospitalized patients receiving high-dose diuretics. To maintain a constant diuresis, continuous intravenous infusion should be considered in ICU patients who have only a short-lived response to bolus therapy.

Edema Presenting During Hospitalization

The previous discussion also applies to patients who develop edema during hospitalization. Some patients with compensated heart failure, nephrotic syndrome, or cirrhosis develop edema during hospitalization because the underlying condition worsens. However, most patients develop edema because of iatrogenic reasons. Rigorous fluid resuscitation in the ICU may initiate edema formation, and many causative factors unique to the ICU may maintain the edema. Sodium retention is triggered by the following three factors: (1) mechanical ventilation with positive end-expiratory pressure, which decreases cardiac output; (2) reduced muscle-pump activity, which reduces venous return; and (3) cytokine release from sepsis, causing hypotension, cardiac depression, and increased capillary permeability. The edema usually resolves with improvement of the underlying illness that necessitated ICU admission. Diuretic therapy is indicated only in those patients with clinical signs of volume overload as evidenced by pulmonary edema, or abnormal invasive monitoring variables, such as a high pulmonary capillary wedge pressure.

Elevated BUN and Creatinine

Presenting at the Time of Admission

Description and Differential Diagnosis

Elevated BUN and creatinine levels in patients presenting to the hospital are usually indicative of decreases in GFR. The term *renal insufficiency* usually is applied to patients with mild-to-moderate decreases in GFR who do not require dialytic support. Decreases in GFR can be either acute or chronic. Chronic renal insufficiency or failure usually is a slowly progressive irreversible loss of renal function that results in end-stage renal disease.

Before assuming that elevated BUN and creatinine indicate renal dysfunction, the possibility of nonrenal factors should be considered. Because creatinine is freely filtered across the glomerulus and is not reabsorbed by the kidney, measurement of the serum creatinine concentration is a good endogenous indicator of GFR. However, there is some tubular secretion of creatinine (10%–40%); thus, the creatinine clearance may overestimate the true GFR by the same margin. Drugs such as trimethoprim and cimetidine that block the secretion of creatinine result in an increase in serum creatinine level unrelated to any changes in GFR. Similar to creatinine, urea is excreted primarily by glomerular filtration. Therefore, the BUN level tends to vary inversely with GFR. However, there are factors that can increase the BUN level without affecting the GFR. These conditions include a high-protein diet, hyperalimentation, gastrointestinal bleeding, severe catabolic states, and the administration of corticosteroids or tetracycline. Conversely, a low-protein diet or liver disease can result in a

lower BUN concentration. The percentage of urea reabsorption increases during volume depletion, resulting in elevation of the BUN level without decreases in GFR.

Evaluation

The first question to consider in evaluating a patient presenting with elevated BUN and creatinine levels is whether renal insufficiency is acute or chronic (3). An important historical clue is prior measurements of serum creatinine concentration. Reviewing the medical record may reveal an abnormal urinalysis in the past, which may suggest a chronic process. Oliguria is an unusual finding in patients with chronic renal insufficiency and suggests that the process is acute. Serial measurements of serum creatinine may be helpful; a stable value is more consistent with a chronic process. The presence of anemia also is suggestive of chronic renal insufficiency. Determining the kidney size by ultrasound imaging is helpful, because small kidneys are more indicative of chronic renal insufficiency. Although normal- to large-sized kidneys in a patient with renal insufficiency usually are suggestive of an acute process, there are five chronic conditions associated with normal- to large-sized kidneys: diabetic nephropathy, amyloidosis, HIV-associated nephropathy, adult polycystic kidney disease, and, rarely, infiltrative disorders of the kidney (e.g., lymphoma, leukemia). Chapter 100 includes a complete discussion of acute renal failure.

For patients in whom it is established that renal insufficiency is chronic, the next question to consider is the cause of the renal disease. Table 99.3 lists the major causes of chronic renal insufficiency. After a careful history and physical examination, the first laboratory tests to be performed in evaluating a patient with chronic renal insufficiency are a urinalysis and a 24-hour urine collection for protein excretion. Figure 99.2 presents a differential diagnosis for the major causes of chronic renal insufficiency based on the results of these two tests (11). A renal ultrasound should be performed in the evaluation of all patients with either acute or chronic renal insufficiency to rule out urinary tract obstruction.

TABLE 99.3
MAJOR CAUSES OF CHRONIC RENAL INSUFFICIENCY

Cause	Prevalence
Diabetes mellitus	31%
Hypertension	27%
Cystic diseases (polycystic kidney disease)	14%
Glomerulonephritis	5%
Urologic diseases	5%
Others/unknown	18%

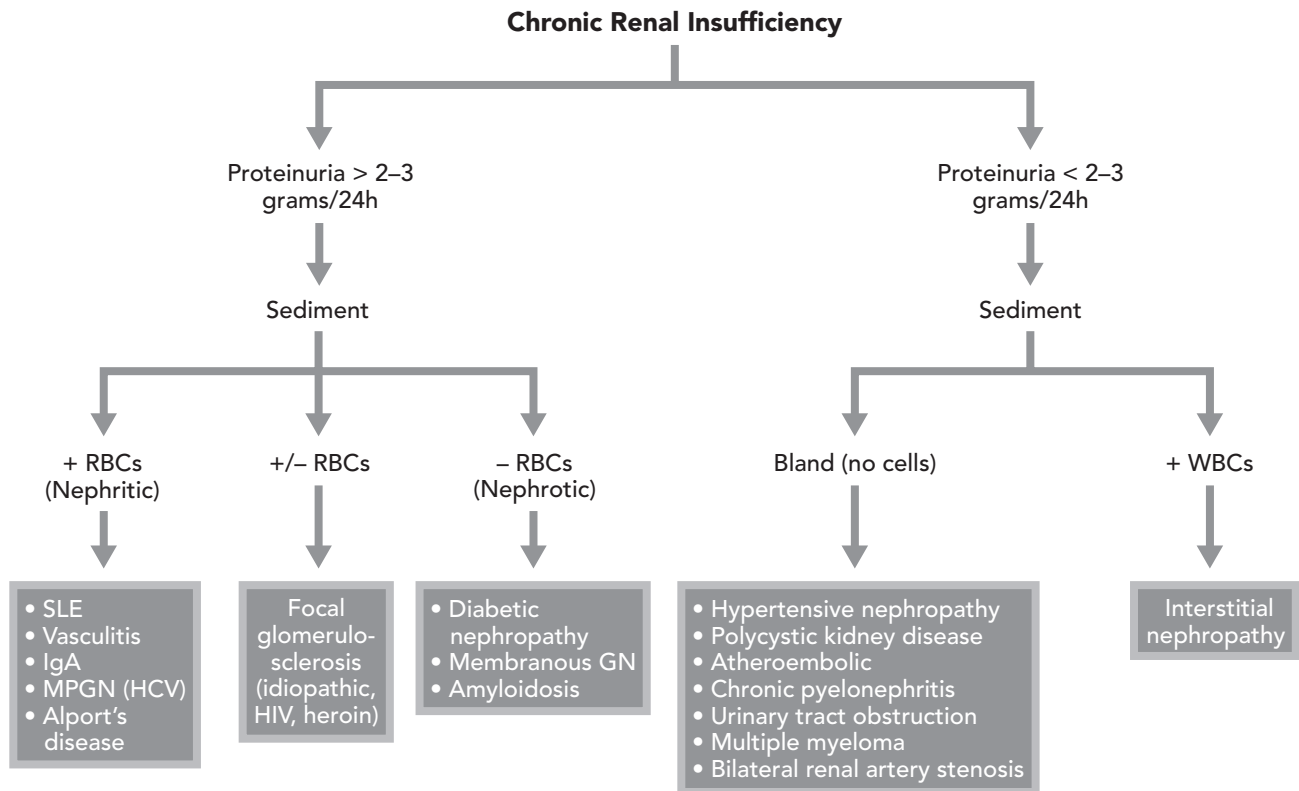

Figure 99.2 Diagnostic approach to chronic renal insufficiency. *GN*, glomerulonephritis; *HCV*, hepatitis C virus; *HIV*, human immunodeficiency virus; *MPGN*, membranoproliferative glomerulonephritis; *RBC*, red blood cells; *SLE*, systemic lupus erythematosus; *WBC*, white blood cells.

Management

Chapter 100 includes a discussion about managing acute renal failure and Chapter 101 discusses dialysis issues. For most patients with chronic renal insufficiency, renal function usually continues to deteriorate over time and progresses inexorably to end-stage renal disease. There is no specific therapy to reverse this progression for most causes of renal disease, but there are treatments that can slow the rate of renal function loss. Control of systemic hypertension is the most important therapeutic maneuver. Also, both experimental and clinical studies have suggested that ACE inhibitors may have a therapeutic advantage over conventional antihypertensive drugs in slowing the progression of many types of renal disease, especially if started early in the course of renal insufficiency. Similar results also have been achieved with the nondihydropyridine calcium channel blockers. Administering ACE inhibitors can produce some negative effects in patients with renal insufficiency, including acute deterioration in renal function, hypotension, hyperkalemia, and a nonproductive cough. Blood pressure, renal function, and serum potassium concentration should be monitored closely during initiation of ACE-inhibitor therapy. Dietary protein restriction also has been advocated as a therapeutic modality to slow progression of chronic renal insufficiency; one meta-analysis and a recent trial suggest that a low-protein diet slows the progression of renal disease (12, 13).

Increased BUN and Creatinine Presenting During Hospitalization

Chapter 100 covers the management of elevated BUN and creatinine levels presenting in hospitalized patients.

KEY POINTS

- Urine microscopy is the most important tool in the evaluation of renal disease and can be invaluable in deciding whether to hospitalize a patient.
- The presence of oliguria or anuria is a critical sign of impaired renal function. It requires immediate evaluation by the admitting physician, because early identification and treatment may restore normal renal function or prevent more prolonged renal dysfunction.
- The cause of localized and generalized edema should be diagnosed quickly on presentation with history and physical examination and few tests. Patients that may require hospital admission include those with the combination of generalized edema and pulmonary edema and those with localized edema.
- Once it is established that an increase in BUN and creatinine levels or the presence of oliguria or anuria in a patient is associated with renal insufficiency, pre-renal, intrinsic renal, or obstructive causes should be considered.

INTRODUCTION

Although there is no consensus regarding a standard definition, acute renal failure (ARF) is most commonly defined as a recent decline in renal function resulting in a reduced ability to excrete nitrogenous waste products, often associated with fluid retention. Elevations in the serum levels of urea nitrogen and creatinine often are used to judge the severity of ARF. From a practical standpoint, ARF can occur *de novo* or be superimposed on previously impaired renal function, and can be community-acquired or develop in the hospital. It also may complicate the course of an ICU patient. The delineation of timing and setting of ARF is of some importance because the strategies for diagnosis and management, and the outcomes, are different (Table 100.1). Recent evidence suggests that ARF may increase the risk for developing nonrenal complications such as sepsis and bleeding. It is thus increasingly evident that early recognition and appropriate management of ARF are important goals. This chapter outlines the key principles for and a sequential approach to the diagnosis and management of ARF.

ACUTE RENAL FAILURE PRESENTING AT THE TIME OF ADMISSION

Community-acquired ARF in the absence of any other problem is a relatively infrequent cause for hospital admission and usually suggests a primary renal process that may have been unrecognized. More commonly, ARF may complicate the course of a patient presenting with other organ dysfunction (e.g., cardiac or hepatic failure, or sepsis). The main issues that require attention are recognition and diagnosis of ARF, initial management to correct reversible factors, and determining the need for and timing of dialytic intervention.

Issues at the Time of Admission

Diagnosis

Patients with ARF usually are identified from a laboratory result demonstrating an elevation in blood urea nitrogen and creatinine levels (most commonly a rise in serum creatinine from a known previous baseline by >1 mg/dL, or an absolute value of >2 mg/dL). This elevation may be associated with a decline in urine volume and symptoms of uremia (fatigue, fluid retention, easy bruising, and confusion). Often these findings are overshadowed by the clinical features of other organ failure. It is thus important to evaluate the setting in which ARF is identified and determine possible contributing factors.

Traditionally, causes of ARF have been delineated as *prerenal*, *renal*, and *postrenal*. This approach utilizes an anatomic separation of the possible factors responsible for ARF, permitting an easy method for considering the possible causes. However, an alternative and equally useful classification of ARF is based on the *anticipated course of the disease and the reversibility of the lesion* (Table 100.2). This approach suggests that initial efforts should be directed toward determining whether the process can be reversed easily, as is the case in many prerenal and postrenal conditions (e.g., volume depletion and obstructive uropathy). Similarly, it is equally important to ascertain if there is potentially irreversible damage to the kidney (e.g., vascular occlusion), which may leave a limited window of opportunity for reversal. For the remaining clinical entities, diagnostic strategies are currently helpful only in a limited way, because the therapeutic approaches are similar (except if ARF is caused by an aggressive acute glomerulonephritis, as discussed later).

A standardized approach to diagnosing ARF begins with a detailed history and chart review to determine recent clinical events and potential nephrotoxin exposure. Volume status should be assessed, as should changes in urinary vol-

TABLE 100.1
CLINICAL SETTING FOR ACUTE RENAL FAILURE

	Community-acquired	Hospital-acquired	ICU-acquired
Incidence	Low (<1%)	Moderate (2%–5%)	High (10%–20%)
Cause	Often single (pre > post > renal)	May be single or multiple	Often multifactorial (pre > renal)
Outcome (patient survival)	Good (70%–95%)	Moderate (30%–50%)	Poor (10%–30%)

Pre, prerenal; Post, postrenal.

ume, color, and symptoms. Every attempt should be made to determine recent intake of prescription and over-the-counter drugs (particularly nonsteroidal anti-inflammatory agents, which are a common cause of renal function decline, especially in elderly patients and those with heart failure or cirrhosis). Evidence of pre-existing renal dysfunction always should be sought; the patient may or may not be aware of the dysfunction. A comprehensive physical examination looking for reversible factors responsible for decreased effective renal perfusion and renal obstruction is an important next step. In the elderly male patient, a rectal examination should be performed to evaluate for prostatic hypertrophy. Auscultation revealing an abdominal bruit may suggest an ischemic cause of ARF. Similarly, the presence of a cardiac arrhythmia such as atrial fibrillation may point to the possibility of embolic disease.

All patients with ARF should have a urinalysis, serum chemistry tests (including measurement of electrolytes, urea nitrogen, creatinine, calcium, phosphate, uric acid, and liver enzymes), and complete blood count with platelets. Evaluation of the anion gap (Chapter 105) can be an important clue to an underlying tubulointerstitial pro-

cess (i.e., renal tubular acidosis) and may even point to the cause of ARF (e.g., myeloma associated with a low anion gap). Urine and serum chemistry tests can provide important clues to the underlying disorder, particularly the presence of prerenal factors. Urine electrolyte patterns associated with prerenal or renal profiles may be influenced by several factors, and their diagnostic utility may be somewhat limited. Nevertheless, tests that measure tubular reabsorption (i.e., fractional excretion) can help indicate whether the condition is caused by tubular (i.e., intrinsic renal) dysfunction or by prerenal factors. The fractional excretion of urea nitrogen ($[\text{urine/plasma urea nitrogen}] \times [\text{plasma/urine creatinine}] \times 100$) may be more accurate than the more commonly used fractional excretion of sodium ($[\text{urine/plasma sodium}] \times [\text{urine/plasma creatinine}] \times 100$) (1). Unlike the fractional excretion of sodium, the fractional excretion of urea nitrogen is relatively unaffected by prior diuretic use and metabolic alkalosis (both conditions may result in high fractional excretion of sodium in the presence of volume depletion). A cut-off of less than 35% is fairly discriminatory for prerenal conditions (the traditional cut-off for the fractional excretion of sodium is <1%) (2). Serum creatinine may be a poor surrogate for estimating the magnitude of decline in renal function, because it is influenced by the patient's age, gender, muscle mass, and volume status. Similarly, in the presence of hepatic failure, serum creatinine levels may be underestimated by chromogenic methods. Quantification of glomerular filtration rate by creatinine clearance is preferable but may not always be possible.

Abdominal ultrasound is usually indicated, and Doppler examination of the renal vasculature also may be useful in some circumstances. In the setting of ARF in the ICU, contrast studies should be avoided in the workup of renal failure. If the integrity of renal perfusion is in question, an isotope scan can provide useful information. If there is any doubt about the quality of the scan, however, a renal angiogram may be necessary.

In the presence of active urine sediment and other features suggestive of glomerulonephritis, immunologic tests for antineutrophilic antibodies, antiglomerular basement antibodies, and complement levels may be useful. Renal biopsy is generally the most definitive way of diagnosing ARF, but this test is often omitted because of fear of com-

plications and/or confidence in the clinical diagnosis. However, in patients with intrinsic renal failure ultimately found to be caused by glomerular disease, biopsy has been shown to change management in more than half the cases (3). As newer therapeutic interventions become available, biopsy is likely to become increasingly important in establishing a specific diagnosis and guiding therapy.

Diagnostic Tests on the Horizon

Because the most commonly used clinical tools for diagnosing renal failure—rise in creatinine and decrease in urine output—are far from ideal, researchers have tried to identify other biomarkers that can quickly and accurately diagnose renal injury (and give a clue as to pathogenesis) at an early stage of ARF. For example, high urinary levels of cysteine-rich protein-61 (CYR61) have been shown in animal studies to distinguish between prerenal causes of ARF and acute tubular necrosis (4). Similarly, urinary levels of the Na-H⁺ antiporter isotype 3 (NHE3), which is the most abundant sodium transporter in the proximal tubule, and kidney injury molecule-1 (KIM-1), which is upregulated in the proximal tubule in response to ischemia, may eventually be used to distinguish between prerenal azotemia, ATN, and intrinsic ARF other than ATN (5, 6). If additional research supports these associations, such biomarkers may allow for more rapid and directed intervention in cases of potentially reversible renal failure.

Indications for Hospitalization and Intensive Care Unit Admission

When a patient presents with an abrupt decline in renal function associated with a marked decrease in urine output, hospitalization should always be considered, because rapid changes in electrolyte, acid-base, and volume status

may occur (Table 100.3). Additionally, a prompt diagnosis of the nature of renal injury may require aggressive diagnostic testing, including renal biopsy, which is easier to perform in the hospital. If urine output is not compromised and renal function changes are gradual (e.g., an increase in serum creatinine of <0.5 mg/dL over 72–96 hours), and if there is no concern that the patient will be lost to follow-up, an initial outpatient evaluation can be initiated with follow-up in 1–2 days. Often, the decision to hospitalize a patient for ARF is influenced by knowledge of the event leading to renal function decline (e.g., exposure to contrast agents). If the nature and timing of a renal insult are well known, it is easier to be more confident in a decision to follow a patient as an outpatient. If the renal insult is unknown or if there is any doubt about the patient's ability to follow instructions, it is safer to hospitalize. If ARF complicates other organ dysfunction, it is always preferable to hospitalize the patient, because the presence of ARF worsens the prognosis of the primary illness and makes it more difficult to manage the patient. In the presence of preexisting renal dysfunction, an acute and significant decline in renal function should prompt hospitalization, because dialytic intervention may be necessary. Patients with severe ARF (blood urea nitrogen level >100 mg/dL or creatinine level >8 mg/dL with uremic complications such as pericarditis), marked electrolyte abnormalities (e.g., potassium >6.5 mEq/L), or marked acidosis (pH <7.33) should be admitted to a monitored floor or an ICU setting for closer observation.

Initial Management and Indications for Consultation

The treatment of ARF has the following goals: maintaining fluid and electrolyte, acid-base, and solute homeostasis; preventing further insults to the kidney; promoting

TABLE 100.3

INDICATIONS FOR HOSPITALIZATION FOR ACUTE RENAL FAILURE (ARF)

Description of case	Outpatient	Hospital	ICU	Nephrology consultation indicated?

healing and renal recovery; and permitting other support measures such as nutrition to proceed without delay. Therapeutic interventions should be designed to achieve these goals and take the clinical course into consideration. Classically, ARF is said to progress through three phases: (1) an *initiation phase*, (2) a *maintenance phase*, and (3) a *recovery phase*. A fourth phase, during which extension of the initial injury occurs, has also been proposed. Although these four phases are not always distinct, their recognition facilitates the development of a treatment plan because therapeutic strategies differ from one phase to another. For example, in the initiation phase, the major emphasis is on preventing and attenuating the severity of the renal dysfunction, whereas once ARF is established the emphasis is on maintaining homeostasis to allow recovery. The latter often requires renal replacement therapy with dialysis. It is often helpful to consult a nephrologist early in the course of the disease (Table 100.3) because appropriate intervention in each phase may influence the need for dialysis and the outcome. Patients with advanced renal dysfunction should always have a nephrology consultation, because dialytic intervention may be required emergently.

Initiation Phase

The initial phase of ARF represents the period of actual insult resulting in glomerular or tubular epithelial injury and resultant decline in renal function. In most circumstances, the effect of the injury is manifested over a few days, thus permitting interventions that may reverse or attenuate the effect of the insult. These interventions should be selected based on the clinical status of the patient; the goal is to correct any reversible contributing factors such as volume depletion and obstruction, to restore renal perfusion and urine output, and to minimize further tubular injury. Several agents, described below, are now available for this purpose; however, they should be used judiciously, because they all can cause deleterious side effects.

Volume Expanders Volume expanders should be considered early in the management of ARF, particularly if there is evidence of intravascular volume contraction. The use of volume expanders can be both diagnostic and therapeutic in potential prerenal states. Saline infusions have been shown to have a beneficial effect in experimental ARF and to attenuate the nephrotoxic potential of aminoglycosides and amphotericin. In the hypoalbuminemic patient, it is preferable to use a colloid solution. Although albumin has traditionally been used in this setting, recent data suggest ICU patients resuscitated with albumin do no better than those resuscitated with normal saline (7). As such, if colloid administration is deemed necessary because of presumed inadequate intravascular oncotic pressure, packed red blood cell transfusions may be preferable to albumin administration, because the former are likely

to be retained in the intravascular compartment longer and theoretically should improve oxygen-carrying capacity as well.

The amount of volume and the rate of administration must be individualized depending on the patient's clinical status. Hemodynamic monitoring can help determine the rate of fluid replacement and reduce the potential for fluid overload in severely ill patients (Chapter 25). In general, in a volume-contracted patient with hemodynamic compromise, rapid volume expansion with 0.9% saline should be initiated at a rate of 250–500 mL/h for 1–3 hours, after which the volume status and urinary output should be reassessed. If the initial volume replacement results in an improvement in urinary output, volume expansion should continue, with the rate of infusion based on the clinical response. If there is no improvement in urinary output, a diuretic challenge can be employed (see later in this chapter). If this fails, the rate of fluid administered should be reduced to avoid volume overload.

Diuretics The use of diuretics in the initial phase of ARF is based on observations from experimental and clinical studies. In addition to improving urine flow, these agents may reduce smooth-muscle swelling and tubular obstruction (8). They also have a vasodilatory action, which is beneficial in maintaining renal perfusion. However, it is also apparent from several studies that there is a limited window of opportunity during which diuretics are efficacious. In animal models, the use of mannitol from a period beginning an hour before to 10–15 minutes after an acute ischemic insult prevents or attenuates ARF. Unfortunately, in clinical practice it is rarely possible to anticipate an insult.

An initial diuretic challenge should be undertaken only once the patient is volume replete. An intravenous bolus dose of a loop diuretic (40–80 mg of furosemide or 1–2 mg of bumetanide) is usually sufficient to elicit a response. If the urine output does not increase, it is unlikely that the patient will benefit from a continuous infusion of the diuretic. If an initial response is obtained (increase in urine output by 50–200 mL/h), the diuretic can be given as frequent bolus injections (every 4–6 hours) or as a continuous infusion (20–80 mg/h furosemide or 0.5–2.0 mg/h bumetanide). The effect of a loop diuretic can be enhanced by giving a thiazide diuretic (metolazone 5 mg or hydrodiuril 50–100 mg) about 30 minutes beforehand. However, sustained high-dose diuretic therapy to force urine from a relatively diuretic-resistant ICU patient (i.e., a patient who requires >1 mg furosemide per 1 ml urine output) is discouraged because diuretic use in this setting has been associated with higher mortality (9). Although this association may not be causal, the available evidence indicates that patients resistant to diuretics are unlikely to benefit from continued aggressive diuretic therapy, and more definitive therapy (i.e., dialysis) should be administered.

Vasoactive Agents Renal blood flow changes are a common feature of all forms of ARF. As a consequence, there has been a significant interest in use of renal vasodilators to improve the course of the disease. The use of “renal-dose dopamine” (0.5–3 mcg/kg/min) is based on the selective and specific effect of dopamine on DA1 receptors, resulting in renal vasodilatation without effects on the β - and α -receptors. Adding low-dose dopamine has been shown to increase urine flow rates in diuretic-resistant oliguric ARF. However, no large trials have demonstrated any benefit of renal-dose dopamine in ARF; there is no change in the requirement for dialysis or ultimate outcome (8, 10). Because of this absence of evidence, *the use of renal-dose dopamine to enhance urine output cannot be supported*, although it continues to be used widely in practice. Other vasoactive agents, such as norepinephrine or phenylephrine, are increasingly being used to improve hemodynamics and maximize oxygen delivery and cardiac output in septic patients, and this has been associated with improved outcomes (Chapter 26). It is likely, however, that improved urine output and renal outcomes are the result of enhanced cardiac performance rather than any specific effect on the renal vasculature. As such, the choice of inotropic therapy should be based on individual patient parameters and guided by right-heart catheterization, if necessary; it should not be instituted simply to influence renal perfusion (Chapter 25).

Natriuretic Peptides Atrial natriuretic peptide (ANP) increases glomerular filtration rate and renal blood flow in several forms of experimental renal failure and has also been shown to be effective in clinical studies. The increase in glomerular filtration rate occurs despite a decrease in systemic arterial pressure. It results from glomerular afferent arteriolar dilatation and efferent arteriolar constriction; the overall effect is to increase the intraglomerular pressure gradient. In animal models, ANP has been shown to be protective and also improves the recovery from established ARF. Combining this peptide with dopamine appears to attenuate the hypotensive effect. The biological half-life of ANP is short because it is cleared from the circulation by its receptor, filtered by the glomeruli, and metabolized by tubule cells. Initial clinical studies are promising but mixed. The recombinant form of ANP has been evaluated in two multi-center trials for treating ARF that results from acute tubular necrosis. While the first showed a reduced need for dialysis and improved 21-day mortality rate in oliguric patients (but not in nonoliguric patients) (11), subsequent trials failed to show any benefit of ANP (12). Currently, no other natriuretic peptide is available in the United States for treating ARF.

Calcium Channel Blockers Experimental evidence suggests that cellular damage in ARF results in an increase in cytosolic calcium, which can damage cellular integrity by

several pathways. It, thus, has been proposed that calcium channel blockers may attenuate the injury. Although several studies have shown that calcium channel blockers may help preserve renal perfusion in the posts ischemic state if administered before the insult, they have been variably protective when given after the insult (8). Verapamil and diltiazem have been used to perfuse renal allografts before transplantation and have been shown to reduce the incidence of delayed graft function (Chapter 102). Human studies are limited, and there is insufficient evidence to support their general use for ARF.

Other Potentially Promising Agents Growth factors have shown some promising results in experimental models of ARF, particularly that caused by ischemia. However, there are no clinically available therapies in this class because many of the growth factors that appeared promising in experimental models have been less impressive in animal or human trials (e.g., insulin-like growth factor-1 [13], epidermal growth factor, transforming growth factors, and hepatocyte growth factor).

Oxygen-radical scavengers, such as glutathione, superoxide dismutase, and allopurinol, have been used to block the effects of free oxygen radicals in causing cellular injury, but the results are not consistent. Adenine nucleotides have shown a protective effect in experimental ARF and can be beneficial, even if administered several hours after ischemia. Human trials have suggested an improved survival rate from ARF (14), but hemodynamic effects (particularly hypotension) limit their use. Modulation of endothelin and endothelium-derived relaxing factor seemed promising, but trials in contrast nephropathy revealed a detrimental effect (15). Finally, in a mouse model of sepsis and acute renal failure, a single intravenous dose of ethyl pyruvate inhibited functional and histologic renal damage and other organ damage, even when given hours after the insult (16). Although none of these agents are currently available for general use, it is likely that some will be in the future.

Issues During the Course of Hospitalization

Prevention of Contrast-Induced Nephropathy

In addition to the obvious measures such as avoidance of known nephrotoxins and potential prerenal states, a special consideration should be given to prevention, or at least mitigation, of contrast-induced nephropathy. Given the ubiquity of imaging-based diagnosis, administration of radio-contrast media often cannot be avoided even in a patient at high risk for contrast nephropathy (i.e., diabetics, patients with acute or chronic kidney disease, etc.). Luckily, a variety of preventive therapies may lessen the chance for contrast-induced renal failure. These therapies include periprocedural ingestion of N-acetylcysteine and infusion of normal saline or sodium bicarbonate. One

prominent study demonstrated a marked protective effect from N-acetylcysteine administered to patients with CRI undergoing contrast studies (17), presumably by scavenging free radicals. Although subsequent studies failed to confirm this benefit, use of this agent remains widespread because it has few side effects and is inexpensive. More recently, the infusion of sodium bicarbonate (given 3 ml/kg/hr for 1 hour prior to the procedure, 1 ml/kg/hr during, and for 6 hours after) was also found to significantly improve outcomes when compared with normal saline treatment in patients with mild renal insufficiency (creatinine 1.7–1.8) (18). Another study demonstrated benefit from periprocedural prophylactic continuous venovenous hemofiltration in high-risk patients; it is unclear whether the benefit was from tighter volume control or a reduction in contrast toxicity. We recommend the use of sodium bicarbonate as first-line prophylactic therapy, reserving dialytic support for patients with very low hemodynamic reserve. In addition, a nonionic, iso-osmolar contrast agent such as iodixanol should be used because it may be less nephrotoxic than ionic or higher osmolarity agents (19).

Extension Phase

Though not part of the classical description of the natural history of ARF, Molitoris and colleagues have proposed an *extension phase* (20), during which renal endothelial dysfunction and ischemia lead to vascular congestion, inflammation, and coagulopathy in the microvasculature of the corticomedullary junction, even after the initial tubular or glomerular insult has subsided. This poorly characterized and short-lived (likely <24 hours) phase may represent a future therapeutic window during which inhibitors of the inflammatory cascade might be administered and extension of ARF mitigated.

Maintenance Phase

Once ARF is established, fluid, electrolyte, and solute balance need to be maintained and new insults prevented. Attention to detail is crucial in this phase and is best assured with the help of a nephrologist.

Fluid and Electrolyte Balance

The development of ARF limits the kidney's ability to maintain fluid balance and electrolyte composition. Oliguric ARF is more limiting in this respect than nonoliguric states. The daily fluid requirement for patients with ARF should be equal to urine output, nonurinary losses (through the gastrointestinal tract, drains, etc.), and insensible water losses. This balance is often difficult to achieve because of obligate intakes necessary for drugs, transfusions, and nutrition. In this situation, clinicians sometimes restrict nutrition to reduce the volume deliv-

ered. It is better, however, to consider earlier intervention with dialysis to allow for both fluid removal and nutritional support. With the newer methods of continuous dialysis described in Chapter 101, it is possible to keep patients in fluid balance without compromising supportive measures. Fluid management is crucial in these patients, because volume overload has been associated with increased morbidity and mortality rates.

Acid-Base Abnormalities

Metabolic acidosis is common in ARF and is caused by the kidney's inability to excrete hydrogen ions. The retained acid is largely buffered by bicarbonate; some is excreted by the lungs as carbon dioxide. Both anion-gap and non-anion-gap acidosis can occur in ARF patients. The former is more likely in the hypotensive septic patient; the latter often can be seen if there are large losses of bicarbonate-rich intestinal secretions. Bicarbonate therapy for acidosis should be used with caution to avoid rebound metabolic alkalosis (Chapter 105). Dialysis may be required if the acidosis is profound and persistent. Metabolic alkalosis is also a common finding in ARF, especially if there are large nasogastric losses. Citrate load from blood-product transfusions also can contribute to alkalosis.

Medications

All renally excreted medications need to be dosage-adjusted in patients with ARF or those on dialysis. It is also important to limit the use of nephrotoxic antibiotics. Opiate doses should be modified; meperidine (Demerol) should be avoided because its metabolites are retained in renal failure, are not easily dialyzed, and may cause seizures. Injectable nonsteroidal anti-inflammatory drugs (e.g., ketorolac) block renal prostaglandin synthesis, which is required to maintain blood flow, and thus should also be avoided.

Dialysis

Dialytic intervention in ARF usually is considered if there is clinical evidence of uremic symptoms or biochemical features of solute and fluid imbalance (Table 100.4). Unfortunately, there is no consensus on the optimal timing of dialytic intervention. The strategy in treating ARF is to minimize and avoid uremic complications; thus, it is not necessary to wait for progressive uremia to initiate dialytic support. On the contrary, there is some evidence that "early" or "prophylactic" dialysis may improve outcome in this setting (21), although comprehensive data on this strategy is lacking. In critically ill patients, the need for dialysis may be dictated by volume overload rather than azotemia. In the ICU setting, dialysis should be viewed as an overall support modality whose use is not limited to replacement of renal function.

The choice of dialysis method influences the frequency of dialytic intervention. Several methods of dialysis are cur-

TABLE 100.4
COMMONLY USED INDICATIONS FOR DIALYSIS

Uremic encephalopathy
Uremic pericarditis
Uremic bleeding (e.g., gastrointestinal hemorrhage)

rently available for renal replacement therapy and are discussed in detail in Chapter 101. *Intermittent hemodialysis* (IHD) has been used widely for the past four decades for patients with end-stage renal disease and ARF. It remains the standard form of therapy for treatment of ARF in both the ICU and non-ICU settings. Continuous dialysis modalities are increasingly in use, as well, especially in critically ill or otherwise hemodynamically unstable patients. *Peritoneal dialysis* (PD) has limited application for ARF in the ICU but can be used in some settings when ARF is isolated and the patient weighs less than 100 kg. Its advantages include possible cost savings and that it does not require specialized ICU staff to operate. However, its disadvantages include detrimental effects on respiratory status resulting from diaphragmatic splinting, technical limitations in patients with abdominal sepsis or abdominal surgery, relative inefficiency in removing waste products in catabolic patients, and association with a high incidence of peritonitis. It is inferior to continuous venovenous hemofiltration in ICU patients with ARF (22). The availability of highly permeable membranes has allowed development of *continuous renal replacement techniques* (CRRT) that gradually remove fluids and solutes from the vasculature, resulting in better hemodynamic stability and fluid and solute control. In addition, these modalities may ultimately provide the (as yet unrealized) potential to offer not only renal support but also therapy with sorbents and high-flux membranes that remove harmful inflammatory mediators in a way not previously possible. These methods are limited to the ICU setting, because they require close monitoring and frequent adjustment of fluid balance.

The choice of intermittent hemodialysis versus continuous renal replacement techniques currently is based largely on the local availability of these techniques and the familiarity of the nephrologist and other personnel (particularly ICU staff) with the procedures. Despite the intuitive notion that CRRT should produce better outcomes than IHD, clinical trials have not demonstrated a consistent benefit (23).

Determining the *frequency* of dialysis is a major issue in patients undergoing intermittent therapy. It usually is determined by the patient's clinical and biochemical status (particularly the blood urea nitrogen level and electrolyte and acid-base status). Whether there is benefit from dialyz-

ing patients beyond a given metabolic parameter using IHD is still a matter of contention, and studies on this question have yielded mixed results (24, 25). On the other hand, because CRRT by nature runs continuously, frequency of administered therapy is not an issue. As with intermittent dialysis, it remains controversial whether aggressive, high-dose CRRT improves the outcome of ARF. Recent data suggest a possible benefit to higher dose CRRT, especially in septic patients (26), but this practice is not universally followed.

The *duration* of dialysis for ARF is determined largely by the underlying renal disease and also by any additional insults to the kidney during the course of ARF. In most circumstances, dialysis is discontinued when renal function recovers. Traditional teaching suggests that most patients with reversible ARF improve within 4–6 weeks and that the need for dialysis beyond this period likely represents chronicity. Although this is true in most instances, two important factors need to be considered. First, some patients with ARF in the ICU setting may require prolonged dialysis support (>8 weeks) before recovering renal function, and recovery may be incomplete. Second, the duration of dialysis support may need to be limited (and sometimes predefined) in some patients with ARF if other organ-system failure accompanies ARF (Chapter 25). In this situation, the ultimate prognosis depends on the recovery of other organ systems, and dialytic support may serve only to prolong the dying process (Chapters 17 and 19).

Nutritional Considerations

Aggressive nutritional support is a key component in the management of the patient with ARF. Malnutrition is an independent risk factor for death. In general, nutritional support should take precedence over dialytic intervention, and nutrition should not be withheld to prevent dialysis (i.e., for fear of fluid overload). Rather, early dialysis should be instituted to allow adequate nutrition. Continuous renal replacement techniques offer an advantage over intermittent hemodialysis in this respect. The nutritional prescription should be based on the patient's energy needs. Protein goals should be established to achieve positive nitrogen balance, and carbohydrate and fat amounts prescribed should allow for an appropriate mix of substrates. The contribution of renal replacement therapy to protein and amino-acid losses and glucose absorption should be accounted for in the calculations. It is preferable to use the enteral route whenever possible (Chapter 15). If the parenteral route is used, however, specific renal formulas such as Nephramine or Travesol may be utilized.

Recovery Phase

The recovery phase is characterized by a gradual return of renal function to a level allowing discontinuation of dialysis. This phase often is prolonged, and renal function may not return to baseline levels. During this phase, the main

strategy is to maintain adequate fluid and electrolyte balance and prevent further insults to the kidneys. The decision to discontinue dialysis is often difficult and may require gradual weaning with a progressive increase of time between dialysis treatments. Unfortunately, there currently are no specific agents that can speed the recovery phase.

ACUTE RENAL FAILURE DEVELOPING IN THE HOSPITAL

ARF that develops in the hospital carries a worse prognosis than ARF present at the time of admission. In a large study of more than 740 patients from 13 tertiary-care hospitals in Madrid, Spain, 45% of the cases of hospital-acquired ARF were caused by acute tubular necrosis, 21% by prerenal causes, 10% by postrenal causes, 3% by renal vascular disorders, 3% by glomerulonephritis, and 2% by acute interstitial nephritis (27). In a French multi-center study of severe ARF in the ICU (serum creatinine level >3.5 mg/dL), ischemic acute tubular necrosis was the most common reason identified for ARF, although the cause was often unknown or multifactorial (28). Patients who developed ARF during the course of their ICU stays had worse prognoses than those who had ARF at the time of ICU admission.

Recognition

The basic approach for diagnosing ARF in hospitalized patients is similar to that described earlier for ARF at the time of admission. In addition, it helps to remember a few settings in which ARF is particularly common, including the postoperative state and after solid organ and bone-marrow transplantation. In addition, patients with advanced cardiovascular disease, multiple organ failure, sepsis, malignancy, and HIV infection are predisposed to ARF in the hospital. Factors contributing to renal failure are volume depletion, hemodynamic instability, hypotension, and nephrotoxic agents. It should also be recognized that by the time sizable changes in the serum creatinine level occur in the high-risk patient, significant renal damage may have already occurred and the patient's prognosis dramatically affected. Indeed, a recent study suggests that even small, seemingly insignificant changes in creatinine are associated with adverse outcomes in postoperative cardiothoracic surgery patients (29). As such, careful attention to even small changes in renal function (e.g., increases or decreases of creatinine of >0.3 mg/dL) and to the context in which those changes occur is of paramount importance and may lead to improved outcomes if specific supportive therapy can be instituted before the situation deteriorates further. Unfortunately, it is often difficult to pinpoint a single factor, and in many instances there is no evidence of any specific precipitant. In those cases, it is important to utilize a systematic approach to diagnosing ARF.

Management

The initial management of ARF developing in the hospital is similar to that for ARF at the time of hospital admission with the following exception: The course preceding the decline in renal function can be assessed more easily and can be extremely helpful in determining the intervention required. A gradual decline in renal function without obvious evidence of fluid overload should prompt an initial limited volume and diuretic challenge, whereas a rapid elevation in serum creatinine, oliguric state, and fluid overload may require dialytic intervention. It is essential to utilize the information obtained from the patient's observed course to guide therapeutic interventions. Early consultation with a nephrologist may be beneficial, particularly if the exact cause is unclear and ARF complicates pre-existing renal dysfunction.

Outcome

It is well recognized that uncomplicated ARF usually can be managed outside the ICU setting and carries an excellent overall prognosis, with mortality rates usually less than 10%. In contrast, ARF complicating other organ failure in the ICU setting carries mortality rates of more than 50% (Table 100.1) (12, 30). Despite significant advances in the management of ARF during the past four decades, these mortality figures have not changed appreciably; the availability of dialysis has not led to an unequivocal improvement in survival. Although death is an important outcome from ARF, it should not be the only outcome considered, because it often is influenced by multiple factors. For example, renal function recovery is an independent outcome of interest but one that is conditioned by the final outcome of patient death. Survival with full renal recovery is the ideal outcome, but for some patients survival may come at the expense of chronic dialysis. The impact of ARF on the length of stay in the ICU and the resultant costs of care are of obvious additional interest.

There are multiple factors that influence outcomes from ARF. It is possible to broadly classify these as (a) patient characteristics contributing to the nature and severity of the underlying disease associated with ARF, (b) the effects of dialysis itself, and (c) other factors including practice variability and the impact of post-ARF interventions.

Patient Characteristics

The development of ARF is associated with an increase in mortality rate, and patients with ARF as part of multiorgan system failure have a higher mortality rate than those with limited ARF (12, 23). One study in four ICUs found that patients who received nephrology consultation within 48 hours had a lower mortality rate than those who had consultation after 48 hours, an effect that was independent of severity of illness (31). These data suggest that ARF com-

pounds the effects of multiorgan failure and, if unrecognized, can affect outcome adversely.

There appears to be a relationship between the cause and type of ARF and outcome. Patients with ARF secondary to multisystem disorders (e.g., lupus nephritis) have the lowest mortality rate; the highest rate is seen in ischemic acute tubular necrosis. Nephrotoxic acute tubular necrosis has an intermediate mortality rate. Although nonoliguric ARF carries a better prognosis than oliguric ARF, recent data suggest that nonoliguric ARF may have a worse prognosis in ICU patients. A possible explanation is that nonoliguric states lead clinicians to overestimate renal function, leading to a delay in initiation of dialysis. In general, patients do better if the cause of renal dysfunction is quickly identified and specific treatment is instituted.

Dialysis Process Factors

The timing of renal replacement therapy, the amount and frequency of dialysis, and the duration of therapy all impact the eventual outcome. Because physician preferences and experience are variable and universal guidelines for dialysis are not followed, comparing outcomes between centers or patients is difficult. Further discussion of these issues is in Chapter 101.

Practice Variation and Post-Acute Renal Failure Interventions

The provision of ancillary support for ARF patients may also affect outcomes. Several studies in ICU patients suggest that malnutrition worsens outcome, and calorie deprivation has been associated with poor outcomes in dialyzed ARF patients. The importance of other interventions after ARF is established also should be considered. For instance, angiographic or surgical procedures and the use of nephrotoxic agents and antibiotics all may prolong the duration of ARF and increase the mortality rate.

DISCHARGE ISSUES

As described previously, the main goal in managing ARF is to provide supportive therapy to enable the patient to regain renal function. The nature and severity of renal injury and the interventions required to maintain homeostasis are key determinants of outcomes. Discharge planning should incorporate a strategy to monitor renal function at frequent intervals. Patients with new-onset ARF who do not undergo dialysis in the hospital and who regain renal function should have outpatient follow-up to ensure that the recovery is maintained, and they should be advised to avoid nephrotoxic agents and renal insults. If renal function recovery is incomplete, follow-up with a nephrologist may be indicated for periodic monitoring of renal function. Any medications prescribed should be adjusted for the level of

renal function, and patients should be cautioned not to take over-the-counter medications (particularly nonsteroidal anti-inflammatory agents) without checking with their physicians. Patients with pre-existing renal dysfunction who suffer an episode of ARF should have follow-up with a nephrologist because the recent insult may worsen the progression of renal failure and hasten the need for subsequent dialytic intervention. Specific strategies to reduce progression of renal disease may need to be instituted depending on the clinical circumstance (e.g., use of ACE inhibitors in diabetic nephropathy). For patients who require dialysis in the hospital, the continued need for dialytic support is an important consideration (32). If dialysis continues to be required at the time of hospital discharge, an outpatient dialysis regimen must be established. The consulting nephrologist who provides the dialytic support in the hospital can usually secure this follow-up. A major factor in this case is whether the patient is likely to recover enough function to discontinue dialysis or is likely to remain dialysis-dependent. In the latter circumstance, the diagnosis of end-stage renal disease permits the institution of long-term dialysis and establishes a payer (in the United States, Medicare) for the dialysis treatments. Often patients have to transition to a rehabilitation facility before returning home and may require dialysis at that or another facility.

COST CONSIDERATIONS AND RESOURCE UTILIZATION

The development of ARF adds to the overall cost of a patient's hospitalization, particularly if dialytic intervention is required (8, 12, 26). Early recognition, along with appropriate and timely intervention, can minimize the effect of ARF on other organ function. Timely consultation with a nephrologist may help in streamlining the management of the patient and facilitate early dialytic intervention. If dialysis is required, the choice of modality, frequency of intervention, and duration all affect the cost (Chapter 101). More importantly, the long-term costs from an episode of ARF are influenced by the recovery of renal function and need for chronic dialysis. All attempts should be made to prevent this complication in high-risk patients and situations. Resources can be monitored by evaluating the frequency with which patients require dialysis and the frequency of renal functional recovery.

KEY POINTS

- ARF is an important complication that has a variable frequency but is predictable in certain circumstances.
- Recognition of the risk for ARF should result in the initiation of strategies to prevent ARF and attenuate the insult.
- In the high-risk (i.e., postoperative) patient, even subtle changes in serum creatinine level can indicate a potentially worse outcome.

- Early recognition of renal dysfunction, understanding of the clinical context, and management are keys to ensuring a good outcome. Understanding the natural history of this disorder should permit appropriate and timely decisions for therapeutic intervention. Although ARF has been divided traditionally into prerenal, renal, and postrenal causes, an equally useful nosology is to divide cases into reversible, self-limited, and irreversible causes.
- Several therapeutic options are now available for the nondialytic and dialytic management of ARF. The former include the use of volume, diuretics, and vasoactive agents (although “renal-dose dopamine” has not been shown to be beneficial). The latter include intermittent or continuous hemodialysis, as well as peritoneal dialysis for a limited number of indications.

Management of the Hospitalized Patient on Dialysis

Glenn M. Chertow

INTRODUCTION

In 2004, there were more than 325,000 patients being treated with hemodialysis and peritoneal dialysis in the United States (1). Given the myriad complications associated with end-stage renal disease (ESRD), it is not surprising that patients with ESRD are far more likely than the general population to be hospitalized, and that the length of hospital stay, compared with the general population, is significantly longer. ESRD can result in widespread organ dysfunction, either as a result of the disease processes that lead to chronic kidney disease, or because of uremia or the physiologic disturbances associated with renal replacement therapy itself. This chapter outlines the unique disease entities that must be considered in caring for the hospitalized patient on dialysis and management strategies to address these conditions.

DIALYSIS PRIMER

Renal replacement therapy is a term used frequently to describe the global approach to patients with ESRD. The kidneys perform four major functions: regulation of electrolyte and acid-base balance, disposition of metabolic byproducts and drugs, maintenance of volume status, and organ-specific endocrine and metabolic effects. Kidney transplantation can replace all four functions and is appropriately called renal replacement therapy (Chapter 102).

Dialysis can assist with the first three functions, and the fourth can be regulated with the help of exogenous hormone replacement, which is also discussed.

Hemodialysis

In the United States, hemodialysis is the dialytic modality prescribed for most patients. More than 80% of dialysis patients undergo hemodialysis, usually three times weekly in a hospital-affiliated or independent outpatient dialysis center (1). The key to successful provision of hemodialysis is the *vascular access*, because high blood flow rates (≥ 300 mL/min) are required to perform solute clearance most efficiently. The most reliable vascular access is the native arteriovenous (Brescia-Cimino) fistula, usually an end-to-side anastomosis of the cephalic vein to radial artery at the wrist. Variations on the Brescia-Cimino fistula also are seen in the upper arm and, rarely, in the leg. The most common permanent vascular access for hemodialysis is the arteriovenous graft, usually constructed as a loop graft of polytetrafluoroethylene in the forearm. For patients whose permanent vascular access has not matured (in the case of a fistula) or healed, a variety of percutaneous and tunneled central venous catheters are available, which can provide temporary access to the circulation for the dialysis procedure.

The duration of dialysis (typically 3–4 hours per session) depends on the needs of the patient and is typically driven by quantitative assessment of the adequacy of clearance, using urea as the marker solute. For a given dialyzer type,

blood flow rate, dialysate flow rate, and vascular access, a longer treatment results in more efficient solute clearance. Longer dialysis times may also be required to facilitate ultrafiltration to “dry weight,” because rapid ultrafiltration rates may exceed the body’s vascular refill capacity.

In the outpatient setting, the net health-related benefits of prolonged dialysis times must be balanced against the potential effects on quality of life and convenience. In the inpatient setting, the constraints on the provision of dialysis are quite different, because dialysis competes with diagnostic tests and surgical procedures for precious time during daytime hours. It has been observed that patients with ESRD tend to receive a lower dose of dialysis when hospitalized, at precisely the time that more thorough treatments may be required because of stress (including cardiovascular dysfunction, inflammation, and sepsis, often accompanied by hypotension) and catabolism (promoting azotemia). It is important to ensure that sufficient dialysis time be provided to hospitalized patients by coordinating schedules at least 1 day in advance of the need for dialysis.

Peritoneal Dialysis

Peritoneal dialysis typically is provided in one of two ways: either with manual exchanges several times during the day (*continuous ambulatory peritoneal dialysis*) or with automated exchanges delivered by a device (a “cycler”) usually for 10–12 hours at night (*continuous cyclic peritoneal dialysis*). Most patients have a flexible silastic catheter placed within the peritoneal cavity. The concentration of dextrose in the dialysate is the principal variable in therapy, with 1.5%, 2.5%, and 4.25% dextrose concentrations being the most common. It is the concentration of dextrose that drives ultrafiltration of plasma water, again by diffusion across the semipermeable membrane. Higher dextrose concentrations are associated with higher rates of ultrafiltration. Patients on peritoneal dialysis usually can continue their regular home dialysis schedule if hospitalized.

Table 101.1 lists the major complications of the dialysis procedure. In addition to hemodialysis and peritoneal dialysis, newer methods of dialysis have been developed principally to assist in the management of critically ill, hospitalized patients: the *continuous renal replacement therapies*. An outline of the methods and potential indications for these therapies is given in Table 101.2.

MANAGEMENT OF THE HOSPITALIZED DIALYSIS PATIENT

General Issues

Subsequent sections describe specific conditions that frequently result in hospitalizations for patients on dialysis. This section discusses several general inpatient management issues that require modification for dialysis patients.

Admission Orders

If a patient with ESRD is admitted to the hospital, several things should be done immediately. First, the dialysis unit and the nephrologist who care for the patient should be informed of the admission; the dialysis unit often maintains its own set of comprehensive medical records, and certain information relevant to the acute problem requiring hospitalization, including recent laboratory values, may be unavailable to the hospital staff. If the hospital has an inpatient dialysis program, that unit should be informed, as well, to assist in the organization of the dialysis schedule.

Blood pressure should be taken in the arm *contralateral* to the vascular access if an arteriovenous fistula or graft is present. Otherwise, repeated compression of the vascular access by the sphygmomanometer cuff can result in access thrombosis. Elderly patients with ESRD and patients with ESRD and diabetes tend to be unsteady in the few hours following dialysis treatment because of autonomic dysfunction and delayed vascular refill. Although bedrest may not be necessary, physical activity in the 2–4 hours following dialysis generally should be supervised. Routine placement of an intravenous catheter should be discouraged, unless clearly clinically indicated. Many medications and blood products can be administered during or just after the dialysis procedure with greater safety because of concurrent ultrafiltration. Furthermore, the puncture and subsequent scarring that often occurs if veins of the upper extremities are cannulated can result in the loss of potential venous sites for future permanent vascular access. Venous sclerosis is a particularly troublesome complication of therapy with nafcillin or oxacillin, drugs frequently prescribed to patients on dialysis with infectious complications. If an intravenous line is required, it should be placed distal to the arteriovenous fistula or graft, or in a vein of the contralateral arm, preferably in the hand.

Several *medications* routinely administered in hospitalized patients should be used with caution in ESRD patients. Antacids containing magnesium are relatively safe in small quantities but can lead to hypermagnesemia in patients treated with large doses over several days. Sedative drugs tend to be poorly tolerated in ESRD patients. The risks of delirium and other central nervous system effects increase in ESRD patients treated with anticholinergic drugs, such as diphenhydramine. Short-acting benzodiazepines can lead to a paradoxical agitated state.

The *diet order* requires careful thought in most patients with ESRD and should be individualized. The “renal diet” in most hospitals is typically low in protein (<60 g/d) and potassium (<2 g/d), and usually low in sodium (<2 g/d) and phosphorus (<1 g/d). The restrictions on sodium and potassium sometimes, but not always, are required, depending on the type of kidney disease and the effectiveness of medications, including diuretic agents and dialysis. There is little rationale for the restriction of dietary protein. Although over the long term there is some evidence that

TABLE 101.1**SELECTED MAJOR COMPLICATIONS OF THE DIALYSIS PROCEDURE AND METHODS OF PREVENTION**

Complication	Preventive measures
Hemodialysis	
Hypotension	Extend dialysis time Perform sequential ultrafiltration-hemodialysis Discontinue antihypertensive (not antianginal) agents Decrease dialysate temperature Increase dialysate calcium concentration Increase hemoglobin concentration Consider administration of colloid Consider change in estimated dry weight
Arrhythmia	Increase dialysate potassium concentration Consider discontinuing digoxin and other antiarrhythmic agents Supplemental oxygen during dialysis
Muscle cramps	Extend dialysis time Consider hypertonic saline Consider vitamin E Consider quinine sulfate
Pyrogen reaction	Culture dialysate Immediate water testing for lipopolysaccharide
Dialysis disequilibrium	Attenuate clearance by limiting time, dialyzer surface area, blood flow, and dialysate flow Consider mannitol
Hypoxemia	Use noncellulosic dialyzer Supplemental oxygen during dialysis
Hemolysis	Examine blood lines Immediate water testing for chloramine
Peritoneal Dialysis	
Constipation	Regular administration of lactulose or other nonstimulant cathartic Consider changing phosphate binder
Early satiety	Consider change from continuous ambulatory peritoneal dialysis to continuous cyclic peritoneal dialysis
Hyperglycemia	Investigate for infection Consider adding (or increasing) insulin in dialysate Limit dextrose concentration Consider diuretics to augment ultrafiltration

protein restriction can attenuate the progression of certain types of renal disease (2), the net benefits are small and must be balanced against the potential for contributing to the development of protein malnutrition (3). Because protein-rich foods tend to be high in phosphorus content, the restriction of dietary phosphorus is counterproductive. The administration of phosphate binders is a better strategy for phosphorus control. Because malnutrition is an important contributing factor to hospitalization in patients undergoing dialysis, these individuals should not be subjected to dietary restrictions while in the hospital (4). The exception is patients with vascular access failure or another reason for inefficient dialysis, because they tend to be hyperkalemic and cannot afford a diet high in potassium.

Laboratory tests that require venipuncture, including blood cultures, can be performed easily at the start of the hemodialysis session, and nonessential tests should be de-

ferred on nondialysis days. The serum potassium concentration should not be checked for at least 4 hours following the dialysis procedure to allow for rebound of potassium from intracellular stores. This avoids the unnecessary and potentially unsafe practice of potassium supplementation when an early postdialysis potassium concentration returns in the range less than 4 mEq/L.

Examination and Laboratory Findings in Patients with End-Stage Renal Disease

Certain aspects of the general physical examination and laboratory profile are characteristic of this population. On initial observation, many dialysis patients appear thin, with overt muscle wasting. Depending on the nutritional assessment method used, 50%–90% of patients on dialysis have some evidence of malnutrition. If there is muscle

TABLE 101.2**ALTERNATIVE METHODS OF DIALYSIS FOR ACUTE RENAL FAILURE**

Method	Intensity of nursing effort ^b	Cost ^b	Potential indications
Intermittent hemodialysis	+	++	Hyperkalemia Mild-to-moderate volume overload Hemodynamic stability ICU or non-ICU setting
Peritoneal dialysis	++	+	Poisoning No abdominal surgery or active issues Pregnancy Pediatrics
Continuous renal replacement therapy ^a	++++	+++	ICU or non-ICU setting Hemodynamic instability Large obligate fluid load (including blood products and parenteral nutrition) Moderate-to-massive volume overload Severe metabolic acidosis ICU setting

^a Hemofiltration alone (continuous venovenous hemofiltration) or hemodiafiltration (continuous venovenous hemodiafiltration).

^b Semi-quantitative scale, with "+" representing lowest and "++++" representing highest.

wasting and other overt signs of malnutrition, the risk of death or injury increases. Therefore, the lean dialysis patient should be considered at high risk. Hypertension is likewise extremely common in dialysis patients. Elevated blood pressure is often indicative of volume overload and should be managed with the patient's dialysis schedule and hospital presentation in mind. Physical examination should always include careful auscultation of the chest, in search of an uremic pericardial or pleural rub. Systolic flow murmurs are common, especially among patients with anemia. These should be carefully differentiated from sounds transmitted from an arteriovenous fistula, which tend to be harsher and often extend through systole and diastole. The abdomen should be carefully examined for signs of hepatic congestion. A detailed neurologic examination should be performed if uremia is implicated in a change in cognitive or functional status.

The laboratory profile of dialysis patients is characteristically abnormal. The degree of elevation of urea nitrogen and creatinine levels relative to the patient's overall condition and dialysis history is extremely important. A serum urea nitrogen that is extremely high (e.g., >150 mg/dL) might indicate gastrointestinal bleeding, glucocorticoid therapy, or an overwhelming catabolic process. An extremely low level of serum urea nitrogen (e.g., <30 mg/dL) might be expected several hours after the completion of dialysis but might indicate a marked reduction in dietary protein intake if obtained on a nondialysis day. The electrolytes are frequently abnormal, with a propensity for hyperkalemia and metabolic acidosis. Hyperphosphatemia, hyperuricemia, and an elevated anion gap are common findings in patients on dialysis. Liver enzymes, lactate de-

hydrogenase, and bilirubin concentrations should be normal. The alkaline phosphatase often is elevated, an indication of the effect of secondary hyperparathyroidism on bone. The serum albumin concentration is on average significantly lower in dialysis patients than in age-matched controls; hypoalbuminemia has been shown to predict markedly higher mortality and morbidity rates in these patients (5).

The most common finding on the complete blood count is a low hemoglobin concentration. The problem of "renal anemia" has been alleviated greatly with the introduction of recombinant erythropoietin, which is now administered routinely to patients with chronic kidney disease, sometimes before the initiation of dialysis. Anemia has been further lessened with the more widespread prescription of intravenous iron compounds and better control of hyperparathyroidism. The platelet count and coagulation studies should be normal.

Cardiovascular Disease

Except for procedures related to the vascular access, cardiovascular complications, including congestive heart failure, and coronary, cerebral, and peripheral vascular disease, account for an overwhelming proportion of hospitalizations and considerable morbidity in patients with ESRD. The incidence of atherosclerotic vascular disease is markedly increased in patients with ESRD and accounts, at least in part, for a majority of deaths (6).

Chest pain in a dialysis patient must be taken seriously, given the high pretest probability of disease and the anticipated level of disease severity. Treatment of suspected

ischemia should be similar to that in non-ESRD patients. All patients without other contraindications should receive aspirin. The long-acting β -adrenergic antagonists atenolol and nadolol are eliminated by the kidney and should have their dosages reduced, or alternative agents (e.g., metoprolol) should be used. Most angiotensin-converting enzyme inhibitors are eliminated by the kidney, and lower doses at less frequent intervals initially should be employed in dialysis patients. Parenteral opiate analgesics should be used with caution. Low-dose morphine or hydromorphone are acceptable options; meperidine should be avoided because its major metabolite (normeperidine) is epileptogenic and accumulates in ESRD. Calcium antagonists and nitrates do not require dose adjustment. Short-acting dihydropyridine calcium antagonists should be avoided.

Most if not all antianginal agents should be continued to the time of dialysis. The dialysis procedure is a stressful event, and dialysis patients with known coronary artery disease should be protected from developing tachycardia during dialysis. If hypotension develops during dialysis, ultrafiltration should cease temporarily, and the ultrafiltration rate should be reduced. Sequential ultrafiltration and hemodialysis or an additional treatment of ultrafiltration alone may be required in selected cases. Nonischemic causes of chest pain in patients on dialysis include pericarditis, esophagitis, and a variety of musculoskeletal disorders.

Pericarditis should be suspected in any patient who has not adhered faithfully to the dialysis schedule or who regularly terminates the dialysis session prematurely. The cause of pericarditis cannot easily be determined on clinical grounds. Hemodynamically insignificant posterior pericardial effusions may be present in 15%–20% of stable, asymptomatic dialysis patients. Larger effusions, especially if they are anterior and posterior, usually are related to pericarditis and reflect significant disease. Fever, leukocytosis, a large-sized effusion, and hemodynamic instability suggest a nonuremic cause. Regardless of the suspected cause of pericarditis, more frequent and intensive dialysis should be provided for at least 10–14 days if uremic pericarditis is a possibility. Pericardiocentesis is indicated urgently for tamponade physiology or if a large effusion persists after intensifying the dialysis regimen. Tamponade should be suspected from the usual physical findings (Chapter 46) or if the usual quantity of ultrafiltration at dialysis is not tolerated.

Pulmonary edema in the patient undergoing dialysis can be of cardiac or noncardiac origin. Dietary indiscretion can lead to pulmonary edema, because of the inability to excrete an increased load of salt and water with reduced or absent native kidney function. A pattern of previous episodes and the timing of the event can provide clues to this diagnosis. Another common scenario leading to pulmonary edema is a loss in body cell mass associated with either a period of reduced dietary intake or hypermetabolism. If the goal of postdialysis (“dry”) weight remains the same and the amount of intracellular water decreases, extracellular

fluid is retained in its place, often leading to hypertension and pulmonary edema. Although standard therapies for pulmonary edema can provide some symptomatic relief, mechanical ultrafiltration with or without dialysis is the treatment of choice. Some patients on dialysis maintain urine output for months-to-years following the development of ESRD (especially those on peritoneal dialysis) and may remain responsive to high-dosage diuretics (e.g., furosemide ≥ 160 mg intravenous). Topical and intravenous nitrates, selected opiate analgesics, nesiritide, and nitroprusside may each be useful in selected cases; the latter agent should not be used for >12 hours to avoid significant toxicity. High-output congestive heart failure also should be considered in patients with ESRD. Anemia can contribute to tachycardia and dyspnea, and the presence of an arteriovenous shunt can increase cardiac output significantly. Patients with ESRD and severe degrees of left ventricular hypertrophy tolerate anemia and tachycardia especially poorly. Hyperthyroidism should be considered; typical symptoms may be absent or masked by uremia or dialysis asthenia. Finally, beriberi should be considered as a possible cause of heart failure, especially if a metabolic acidosis is present. Frank thiamine deficiency can develop in dialysis patients with poor or marginal oral intake who fail to take water-soluble vitamin supplements.

Infectious Disease

Infectious complications are common in dialysis patients. The most important infectious complications relate to dialysis access: the arteriovenous graft or central venous catheter for hemodialysis (bacteremia) and the peritoneal catheter for peritoneal dialysis (peritonitis). *Protein-calorie malnutrition* can increase susceptibility to a wide variety of infections and is probably more responsible than uremia for the increased incidence of infection, particularly among patients receiving an adequate dialysis dose. Environmental exposures, the need for blood transfusion, and exposure to immunosuppressive agents following failed kidney transplantation also can increase the risk of infection.

Hemodialysis requires repetitive access to the blood stream. Despite efforts taken to sterilize the skin prior to needle placement, infections of the vascular access are extremely common. The overall rate of serious line infection is approximately one per patient per year (just less than 10% per month), an exceptionally high rate. Most often, the organism is a Gram-positive species, usually *Staphylococcus epidermidis* or *aureus*. Other Gram-positive cocci are frequently seen, including Vancomycin-resistant *Enterococcus* (VRE); Gram-positive rods such as *Bacillus* sp. may also be pathogenic. Gram-negative rods, including *E. Coli* and *Klebsiella* spp., are seen 10%–15% of the time, although their presence in blood cultures should prompt investigation elsewhere, such as the gastrointestinal and genitourinary tracts. Other Gram-negative rods, such as *Stenotrophomonas maltophilia* and *Acinetobacter* spp., have been observed with

increasing frequency in recent years, related to the use of broad-spectrum antibiotics and, potentially, to contaminated environmental sites. Native arteriovenous fistulas are rarely the source of infection, although their repeated puncture may be an entry site for bacteremia. In contrast, a blood-borne infection may harbor at the graft site, an artificial endovascular device prone to seeding. Although parenteral antibiotics are clearly indicated for infection of the vascular graft, the likelihood of clearing grossly infected polytetrafluoroethylene graft is extremely low. Thus, *in most circumstances, the graft should be removed promptly*. Infections in the setting of tunneled hemodialysis catheters should be approached with a similar degree of caution. Attempts to “treat through” line infections with bacteremia typically fail, as catheter “biofilm” serves to harbor bacteria that can cause relapsing infections after antibiotics have been discontinued. Such infections can lead to endocarditis, osteomyelitis, and other serious deep-tissue infections. In the setting of line-associated bacteremia, some advocate removal of all tunneled dialysis catheters followed by placement of temporary catheters until bacteremia has cleared. Others have found that catheter exchange over a wire (when there is no evidence of catheter tunnel infection) has yielded exceptionally low rates of treatment failure (i.e., relapse) and considerably less morbidity. Only in the case of *Staphylococcus epidermidis* infection do we recommend antibiotic therapy without line exchange. The duration of antibiotic therapy for an access-associated infection should be 3 weeks. If there is evidence of endovascular infection, 6 weeks of parenteral antibiotics are recommended. Empiric therapy for suspected infection of the vascular access should be based on the microbiologic epidemiology of the hospital and surrounding region (Chapter 72). Definitive therapy then should be based on microbiologic results.

Actual transmission of infection via dialysate has been reported but is rare, because the dialysate is not infused into the patient. It is clearly possible, however, for bacterial cell-wall products or bacterial fragments to be transmitted to the patient on dialysis, which can result in the *pyrogen reaction*, clinically indistinguishable from sepsis syndrome. Patients with pyrogen reactions typically require hospitalization because of high fever, rigors, and leukocytosis or severe leukopenia, and they must be evaluated and treated for sepsis syndrome (Chapter 26). The signs and symptoms usually resolve within 24 hours, and blood cultures are negative. A cluster of patients with fever and systemic symptoms from the same dialysis unit should raise suspicion that the dialysate may have been contaminated.

Peritonitis is probably the most important complication for peritoneal dialysis patients. It is the most frequent cause of hospitalization, and the principle reason for switching from peritoneal to hemodialysis. As with hemodialysis-associated line infections, skin organisms are the most common pathogens. *Staphylococcus epidermidis* and *aureus* lead the list of responsible pathogens. Gram-negative rods and fungi are especially troublesome, resulting in more fre-

quent hospitalization, catheter removal, and change to hemodialysis. The most common clinical findings are fever, abdominal pain, and cloudy dialysate. *Many patients with peritonitis do not require hospitalization*. If the episode is addressed early, appropriate cell counts and cultures can be obtained and empiric parenteral antibiotic therapy begun, via either the intravenous or intraperitoneal route. Cefazolin and vancomycin are reasonable first-line therapies, and either can be safely administered in the peritoneal dialysate. Hospitalization, if necessary, should be brief (<72 hours). Usually, the patient’s technique is as good as that of the nondialysis nursing staff, and the odds of contracting a resistant organism are lower in the home than in the hospital environment.

Blood-borne viral infections are more common in hemodialysis patients because of shared risk factors (e.g., hepatitis B and C viruses and HIV-associated kidney diseases) and the need for frequent hospitalization and transfusions. It is strongly recommended that all patients with advanced chronic kidney disease be vaccinated against hepatitis B, although the strength and durability of the antibody response are attenuated compared with other populations. Patients who are known to be positive for hepatitis B surface antibody are isolated. Hepatitis C infection should be suspected in any dialysis patient with a history of transfusion, injection drug abuse, or high-risk sexual behaviors.

Respiratory Disease

Pulmonary edema is the most common respiratory manifestation of the dialysis patient. Its management has been discussed previously. Pneumonia, though not specific to ESRD, is an extremely common reason for hospitalization. Pleural effusion is seen with higher frequency than in the population without ESRD, perhaps owing to subtle serosal inflammation or hypoalbuminemia. An increased frequency of pleuritis and hemorrhagic pleural effusion also has been noted. Except if more intensive dialysis and ultrafiltration are required, the management of these syndromes in ESRD is no different than in the general population (see Chapters 39, 65, and 60, respectively for pulmonary edema, pneumonia, and pleural effusion).

Sleep apnea has been reported in up to 60% of patients with ESRD, regardless of modality of dialysis, and can be central or obstructive in origin. Affected dialysis patients are at increased risk for systemic and pulmonary hypertension, as well as for a variety of atrial and ventricular arrhythmias, including sudden death. Acidemia and hyperkalemia induced by uncompensated respiratory acidosis may be the mechanism in many cases. Respiratory therapy with continuous positive airway pressure and supplemental oxygen may be required during hospitalization.

Gastrointestinal Disease

Patients with previously undetected, advanced chronic kidney disease usually seek medical attention (and often

require hospitalization) because of the gastrointestinal manifestations of uremia. These include anorexia, dysgeusia, nausea and vomiting (characteristically upon awakening), gastrointestinal hemorrhage, and the nitrogenous fetor. A variety of gastrointestinal abnormalities persist in ESRD patients after the initiation of dialysis, and some prompt hospitalization. Gastritis and upper gastrointestinal bleeding are more common than in the general population; upper endoscopy is abnormal in approximately 50% of ESRD patients, depending on the severity of symptoms and the indication for study. Although most patients are found to have an inflammatory infiltrate in the gastric epithelium, 5%–15% of patients have evidence of atrophic gastritis. *Helicobacter pylori* infection may contribute to the development of peptic ulcer disease in dialysis patients, although it is not clear if the incidence of *H. pylori* infection increases in this population relative to the general population. Because dialysis patients without serious gastrointestinal disease may have blood loss and iron deficiency caused by increased bleeding tendencies and long-term anticoagulation, the interpretation of guaiac-positive stools or nasogastric aspirate must be tempered. Nevertheless, repeated positive tests should prompt investigation.

The treatment of *peptic ulcer disease* in dialysis patients is similar to that in patients with normal renal function (Chapter 80). If gastric lavage is deemed appropriate, 5% dextrose in water, rather than saline, should be used to avoid sodium overload. Antacids (containing magnesium and aluminum) and sucralfate (containing aluminum) should be used sparingly. Histamine-2 receptor blockers and proton pump inhibitors can be safely used in ESRD; the former should be dose reduced (e.g., daily rather than b.i.d.). Correction of the bleeding diathesis seen in some dialysis patients is described in Chapter 98. Heparinization should be limited during subsequent dialysis treatments.

Common lower gastrointestinal abnormalities in dialysis patients include colonic ulceration, diverticulosis, diverticulitis, spontaneous colonic perforation, and prolonged ileus (7). Diverticulosis is seen in more than 80% of patients who have polycystic kidney disease as a cause of ESRD. Ischemic enteritis and colitis are relatively common in dialysis patients, especially the elderly and diabetics, because of the severity of atherosclerosis (Chapter 87). Ischemic bowel disease should be suspected in patients whose pain is worsened during dialysis. Intestinal necrosis with bowel perforation has been observed following rectal administration of sorbitol with sodium polystyrene sulfonate. If required, sodium polystyrene sulfonate should be mixed with water or, preferentially, given enterally.

There is an increased frequency of acute and chronic *pancreatitis* in dialysis patients. Certain drugs used for kidney diseases should be considered in the differential diagnosis of pancreatitis, including corticosteroids, loop and thiazide diuretics, and a variety of antiretroviral drugs (Chapter 86). Hypercalcemia, hyperparathyroidism, and hypertriglyceridemia are additional risk factors. In general, amylase and

lipase are elevated in ESRD because of reduced renal clearance and minimal clearance with dialysis. Specificity for the diagnosis of pancreatitis increases if the amylase level is greater than three times the upper limit of normal.

Hematologic Disease

In the hospitalized patient with ESRD, the hematologic problem of greatest importance is anemia. The etiology of anemia in ESRD is multifactorial, although the principal cause is related to a deficiency in *erythropoietin*, a growth factor primarily produced in the proximal tubule of the functioning kidney. Table 101.3 outlines other contributing causes to ESRD-related anemia and to potential resistance to the effects of erythropoietin. Most of these conditions are preventable or readily manageable in the outpatient setting.

In addition to correcting the anemia of ESRD, erythropoietin therapy has been shown to improve cardiac hemodynamics, improve oxygen-releasing capacity, and decrease the degree of intradialytic hypotension. These improvements in overall cardiac function have led to tangible improvements in physical activity, work capacity, sexual function, and quality of life. Furthermore, the associated decrease in transfusion requirements has decreased the frequency of hepatitis and presensitization before kidney transplantation. Therefore, it is prudent to continue erythropoietin in maintenance dialysis patients if they are admitted to the hospital. Clinical practice guidelines recommend maintaining hematocrit concentrations in the 33%–36% range, with the liberal use of intravenous iron compounds to maintain transferrin saturation greater than 20% and ferritin concentration greater than 100 mg/L.

TABLE 101.3

CAUSES (BEYOND ERYTHROPOIETIN DEFICIENCY) CONTRIBUTING TO ANEMIA IN END-STAGE RENAL DISEASE

Iron deficiency ^a
Excessive blood draws
Inflammatory disease ^a
Persistent uremia (underdialysis) ^a
Aluminum toxicity
Lead toxicity
Folate deficiency
Vitamin B ₁₂ deficiency
Multiple myeloma
Secondary hyperparathyroidism (osteitis fibrosa cystica) ^a
Hemolysis associated with primary disease (systemic lupus erythematosus)
Hemolysis related to mechanical factors, dialysate contamination, hyper-osmolality, hypo-osmolality, or severe hypophosphatemia

^aMajor causes of erythropoietin resistance.

Carefully conducted clinical trials are still necessary to determine the optimal hemoglobin concentration or hematocrit for maintenance dialysis patients. There are few side effects of erythropoietin therapy. Exacerbation of hypertension and seizures were observed in early studies with erythropoietin but seldom are seen today.

Uremia is associated with a *bleeding diathesis related to platelet dysfunction*. This usually is controlled with adequate dialysis. Nevertheless, there are several maneuvers that can help with the management of the dialysis patient who is bleeding. First, ensure that there has been no unrecognized or mistaken administration of heparin. Typically, central venous double-lumen catheters used for dialysis are instilled with 5,000–7,500 units of heparin in each port to prevent *in situ* catheter thrombosis. If excessive heparin has been administered, protamine or fresh frozen plasma can be given to counteract its effects. If the prothrombin and partial thromboplastin times are normal and there is active bleeding, the patient should be transfused to a hematocrit in excess of 30% to increase blood viscosity. The intensity of dialysis should be maximized, including daily dialysis if necessary. Desmopressin acetate and intravenous estrogens may be of some additional benefit (8) (Chapter 98).

Endocrine Disorders

More than 40% of all new dialysis patients have diabetes as a primary or contributing cause of ESRD or as an important comorbidity. People with diabetes and chronic kidney disease frequently exhibit a decreasing requirement for insulin as GFR declines, sometimes requiring no insulin after many years of insulin dependence. Insulin catabolism is decreased with reduced GFR, and an occult decrease in protein and calorie intake can further decrease the patient's insulin requirement. Hypoglycemia is a relatively common occurrence in patients with ESRD. Causes include alcohol abuse (which tends to be less frequent among dialysis patients than the general population), liver disease (including hepatitis C with minimal transaminitis), sepsis, metabolic acidosis, and especially malnutrition. Patients with reduced muscle mass and reduced glycogen stores are at highest risk for hypoglycemia.

The use of oral sulfonylurea agents can place patients at serious risk for hypoglycemia because of both the increased half-life of insulin and the retention of active metabolites of the sulfonylurea agent. First-generation sulfonylureas (e.g., chlorpropamide, tolazamide) should be avoided in patients with ESRD, and second-generation agents should be used with caution. Insulin therapy should be recommended to all dialysis patients who require glycemic control. *Metformin should not be used in patients with ESRD* because of the risk of serious lactic acidosis. If a sulfonylurea must be used, glipizide is preferred, because its retained metabolites are less active than those of glyburide. Peripherally acting agents that enhance insulin sensitivity (e.g., rosiglitazone, piogli-

tazone) are well tolerated, although long-term safety and efficacy data in patients with ESRD are lacking.

Hyperosmolar coma resulting from hyperglycemia occasionally complicates ESRD, and levels of blood glucose can be extremely high (500–1,000 mg/dL or more). In contrast to patients with nonketotic hyperosmolar syndrome and normal baseline renal function (Chapter 107), volume expansion does not correct the disorder in dialysis patients and should be avoided. Indeed, volume depletion rarely complicates the disorder because of the blunted or absent response to glucose as an osmotic diuretic. In dialysis patients, the most appropriate therapy for hyperglycemia with or without ketoacidosis is an intravenous insulin infusion. Ketoacidosis is an infrequent occurrence in long-term dialysis patients, in contrast to non-ESRD patients with diabetes. The unexplained occurrence of severe hyperglycemia or ketoacidosis in the dialysis patient should raise a strong suspicion for infection.

Some of the signs and symptoms of uremia or dialysis asthenia may be confused with hypothyroidism. Therefore, it is important to appropriately interpret thyroid function tests in this population (Chapter 106). In general, serum total thyroxine and tri-iodothyronine are reduced because of changes in binding protein metabolism and competitive inhibition of binding caused by accumulated organic acids. Free hormone levels, however, tend to be normal or slightly reduced. Thyroid-stimulating hormone levels are usually normal to slightly increased, and there is a blunted response to thyrotropin-releasing hormone. The incidences of frank hypothyroidism and goiter are increased in ESRD, perhaps related to iodine retention secondary to reduced excretion.

Electrolytes, Acid-Base Balance, Metabolism, and Nutrition

Hyperkalemia is the most important electrolyte issue for the hospitalized ESRD patient (see Chapter 104 for a complete discussion). Metabolic acidosis is extremely common in ESRD. In the past, metabolic acidosis was an expected complication of ESRD and was rarely treated. More recently, it has been demonstrated that chronic metabolic acidosis can promote protein catabolism leading to a reduction in lean body mass, and it may accelerate the ill effects of metabolic bone disease. Although it is rarely urgent in the hospital setting, some experts recommend treating a metabolic acidosis (bicarbonate concentration <22 mEq/L) with oral sodium bicarbonate. Sodium citrate should be used sparingly and never in conjunction with aluminum-based compounds (see below).

The optimal management of calcium, phosphorus, parathyroid hormone, and vitamin D is one of the most complex issues in ESRD. In hospitalized patients, the most common abnormality is *hyperphosphatemia*. Hyperphosphatemia should be avoided to prevent complications related to its effects on bone and other tissues. Elevated

phosphate concentrations have been associated with mortality and hospitalization because of cardiovascular disease and fracture (9). Elevated calcium concentrations have also been associated with mortality in ESRD patients; it can usually be avoided by judicious use of calcium-based binders and vitamin D, and with physiologic dialysate calcium concentrations. The best treatment for hyperphosphatemia in the hospital depends on the corresponding level of calcium and on whether or not the patient is eating. Although some phosphorus can be absorbed from the sloughed gut mucosa, the majority of phosphorus absorbed from the gastrointestinal tract is from food. As such, phosphate binders should be given with, rather than in between, meals.

Calcium carbonate and acetate are both effective as phosphate binders. If the levels of serum calcium and calcium-phosphate product are elevated, a short course of aluminum hydroxide can be given. Aluminum alone tends to be extremely constipating. Modest degrees of hyperphosphatemia (4.5–6.5 mg/dL) should be tolerated in the hospital to avert the complications of treatment. Aluminum hydroxide should never be given with citrate-based alkalinizing agents, because citrate markedly enhances aluminum absorption; nor should it be given with sodium polystyrene sulfonate, because intraluminal binding renders both drugs ineffective and often causes severe obstipation. Sevelamer is a polymeric phosphate binder that contains no aluminum or calcium and may prove to be useful in the hospital setting. As a hydrogel, sevelamer may expand within the lumen of feeding tubes; rapid flushing of sevelamer after instillation into feeding tubes is required to avoid mechanical complications.

Metabolic and nutritional abnormalities are extremely common in long-term dialysis patients. These abnormalities exert direct ill effects on organ function in dialysis patients and themselves contribute to the risks for death and injury. The subjective global assessment of nutritional status (Table 16.2), initially developed and validated in hospitalized surgical patients (10), is a simple, reproducible tool that can identify dialysis patients at nutritional risk. Nutrition support should be given to dialysis patients who are moderately or severely malnourished by subjective global assessment criteria, or who have serum albumin concentrations less than 3.5 g/dL. Enteral nutrition should be provided whenever possible. The choice of enteral supplements depends on individual patient factors, such as the need for sodium and potassium restriction and the degree of fluid overload. There are many commercially available products designed for patients on dialysis. Alternatively, total parenteral nutrition or intradialytic parenteral nutrition can be prescribed (Chapter 15).

Neurologic Disorders

Most of the central nervous system manifestations of advanced uremia, such as impaired mentation, lethargy, sleep disorders, asterixis, and multifocal myoclonus, are

reversible with dialysis. In addition to uremic encephalopathy, two neurologic syndromes—dialysis disequilibrium and dialysis dementia—are specific to patients with ESRD and often are confused, although they are quite distinct.

Dialysis disequilibrium refers to a condition characterized by headache, confusion, disorientation, nausea, vomiting, and, rarely, seizures during or just after dialysis. It is thought to be related to the rapid shift of extracellular solutes during the dialysis procedure and the subsequent shift of water into cells of the brain. The risk of this reaction can be reduced by dialysis modifications. Some clinicians infuse mannitol, a substitute osmole that is not removed with dialysis, in an effort to limit fluid shifting. Dialysis against a high sodium bath (145–150 mEq/L) also may limit extracellular to intracellular water shifting. The risk of dialysis disequilibrium is increased with more severe degrees of uremia. In addition to changes in the dialysate and the administration of mannitol, it is reasonable to use phenytoin in patients with a history of seizures or with a known structural brain injury that could serve as a seizure focus (Chapter 118).

Dialysis dementia is characterized by disorders of speech, such as dysarthria and dysphasia, along with dyscalculia, dyslexia, dyspraxia, dysgraphia, impaired memory, poor attention span, depression, paranoia, myoclonus, and seizures. The symptoms are initially intermittent and often most severe during or immediately after dialysis. Dialysis dementia is a progressive dementing disorder and, if untreated, usually progresses to death within 12–15 months. Aluminum was implicated in the pathogenesis of dialysis dementia after finding clusters of cases in dialysis units whose water-collection systems were contaminated with aluminum. The association with osteomalacia and microcytic anemia provided additional evidence, as did the high concentrations of aluminum in the plasma and brains of affected patients.

Although not specific to ESRD, stroke and subdural hematoma are two conditions seen more commonly in dialysis patients than in the general population and should be suspected in the setting of either focal neurologic deficits or nonspecific neurologic findings. Subdural hematoma in particular can present with indolent changes in behavior that may be attributed incorrectly to uremia. Because intermittent heparinization with dialysis can increase the risk of rebleeding, a CT scan of the head should be obtained if subdural hematoma is suspected in a patient with ESRD (Chapter 117).

Drug Disposition

The kidneys are responsible for much of the metabolism of drugs in the human body. Therefore, in caring for the hospitalized patient it is absolutely essential to appreciate not only the effects of drugs on the kidney (nephrotoxicity),

but also the role of the kidney in the disposition of prescription drugs. Drug-related nephrotoxicity is covered in Chapter 100. An exhaustive listing of drugs that require dose and frequency modifications in patients with chronic kidney disease is beyond the scope of this chapter. A computerized order-entry system can considerably reduce excessive dosing and reduce pharmacy costs by more than 10%. Whether renal or other adverse drug events can be reduced, or whether other outcomes (e.g., length of hospital stay, level of renal function at discharge) can be influenced, remains to be determined (Chapter 21).

KEY POINTS

- A nephrologist often functions as the primary or principal care physician for the dialysis patient. Consultation with the nephrologist and outpatient dialysis facility can provide vital information and facilitate effective and efficient inpatient care.
- The most common reasons for hospitalization of the dialysis patient include thrombosis, infection of the vascular or peritoneal access, and a variety of cardiovascular diseases, including congestive heart failure and myocardial infarction.
- Special attention should be paid to the serum potassium concentration. Sliding scales and other liberal methods of potassium repletion should be avoided.
- Routine intravenous fluids should not be administered to patients on dialysis. Routine placement of intravenous lines also should be discouraged.
- The majority of patients with ESRD are either malnourished or at nutritional risk. Physicians should routinely provide nutritional support to dialysis patients who are critically ill or taking nothing by mouth for extended periods.
- Physicians should consider the role of kidney function on drug disposition when prescribing medications. Close attention to these issues may limit adverse drug events and reduce costs.

Renal Transplantation

102

William J.C. Amend, Jr. Flavio Vincenti

INTRODUCTION

Renal transplantation had its successful beginnings in 1954 with the experience of identical-twin transplants at the Peter Bent Brigham Hospital in Boston. Over the next 50 years, there have been major advances in both surgical technique and medical management leading to improved outcomes. The clinician involved in immediate and post-transplant follow-up care should understand the particulars of the transplant implantation (Figure 102.1). It is vital that complete arterial circulation be supplied to both the transplanted kidney and the proximal-to-distal transplanted ureter. This is ensured through careful inspection of donor angiograms (in living donors) or of operative findings of either cadaver or living donors at the time of organ procurement. Multiple renal arteries occur in about 30% of donor kidneys.

For the renal-transplant recipient, inadequate or overlooked arterial supply vessels can lead to early postoperative bleeding, partial graft infarction, segmental acute tubular necrosis, or later ureteral ischemic complications (with a leak caused by necrosis or a transplant ureteral stricture). Currently, most renal transplants have an end-to-side anastomosis to the recipient's arteries, with a decreased incidence of later anastomotic transplant renal artery stenosis compared with an end-to-end arterial anastomosis. The transplanted ureter is implanted with either a tunneling antireflux technique or with an extravesicular re-implant procedure. The disadvantage of the former surgery is a prolonged initial hospital stay with two bladder incisions and the potential for early postoperative leaks. This surgery, however, is associated with less post-transplant ureteral reflux, which may be important in reducing later infections or secondary focal sclerosis in the transplanted kidney.

Careful dissection of the iliac fossa reduces the likelihood of peritransplant hematomas and excessive pooling of lymphatic drainage. The latter presents as a postoperative lymphocele that is usually medial to the transplanted kidney (between the transplant and bladder) (Figure

102.1). Lymphoceles can cause obstructive uropathy or obstructive lower-extremity venous thrombosis; they also can become infected. The incidence of lymphoceles is 3%–20% and varies by surgeon and transplant center. The recipient's diseased kidneys usually are left *in situ*. Indications for pretransplant unilateral or bilateral nephrectomy include infection, hemorrhage, renal-cell cancer, excessively morbid enlargement (as in the case of polycystic kidneys), refractory hypertension, and persistence of the nephrotic syndrome. If there is reflux present, native nephrectomies can be accomplished pre- or post-transplant if infections occur. Occasional ureteral implantation into an ileal loop or augmented bladder is accomplished in patients with urologic abnormalities. Bladders that have been in disuse for many years often are contracted and present post-transplant reconditioning challenges, with possible urologic complications of leak, retention, and infection.

Postoperatively, the donor and recipient solitary kidneys undergo compensatory hypertrophy or hypotrophy, if the recipient is much smaller than the donor. Hypertrophy is characterized by an increase in glomerular filtration rate, renal blood flow, and tubular function to 80% of normal "two-kidney" function. These physiologic recoveries are identical for both the donor and the recipient if immunosuppressives are not used and rejection does not occur. Most recipients who do not receive an identical-twin transplant recover substantial function, but full renal recovery (to 80% of normal) is unusual. There are several reasons for this partial recovery. Rejection and immunosuppressive drugs can cause important physiologic changes. Posturemic endocrinologic abnormalities such as ongoing secondary hyperparathyroidism also may affect post-transplant recipient renal physiology, causing proximal tubular reabsorptive defects of phosphorus and bicarbonate. The kidney donor's renal recovery (donor compensatory hypertrophy) is complete at 6–8 weeks, postdonor nephrectomy. On follow-up of donors for 10–20 years, there appears to be a slightly increased risk of later hypertension in those

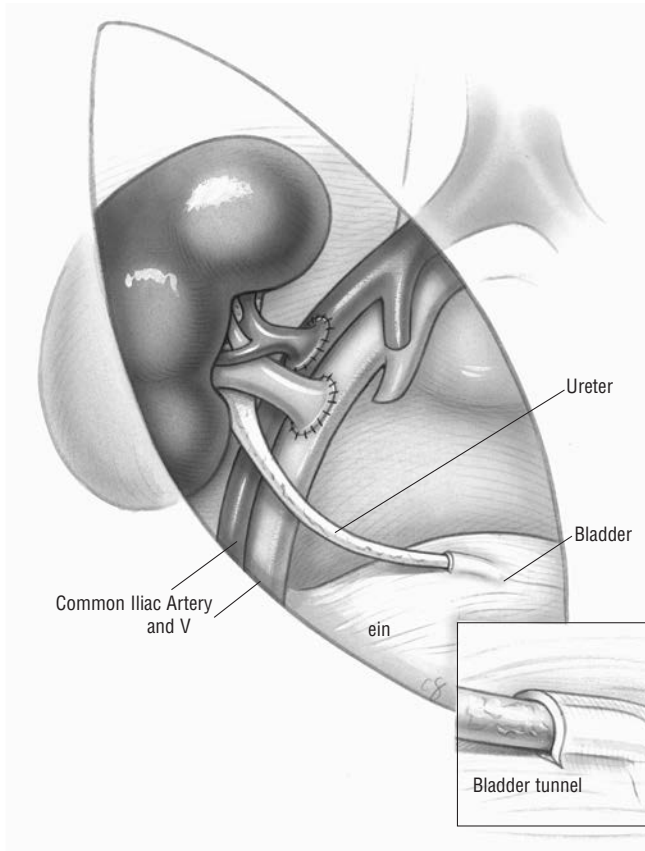

Figure 102.1 Renal transplant with end-to-side vascular anastomosis and bladder implant.

with a family history of hypertension and of proteinuria. It is not yet known whether there is an excessive risk of impaired renal function in donors more than 20 years postnephrectomy.

Renal-transplant donor medical and surgical principles vary depending upon donor source. The surgical team coordinates renal-organ procurement with the *United Network for Organ Sharing (UNOS)* system and its local organ-donor network. If a living volunteer wishes to undergo evaluation, a systematic process is undertaken (Table 102.1)(1). If transplantation is done pre-emptively before dialysis is needed, there is often a more favorable prognosis (2).

Seventy percent of patients in end-stage renal failure lack available living donors and are dependent on cadaver organs for transplants. Many of the steps outlined in Table 102.1 obviously cannot be performed with cadaver donors. Cadaver donors are identified from patients at “low risk” for transmissible diseases who meet brain-death criteria. Because of procurement technique, frequent multiorgan donation, storage, preservation, and shipping to recipient hospitals, both warm and cold ischemic times tend to be longer for cadaveric kidneys than the surgical ischemic times for organs procured from living renal donors. This, along with cadaver donor preprocurement hemodynamic

TABLE 102.1

STEPS IN LIVING KIDNEY DONOR EVALUATION

1. Education/information: review outcomes and risks
2. Immunologic testing
 - (a) Human leukocyte antigen (HLA) typing
 - (b) Donor lymphocyte-recipient sera cross-match
3. Physical examination
4. Multiphasic blood/urine/pulmonary and cardiovascular tests
5. Re-review expected outcomes and donor/recipient risks
6. Radiography
 - (a) Donor intravenous pyelogram
 - (b) Renal angiogram or magnetic resonance angiogram

instability, create an expectedly greater incidence of *delayed graft function*, which manifests itself as nonoliguric or oliguric acute tubular necrosis and, rarely, cortical necrosis. Delayed graft function is the primary cause of early postkidney transplant renal failure; its differential diagnosis and therapy are discussed later. With a relative scarcity of cadaver donors, recent emphasis has been placed on utilizing living unrelated donors; outcomes are comparable to those seen in partially matched related donors. “Marginal” cadaver donors (older, deceased donors with mild degrees of azotemia or with histories of hypertension) are also increasingly being used (3).

Recipient medical and surgical considerations are also important in assessing early and late post-transplant events. Immunologic predictors of outcome include the type of graft, the match grade, and rejection syndromes. *Isografts* (between identical twins) are rare; such recipients have no rejections and have no post-transplant need for immunosuppression but are at higher risk for certain recurrent diseases. The usual kidney transplant is an *allograft* and occurs between genetically disparate individuals. ABO blood group compatibility and a negative immediate pre-transplant lymphocytotoxic cross-match are essential to reduce severe early rejections. Matching for the human leukocyte antigen system is performed; increasing degrees of matching correlate with improved post-transplant outcomes. The most common post-renal transplant organ complication continues to be rejection. The types of rejections include the following:

- *Hyperacute*: a nearly immediate graft loss through an undetected antidonor tissue antibody response with subsequent cortical necrosis.
- *Delayed hyperacute*: a severe cellular and humoral inflammatory response, often treatment-resistant, which likely represents an amnestic or secondary immune response.
- *Acute*: the most common form of rejection, occurring with post-transplant donor antigen-host responses, usually of a cellular variety.

- **Chronic:** developing months-to-years post-transplant and thought to be either effects of cumulative injury from previous acute rejections or a slow vascular injury from antidonor endothelial responses.

Younger individuals, women, patients with lupus, African Americans, and noncompliant individuals are at higher risk of rejection. Conversely, patients with IgA nephropathy have a lower risk. If a patient who has rejected a first kidney receives a subsequent kidney transplant, the immunologic course of the first transplant often is repeated. Better cross-matching and newer immunosuppressive drugs may improve the outcomes for retransplanted patients.

In addition to the matching issues described previously, a patient awaiting transplant may be difficult to match to prospective living or cadaver donors because of increased *lymphocytotoxic antibodies*. These antibodies occur in response to pregnancies, blood transfusions, previous transplants, or other antigenic exposures. Currently, there are no therapies to reduce these tissue-reactive antibodies, so such patients simply must wait until an acceptable (and negative cross-match) donor is available. Cross-matching in such circumstances must be done carefully with multiple sera and sensitive technical methods to avoid early rejection and graft loss.

The recipient's past and immediate pretransplant medical condition needs thorough review. Table 102.2 gives an overview of various medical factors that are most important in determining a kidney transplant patient's candidacy (4). Elevated body mass index is associated with increased morbidity (5). These medical factors include both the presence of various systemic illnesses and features of the patient's primary renal disease. For example, patients with certain primary renal diseases such as idiopathic focal sclerosing glomerulonephritis, IgA nephropathy, and membranoproliferative glomerulonephritis can have kidney-transplant recurrence (6). The presence of hepatitis C in the potential recipient must be thoroughly evaluated, including with a liver biopsy (7). If cirrhosis is present, transplant is contraindicated. Based on these considerations and the patient's pretransplant immune status, estimates of patient and graft outcome can be provided. Overall renal-transplant graft and patient survival outcomes are given in Table 102.3. More precise prognostication can be

TABLE 102.2
IMPORTANT FACTORS TO KNOW ABOUT POTENTIAL KIDNEY-TRANSPLANT RECIPIENTS

Cause of chronic renal failure
Presence or absence of systemic illnesses
Diabetes mellitus
Vasculitis
Genetic disorders
Obesity (body mass index ≥ 30)
Vascular disease
Pulmonary
Chronic illnesses
Acute illnesses (pretransplant)
Gastrointestinal
Hepatitis B and C status
Previous ulcer disease
Diverticular disease
Biliary/pancreas diseases
Preceding neoplastic illness
May require a certain tumor-free interval and often needs tumor-board clearance
Neuropsychiatric
Understanding and compliance issues (best screened with surrogate and social service inputs)

done on a case-by-case basis given the individual patient's surgical, medical, and immunologic status.

Evaluation of a prospective renal-transplant patient requires several steps. This evaluation is depicted in Figure 102.2. The evaluation is easier to complete if the transplant is from a living donor, because planned timing of the transplant means that the recipient's preoperative condition can be assessed and optimized. In contrast, the recipient on the renal-transplant cadaver waiting list may be transplanted several months or years (present average wait is 2–5 years) after this first evaluation. A repeat evaluation usually is recommended if the precadaver renal-transplant waiting period exceeds 2 years. This is in order to screen for later disease development while the patient remains on continued dialysis. This time lag is in contrast to liver (Chapter 85) or

TABLE 102.3
KIDNEY-TRANSPLANT OUTCOMES

Donor source	2-y patient survival, %	2-y graft survival, %	50% graft survival, y
Cadaver	92	78	8–11
Living donor	96		
Unrelated		88	12–15
Partial match		88	12–18

heart and lung (Chapters 40 and 58) transplants, whose recipients are transplanted much closer to the time of their primary pretransplant evaluation. Of particular concern are the various neoplasms that can occur in the population undergoing renal dialysis. Patients should be screened for these neoplasms, because transplant immunosuppression may accelerate tumor growth.

Clinicians must understand the actions and toxicities of various immunosuppressive drugs in order to manage patients after renal and other organ transplantation (8–11). The types of postrenal transplant immunotherapy are

shown in Table 102.4. These drugs have a variety of general and agent-specific side effects, all of which may vary among individuals. The major complications of this group of drugs are infections (of both usual and opportunistic types) and neoplasms. Neoplasms that occur more commonly after transplant include lymphomas and other hematologic malignancies, epithelial cancers, and Kaposi's sarcoma (12). These and other drug complications are reviewed specifically in the remainder of this chapter. A detailed discussion of infections in the immunocompromised host is contained in Chapter 63.

TABLE 102.4**IMMUNOSUPPRESSIVE AGENTS**

Drug group	Drug name generic (brand) name	Mechanism of action	Drug interactions	Major side effects
Corticosteroid	Prednisone	Anti-inflammatory with immunosuppressive effects mediated by decreasing cytokine gene activation	Anticonvulsants decrease immunosuppressive effects	Osteopenia, aseptic necrosis, cataracts, hyperglycemia, cushingoid features
Antiproliferative	Azathioprine (Imuran)	Inhibits purine synthesis in both the <i>de novo</i> and the salvage pathway	Allopurinol potentiates effect	Leukopenia, hepatic dysfunction (hepatitis and cholestasis), pancreatitis, alopecia
	Mycophenolate mofetil (CellCept) (selective inhibition of T- and B-cell proliferation)	Inhibits purine synthesis in the <i>de novo</i> pathway	None	Leukopenia, diarrhea, duodenitis-gastritis, increased risk of cytomegalovirus infection
	Sirolimus (Rapamune)	Inhibits proliferative signal 1	Same as calcineurin inhibitors	Hyperlipidemia, diarrhea, leukopenia, thrombocytopenia interstitial pneumonia, has no nephrotoxicity
Calcineurin inhibitors	Cyclosporine (Sandimmune, Neoral)	Decreases cytokine gene activation by inhibiting calcineurin	Drugs that inhibit cytochrome P-450 (potentiate effects of nondihydropyridine calcium channel blockers, macrolide antibiotics)	Nephrotoxicity, hepatotoxicity, hirsutism, gingival hyperplasia, hyperlipidemia
	Tacrolimus (Prograf)	Same	Drugs that induce cytochrome P-450 reduce effects (isoniazid, rifampin, and anticonvulsants)	Nephrotoxicity, hepatotoxicity, neurotoxicity, hyperglycemia (especially in African-American and Hispanic patients), alopecia
Antilymphocyte agents	Antilymphocyte globulin (ATGAM)	Equine antilymphocyte polyclonal antibody	None	Leukopenia, thrombocytopenia, serum sickness
	Rabbit antithymocyte globulin (Thymoglobulin)	Rabbit antithymocyte polyclonal antibody	None	Leukopenia, thrombocytopenia, serum sickness
	OKT3 (Orthoclone)	Murine anti-CD3 monoclonal antibody	None	Cytokine-release syndrome (fever, chills, headache, rarely acute respiratory distress syndrome and aseptic meningitis after first dose), increased risk of opportunistic infections and lymphoma
Interleukin 2-receptor blockade	Basiliximab (Simulect)	Chimeric anti-interleukin 2 α -receptor monoclonal antibody (half-life 7 d)	None	No drug-specific side effects
	Daclizumab (Zenapax)	Humanized anti-interleukin 2 α -receptor monoclonal antibody (half-life 20 d)	None	No drug-specific side effects

CARE OF THE HOSPITALIZED PATIENT

Preoperative Management

Preoperatively, the prospective renal-transplant recipient must be examined carefully to be sure that there are no cardiorespiratory conditions precluding general anesthesia (Chapter 30) and high-dosage initial post-transplant immunosuppression. Patients with end-stage renal disease are at high risk for atherosclerotic complications and may have cardiac ischemia or dysrhythmia. Antilymphocyte immunosuppressives can be associated with post-transplant acute respiratory distress syndrome, so left ventricular function and volume status should be assessed carefully by an echocardiographic study. Because of autonomic dysfunction, many uremic patients cannot exercise to a maximum heart rate, so persantine thallium stress tests are utilized to screen for coronary artery disease. The recipient should receive pretransplant dialysis to optimize the preoperative electrolytes. Blood potassium levels below 5.5 mEq/L are mandatory for safe general anesthesia. In patients receiving peritoneal dialysis, peritoneal dialysate is tested for cell count and differential, and a concentrate is sent for Gram's stain and culture to exclude latent peritonitis. Assessment and treatment are coordinated closely with the transplant surgeons and anesthesiologists. This evaluation and care must be performed expeditiously in the case of cadaver donor renal transplantation. Outside records and periodic re-examinations by the transplant service help

with adequate and rapid preoperative assessments. The cadaver donor kidney must be implanted within 72 hours (preferably within 12–48 hours) after procurement, because prolonged preservation leads to severe delayed graft function and technical loss.

Initial Postoperative Renal-Transplant Care

Postoperative renal-transplant care is done in close collaboration with the transplant surgical staff. Medical and nephrology input is needed for management of a number of clinical problems, especially delayed graft function, hypertension, diabetes, respiratory distress, and cardiac ischemic events or arrhythmias. The usual post-transplant care of recipients for the first 7–14 days can be directed along a clinical pathway developed after input from both internists and transplant surgeons (Table 102.5). Superimposed complications, such as persistence of renal failure resulting from delayed graft function or a cardiac ischemic event, would alter the clinical pathway.

Before discharge, the patient's outpatient care is coordinated with the referring medical staff, home health agencies, payors, and post-transplant care clinics. Because most renal-transplant rejections occur in the first 3 months, it is vital that follow-up recommendations be addressed thoroughly at the time of post-transplant discharge. Patients with kidney transplants have an initial hospital stay of 7–10 days. An average of 5–10 days per year of hospitalization may be required for the first 2–5 years post-

TABLE 102.5
POST-TRANSPLANT CLINICAL PATHWAY (EXAMPLE)

Day	Surgical	Medical	Nursing
0	Surgical transplant Initiate immunosuppression	Postoperative recovery Floor vs. ICU	Fluid Pain management Monitor graft
1	Wound check Monitor immunosuppression	Monitor transplant function Dialyze, if needed	As above Ambulate
2	As above	As above Medical management (e.g., manage blood pressure, diabetes)	As above Start oral intake
3–4	As above Discontinue Foley catheter	As above	As above Discontinue intravenous fluids Educate
5–6	As above	As above If delayed function, arrange backup dialysis If normal, organize discharge	Review social services As above Patient and family self-medicate
7–10	Discharge Communicate with primary physician and ancillary services	Discharge Communicate with primary physician and ancillary services	Patient takes a "care test" Arrange clinic and local follow-up

If prolonged operative time, early graft dysfunction, or early rejection, the timing of this pathway may need to be extended.

transplant (typical problems are discussed below). Because patients are more independent after transplant than during dialysis, family conferences and instruction with the hospital-based staff are necessary so that patient understanding and adherence can be encouraged.

Acute Renal Failure

One of the most common problems following renal transplant is acute renal failure (ARF). Because recipients have a solitary functioning kidney, surgical and urologic causes of ARF must be excluded routinely. Occasionally, dialysis patients have normal urine outputs; these post-transplant patients may continue to have normal urine volumes despite having severe transplant ARF. In addition, several pathophysiologic processes may be superimposed (e.g., acute rejection during initial delayed graft function) so that diagnostic transplant biopsy may be indicated more frequently than in cases of ARF affecting the general medical patient population (Chapter 100). The overall approach to renal transplant ARF or delayed graft function is presented in Figure 102.3.

Immediate Post-Transplant Acute Renal Failure

If the grafted kidney fails to function post-transplant (a situation seen with 10%–40% of cadaver donors, and 1%–5% of living donors), early diagnostic tests must be done to exclude *obstruction*, *leak*, or *vascular thrombosis*. These usually include renal isotope scans or transplant ultrasound with Doppler flow studies. Abnormalities showing urologic or vascular problems dictate surgical re-exploration.

Hyperacute rejection occurs rarely, and graft thrombosis may occasionally develop in hypercoagulable patients, requiring that the infarcted allograft be removed. More commonly, delayed graft function is on the basis of initial *post-transplant acute tubular necrosis* and, in the case of cadaver donation, reflects procurement renal hemodynamic changes as well as injury during preservation time. Recipients of cadaver transplants from the same donor usually both develop delayed graft function, demonstrating the influence of cadaver-procurement issues on the probability of success.

Early Post-Transplant Acute Renal Failure (One Week to Three Months)

One week to three months is the most common time frame in which post-transplant ARF presents a diagnostic dilemma. ARF may be superimposed on delayed graft function or may occur after good initial graft function. Although change in serum creatinine is an imperfect measure of altered glomerular filtration rate, its use is standard because of its wide availability. Its utility can be maximized by having the blood tested at a similar time of day with steady-state degrees of exercise, activity, and diet.

Post-transplant pyelonephritis frequently causes a degree of ARF, because the infection is in a solitary kidney. The post-transplant patient with ARF secondary to pyelonephritis usually has both local and general symptoms.

After measuring cyclosporine or tacrolimus levels, testing should turn to evaluating the possibility of transplant prerenal and postrenal failure. Because of the solitary transplant kidney, imaging studies are ordered much more commonly than in native kidney settings of ARF. Surgical consultation is necessary if these studies show obstruction, urinary leak, or possible arterial stenosis. Many times, interventional radiologists can provide temporary relief with stents, but the therapeutic approach needs to be reviewed by the transplant surgical staff.

Most cases of early post-transplant ARF require either drug modification (lowering of cyclosporin or tacrolimus dosages) or alterations in immunotherapy. Sonographically directed renal-transplant biopsies are standard and clinically safe. Based upon the biopsy results (Figure 102.3), the diagnosis of post-transplant ARF may be made with precision, and appropriate therapy can be rendered.

Late Post-Transplant Acute Renal Failure (Longer Than Three Months)

Post-transplant acute renal failure occurring after 3 months usually is diagnosed by a confirmed change in serum creatinine. Of note, any significant change in the degree of physical exertion may elevate serum creatinine without necessarily representing ARF. The approach to ARF in this time frame initially may be carried out in the outpatient setting. Allografts in patients receiving cyclosporine or tacrolimus are very sensitive to renal blood flow alteration. Such grafts often develop prerenal azotemia in the setting of fluid losses and dehydration and recover well with intravenous volume resuscitation. In addition, late acute rejections may present as asymptomatic ARF in the setting of drug noncompliance or several weeks after a flu-like illness. Follow-up laboratory tests should be obtained after any viral illness. Recently, many cases of a BK polyomavirus infection of the renal graft have been observed, often progressing to full transplant failure (13). Patients have no systemic symptoms or signs. There is no known effective treatment.

Drug toxicity also can lead to ARF. Patients may be very sensitive to nonsteroidal anti-inflammatory drugs and develop ARF after their use. Post-transplant ARF may be caused by the use of angiotensin-converting enzyme inhibitors, especially if there is concurrent renal-transplant artery stenosis. Hospitalization becomes necessary to perform diagnostic biopsies or for urologic or vascular reconstructive procedures. Late postrenal transplant ARF can occur during hospitalization for transplant pyelonephritis, as a consequence of contrast dye used for angiographic studies (often needed because so many patients have atherosclerosis), or from significant sepsis or pancreatitis producing late post-transplant acute tubular necrosis.

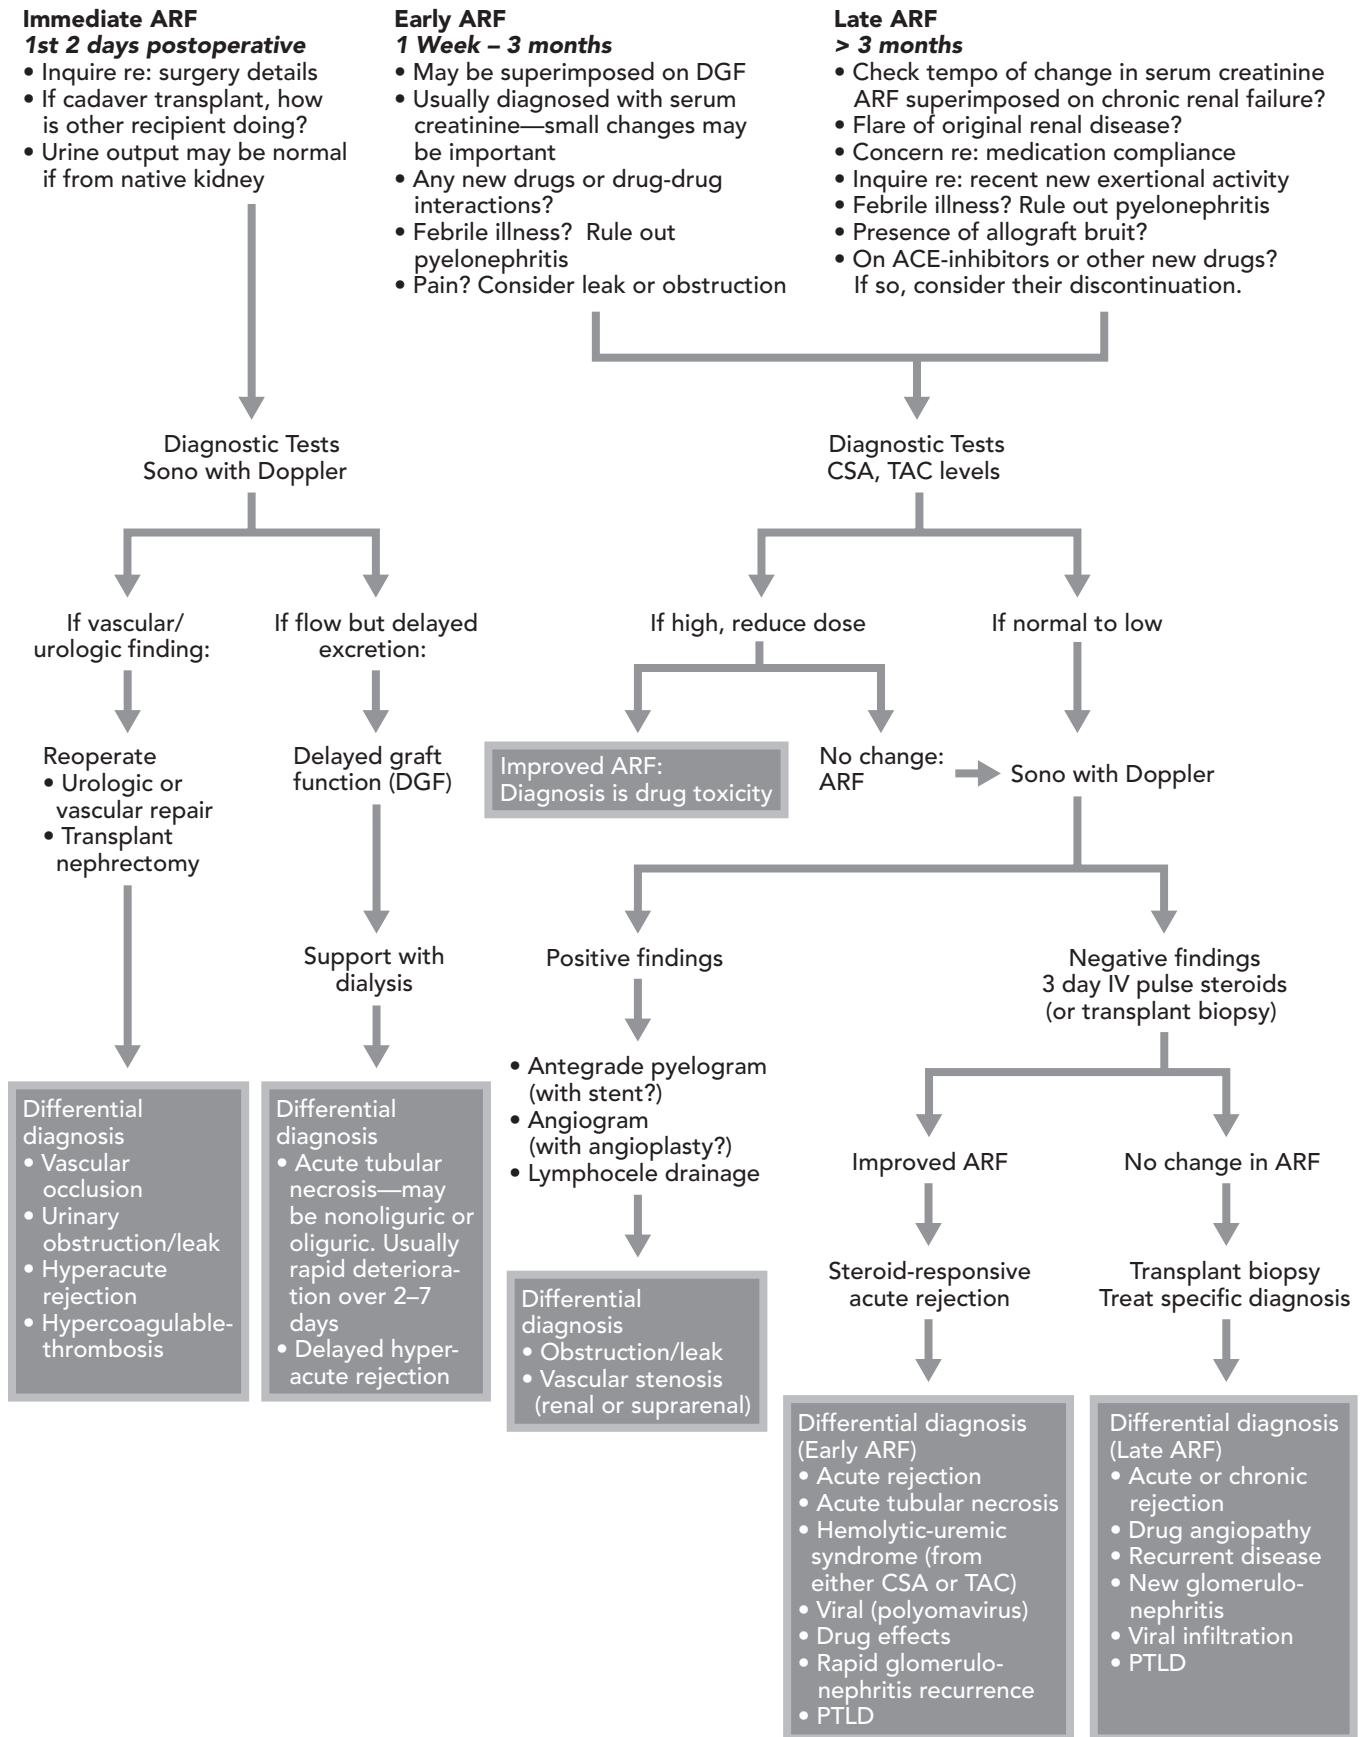

Figure 102.3 Approach to renal transplant patients with acute renal failure (ARF). ACE, angiotensin-converting enzyme; CSA, cyclosporine; DGF, delayed graft function; IV, intravenous; PTLD, post-transplant lymphoproliferative disease; Sono, renal sonogram; TAC, tacrolimus.

Fever

Certain features should be emphasized in considering fever in the renal-transplant recipient. First, uremic patients may not exhibit normal temperature curves; they may even be hypothermic if infected. Second, immunosuppression may reduce pyrexia, as well. Foremost among potential causes of fever in the hospitalized transplant patient is infection. In the first month, bacterial infections are most common. Thereafter, the most common infection causing fever is cytomegalovirus, either as an isolated febrile syndrome or with tissue site infection. Infection always must be considered in any ill renal transplant recipient; an approach is detailed in Chapter 63. A chest radiograph should be obtained, because there is often a paucity of auscultatory findings despite pneumonia. In addition, drugs and nosocomial infections are in the differential diagnosis of fever. Attention must be paid to *in situ* intravascular catheters or retained peritoneal dialysis catheters. If these are present, surgeons should be consulted for their removal, if possible.

With current immunosuppressive regimens, acute rejection rarely is associated with fever. More often, febrile patients with post-transplant ARF have transplant pyelonephritis. However, "end-stage" rejection that occurs after the patient has returned to dialysis can present with fever, cachexia, weight loss, anemia, hematuria, and graft discomfort. These patients require hospitalization, surgical consultation, and transplant nephrectomy, with medical and dialysis supportive management.

Abdominal Pain

Patients with abdominal pain require early surgical consultation because there may be a paucity of physical examination findings in the setting of immunosuppression. Some of the conditions causing abdominal pain are transplant-related and include urinary leak, pyelonephritis, perirenal trauma and hematoma, renal artery aneurysm, and internal hernia into the iliac fossa. Because kidney transplants are denervated, transplant renal stones are painless. Pain unrelated to the graft can be caused by biliary (Chapter 84) and pancreatic (Chapter 86) diseases (which occur at a higher incidence in this population), ulcer disorders (Chapter 80), acute reflux esophagitis (Chapter 79), and diverticulitis (Chapter 87). In the renal-transplant patient whose primary renal disease resulted from adult-onset polycystic kidney disease, pain may be caused by bleeding into native kidney or liver cysts. Finally, patients with preceding peritoneal dialysis are at higher risk for peritoneal adhesion and intestinal obstruction.

Respiratory Distress

Renal-transplant patients may be hospitalized with respiratory distress. In a high percentage of these cases, chest radiographs indicate either a diffuse, segmental, or nodular

pattern providing clues to an infectious cause. Pulmonary consultation should be obtained. The diagnostic and therapeutic approach is detailed in Chapter 63. In addition, there is a higher incidence of pulmonary emboli in transplant patients, particularly if there is post-transplant erythrocytosis or if the patient has been inactive. The embolic source may be in the pelvic venous plexus. If so, the patient generally has no peripheral deep venous findings. The approach is the same as with other patients with pulmonary embolus (Chapter 53). If an inferior vena caval filter is indicated, the surgical transplant staff should be consulted along with interventional radiology. The filter should be placed via the femoral vein opposite the renal transplant if possible.

Altered Mental Status

Encephalopathy can occur soon after the transplant and usually is associated with high-dosage steroids or administration of OKT3. This is especially common in older recipients, in whom psychosis is accompanied by visual hallucinations. If there are profound post-transplant alterations in electrolytes (e.g., declines in serum calcium, phosphorous, or magnesium levels), lethargy can occur. Occasionally, either cyclosporine or tacrolimus can lead to early idiosyncratic central nervous system effects that are unrelated to drug levels. These psychotic responses are reversible over days after drug substitution. In addition, both drugs rarely are associated with central nervous symptoms in the late post-transplant period. These patients may have white matter changes on CT scan, which usually are discovered during evaluation of encephalopathy or other neurologic complaints.

New psychological or cognitive symptoms in the long-term transplant patient should be taken seriously. Important in the differential diagnosis are central nervous system neoplasms (especially lymphoma), infectious meningitides (fungal or parasitic), or progressive leukoencephalopathy. Urgent cerebral imaging study, lumbar puncture, and neurologic consultation all should be considered.

Hypertensive Emergency

Although hypertension is common post-transplant, only rarely do patients require hospitalization for a severe exacerbation of hypertension. It is important to inquire about cessation of or noncompliance with previously prescribed antihypertensive regimens (Chapter 48 discusses standard management). The patient's transplanted kidney should be auscultated for the presence of a bruit. In addition, ultrasonography may reveal the development of renal artery stenosis (which is more common if an end-to-end arterial anastomosis was performed) or the development of a urologic transplant obstruction. In either case, the transplant surgical staff should be consulted, and operative or percutaneous interventional therapy provided.

KEY POINTS

- Because of advances in immunosuppressive and surgical techniques, renal transplantation is becoming more common, and patients, therefore, are encountered more frequently in general clinical practice.
- Post-transplant patients all have solitary kidneys, so radiographic studies are often indicated to assess transplant complications.
- Transplant patients are highly sensitive to states of renal hypoperfusion, especially because of volume depletion or the use of concomitant nonsteroidal or angiotensin-converting enzyme inhibitor.
- Other problems may be associated with immunosuppressive drug side effects, systemic complications, or the patient's underlying renal disease.
- Close communication with the patient's transplant center is helpful because pre- and perioperative factors may be correlated with later events.

Renal Stone Disease and Obstruction

103

David S. Goldfarb Fredric L. Coe

INTRODUCTION

The anatomy of the urinary tract can be divided into the upper tract, composed of the ureters and the kidneys, and the lower tract, composed of the bladder and the urethra. Obstruction by kidney stones tends to occur at sites of relative narrowing, where stones can become impacted. The renal calyces drain into the renal pelvis via a narrow infundibulum, and focal calyceal dilatation can occur if the infundibulum is obstructed. Beyond the calyces, common sites of stone impaction include the ureteropelvic junction, the distal third of the ureters (where they are crossed by large blood vessels), the ureterovesical junction, and the bladder neck or proximal urethra.

At least 80% of kidney stones contain calcium. Most of these are composed mostly of calcium oxalate, and a smaller proportion are predominantly calcium phosphate. Stones composed predominantly of calcium phosphate suggest the diagnoses of hyperparathyroidism and renal tubular acidosis. Uric acid, struvite, and cystine stones compose the rest. Stones occur more often in men than in women, at a ratio of 2:1. A synopsis of the pathophysiology of renal stone formation is presented in Table 103.1 (1).

The presentation of renal obstruction resulting from kidney stones is often relatively easy to diagnose. In fact, the patient often already has made the diagnosis at the time of presentation. Internists, emergency-room physicians, and urologists most frequently see the patient at that point and need to make decisions about the need for diagnostic testing, hospitalization, and requisite medications. Decisions about utilization of modalities to remove stones that do not pass spontaneously from the urinary tract are made most often by urologists. Stone disease today usually is managed in the outpatient setting. Renal obstruction re-

sulting from causes other than stones generally is more insidious in onset and more likely to require admission for diagnosis and management. However, stones sometimes can cause painless obstruction that damages the kidney. Whatever the cause, the more rapidly obstruction is relieved, the more likely is complete recovery of the pre-morbid glomerular filtration rate. A delay in relief of obstruction, especially in the setting of infection, is likely to lead to irreversible loss of kidney function.

CLINICAL PRESENTATION

The vast majority of patients with obstructing kidney stones present with renal colic. This syndrome usually is characterized by sudden onset of flank pain that radiates anteriorly and downward into the scrotum or labia as the stone moves. At first the pain is usually modest; with continued ureteral contractions, it worsens and then remains steady after reaching a plateau of severity. The evolution from onset to plateau typically takes 30 minutes. The patient may describe the pain as the worst he or she has ever experienced. Nausea and vomiting may accompany the pain. When a stone passes, relief of pain is sudden and complete.

About 40% of patients have a family history of nephrolithiasis, so this specific history has some positive predictive value. Gross hematuria is noted in many cases, but microscopic hematuria is neither very sensitive nor specific for diagnosing ureteral obstruction caused by stones (2). If hematuria is defined as more than five red blood cells per high-power field, urinalysis has a sensitivity of 67% and a specificity of 66%. Using definitions of hematuria that require fewer red blood cells per high-power field increases sensitivity but significantly reduces the specificity

TABLE 103.1
CAUSES OF KIDNEY STONE FORMATION

Calcium stones

Low urine volume	Hyperoxaluria
Hypercalciuria	Idiopathic
With hypercalcemia	Dietary
Primary hyperparathyroidism	Primary (enzymatic defects)
Sarcoidosis	
Normal serum calcium	Hypocitraturia
Increased intestinal absorption	Idiopathic
Decreased renal re-absorption	Metabolic acidosis
Increased release from bone	Renal tubular acidosis
Metabolic acidosis	Diarrhea/ileostomy (also causes low urine volume)
Increased protein and salt ingestion	Acid loads (e.g., protein ingestion)
Decreased renal phosphate re-absorption	

Uric acid stones

Low urine pH	Hyperuricosuria
Idiopathic	Gout
Chronic intestinal disease	Increased purine ingestion
Associated with gout	
Renal insufficiency	Low urine volume
Hyporenin, hypoaldosteronism	
Diabetes mellitus	
Obesity	

Struvite stones

Infection with urease-producing organisms

Cystine stones

Cystinuria

Drugs (partial list)

Indinavir	Sulfonamides	Topiramate
Triamterene	Acyclovir	Felbamate

of the finding. Crystalluria is not specific for stone disease, although in the setting of proven stones, the nature of the crystals usually correlates with stone composition.

Obstruction by other causes rarely results in the syndrome of renal colic. These cases can be divided into obstruction of the lower and upper urinary tracts. Lower-tract obstruction refers to the bladder neck or urethra. Renal failure is an unusual manifestation of lower-tract cases, because symptoms of obstruction and bladder irritation usually lead to medical attention before the ureterovesical valves become incompetent. Patients almost always complain of acute urinary retention, diminished strength of urinary stream, dribbling, low-volume polyuria, and nocturia long before renal failure occurs. In men, benign prostatic hypertrophy and prostate cancer account for almost

all such cases. In women, this syndrome is much less common on an anatomic basis but can be caused by large uterine fibroids, pelvic carcinomas, or occasionally urethral strictures. If renal failure does occur because of outflow obstruction, the bladder hypertrophies, and for a long interval the kidneys are protected by competent ureterovesical valves. As the bladder wall dilates, the valves become incompetent and renal damage occurs.

Renal failure as a result of lower-tract obstruction more commonly occurs in patients with loss of normal bladder sensation (e.g., in diabetes), bladder sphincter dysfunction (in Parkinson's disease or multiple sclerosis), or spinal cord injury affecting bladder motor segments. Overdistention and smooth muscle decompensation follow. Complete interruption of sensory and motor pathways to and from the spinal cord after trauma results in a reflex neurogenic bladder. In this case, the bladder empties well reflexively, and the ureterovesical valves are intact. Nevertheless, chronic catheterization is necessary because of incontinence and sphincteric dysfunction, and this leads to infection and struvite stones. Renal failure may ensue. Lower tract obstruction caused by unnoticed urinary retention also occurs in patients with moderate-to-severe dementia.

Upper urinary tract obstruction from lesions other than stones is often chronic and fails to evoke ureteral contractions. It is therefore most often, silent, without the pain and colic of stone disease. Most often, such patients present with vague discomfort or are diagnosed only when their other medical problems lead them to seek evaluation. Asymptomatic renal obstruction may be found in the patient being evaluated for any number of malignancies, particularly lymphoma, colon cancer, and bladder tumors. Renal failure is unusual because this requires obstruction of two kidneys. It tends to occur only with the bulkiest tumors, or with significant retroperitoneal lymphadenopathy or fibrosis. About 0.1% of people have only one kidney, either on a congenital basis or resulting from surgery. Such patients are at greater risk for renal failure caused by obstruction. Stone disease easily may cause renal failure in this setting.

Differential Diagnosis and Initial Evaluation

The differential diagnosis of flank pain and colic is detailed in Table 103.2. The classic syndrome of renal colic also may be the initial presentation of pyelonephritis (Chapter 68). Confusion can result from the ability of obstructing stones to lead to concomitant urinary tract infection. The key distinguishing feature is that neither fever nor pyuria are signs of stone disease unaccompanied by infection. Urine is sterile in the case of most stones, except for struvite stones, which arise after infection with urease-producing organisms such as *Proteus* spp. and are often associated with urine pH values greater than or equal to 8. However, these stones are less likely to produce the syndrome of acute renal colic. Although renal colic may cause leukocytosis, high white blood cell counts (>12,000 cells/ μ L) suggest infec-

TABLE 103.2**DIFFERENTIAL DIAGNOSIS OF FLANK PAIN/RENAL COLIC**

Condition	Distinguishing diagnostic features
Common causes of flank pain	
Stones	Hematuria is common (but not invariable), normal-to-slightly high WBC, absence of fever; onset of pain is acute, not positional
At the ureteropelvic junction	Flank pain predominates
At the crossing iliac vessels	Flank pain with radiation to genitalia
At the ureterovesical junction	Voiding symptoms, radiation to genitalia
At the bladder neck	Anuria, suprapubic discomfort
Pyelonephritis	Fever, leukocytosis, pyuria; onset of pain is more subacute, more constant; WBC casts
Nephrolithiasis and infection	Features of both stones and pyelonephritis
Unusual causes of flank pain	
Renal infarction	In setting of atrial fibrillation, dilated cardiomyopathy, hypercoagulable states, polyarteritis nodosa, cocaine use
Acute interstitial nephritis	In setting of drug use associated with syndrome; rash, fever, pyuria, eosinophilia
Acute glomerulonephritis	In setting of streptococcal infection; hematuria, proteinuria, RBC casts
Renal vein thrombosis	In setting of nephrotic syndrome, especially membranous nephropathy; hypercoagulable states
Non-nephrologic/non-urologic causes	
Ovarian cysts, torsion	
Ectopic pregnancy	
Diverticulitis	
Intestinal obstruction	
Appendicitis	

RBC, red blood cell; WBC, white blood cell count.

tion. *Papillary necrosis* occurs with pyelonephritis (particularly in the setting of diabetes), analgesic nephropathy, and sickle-cell disease or trait. The syndrome may cause renal obstruction as papillae lodge at the ureterovesical junction. Without radiologic studies, this condition may not be readily distinguishable from stone disease causing obstruction. *Renal infarction* can present with flank pain and hematuria. This diagnosis should be suspected in patients with atrial fibrillation, hypercoagulability, cocaine use, or vasculitis, and is usually associated with elevated serum and urine lactate dehydrogenase levels, with isoenzyme one level greater than that of isoenzyme 2.

Diagnosing obstruction by stones is often straightforward in the patient with the appropriate history, hematuria, and a plain radiograph of the abdomen that demonstrates a radio-opaque stone. Even with a clear-cut diagnosis, management decisions still may require more elaborate imaging studies such as ultrasound, computed tomography, or intravenous pyelogram to define urinary-tract anatomy. These studies also are indicated if the history, examination, and laboratory data do not lead to an obvious diagnosis of nephrolithiasis. Plain radiographs

do not disclose radiolucent stones and cannot diagnose obstruction resulting from other causes besides stone disease.

The dominant test in diagnosing and managing stone disease has traditionally been the intravenous pyelogram. The risk of nephrotoxicity despite the use of nonionic contrast agents, and the relative ease and speed of helical computed tomography, have diminished the intravenous pyelogram's role (3). Helical, or spiral, computed tomography has the advantages of being much faster than other tests (it can be completed in 5 minutes) and not requiring intravenous or oral contrast. Both its sensitivity and specificity are superior to ultrasound and IVP. The cost of CT is falling and now approaching that of IVP. Radiolucent uric acid stones (which appear as filling defects in IVPs) can be visualized directly by helical computed tomography and distinguished from intraluminal clot, tumors, and other obstructing masses. Ultrasound may miss stones causing obstruction, especially in the lower ureter, but the test does detect hydronephrosis well.

For obstruction resulting from causes other than stones, the diagnosis of lower urinary tract obstruction

TABLE 103.3**DIFFERENTIAL DIAGNOSIS OF LOWER URINARY TRACT OBSTRUCTION**

Lower-tract obstruction	Distinguishing diagnostic features
All causes	Suprapubic pain; voiding symptoms: low-volume polyuria, nocturia, diminished stream, dribbling, progressing to anuria
Specific disorders	
Prostatic hypertrophy	Smooth, symmetrical, firm gland
Prostatic cancer	Nodular, asymmetrical, hard gland
Cervical/uterine cancers	Appropriate pelvic examination
Bladder stones	History of stone, occasional hematuria, often associated with prostatic hypertrophy
Urethral stricture/bladder neck stenosis	Difficult passage of Foley catheter
Neurologic diseases (e.g., spinal-cord injury)	Appropriate neurologic history, examination
Pain	Postoperative or posttraumatic
Hysteria	

should be considered in patients with symptoms of voiding difficulties. The differential diagnosis is reviewed in Table 103.3. The physical examination should focus on the rectal examination in men, looking for prostatic hypertrophy and carcinoma. Women should undergo pelvic examination. The bladder may be distended and palpable as a large suprapubic mass. After the patient voids (assuming anuria is not present), suprapubic ultrasound can estimate the postvoiding residual volume. If this modality is not available, a Foley catheter should be placed and the postvoid residual volume estimated. If the residual volume is less than 250 mL, the catheter should be removed. Although volumes of less than 150 mL normally are expected, volumes less than 1 L are unlikely to be associated with renal failure.

Upper urinary tract obstruction is readily diagnosed by ultrasound. This is a safe, relatively inexpensive, and sensitive (98%) test for this diagnosis (3). False negative results, such as in cases of obstruction of such short duration that the finding of hydronephrosis is not evident, or in conditions such as retroperitoneal fibrosis, in which ureteral entrapment prevents the development of hydroureter despite obstruction, are highly unusual. The ability of ultrasound to disclose the exact cause and location of obstruction is limited by its poorer visualization of the ureters and pelvis. The test's specificity (78%–90%) also is diminished by hydronephrosis not caused by obstruction (e.g., pregnancy and diuresis) and lesions with similar radiographic presentation, such as renal sinus cysts (4). For all of these reasons, helical computed tomography may soon supplant the intravenous pyelogram and ultrasound in visualization of the urinary tract (5). Magnetic resonance imaging is expensive, of no proven utility in the diagnosis of urinary tract obstruction, and does not visualize stones well.

ISSUES AT THE TIME OF ADMISSION

Indications for Hospitalization

One review indicates that up to 98% of stones smaller than 5 mm in diameter, especially those in the distal ureter, pass spontaneously (6). Stones greater than 7–8 mm have less than a 20% chance of spontaneous passage. These figures should contribute to the decision regarding observation, hospitalization, or immediate intervention. Controlled trials have demonstrated that passage of distal ureteral stones can be facilitated by administration of steroids to reduce ureteral edema and nifedipine or tamsulosin to reduce ureteral spasm (7). These trials have been performed in outpatients; whether such regimens could reduce hospitalizations is not clear.

Patients with urinary tract infection and obstruction are at risk for renal parenchymal damage and urosepsis and, therefore, should be hospitalized. Relief of obstruction should be accomplished rapidly by urologic or interventional radiologic intervention, and parenteral antibiotics should be administered. Although renal colic often is manageable in outpatients with oral medication, intractable pain, accompanied by nausea and vomiting, also leads to hospitalization. Patients with higher grades of obstruction are more likely to lose renal function over time if obstruction is unrelieved. Larger stones are less likely to pass and more often lead to hospitalization. Anatomic anomalies, such as horseshoe kidneys or duplicated collecting systems, also impede spontaneous stone passage and may support the admission decision. Renal failure of a degree approaching the need for dialysis arising from bilateral obstruction, or from obstruction of a solitary kidney, is always an indication for admission.

Patients with urinary retention resulting from benign prostatic hypertrophy relieved by catheterization need not be admitted if adequately instructed regarding the use of a drainage bag. Definitive therapy can include immediate institution of α -blockers leading to a trial of catheter removal. If this fails, surgery or other ablative therapies for benign prostatic hypertrophy may be required.

Indications for Initial Intensive Care Unit Admission

Acute renal obstruction rarely requires ICU admission. ICU monitoring is prudent if the sepsis syndrome (Chapter 26) is present. Urinary tract infection proximal to an obstructed ureter can lead to pyonephrosis, which in turn is associated with pyelonephritis, papillary necrosis, and destruction of renal parenchyma, with progressive loss of kidney function. Renal failure resulting from bilateral obstruction, or obstruction of a single kidney, may be an indication for ICU admission if severe complications develop, such as refractory hyperkalemia, metabolic acidosis, circulatory congestion, or deteriorating mental status caused by uremia (Chapter 100). If such effects cannot be reversed rapidly by prompt relief of obstruction or by dialysis, ICU management of these complications may be needed.

Initial Therapy

The choices for pain relief of renal colic are nonsteroidal anti-inflammatory drugs (NSAIDs) or opiate agonists. Both have advantages and disadvantages (Chapter 18). One randomized trial demonstrated that ketorolac was slightly superior to morphine for renal colic, with better pain control and faster discharge from the emergency room (8). The sedative properties of opiates make them less desirable for patients who are not admitted or who are discharged with stones still in place. Opiates in general, and meperidine specifically, can cause nausea, vomiting, and constipation. Meperidine also is contraindicated in renal failure because accumulation of its renally-cleared metabolite normeperidine has been associated with seizures. Morphine also has a glucuronide metabolite that accumulates in renal insufficiency and can be toxic when it accumulates in neurons. NSAIDs such as ketorolac provide effective, non-sedating analgesia and diminish ureteral motility, but have the disadvantages of causing gastric irritation (particularly in the elderly) and diminished renal function (particularly in those with extracellular fluid volume depletion or other causes of renal insufficiency). They are also more expensive than opiates. Antibiotics should be administered in any patient with evidence or suspicion of infection. The most common organisms in patients who are not immunosuppressed and have not received multiple courses of antibiotics are Gram-negative rods, such as *Escherichia coli*, *Proteus* spp., and *Klebsiella* spp., and the enterococci. Chapter 68 suggests empiric antibiotic regimens.

Attention to repletion of intravascular volume in the patient with nausea and vomiting, and correction of electrolyte derangements associated with acute renal failure, are addressed in Chapters 100 and 104. Administration of saline and forced diuresis have not been shown to increase likelihood of spontaneous stone passage and may increase intra-ureteral pressure and pain.

Indications for Early Consultation

Most patients with small stones (5 mm or less) can be managed with analgesia as appropriate and without urologic consultation. Larger stones are associated with a progressively smaller likelihood of spontaneous passage. A urologist must evaluate such patients in anticipation of a definitive intervention. Any patient requiring hospitalization for a large stone, accompanying infection, renal failure, or with a solitary kidney should be seen by a urologist as quickly as possible. Urology consultation should also be sought for patients with urinary retention and significant postvoid residual volumes.

For patients with acute renal failure, consultation with a nephrologist in anticipation of possible dialysis is generally prudent, particularly in cases complicated by uremia and more severely deranged serum electrolyte concentrations. In many cases, dialysis may be obviated by prompt treatment to relieve obstruction, which produces an immediate improvement in renal function.

ISSUES DURING THE COURSE OF HOSPITALIZATION

The key decisions during the first hospital day involve choosing a means to relieve renal obstruction. In the case of lower-tract obstruction, it is easily relieved by placing a Foley catheter. Larger catheters (22 or 24 Fr) with coude tips may allow passage past an enlarged prostate. If this is not possible, a urologist needs to perform suprapubic cystostomy. α -blockers (e.g., terazosin or tamsulosin) can be started immediately if prostatic obstruction is present. For upper-tract obstruction, options include passing a retrograde stent into the ureter via cystoscopy, passing a percutaneous nephrostomy tube with antegrade passage of a stent, or prompt removal of an obstructing stone by percutaneous nephrolithotomy, extracorporeal shock-wave lithotripsy (ESWL), or ureteroscopy. If a stent is passed via cystoscopy, pain and infection can occur and more definitive therapy can be scheduled in the outpatient setting. Open surgery for stone disease is almost never required. Long-term management of obstruction that cannot readily be relieved, such as bilateral obstruction caused by advanced carcinoma of the bladder, may require urinary diversion such as construction of an ileal conduit.

On day 2, after obstruction in patients with bilateral obstruction and renal failure is relieved, an immediate

improvement in renal function should occur. A poor prognostic feature is if little recovery has occurred after 2–3 days. A postobstructive diuresis often accompanies the fall in creatinine. Extracellular fluid volume must be assessed carefully to ensure that the patient does not become volume-depleted. Though recommendations often are made to replace a certain proportion of the urine volume, it is preferable to monitor the patient's requirements by monitoring for signs of extracellular fluid volume depletion. If necessary, hypotonic fluid administration (e.g., 0.45% normal saline) can be used to replace some proportion of the urinary losses.

On subsequent days, diagnosis of specific causes of obstruction should be made if not previously established, and therapy instituted for the underlying disorder, if possible.

DISCHARGE ISSUES

Patients with stones still in place can be discharged if pain and obstruction are largely relieved and infection, if present, is under control (e.g., resolution of fever and leukocytosis). Definitive treatment of stones remaining in the urinary tract can be scheduled on an outpatient basis if these criteria are met. Mild pain still may be present but should be manageable with either NSAIDs or lower doses of oral opiates. The patient's ability to function normally and go to work or school on such a regimen should be taken into account before delaying definitive treatment. Patients with stents in place may be troubled by flank pain, because voiding causes urinary reflux, or by urinary frequency caused by bladder irritation. A string may be left exiting from the urethra to allow easy removal of the stent in the office without cystoscopy.

Patients should be given a strainer for screening urine for passed stones or fragments if none have been recovered by the time of discharge. This allows stone analysis to be done and confirms passage of stones and fragments. Stone analysis is very inexpensive and can produce insight into the patient's pathophysiology.

Dietary recommendations on discharge of patients with nephrolithiasis can await definitive evaluation of the urinary chemistries. However, certain dietary advice is always appropriate (9). Restriction of protein intake to 8 ounces each day should be stressed. This reduces urinary calcium, uric acid, and cystine excretion and increases urinary citrate excretion and urine pH. Restriction of salt intake also can reduce calcium, uric acid, and cystine excretion, and it reduces hypokalemia caused by thiazides. Dietary oxalate accounts for a variable proportion of urinary oxalate, but even small reductions may significantly reduce calcium oxalate supersaturation. Restriction of calcium intake has not been shown to prevent stone recurrence and may lead to bone demineralization. In patients with hypercalciuria, there is nearly a 50% reduction in stone recurrence when patients ingest 1200 mg of elemental calcium accompanied by decreased dietary salt, protein, and oxalate, compared

with patients eating an oxalate-restricted diet containing only 400 mg of calcium per day (10).

Patients with benign prostatic hypertrophy may be treated with α -blockers. These drugs improve voiding symptoms but can be associated with orthostasis, particularly with the first dose. Patients should be instructed to take the first dose at night in bed to minimize the incidence of syncope. The drug can be started while a Foley catheter is still in place, and the patient can be discharged if voiding is then possible. If α -blockers are ineffective, transurethral resection of the prostate may be indicated.

Patients with obstructive renal failure may be discharged after nephrostomies are removed, if possible, and after internal stent placement. Alternatively, they may go home with the nephrostomy draining externally. This may be painful and require analgesia. Patients require instruction on the proper care and maintenance of the tube and site and may need assistance. Postobstructive diuresis may persist for several days. Patients should not be discharged if they still require intravenous fluids to replace inappropriate urinary sodium losses.

ASSESSMENT AND MANAGEMENT OF THE PATIENT PRESENTING WITH RENAL OBSTRUCTION DURING HOSPITALIZATION

Patients who develop acute renal failure while hospitalized most commonly have acute tubular necrosis, disorders of renal perfusion ("prerenal renal failure"), and nephrotoxic effects of radiocontrast, aminoglycosides, or NSAIDs (Chapter 100). If no other explanation is readily apparent, the possibility of obstruction is worth investigating. Most patients with other diagnoses may be oliguric or nonoliguric, but anuria is rare. Anuria does occur with complete obstruction. If voiding symptoms or a palpable bladder are detected, the postvoiding residual volume should be estimated by ultrasound or directly measured by a Foley catheter. The catheter should be left in only if a significant postvoiding residual volume is detected, because it otherwise constitutes a substantial risk for urinary tract infection. Ultrasound of the kidneys should be performed if a diagnosis still is not apparent.

Intratubular obstruction resulting from crystal formation in nephrons can cause renal failure often accompanied by bilateral flank pain. Hydronephrosis is absent in such cases. Urinalysis can disclose acid urine pH and uric-acid crystals associated with urate nephropathy. This most often occurs after chemotherapy for bulky lymphomas or chronic lymphocytic leukemia. Sulfa crystals can cause a similar syndrome, although usually this is seen if sulfadiazine is given in larger doses. Acyclovir causes renal dysfunction via a similar mechanism in patients receiving high doses intravenously. The protease inhibitor indinavir can also present with renal insufficiency, crystalluria, or stones; such stones are not visualized by CT scanning.

The underlying diagnosis for which the patient is hospitalized should be considered in formulating a differential diagnosis of acute renal failure. Cancer of the colon, cervix, prostate, and bladder, and lymphomas are the most common causes of extrinsic obstruction of the urinary tract. Inflammatory diseases such as Crohn’s disease and endometriosis can cause obstruction, as can surgical complications and aneurysms of the aorta or iliac vessels. The evaluation should be similar to that in patients first seen as outpatients.

COST CONSIDERATIONS AND RESOURCE USE

Patients with symptomatic stones can be treated as outpatients once they are pain-free and obstruction has been relieved. In managing stone disease, the choice among ESWL, ureteroscopy, and percutaneous nephrolithotomy is based mostly on technical issues, reviewed in part in Table 103.4. ESWL initially may be less expensive if the procedure is successful. However, second-generation ESWL machines are somewhat less powerful than their predecessors, so that efficacy is lower, though less intense sedation is required. Calculation of expense then must take into account the possibility of multiple courses of therapy. On the other hand, use of these machines does not require much anesthesia and should allow outpatient therapy. Percutaneous nephrolithotomy and ureteroscopy both are more likely to be successful with a single course, though both require greater skill (11). ESWL also is more likely to leave stone fragments in the kidney, especially when used for treating lower pole stones. These may serve as the nidus for new stones. Again, more invasive procedures may allow more thorough removal of these fragments, ultimately resulting in lower costs.

Evaluation of the metabolic factors responsible for stone formation has been shown to lead to significant savings (12). Abnormalities are disclosed in more than 90%

of patients. Classification of the specific causes of hypercalciuria, the most common abnormality, has no specific consequences for therapy. Thiazides are effective for idiopathic hypercalciuria, regardless of the specific cause (13). Increased fluid intake to achieve urine volumes of more than 2 L is especially useful for calcium oxalate and cystine stones. Potassium citrate is given for hypocitraturia and calcium stones, and also for urinary alkalization for uric acid and cystine stones. Dietary therapy has been discussed previously. Allopurinol is useful if diet fails and calcium stones persist in the setting of hyperuricosuria. Surgery is indicated for primary hyperparathyroidism. All of these therapies are relatively inexpensive, and all are cost-effective.

KEY POINTS

- The diagnosis of urinary tract obstruction is most often suggested by history and physical examination.
- Modern imaging options make confirmation of the diagnosis relatively easy. The diagnosis of renal obstruction, from stones or other causes, therefore has been expedited dramatically.
- The advent of flexible ureteroscopy, ESWL, and smaller percutaneous nephrolithotomy instruments has also had a beneficial impact on management of obstruction and stone disease. These therapeutic options have made open surgery nearly obsolete and almost never indicated. The results of these advances are much lower hospitalization rates and minimally invasive outpatient surgery.
- Stones smaller than 5 mm most often pass spontaneously and often do not require intervention.
- Recent demonstrations of the efficacy and cost-effectiveness of metabolic evaluation and treatment for prevention of recurrent stone formation may shift attention to prophylaxis for a larger proportion of afflicted patients.

TABLE 103.4
TREATMENT RECOMMENDATIONS FOR MANAGEMENT OF SYMPTOMATIC URETERAL STONES

Condition	Recommended therapy	Comment
Stone with high probability of passage (<5 mm)	Observation	Intervention appropriate if symptoms demand
Stone <10 mm in proximal ureter	ESWL	PNL or USC if needed
Stone >10 mm in proximal ureter	ESWL, PNL, or USC	PNL becomes more appropriate with larger stones
Stones <10 mm in distal ureter	ESWL, USC	ESWL may require more procedures, cost more
Stones >10 mm in distal ureter	USC, ESWL	USC may be preferable with larger stones, lower pole stones

ESWL, extracorporeal shock-wave lithotripsy; PNL, percutaneous nephrolithotomy; USC, ureteroscopy. Adapted from Segura JW, Preminger GM, Assimos DG, et al. Ureteral stones clinical guidelines panel summary report on the management of ureteral calculi. *J Urol* 1997;158:1915–1921.

Disorders

Kerry C. Cho

INTRODUCTION

Disorders of sodium and potassium are the most common electrolyte disorders in hospital medicine. Electrolyte abnormalities may be incidental findings on routine laboratory tests and have few symptoms and little clinical significance. Severe disturbances, complicated by or resulting from other medical conditions, may require hospitalization or even intensive care monitoring. The diagnostic evaluations of potassium and sodium disorders in clinical practice are often incomplete and unfocused (1). Furthermore, therapy for electrolyte disorders can be overly aggressive and have disastrous results if basic pathophysiologic rules are violated. One fundamental rule guides the approach to common electrolyte disorders: *potassium disorders result from abnormal potassium handling, but sodium disorders result from abnormal water handling.*

SODIUM

Hyponatremia

Hyponatremia, defined as a plasma sodium concentration less than 135 mEq/L, is the most common electrolyte abnormality in hospitalized patients. The majority of cases reflect hypotonicity because sodium is the main solute that determines serum osmolality (Table 104.1). Hypertonic and isotonic forms of hyponatremia occur infrequently. Hypertonic hyponatremia occurs with hyperglycemia or mannitol infusion. The movement of water from the intracellular space driven by the hypertonicity of the extracellular compartment dilutes the sodium concentration and produces hyponatremia. The standard correction factor for

hyperglycemic hyponatremia is a 1.6 mEq/L decrease in sodium concentration per 100 mg/dL increase in glucose (2). A revised correction factor of 2.4 mEq/L Na⁺ per 100 mg/dL glucose has been proposed recently (3). The incidence of isotonic *pseudohyponatremia*, a laboratory artifact produced by hypertriglyceridemia or hyperproteinemia, has decreased with the direct measurement of sodium by ion-specific electrodes.

The total body sodium in hyponatremic patients may be low, normal, or high. Thus, patients may be hypovolemic, isovolemic, or hypervolemic. Although the serum sodium concentration does not reflect total body sodium or water, there is always a relative excess of water to sodium in all cases of hyponatremia. In general, hypotonic hyponatremia results from primary sodium loss (with secondary water gain), primary water gain (with secondary sodium loss), or primary sodium gain (with excessive water gain). The first category includes patients with sodium losses from either renal or nonrenal sources. Examples of renal sodium loss include the use of thiazide diuretics, osmotic diuresis, post-obstructive diuresis, nonoliguric acute tubular necrosis, and salt-wasting nephropathy. Nonrenal sources of sodium loss include insensible losses from the respiratory tract or skin and gastrointestinal losses (vomiting, nasogastric suctioning, and diarrhea). Whether renal or nonrenal, the sodium loss produces contraction of the extracellular fluid volume, stimulation of thirst, increased fluid intake, and increased ADH release. The net result of increased water intake and decreased renal water excretion is hyponatremia.

The category of primary water gain includes the syndrome of inappropriate antidiuretic hormone release (SIADH), hormonal disorders, primary polydipsia, and chronic renal insufficiency. The main disturbance in these conditions is decreased renal water excretion (or water

TABLE 104.1
MAJOR CAUSES OF HYPONATREMIA

Pseudohyponatremia
Hypertriglyceridemia
Hyperproteinemia
Hypertonic hyponatremia
Hyperglycemia
Mannitol administration
Hypotonic hyponatremia
Hypovolemic (primary sodium loss with secondary water gain):
Thiazide diuretics and other renal losses, gastrointestinal losses, insensible losses
Euvolemic (primary water gain with secondary sodium loss):
Syndrome of inappropriate antidiuretic hormone, primary polydipsia, glucocorticoid deficiency, hypothyroidism, chronic renal disease
Hypervolemic (primary sodium gain with excessive water gain):
Congestive heart failure, cirrhosis, nephrotic syndrome

intake exceeding excretory capacity in the case of primary polydipsia). High levels of ADH alone are usually insufficient to produce hyponatremia; increased water intake or administration must also be present. SIADH is the most common cause of isovolemic, hypotonic hyponatremia. The ADH release is nonphysiologic (“inappropriate”) in the absence of hypovolemia or hyperosmolality, the usual triggers for ADH. The numerous causes of SIADH can be classified into the following broad categories: malignancy, pulmonary disorders, central nervous system disorders, and medications. Deficiencies of cortisol and thyroid hormone can produce hyponatremia by directly or indirectly stimulating ADH release; these hormone deficiencies should be differentiated from SIADH for evaluation and treatment purposes.

In primary or psychogenic polydipsia, massive water intake overwhelms the renal water excretory capacity of 12 L/day. Increased water intake in psychiatric patients may be due to phenothiazines, which enhance thirst perception by causing dry mouth. In beer potomania, decreased dietary intake and cachexia limit the daily solute load. If the kidneys have a limited supply of solutes and the minimum urine osmolality is fixed at 50 mOsm/kg, then a moderately increased daily water intake can exceed the diminished renal water excretory capacity. For example, a beer drinker may have a daily solute load of only 250 mOsm, compared with the 600 mOsm/day generated by the metabolism of a normal diet. With a solute load of 250 mOsm/day, the renal excretory capacity is limited to 5 L/day at the minimum urine osmolality of 50 mOsm/kg.

Hypervolemic hyponatremia reflects primary sodium gain with excessive water gain, typified by the edematous states of heart failure, cirrhosis, and the nephrotic syndrome. Heart failure and cirrhosis are states with decreased effective circulating volume, due to either decreased cardiac

output or decreased systemic vascular resistance (4). Activation of the renin-angiotensin-aldosterone system increases ADH release and sodium and water retention in an attempt to restore effective circulating volume, at the expense of hypo-osmolality and hyponatremia. The severity of hyponatremia in heart failure and cirrhosis has been shown to be an important predictor of survival.

Clinical Manifestations

Hyponatremia causes primarily neurologic manifestations. The severity and rate of change of the serum sodium concentration determine the extent of symptoms. Most patients with mild hyponatremia (sodium >125 mEq/L) are asymptomatic. Chronic, slowly developing hyponatremia is usually better tolerated because the brain decreases its intracellular tonicity, limiting cellular edema. Early symptoms of hyponatremic encephalopathy include headaches, nausea, malaise, lethargy, muscle cramps, and hyperreflexia. More severe symptoms include obtundation, bizarre behavior, hallucinations, asterixis, and incontinence. Advanced symptoms include seizures, coma, brain stem herniation, central diabetes insipidus, permanent brain injury, respiratory arrest, and death. Patients at increased risk for cerebral edema and hyponatremic encephalopathy include prepubertal children, postoperative patients, menstruant women, psychiatric patients with polydipsia, hypoxic patients, and elderly women recently started on thiazide diuretics (5,6). Figure 104.1 contains a diagnostic algorithm.

Therapy

Hospitalization should be considered for symptomatic patients, especially in the presence of significant medical comorbidities. Severe neurological symptoms require intensive care monitoring and frequent sodium measurements. The goals of therapy for hyponatremia include correction of the underlying disease (if possible), correction of sodium concentration by restricting free water intake and promoting water loss, and avoidance of overly rapid sodium correction. Medications that cause or contribute to hyponatremia should be stopped if possible; these include sedatives, hypnotics, analgesics, tranquilizers, oral hypoglycemics, opiates, antineoplastic drugs, antidepressants, and diuretics (5). Hypovolemic patients may require fluid resuscitation with normal saline, while hypervolemic patients may require diuretics and/or dialysis to correct volume overload.

Correction of the sodium concentration is potentially hazardous because serum tonicity may increase more quickly than brain tonicity, especially if the brain has adapted to chronic hyponatremia. *Overly rapid correction may lead to cerebral osmotic demyelination.* Originally called central pontine myelinolysis, this pathologic process can also occur in extrapontine sites. Demyelination is more

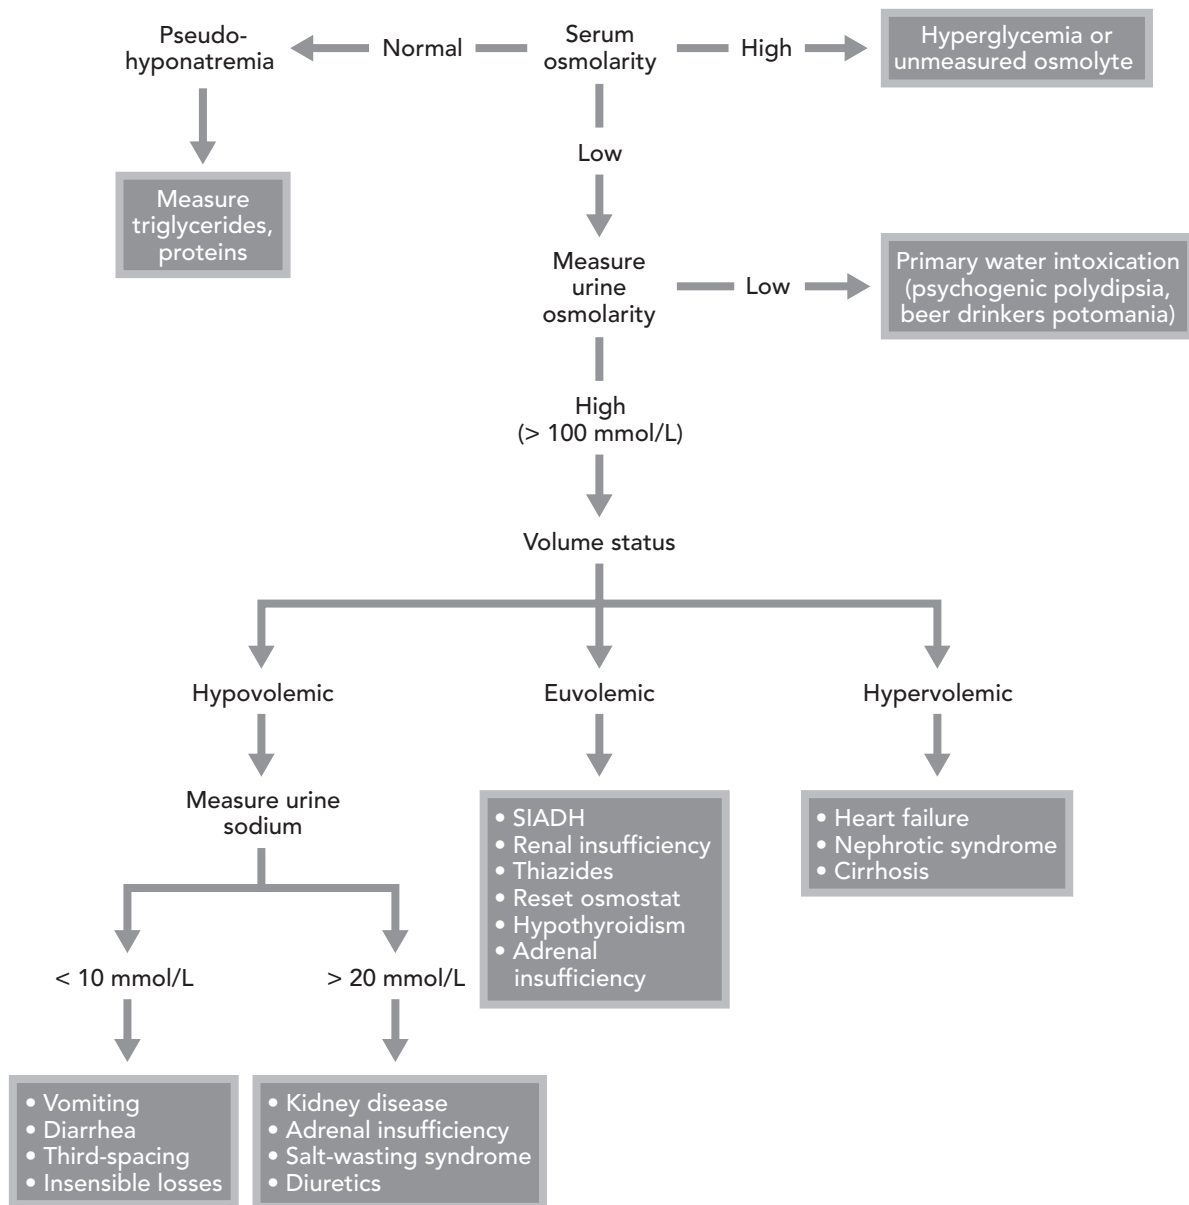

Figure 104.1 Approach to the patient with hyponatremia. CHF, congestive heart failure; SIADH, syndrome of inappropriate antidiuretic hormone.

likely to occur with chronic hyponatremia (>48 hours) and in certain clinical settings: alcoholism, malnutrition, hypokalemia, burns, and thiazide diuretic use (6). Symptoms include mutism and dysarthria initially, followed by spastic quadriparesis and pseudobulbar palsy. Computed tomography and magnetic resonance imaging may not detect radiographic evidence of myelinolysis within the first 2 weeks. There is no specific therapy for myelinolysis.

When considering the appropriate management, physicians must weigh the risk of sodium correction and myelinolysis against the risks of hyponatremic encephalopathy. The chronicity of hyponatremia and the severity of symptoms are the major guides to appropriate therapy. Chronic hyponatremia is generally well tolerated and causes fewer

symptoms than acute hyponatremia, but it carries the highest risk of osmotic demyelination. Thus, in the absence of symptoms, management should be conservative. Free water restriction alone may be sufficient, although the rate of sodium correction may not exceed 1.5 mEq/L per day. Some patients with SIADH may require *demeclocycline* (150 mg four times daily) to antagonize ADH effect by inducing a nephrogenic diabetes insipidus, but its use may be complicated by nephrotoxicity.

Severely symptomatic patients generally require hypertonic saline (3% NaCl) at approximately 1–2 mL/kg/hr. Acute hyponatremia (<48 hours) can be corrected quickly (i.e. 2.0–2.5 mEq/L/hour), while chronic hyponatremia correction should not exceed 1.0–1.5 mEq/L/hr. There is

likely no correction rate that is completely risk free, unfortunately. Many authorities have proposed correction rates ranging from 8–15 mEq/L/day (5–9). Loop diuretics may be required to augment free water excretion and prevent hypervolemia. Serum sodium levels should be checked as frequently as every 1–2 hours. Sodium correction should stop if the patient is no longer acutely symptomatic or if the serum sodium has been corrected to a mild level of hyponatremia (125–130 mEq/L).

Nephrology consultation should be considered for severely symptomatic patients, neurological or neurosurgical patients, obstetrical patients, or whenever hypertonic saline, hemodialysis, or demeclocycline are being considered.

Hypernatremia

Hypernatremia is defined as a plasma sodium concentration >145 mEq/L. Unlike hyponatremia, where osmolality may be decreased, normal, or increased, *hypernatremia always reflects a hyperosmolar state*. The hyperosmolality of the extracellular compartment moves fluid out of cells and causes intracellular fluid contraction. The appropriate physiologic response to hypernatremia is thirst, increased water intake, and excretion of a minimum volume (500 mL/day) of maximally concentrated urine (>800 mOsm/kg) caused by ADH release. Hypernatremia usually does not develop unless a defective thirst mechanism or limited access to water impairs the protective response. Common clinical settings include altered mental status, physical handicaps, the postoperative state, mechanical ventilation, and primary hypodipsia caused by hypothalamic disorders.

Most hypernatremia occurs with hypotonic fluid losses and inadequate intake of sodium and water (Table 104.2). These patients are either hypovolemic or euvolemic. Non-renal sources of water loss include insensible losses from the skin and respiratory tract, gastrointestinal losses, or wound losses (including surgical drains). Fever, heat exposure, exercise, severe burns, and mechanical ventilation

may increase insensible losses. Gastrointestinal losses are caused by vomiting, nasogastric suctioning, enterocutaneous fistulas, and diarrhea. Although any form of diarrhea can produce volume contraction, osmotic diarrheas (from lactulose, sorbitol, or carbohydrate malabsorption) and viral gastroenteritides are particularly likely to present with hypernatremia because of water losses in excess of sodium losses.

The kidney is also a potential source of hypotonic fluid losses. Osmotic diuresis from mannitol administration, hyperglycemia, or excessive protein loads can promote excess water loss, leading to hypernatremia and volume depletion. These patients have polyuria with submaximal urine osmolality. A dilute urine (urine osmolality <100 mOsm/L) is an inappropriate response to hypernatremia, raising the suspicion for either *central or nephrogenic diabetes insipidus (DI)*. Central DI results from trauma, surgery, infection, granulomatous disease, malignancy, and vascular events. Nephrogenic DI may result from drugs (most commonly lithium), hypercalcemia, hypokalemia, papillary necrosis, and pregnancy (because of increased amounts of vasopressinase by the placenta during the second and third trimester). There are also congenital forms of central and nephrogenic DI caused by mutations in genes for ADH, its V_2 receptor, or the aquaporin-2 water channel.

Hypernatremia may also (uncommonly) be caused by excess total body sodium. Examples include ingestion or administration of hypertonic sodium solutions (chloride or bicarbonate salts) and hypertonic feeding preparations. Primary hyperaldosteronism and Cushing syndrome are rare causes of hypertonic hypernatremia with hypervolemia. A review of seven patients with hospital-acquired hypernatremia and edema demonstrated that patients shared several key characteristics: medical comorbidities, isotonic fluid resuscitation, marked weight gain, hypoalbuminemia, and diminished glomerular filtration rate (10).

Clinical Manifestations

As with hyponatremia, the signs and symptoms of hypernatremia are mainly neurologic (11,12). Whether an individual develops symptoms depends on the rate of rise of the sodium concentration and the absolute value. Symptoms include thirst, irritability, lethargy, and weakness. As hypernatremia progresses, confusion, agitation, hyperreflexia, myoclonus, seizures, and coma can develop. In severe cases, brain shrinkage applies traction on the dural veins and venous sinuses, resulting in intracranial hemorrhage. Physical findings include tachycardia, poor skin turgor, dry mucous membranes, and warm, dry skin. Patients admitted with hypernatremia are usually elderly and often have coexisting fever or hyperglycemia. However, hospital-acquired hypernatremia is often iatrogenic and can occur in younger patients with restricted access to free water.

TABLE 104.2
MAJOR CAUSES OF HYPERNATREMIA

Water losses
Gastrointestinal losses
Diabetes insipidus, either central or nephrogenic
Diuretics
Increased insensible losses through respiration and skin
Hypothalamic lesions with impaired thirst perception
Sodium overload
Hypertonic sodium intravenous fluids
Hypertonic feeding preparations
Primary hyperaldosteronism
Cushing syndrome

Therapy

The goals of hypernatremia management are to replace the free water deficit and to stop or decrease ongoing water losses if possible. The first step is to review iatrogenic factors: hypertonic solutions, feeding preparations, diuretics, and other medications. The next step is volume resuscitation of hypovolemic patients with isotonic saline. The free water deficit can be estimated from the following formula: free water deficit (liters) = $0.6 \times \text{body weight (in kg)} \times [(\text{serum sodium}/140) - 1]$. As with hyponatremia, overly rapid correction of hypernatremia is potentially hazardous. *To avoid cerebral edema, the correction rate should not exceed 0.5 mEq/L/hr.* If mental status worsens during the correction of hypernatremia, cerebral edema may have occurred; free water administration should be stopped until symptoms improve. The preferred route of water administration is via oral intake or nasogastric tube; 5% dextrose is the intravenous equivalent. The fluid replacement rate should account for ongoing water losses. Patients with hypervolemic hypernatremia need slow free water replacement to avoid volume overload. Diuretics are used to maximize natriuresis, but hemodialysis may be required to correct the combined sodium and water imbalance.

Patients with central diabetes insipidus or partial nephrogenic DI may require desmopressin (ddAVP), the synthetic analogue of AVP. Complete nephrogenic DI is a therapeutic challenge. Most patients require large amounts of water intake because of obligate renal water losses, but the water requirement may decrease with judicious use of thiazide diuretics, nonsteroidal anti-inflammatory drugs, and dietary sodium restriction. Chlorpropamide, clofibrate, and carbamazepine have been used to stimulate AVP secretion or enhance its action.

Consultation for hypernatremia is generally not required unless diabetes insipidus is suspected. A nephrologist or endocrinologist should assist with the diagnosis of diabetes insipidus, its differentiation (nephrogenic versus central) via a water-deprivation test, and appropriate therapy. Patients with hypervolemic hypernatremia and concomitant chronic renal failure may require nephrology consultation for diuretic recommendations or hemodialysis.

Outcomes

Patients admitted with hypernatremia are often geriatric patients transferred from nursing homes, whereas hospital-acquired hypernatremia occurs in younger patients with an age distribution that resembles the overall hospital population (13). Hypernatremia carries a high mortality rate. A recent study of 116 patients admitted with hypernatremia (serum sodium >145 mEq/L) found that 77 (or 66%) expired (14). Another report noted hypernatremia (serum sodium >150 mEq/L) in 111 (3.46%) of 3,209 hospitalizations (15). Sixty-five patients were hypernatremic on admission, while 45 developed hypernatremia while hos-

pitalized. Hospital mortality for all hypernatremic patients was 48.6%.

Hospital-acquired hypernatremia is often iatrogenic and/or preventable. In 85 patients with hospital-acquired hypernatremia, Palevsky et al. found that 86% lacked free access to water, 94% received less than 1 L/day of IV electrolyte-free water during the development of hypernatremia, and 49% received no supplemental electrolyte-free water during the first 24 hours of hypernatremia (13). One group has proposed using hypernatremia as an indicator of poor quality of care in the medical intensive care unit (16).

POTASSIUM

The normal plasma potassium concentration is 3.5 to 5.0 mEq/L, but extracellular potassium comprises only 2% of the total body potassium content of 4,000 mEq. At a concentration of 140 mEq/L, intracellular potassium is the major cation generating the membrane potential for normal neuromuscular function. The $\text{Na}^+ - \text{K}^+$ -ATPase pump maintains the ratio of intracellular-to-extracellular potassium concentrations. Hormones, acid-base status, osmolality, and cell turnover affect potassium distribution between the two compartments. Insulin increases $\text{Na}^+ - \text{K}^+$ -ATPase activity, increasing uptake of plasma K^+ into liver and skeletal muscle cells. Catecholamines have varied effects; β_2 -adrenergic agonists increase $\text{Na}^+ - \text{K}^+$ -ATPase activity, while α -adrenergic agonists decrease activity. Metabolic acidosis promotes exchange of intracellular K^+ for extracellular H^+ , resulting in hyperkalemia. Organic acidoses such as lactic acidosis or diabetic ketoacidosis may not produce hyperkalemia, because lactate and β -hydroxybutyrate anions can shift into cells along with H^+ . Metabolic alkalosis produces hypokalemia as potassium moves into cells to buffer the outward shift of H^+ .

The gastrointestinal tract absorbs 90% of dietary potassium, which is 40–120 mEq/day on an average western diet, an amount equivalent to that of extracellular potassium. Stimulated by insulin and catecholamines, intracellular potassium uptake prevents immediate postprandial hyperkalemia. Stool losses account for 10–20 mEq/day of potassium excretion, but this amount can increase with diarrhea and chronic renal insufficiency. The kidney regulates net potassium balance via the principal cells in the distal nephron. In response to hyperkalemia or high renin and angiotensin II levels, aldosterone increases potassium excretion by stimulation of the basolateral $\text{Na}^+ - \text{K}^+$ -ATPase pump.

Hypokalemia

Etiology and Differential Diagnosis

Defined as a plasma $[\text{K}^+] < 3.5$ mEq/L, hypokalemia results from decreased intake, increased loss, or intracellular redistribution (17,18). Pseudohypokalemia may occur rarely in

leukemia patients when abnormal leukocytes take up extracellular potassium after phlebotomy. Rapid separation of the plasma after phlebotomy prevents this artifact. In an individual patient with true hypokalemia, one or more pathophysiological mechanisms may be implicated. Low dietary intake rarely produces hypokalemia because renal excretion can decrease to less than 15 mEq/day. Starvation may reduce total body potassium stores, but tissue catabolism will preserve serum $[K^+]$. Causes of increased potassium loss can be either renal, gastrointestinal, or dermal (via excessive sweating). Gastrointestinal losses result from diarrhea, fistulas, and cathartic use. Renal potassium losses fall into two categories: mineralocorticoid excess (either real or apparent) and impaired renal sodium-chloride transport (Barter syndrome and Gitelman syndrome). The mineralocorticoid group includes primary hyperaldosteronism, adrenal hyperplasia, Cushing syndrome, Liddle syndrome, and others (18,19). Redistribution hypokalemia includes hyperthyroidism, familial hypokalemic periodic paralysis, delirium tremens, and increased cell production (treatment of anemia with vitamin B₁₂ or folate, granulocyte colony stimulating factor (GM-CSF) therapy, and parenteral nutrition).

Numerous medications cause hypokalemia (18). Excluding cathartic agents, drugs cause hypokalemia either by redistributing potassium into cells or by increasing renal potassium excretion (Table 104.3).

TABLE 104.3
MAJOR CAUSES OF HYPOKALEMIA

Pseudohypokalemia
Redistribution
Hyperthyroidism
Familial hypokalemic periodic paralysis
Delirium tremens
Increased cell production
Decreased intake
Gastrointestinal losses
Diarrhea
Fistulas
Renal losses
Mineralocorticoid excess
Barter syndrome and Gitelman syndrome
Drugs that redistribute potassium into cells
β_2 -agonists (epinephrine, decongestants, bronchodilators, tocolytics)
Xanthines (caffeine, theophylline)
Verapamil
Chloroquine
Insulin
Drugs that increase renal potassium excretion
Diuretics
Mineralocorticoids
High-dose glucocorticoids and antibiotics
Magnesium-depleting drugs (aminoglycosides, cisplatin, foscarnet, and amphotericin B)

Clinical Manifestations

Hypokalemia is usually asymptomatic unless the plasma concentration falls below 3.0 mEq/L. In contrast to dysnatremias, where the symptoms are primarily neurologic, symptoms of potassium disorders are primarily muscular and cardiac. The first manifestations are fatigue, myalgias, and muscle weakness of the lower extremities. Severe hypokalemia may progress to respiratory muscle depression, hypoventilation, complete ascending paralysis, and death. Smooth muscle dysfunction may manifest as a paralytic ileus. Rhabdomyolysis with myoglobinuria and renal failure can also be seen. Electrocardiographic (ECG) changes are caused by delayed ventricular repolarization but do not correlate well with the severity of hypokalemia. Early changes include flattening or inversion of the T wave, a prominent U wave, ST-segment depression, and prolonged QT interval. Severe hypokalemia may result in PR-interval prolongation, widening of the QRS complex, and ventricular arrhythmias. Cardiac ischemia, heart failure, and left ventricular hypertrophy increase the likelihood of arrhythmias. Hypokalemia increases the risk of digoxin toxicity; both can cause ST-segment depression on ECG. Rapid changes in plasma $[K^+]$ should be avoided during hemodialysis in patients taking digoxin. Hypokalemia can exacerbate hypertension, particularly in African-Americans. Hypokalemia promotes ammoniogenesis and may increase hepatic encephalopathy in susceptible patients.

Therapy

Therapeutic goals are correction of potassium level, avoidance of iatrogenic hyperkalemia, and correction of the underlying cause if possible. The plasma potassium concentration does not correlate well with total body stores in cases of redistribution. The classic example is diabetic ketoacidosis, where renal potassium losses from osmotic diuresis can be masked by insulin deficiency and extracellular redistribution of intracellular potassium. These patients may have intracellular hypokalemia and low total body potassium stores, with normal or high serum potassium levels. However, in the absence of potassium redistribution, each 1.0 mEq/L decrease in the serum concentration reflects a 200 to 300 mEq reduction in total body stores. Oral replacement is the preferred route because the slower absorption prevents hyperkalemia. Except in patients with metabolic acidosis, potassium chloride is preferred over bicarbonate or citrate-based formulations because chloride minimizes renal potassium losses. Potassium phosphate may be used in patients with concomitant hypophosphatemia. Intravenous replacement can be given at 10 mEq/hr through a peripheral IV, 20 mEq/hr via a central line, or 40 mEq/hr via a central line with continuous ECG monitoring. In nondiabetic patients, intravenous potassium in dextrose solution can paradoxically decrease

plasma levels by causing redistribution of potassium into cells. Thus, intravenous potassium should be delivered in saline. Hypomagnesemia can produce renal potassium wasting and refractory hypokalemia. Patients with diuretic-induced hypokalemia may require chronic potassium supplementation, a high potassium diet, or the addition of a potassium-sparing diuretic (e.g., triamterene, amiloride, or spironolactone).

Criteria for hospitalization, ECG monitoring, and ICU admission are neither clearly defined nor universally accepted. Symptomatic hypokalemia requires aggressive replacement, frequent monitoring of plasma potassium, and possible hospitalization. Patients with ECG changes should be considered for continuous monitoring and ICU admission. Nephrology consultation may be required in cases of renal potassium wasting without an identifiable cause. Cases of surreptitious diuretic use, laxative use, and self-induced vomiting may benefit from social services or psychiatric consultation.

Outcomes

A recent retrospective analysis examined the management of inpatients with severe hypokalemia (defined as $[K^+] < 3.0$ mEq/L) in a university hospital (20). Hypokalemia was present in 2.6% of all patients; 28% were admitted with hypokalemia, while 72% developed hypokalemia during hospitalization. Hospital mortality was 20.4% in hypokalemic patients, compared with 1.9% for all patients. Mortality rates increased with the degree of hypokalemia. Thirty percent of patients were discharged with hypokalemia. A random sample of 100 medical records were reviewed for "appropriate management," defined as potassium replacement or initiation of potassium-sparing agents. In 76% of cases, medical management was considered adequate (20).

Hyperkalemia

Etiology and Differential Diagnosis

Defined as a plasma concentration greater than 5.0 mEq/L, hyperkalemia results from increased intake, redistribution, and impaired renal excretion (Table 104.4). Increased intake is rarely a cause of hyperkalemia unless there is impaired renal excretion. However, herbal supplements, salt substitutes, and blood transfusion are exogenous potassium sources that can cause hyperkalemia (21). Iatrogenic hyperkalemia may result from inappropriate potassium replacement. Pathological conditions such as intravascular hemolysis, rhabdomyolysis, and tumor lysis syndrome can produce hyperkalemia via redistribution and release of intracellular potassium. Redistribution hyperkalemia can also result from hyperglycemia, insulin deficiency, hypertonicity, and acidosis. Impaired renal excretion of potassium may involve decreased glomerular filtration (either acute or chronic) or an intrinsic

defect in excretion (e.g., a renal tubular acidosis). Medications can cause hyperkalemia through redistribution or impaired excretion. *Pseudohyperkalemia* results from release of intracellular potassium caused by fist clenching, prolonged tourniquet use, and marked leukocytosis or thrombocytosis. This diagnosis should be considered in any asymptomatic patient with an elevated serum potassium but no obvious cause of hyperkalemia.

A recent study in a tertiary care university hospital found that hyperkalemia was often multifactorial; 77% of patients had renal failure, 63% were on medications that can contribute to hyperkalemia, 49% were hyperglycemic, 17% were acidemic, and 15% were receiving potassium supplements or total parenteral nutrition (22).

Clinical Features

By increasing the resting membrane potential, hyperkalemia may cause prolonged depolarization, producing weakness, flaccid paralysis, and respiratory muscle weakness with hypoventilation. As with hypokalemia, ECG changes correlate poorly with the severity of hyperkalemia. Early signs include T-wave peaking and progress to PR-interval prolongation, widening of the QRS complex, and loss of P waves. Patients with left ventricular hypertrophy

and/or congestive heart failure are more susceptible to malignant arrhythmias such as ventricular tachycardia, ventricular fibrillation, and sudden cardiac death. The cardiac effects of hyperkalemia are enhanced by hyponatremia, hypocalcemia, and acidemia.

Treatment

The degree of hyperkalemia, muscle weakness, and ECG changes determines the necessity for and rapidity of treatment. Emergent therapy for severe hyperkalemia has three components: minimizing membrane depolarization, shifting potassium into cells, and removing potassium from the body (23,24). Therapy should also include correcting the underlying cause if possible, stopping or avoiding offending medications, and removing all exogenous potassium sources. The initial therapy for patients with hyperkalemic ECG changes is intravenous calcium (e.g., 10 mL of 10% calcium gluconate), which decreases membrane excitability and reverses ECG changes within minutes. Its effect is short-lived (30–60 minutes). The transient hypercalcemia of calcium infusions may enhance the cardiac toxicity of digoxin; calcium should be given as a slow infusion over 30 minutes. Insulin (e.g., 10 units of regular insulin IV) shifts potassium into cells and will decrease $[K^+]$ by 0.5–1.5 mEq/L in 15–30 minutes. The effect may last for several hours. Glucose (25–50 grams IV) is given to prevent hypoglycemia but should be withheld in hyperglycemic patients. Nebulized albuterol, a β_2 -adrenergic agonist, in doses of 10–20 mg (compared with 2.5 mg for bronchodilation) will have a similar onset of action and effect as insulin. Intravenous sodium bicarbonate (e.g., an isotonic solution of three ampules, or 150 mEq/L in D5W) should be reserved for patients with concomitant metabolic acidosis and may be ineffective in patients with end-stage renal disease. Patients with volume overload may not tolerate the additional sodium load.

Definitive therapy, potassium removal, can be achieved with diuretics, cation-exchange resin, or hemodialysis. Loop and thiazide diuretics increase potassium excretion if renal function is adequate. Sodium polystyrene sulfonate (Kayexalate) is a cation exchange resin that absorbs gastrointestinal potassium in exchange for sodium; each gram binds 1 mEq of potassium. Given orally or rectally in doses of 30–60 grams, the resin is usually delivered with sorbitol to prevent constipation. This mixture should be avoided in postoperative patients because of the risk of sorbitol-induced colonic necrosis, especially in renal transplantation patients. While effective, the resin has a delayed onset of action of 1–2 hours. Hemodialysis effectively and quickly removes potassium and corrects metabolic acidosis, but significant time may be required for nephrology consultation, catheter insertion, and dialysis preparation. Peritoneal dialysis and continuous renal replacement therapy correct potassium too slowly for treatment of acute hyperkalemia.

Criteria for hospitalization are poorly defined. A recent retrospective analysis compared patients hospitalized for

hyperkalemia to those treated as outpatients; no significant differences in acid-base status, electrolyte levels, and renal function were found (25). Failure to discontinue use of all medications that promote hyperkalemia was common. The authors suggested hospitalization for severe hyperkalemia (≥ 8.0 mEq/L with ECG changes other than peaked T waves), acute worsening of renal function, and supervening medical problems (26). Patients with $[K^+]$ between 6.5 and 8.0 mEq/L and ECG changes limited to peaked T waves can be successfully treated in the emergency department. Patients with milder hyperkalemia can be treated as outpatients. Continuous electrocardiographic monitoring is indicated for patients with severe hyperkalemia and/or ECG changes, although there are no universally accepted criteria for monitoring. Nephrology consultation should be considered for patients with end-stage renal disease, hyperkalemia with ECG changes, and renal tubular acidosis.

Outcomes

Recent evidence suggests that physicians poorly manage in-hospital hyperkalemia. One study found that only 39% of episodes satisfied published criteria for diagnosis, treatment, and follow-up of hyperkalemia (22). Only 30% of patients had a 12-lead ECG, 46% of which had typical changes of hyperkalemia (despite the study threshold of $[K^+] > 6.0$ mEq/L). Computer ECG interpretations were not reliable; only one of 33 available interpretations was consistent with hyperkalemia (22). The mortality of patients hospitalized with hyperkalemia is difficult to estimate. One study reported a mortality rate of 17% among 35 adult inpatients with $[K^+] > 5.5$ mEq/L, although none died of hyperkalemic arrhythmias (25). Another study of 242 episodes reported no deaths from hyperkalemia and no significant morbid events from treatment (22).

KEY POINTS

- Many electrolyte abnormalities can be prevented by careful review of medications and proper fluid management.
- Potassium disorders reflect abnormal potassium handling, while sodium disorders reflect abnormal water handling.
- Dysnatremias lead to primarily neurologic symptoms, while dyskalemias are associated with muscular and cardiac symptoms.
- Treatment of hyponatremia may be more hazardous than the hyponatremia itself.
- Hypernatremia reflects a free water deficit and often occurs with decreased access to free water. It is frequently preventable or iatrogenic.
- ECG changes correlate poorly with the degree of potassium disturbance.
- Hyperkalemia is often multifactorial; renal failure is often implicated.

Common Acid–Base Disorders

105

Orson W. Moe Daniel Fuster Robert J. Alpern

INTRODUCTION

Acid–base disturbances represent a diverse group of disorders commonly encountered in patients presenting to the emergency room as well as in hospitalized patients. The identification of acid–base disorders per se does not establish an end point in the diagnostic process but rather serves to alert and direct the clinician to search for and address the underlying diseases that generated the disturbances. The treatment of acid–base disorders is largely directed at the underlying cause, although primary correction of the alkali or acid deficit also is indicated in certain situations. The spectrum of clinical outcomes of diseases associated with acid–base disturbances ranges from the completely benign to the imminently life-threatening. Therefore, the hospital physician must come rapidly to the correct diagnosis and initiate the appropriate treatment.

Although the body continually is faced with acid loads that are many orders of magnitude higher than the free hydrogen concentration in the plasma, normal individuals are able to maintain the plasma pH within a narrow range. Two defense mechanisms contribute to this homeostasis. First, buffers are present in all body compartments and cushion the effect of any acid or alkali assault. Second, external acid–base balance is maintained by eliminating acid (or alkali) in an amount commensurate to that added to the body. A mismatch between addition and excretion of acid (or alkali) constitutes the fundamental pathophysiology of all acid–base disorders. Volatile acids such as carbonic acid are excreted in the lungs; nonvolatile acids such as those derived from dietary proteins are excreted by the kidneys. Clinical disorders of acid–base balance are divided into those of *respiratory* and *metabolic* origin. In respiratory acid–base disorders, carbon dioxide accumulation

or depletion results from primary abnormalities of lung function. In metabolic disorders, nonvolatile acid or alkali accumulates as a result of renal or extrarenal derangements.

Because acid–base disorders are largely laboratory diagnoses, several concepts deserve emphasis. One is the distinction between *acidemia* (or *alkalemia*) and *acidosis* (or *alkalosis*). Acidemia and alkalemia simply refer to deviations of blood pH from normal. Acidosis and alkalosis refer to processes that lead to an abnormal excess of acid or alkali. A patient with a well-compensated acidosis can have a near-normal blood pH; one with a mixed acid–base disorder can have a completely normal pH. The terms *acidosis* and *alkalosis* always indicate pathology and should not be used to describe a normal compensatory process. For example, a normal physiologic increase in ventilation and lowering of blood carbon dioxide tension ($p\text{CO}_2$) in response to a metabolic acidosis should not be referred to as respiratory alkalosis.

Although the interpretation of electrolytes alone is informative and often can reveal the correct acid–base diagnosis, *it is frequently necessary to obtain blood-gas measurements* to be certain of the diagnosis. For example, a patient with a high plasma bicarbonate concentration ($[\text{HCO}_3^-]$) is either suffering from a metabolic alkalosis or compensating for a respiratory acidosis. Likewise, a patient with a low plasma $[\text{HCO}_3^-]$ either has a metabolic acidosis or is compensating for a respiratory alkalosis. In each of these examples, the clinical history and a careful physical examination often can distinguish the two possibilities. However, blood gases yield additional and often critical information. For instance, no matter what the primary disorder is, one needs to know whether the secondary compensation is appropriate. Thus, blood-gas analysis may provide the sole indication of a mixed acid–base disorder. For primary respiratory

acid–base disturbances, knowledge of the arterial oxygen tension and the calculated alveolar–arterial oxygen tension (pO_2) is an integral part of the laboratory interpretation and guides management of the patient.

Once these analyses have been completed, the physician should know whether he or she is dealing with an acidosis or an alkalosis, whether it is metabolic or respiratory in origin, and whether the appropriate compensations have occurred. In this chapter, a brief summary is presented for each of these disorders. Although these diagnoses are largely based on laboratory data, one must underscore the importance of the clinical history and examination in alerting the clinician to look for mixed disorders and in identifying the cause of the acid–base disturbances.

METABOLIC ACIDOSIS

In general, metabolic acidosis is rarely the sole reason for admission to the hospital, but *the presence of metabolic acidosis always necessitates a careful search for an underlying cause*. Patients with metabolic acidosis are admitted for conditions that may or may not be related causally to the acidosis. Metabolic acidosis is usually detected as a low serum $[HCO_3^-]$. It is important to remember that a low serum $[HCO_3^-]$ associated with a normal to slightly increased anion gap may result from primary respiratory alkalosis with metabolic compensation. If the clinical setting suggests the cause of a primary metabolic acidosis, it may not be necessary to measure an arterial blood gas. The only finding on physical examination indicative of a metabolic acidosis is the slow, deep breathing pattern known as Kussmaul respirations.

Diagnostic Approach

After a primary metabolic acidosis is documented, the next step in the clinical approach is to assess the plasma or serum *anion gap* (Figure 105.1), the difference between unmeasured cations and unmeasured anions. This is calculated as: $Anion\ gap = Na^+ - (Cl^- + HCO_3^-)$.

A normal anion gap is 8 to 16 mEq/L. An increased anion gap can help pinpoint the underlying cause of metabolic acidosis. Because the normal range of the anion gap is rather broad, a mild elevation on a single laboratory sample should not be considered diagnostic.

Elevated Anion Gap

Conditions associated with an increased anion gap include ketoacidosis, lactic acidosis, ingestion of poisons, and advanced renal failure. With the possible exception of renal failure, all these conditions are medical emergencies that require rapid definitive diagnosis. The clinical effects of severe metabolic acidosis are myriad and affect multiple organs. In the acute setting, the most life-threatening

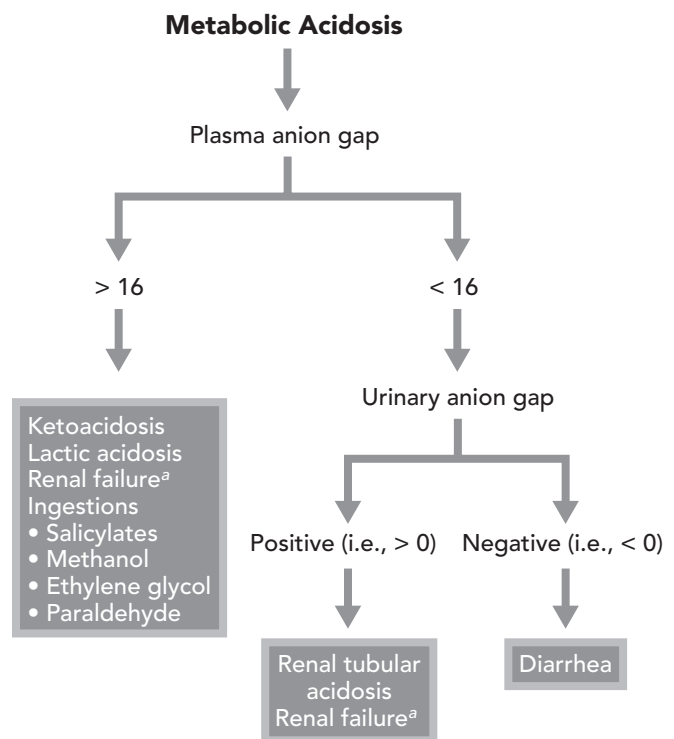

Figure 105.1 Approach to the patient with primary metabolic acidosis. ^a Renal insufficiency may be associated with a normal or increased anion gap.

sequelae are depressed cardiac contractility and vascular collapse. *Lactic acidosis* usually occurs secondary to tissue hypoxia. It should be suspected in a patient with low blood pressure or a known infection. *Ketoacidosis* occurs in conditions in which the body switches from carbohydrate to fat metabolism. Known diabetic and alcoholic patients who recently have stopped ingesting food are at risk for ketoacidosis. Measurement of serum lactate and ketones confirms the diagnosis of lactic acidosis and ketoacidosis, respectively. *Overdoses and ingestions* associated with anion-gap acidosis include salicylates (which can generate lactic and ketoacidosis) and methanol or ethylene glycol, which are metabolized to organic acids. Salicylate overdoses are suggested by a coexistent respiratory alkalosis and tinnitus. Methanol and ethylene glycol intoxication are associated with an increased osmolar gap; measured plasma osmolality is more than 10 mOsm/L greater than that calculated from the following formula: $Plasma\ osmolality\ (calculated) = 2\ Na^+ + glucose / 18 + blood\ urea\ nitrogen / 2.8$.

Methanol intoxication is associated with retinal pallor and visual complaints; ethylene glycol intoxication causes renal failure, calcium oxalate crystalluria, and symptoms of hypocalcemia. These clinical features are often absent, in which case the only clue to these diagnoses is elevation of both the osmolar and anion gaps. Delays in the recognition and treatment of methanol or ethylene glycol poisoning

result in poor outcomes; early recognition and management (including dialytic therapy) are highly effective (Chapter 121).

Normal Anion Gap

A significant proportion of regulated acid excretion is in the form of NH_4^+ . For clinical purposes, urinary NH_4^+ level can be used to assess renal acid excretion. In anion gap acidoses such as ketoacidosis, lactic acidosis, or poisons, measuring renal acid excretion is of little relevance because the acid production rate is so high that even a perfect renal response would not be able to correct the acidosis. Renal acid excretion is of more clinical interest if there is a normal anion-gap metabolic acidosis. This form of metabolic acidosis can result from gastrointestinal bicarbonate loss (e.g., massive diarrhea) or failure of the kidneys to excrete acid (i.e., renal acidosis). The distinction between these two groups of disorders is based on the urinary NH_4^+ excretion. In extrarenal acidoses such as diarrhea, urinary NH_4^+ excretion is increased. In renal acidosis, the urinary NH_4^+ level is inappropriately low. Urinary NH_4^+ excretion is regulated by changes in NH_3 synthesis, as well as by H^+ secretion. Urinary pH is a poor indicator of acid excretion in the urine because the amount of acid (primarily NH_4^+) in the urine cannot be estimated from the urinary pH alone. In patients with chronic diarrhea, increased urinary NH_4^+ excretion is associated with a urinary pH greater than 5.5. Conversely, in acidosis of chronic renal disease, NH_3 synthesis is decreased and low levels of urinary NH_4^+ excretion are associated with a low urine pH (<5.5).

Clinically, the most readily available estimate of urinary ammonium excretion is based on the *urinary anion gap*, which is calculated as follows: urinary anion gap = urinary Na + urinary K – urinary Cl.

In the normal physiological steady state, when urinary NH_4^+ excretion is in the normal range, the urinary anion gap is positive (20–60 mmol/L). In patients with a chronic metabolic acidosis of extrarenal origin and normal renal function, urinary NH_4^+ excretion increases significantly. Because NH_4^+ is excreted as NH_4Cl , this leads to a significant increase in urinary $[\text{Cl}^-]$, causing the urinary anion gap to become more negative (<0 mmol/L). Patients with all forms of acidosis of renal origin fail to increase urinary NH_4^+ excretion appropriately for the level of acidosis and thus have a positive urinary anion gap (>0 mmol/L).

Patients with renal acidosis may have either renal insufficiency or a renal tubular acidosis. It is important to remember that renal insufficiency can be associated with a normal or increased plasma anion gap. The high anion gap results from a failure of the kidney to excrete unmeasured anions such as sulfate, while the generation of acidosis results from a failure of the kidney to excrete sufficient acid (NH_4^+) in the urine. Although these defects both frequently occur around a glomerular filtration rate of 20 mL/min, they can occur independent of each other.

Figure 105.2 shows the workup for a patient with renal tubular acidosis. Table 105.1 lists the causes of renal tubular acidosis. Hyperkalemic distal renal tubular acidosis is caused either by a decrease in mineralocorticoid activity or by an abnormal cortical collecting duct. These defects lead to defects in both K^+ and H^+ secretion, resulting in hyperkalemic acidosis (1). Low mineralocorticoid states can be associated with low renin and aldosterone levels (*hyporeninemic hypoaldosteronism*) or with isolated decreases in aldosterone secretion (*hypoaldosteronism*). Hypokalemic distal renal tubular acidosis is most commonly associated with hypergammaglobulinemic disorders, such as Sjögren syndrome in adults. It also can be seen with amphotericin B therapy. Proximal renal tubular acidosis and Fanconi syndrome (generalized proximal tubule dysfunction) occurring in adults is usually associated with dysproteinemic disorders such as multiple myeloma and monoclonal gammopathies. Regardless of the cause of the metabolic acidosis, the lung compensates for the low $[\text{HCO}_3^-]$ by

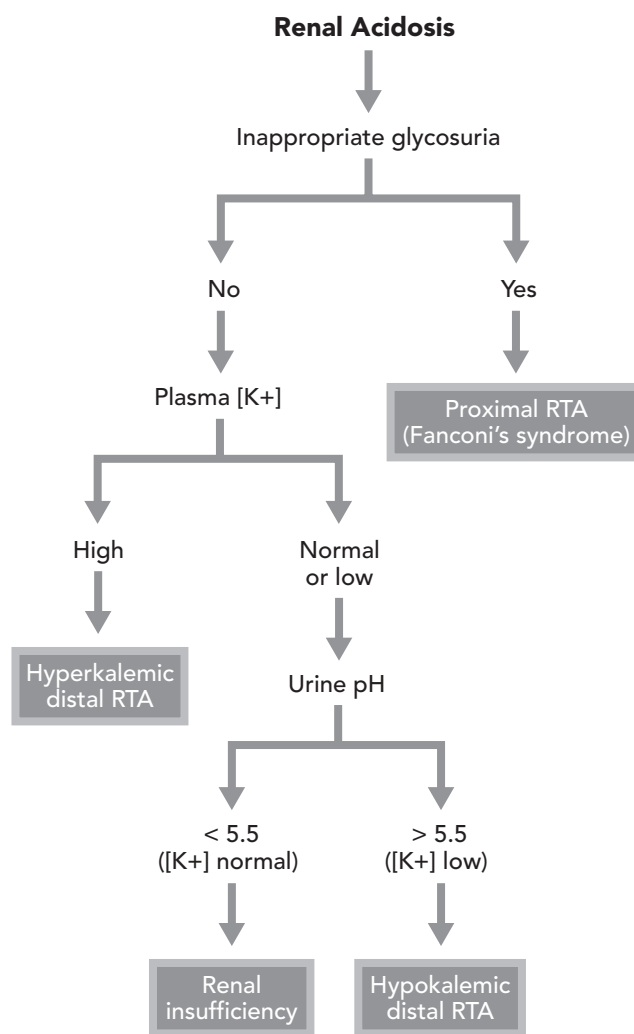

Figure 105.2 Workup of the patient with renal acidosis. RTA, renal tubular acidosis.

CAUSES OF RENAL TUBULAR ACIDOSIS

Hyperkalemic distal
Decreased mineralocorticoid activity
Hyporeninemic hypoaldosteronism
Glomerular and interstitial disease, e.g., diabetes
Nonsteroidal anti-inflammatory drugs
Hypoaldosteronism
Adrenal insufficiency
Heparin
Angiotensin-converting enzyme inhibitor
Abnormal cortical collecting duct
Obstruction
Systemic lupus erythematosus
Diabetes
Sickle-cell disease
Hypokalemic distal
Hypergammaglobulinemic disorders: Sjögren syndrome
Amphotericin B
Congenital disorders of H ⁺ or HCO ₃ ⁻ transporters
Proximal
Dysproteinemias
Multiple myeloma
Monoclonal gammopathies
Amyloidosis
Congenital disorders of HCO ₃ ⁻ transporter

increasing alveolar ventilation and lowering pCO₂. For every 10 mEq/L fall in serum [HCO₃⁻], one expects a fall in pCO₂ of 10 to 15 mm Hg. Deviation from the expected compensation should alert the clinician to look for superimposed respiratory acid–base disturbances.

Treatment Issues

The management of acute metabolic acidosis in the hospital usually is directed at the underlying disorder. Level of care and monitoring are dictated by the nature of the causative disorder. One key decision related to metabolic acidosis is whether to administer bicarbonate or to wait for other treatment to correct the acidosis. In general, it is not necessary to treat with alkali, because most levels of metabolic acidosis seen clinically are not immediately life threatening. However, if the plasma pH is less than 7.15 and reversal of the underlying disorder of acid generation is not imminent, alkali therapy can be administered. If one does treat metabolic acidosis, it is important to give enough bicarbonate to accomplish one's goal. Because metabolic acidosis is associated with increased acid–base buffering and an increased apparent volume of distribution of bicarbonate, one can use the following equation to guide the therapy: administered HCO₃⁻ = ΔHCO₃⁻_{serum} × body weight in kg (Example: 4 ampules of each 50 ml 8.4% NaHCO₃⁻-solution [ampule [HCO₃⁻] concentration 1 mmol/mL] administered to a patient with a body weight of 100 kg would increase the patient's serum [HCO₃⁻] by 2 mmol/L).

It is important to note that this equation merely guides the initial dose of bicarbonate. As bicarbonate deficits vary tremendously among individuals with the same plasma bicarbonate concentration, modifications must be made based on response. It is imperative that one not neglect the reversal of the underlying disease simply because alkali therapy is correcting the plasma bicarbonate level transiently.

In adult ethylene glycol and methanol poisoning, metabolism of the poisons to their toxic metabolites can be inhibited by the administration of *fomepizole*, an alcohol dehydrogenase inhibitor (2,3). Fomepizole treatment can be combined with hemodialysis and has proven safe and effective. After initial loading of 15 mg/kg intravenously, 10 mg/kg q 12 hrs intravenously for four doses are administered, followed by 15 mg/kg q 12 hrs intravenously until methanol or ethylene glycol levels become undetectable. With simultaneous hemodialysis, dosage frequency needs to be increased to q 4 hrs.

Although alkali treatment of acute metabolic acidosis is usually unnecessary, the treatment of chronic metabolic acidosis is important. The sequelae of untreated chronic metabolic acidosis include muscle wasting, nephrocalcinosis, nephrolithiasis, and loss of bone density. Patients with this problem can be given either bicarbonate or citrate. Citrate is better tolerated but cannot be used in patients with renal insufficiency who are taking aluminum-containing phosphate binders, because it enhances aluminum absorption. Alkali can be administered as Na⁺ or K⁺ salts. K⁺ salts are somewhat advantageous in that Na⁺ administration increases urinary Ca²⁺ excretion and also can worsen hypertension. Such treatment regimens need not be started in the hospital but are most conveniently initiated before discharge.

METABOLIC ALKALOSIS

Again, patients are rarely admitted for the sole indication of metabolic alkalosis but generally are admitted for conditions either causative of or concurrent with metabolic alkalosis. This problem usually manifests as a high plasma HCO₃⁻ level. Elevated plasma [HCO₃⁻] can be caused by either a primary metabolic alkalosis or a primary respiratory acidosis with metabolic compensation. If the cause of metabolic alkalosis is obvious and hypoventilation is not suspected, arterial blood-gas measurements are not necessary. The finding of hypokalemia with a high serum [HCO₃⁻] also suggests metabolic alkalosis rather than respiratory acidosis. The respiratory compensation for metabolic alkalosis can be incomplete because the alkalemia-induced ventilatory suppression is overridden by secondary hypoxemia.

Diagnostic Approach

The differential diagnosis of metabolic alkalosis depends on the assessment of the effective arterial volume (Figure

105.3). In most patients with metabolic alkalosis, effective arterial volume is decreased, and the kidney attempts to compensate by retaining sodium bicarbonate. Metabolic alkalosis is not an invariant finding in all patients with a low effective arterial volume. However, once alkalosis is generated, a low effective arterial volume triggers the kidney to maintain the alkalosis. A low effective arterial volume is suggested by a constellation of findings, including postural changes in pulse or blood pressure, low central venous pressure, a low urinary $[\text{Na}^+]$ or $[\text{Cl}^-]$, and a high blood urea nitrogen or serum uric acid level.

The two most common conditions causing low effective arterial volume are vomiting and diuretic use. In vomiting, loss of hydrochloric acid (HCl) from the stomach generates an alkalosis, and low effective arterial volume maintains it. With diuretics, the kidney is responsible for both the generation and maintenance of the metabolic alkalosis. In patients with no apparent cause of metabolic alkalosis, magnesium deficiency should be considered because it also can lead to renal generation and maintenance of the alkalosis. *Posthypercapnic alkalosis* refers to chronic hypercapnia, leading to a compensatory increase in the serum $[\text{HCO}_3^-]$. Correction of the hypercapnia then should lead to correction of the alkalosis. However, if a patient is volume contracted, alkalosis fails to correct and there is a persistent posthypercapnic alkalosis.

Metabolic alkalosis also may be associated with an increased effective arterial volume and hypertension. In this setting, it is maintained by increased mineralocorticoid activity or level, which stimulates urinary acid excretion. These disorders represent the most common causes of curable secondary hypertension. Importantly, the triad of hypertension, metabolic alkalosis, and hypokalemia is not always present in hyperaldosterone states.

If volume depletion is absent in a patient with metabolic alkalosis, the next diagnostic step depends upon serum renin and aldosterone levels. Because there are wide ranges of normal plasma renin and aldosterone levels, random plasma levels should be interpreted cautiously, in the context of volume status and dietary NaCl intake. Simultaneous low renin and high aldosterone levels can be diagnostic regardless of volume status. As shown in Figure 105.3, renin and aldosterone levels may both be high (*primary hyperreninemia*), renin may be low and aldosterone high (*primary hyperaldosteronism*), or both renin and aldosterone levels may be low (*aldosterone-independent mineralocorticoid effect*). In the case of both high renin and high aldosterone levels, it is important to distinguish primary hyperreninism from low effective arterial volume. All causes of metabolic alkalosis associated with a low effective arterial volume are associated with high renin and aldosterone levels. If uncertainty exists about the effective arterial volume, it is useful

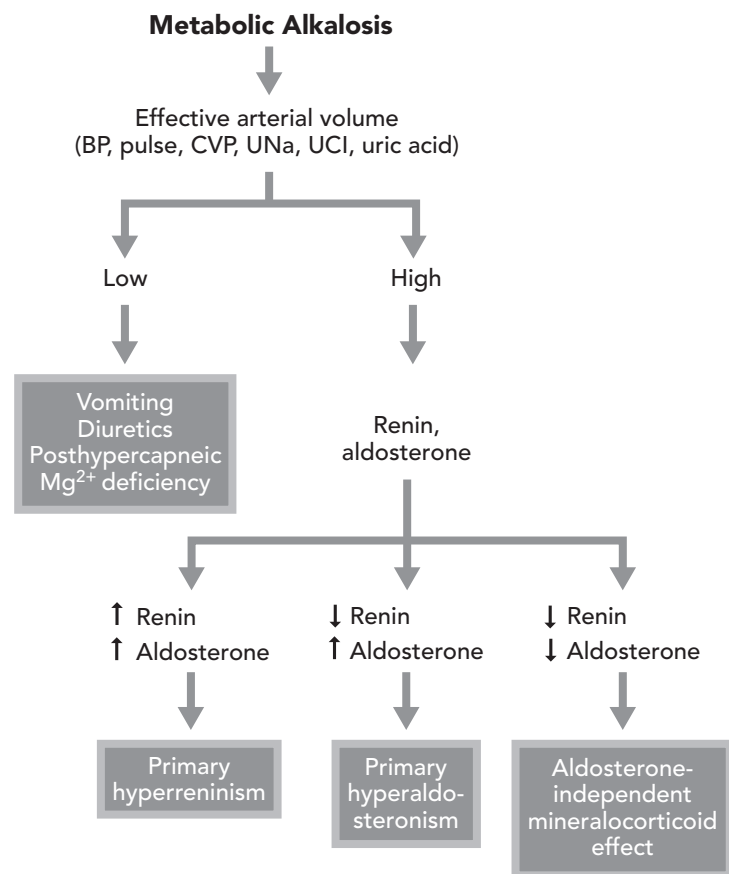

Figure 105.3 Approach to the patient with metabolic alkalosis. BP, blood pressure; CVP, central venous pressure; UCl, urine chloride; UNa, urine sodium.

to perform a saline-suppression test. The high renin and aldosterone levels secondary to hypovolemia normalize in response to saline infusion, whereas this response is not seen with primary hyperreninism.

Table 105.2 lists the more common causes of metabolic alkalosis associated with hypermineralocorticoid states. Primary hyperreninism is most frequently associated with *renovascular disease*, although a majority of patients with renovascular disease do not exhibit hypokalemic alkalosis. Renovascular disease can be diagnosed by renal angiography (Chapter 48). Primary hyperaldosteronism usually is caused either by an adrenal adenoma or a bilateral adrenocortical hyperplasia. The distinction between these disorders is extremely important, because aldosterone-secreting adenomas can be cured by unilateral adrenalectomy. In contrast, adrenalectomy is not recommended for bilateral adrenocortical hyperplasia. The distinction between these two disorders is based upon computed tomography results and adrenal vein sampling.

The combination of metabolic alkalosis, hypertension, and low renin and aldosterone levels frequently occurs in patients with *Cushing syndrome* (Chapter 106). The magnitude of the hypokalemia and alkalosis depend on the level of cortisol and typically are most severe in ectopic ACTH syndrome. Other possibilities to consider in this setting are licorice ingestion and Liddle syndrome, a rare familial disorder caused by a mutation in the cortical collecting duct luminal membrane Na^+ channel.

Treatment Issues

Clinical decisions regarding hospitalization or ICU admission are based on the associated disorders rather than the metabolic alkalosis per se. Metabolic alkalosis usually does not require treatment acutely. However, there are a few situations in which acute treatment is recommended. In patients with chronic obstructive lung disease, respiratory suppression caused by the metabolic alkalosis may be problematic. Also, in patients with cerebral or cardiac ischemia, tissue hypoxemia may occur secondary to an alkalo-

losis-induced increase in the oxygen affinity of hemoglobin and vasoconstriction. In these settings, the alkalosis can be corrected by treating the cause responsible for maintenance of the alkalosis (decreased effective arterial volume, primary increase in mineralocorticoid). If one cannot treat the primary cause and if pH is greater than 7.55, metabolic alkalosis can be corrected with carbonic anhydrase inhibitors such as acetazolamide, 250 to 500 mg given orally every 8 hours with strict monitoring of electrolytes. Alternatively, 0.1-N hydrochloric acid can be administered via central line at a rate of 10 to 20 mEq/h; this is generally safe if administered slowly.

RESPIRATORY ACIDOSIS

In general, respiratory acid–base disturbances have less complex underlying pathophysiologies than the metabolic disorders described previously. Metabolic acidosis may result from increased acid production, reduced acid disposal, or both. *In respiratory acidosis, the acid load is always from metabolic carbon dioxide.* However, increased carbon dioxide production alone does not lead to carbon dioxide accumulation if the ventilatory system is intact. For example, plasma pCO_2 changes minimally when carbon dioxide production rises from 15,000 mmol/d at rest to 450,000 mmol/d with heavy exercise. This 30-fold increase in carbon dioxide production is compensated completely by an increase in carbon dioxide excretion. Respiratory acidosis is invariably caused by abnormal carbon dioxide clearance, not increased production. In other words, in respiratory acidosis, one is dealing exclusively with a ventilatory problem, and therefore, for clinical purposes, one can *equate respiratory acidosis with alveolar hypoventilation*. Causes of alveolar hypoventilation are reviewed subsequently.

Diagnostic Approach

The clinical presentation of respiratory acidosis reflects the underlying pulmonary disease (Chapter 24). Carbon dioxide retention can lead to lethargy and coma (*carbon dioxide narcosis*), increased intracranial pressure, cardiac dysrhythmias, and impaired myocardial contractility. These effects are more pronounced if the carbon dioxide retention is acute. Of note is that physiologic hypoventilation secondary to metabolic alkalosis never compromises arterial oxygenation. Respiratory acidosis should be considered if there is a high plasma pCO_2 level (hypercapnia). If arterial blood gases have not been drawn, respiratory acidosis may be suggested by an elevated plasma $[\text{HCO}_3^-]$, reflecting renal compensation. Therefore, in a patient with a high plasma $[\text{HCO}_3^-]$, respiratory acidosis always should be excluded by measurement of arterial blood gases before proceeding to a full workup of metabolic alkalosis. Figure 105.4 shows an algorithm for the evaluation of respiratory acidosis.

Liddle syndrome

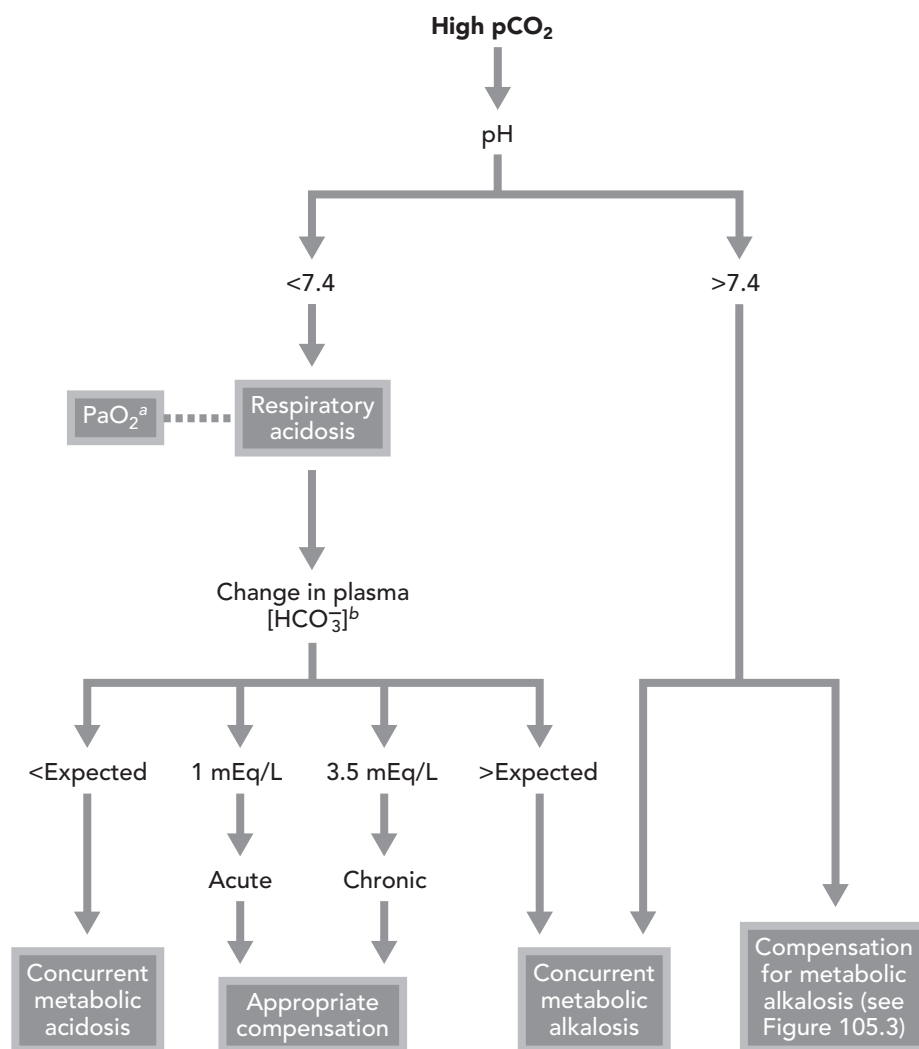

Figure 105.4 Approach to the patient with elevated $p\text{CO}_2$.

^a Hypoxemia may pose the most acute threat to patients with alveolar hypoventilation; oxygenation should be checked and treated promptly. ^b For each 10 mm Hg increase in $p\text{CO}_2$, in primary respiratory acidosis one expects serum $[\text{HCO}_3^-]$ to increase (from 24 meq/L) by 1 meq/L (in acute respiratory acidosis) to 3.5 meq/L (in chronic respiratory acidosis). $p\text{CO}_2$, partial pressure of carbon dioxide; PaO_2 , partial pressure of oxygen.

In a patient with hypercapnia, the clinician first should examine the blood pH. A high $p\text{CO}_2$ in the presence of alkalemia usually is caused by respiratory compensation for metabolic alkalosis. A high $p\text{CO}_2$ with acidemia secures the diagnosis of respiratory acidosis. There are then two further issues to consider. The first is the degree of rise in $[\text{HCO}_3^-]$ in response to carbon dioxide retention. The magnitude of the secondary change in serum $[\text{HCO}_3^-]$ may indicate superimposed metabolic disorders. For example, in a patient with chronic obstructive pulmonary disease and right-heart failure being treated with diuretics, a $p\text{CO}_2$ of 58 mm Hg and a pH of 7.36 would establish the diagnosis of respiratory acidosis. If the serum $[\text{HCO}_3^-]$ were 40 mmol/L, this would be inappropriately high for physiologic renal com-

ensation (expected serum $[\text{HCO}_3^-]$ around 32 mmol/L) and would indicate a mixed disorder of respiratory acidosis and metabolic alkalosis.

The second issue after establishing the diagnosis of respiratory acidosis is to determine the cause of the alveolar hypoventilation (Table 105.3). The first two categories ("would not breathe" and "could not breathe") represent pathologic alveolar hypoventilation; the third represents physiologic hypoventilation. A discussion of the neuroanatomy and pulmonary mechanics of ventilatory control is beyond the scope of this chapter, but hypoventilation can result from lesions in the respiratory center, the peripheral nerves controlling the diaphragm, the thoracic cage, and the lower and upper airways.

TABLE 105.3
CAUSES OF ALVEOLAR HYPOVENTILATION

"Would not breathe": pathologic decrease in central respiratory drive

- Pharmacologic respiratory depressants
 - Sedatives
 - Opiates
 - General anesthetics
- Primary central nervous system diseases
 - Neoplasm
 - Infection
 - Inflammatory
 - Hemorrhage
 - Idiopathic

"Could not breathe": impairment of ventilatory mechanisms

- Peripheral nerve
 - Pharmacologic: e.g., succinylcholine
 - Traumatic
 - Neoplastic invasion
 - Inflammatory: e.g., Guillain-Barré syndrome
- Diaphragm
 - Massive ascites
 - Myopathies
- Thoracic spine: kyphoscoliosis
- Chest wall/thorax
 - Flail chest
 - Malignant obesity
 - Pneumothorax
- Airway obstruction
 - Chronic obstructive pulmonary disease
 - Bronchospasm
 - Upper airway obstruction

"Should not breathe": physiologic decrease in central ventilatory drive

- Metabolic alkalosis

Treatment Issues

The management of respiratory acidosis is directed at the underlying cause. Indications for intubation and mechanical ventilation are covered in Chapter 23. Although the acidemia from hypercapnia may be dangerous, accompanying hypoxemia often poses the most immediate risk to survival. Two points regarding the acid–base aspects of hypoventilation management are key. The first concerns the rate of correction of the hypercapnia. If chronic respiratory acidosis is treated with mechanical ventilation, the compensatory metabolic changes persist after the normalization of $p\text{CO}_2$. If eucapnia is restored suddenly, formerly adaptive mechanisms can become detrimental. An example is the change that occurs in the affinity of hemoglobin for oxygen. Acidemia lowers the oxygen affinity of hemoglobin, which thereby enhances tissue oxygen delivery. During chronic respiratory acidosis, intraerythrocytic metabolic changes increase and restore the oxygen affinity of hemoglobin back toward normal. Upon sudden normalization of $p\text{CO}_2$, acidemia disappears, and the high serum $[\text{HCO}_3^-]$ greatly enhances the oxygen affinity of

hemoglobin, impairing oxygen release to tissues. This may result in tissue hypoxia, despite the presence of well-oxygenated arterial blood. The sudden alkalemia and the vasoconstriction it induces further aggravate this situation. Thus, one should not immediately and completely correct $p\text{CO}_2$ in treating a hypercapnic patient.

Chronic respiratory acidosis is frequently associated with metabolic alkalosis, particularly if diuretic agents are used. Even if metabolic alkalosis is not initially present, it may develop as hypercapnia is being corrected (see later in this chapter). Alkalemia suppresses ventilatory drive and thus may delay and impair the ability to improve ventilation and oxygenation. Carbonic anhydrase inhibitors such as acetazolamide (250 mg orally twice or three times daily) induce sufficient bicarbonaturia to lower plasma $[\text{HCO}_3^-]$ toward normal. Use of acetazolamide should be considered daily, with continued assessment of the patient's clinical and laboratory status guiding dosage modification or cessation. Acetazolamide therapy can lead to life-threatening hypokalemia, "overshoot" metabolic acidosis, and aggravate extracellular fluid volume contraction. Concurrent NaCl and KCl supplementation are frequently necessary. An alternative way of lowering serum $[\text{HCO}_3^-]$ is to infuse dilute HCl through a central venous catheter or to administer it orally. Either of these maneuvers can be used to facilitate weaning from mechanical ventilation or to improve oxygenation after transfer from the ICU.

The outcome of respiratory acidosis depends on the underlying cause. One cannot overemphasize the frequency and lack of recognition of metabolic alkalosis in patients with chronic respiratory acidosis. Chronic diuretic use is a common culprit. In addition to metabolic alkalosis, the potassium depletion caused by diuretic therapy can lead to respiratory muscle weakness and worsened hypoventilation. Aggressive diuretic therapy, therefore, should be reserved for patients with severe pulmonary, gastrointestinal, or peripheral edema, those with anorexia or dyspnea from ascites, or those with hepatic congestion.

RESPIRATORY ALKALOSIS

A number of the pathophysiologic principles discussed previously can be applied to respiratory alkalosis. *Respiratory alkalosis is synonymous with alveolar hyperventilation*. If the cause of alveolar hyperventilation is hypoxemia, respiratory alkalosis is an appropriate compensation to maintain oxygen saturation at the expense of acid–base homeostasis. A patient presenting with pulmonary disease and respiratory alkalosis who "normalizes" the $p\text{CO}_2$ and pH may be tiring and on the verge of impending respiratory failure (Chapter 24).

The clinical presentation of respiratory alkalosis reflects the underlying disease. The clinical examination may reveal dyspnea; increased respiration rate and tidal volume; symptoms and signs of neuromuscular irritability such as acroparesthesia, carpopedal spasm, or seizures; and cardiac

dysrhythmias. Hyperventilation is not pathognomonic for respiratory alkalosis because it may be a response to metabolic acidosis. Like respiratory acidosis, the diagnosis of respiratory alkalosis relies on laboratory data, especially arterial blood gases. Abnormalities in routine blood chemistries may be indistinguishable from those seen in the setting of normal anion gap metabolic acidosis. This confusion is compounded further by the fact that patients with metabolic acidosis usually have evidence of compensatory hyperventilation on physical examination. The reduced plasma $[\text{HCO}_3^-]$ level seen in patients with primary respiratory alkalosis may not be completely offset by an equivalent rise in Cl^- ; this results in a slight elevation of the anion gap. Therefore, it is imperative that arterial blood-gas measurements be used to evaluate the patient with respiratory alkalosis.

Diagnostic Approach

Figure 105.5 outlines the approach to a patient with a low pCO_2 . The presence of acidemia suggests that the hyperventilation is secondary to metabolic acidosis; the evaluation of the patient should proceed as outlined in Figure 105.1. Hypocapnia and alkalemia establishes the diagnosis of respiratory alkalosis. As discussed in the preceding section, hypocapnia causes secondary changes in serum $[\text{HCO}_3^-]$. Acute or chronic reduction in pCO_2 leads to lowering of the serum $[\text{HCO}_3^-]$, which minimizes the change in plasma pH. Because the renal response develops gradually, there is no sharp distinction between acute and chronic phases. An analysis of the serum $[\text{HCO}_3^-]$ helps identify possible superimposed metabolic disorders,

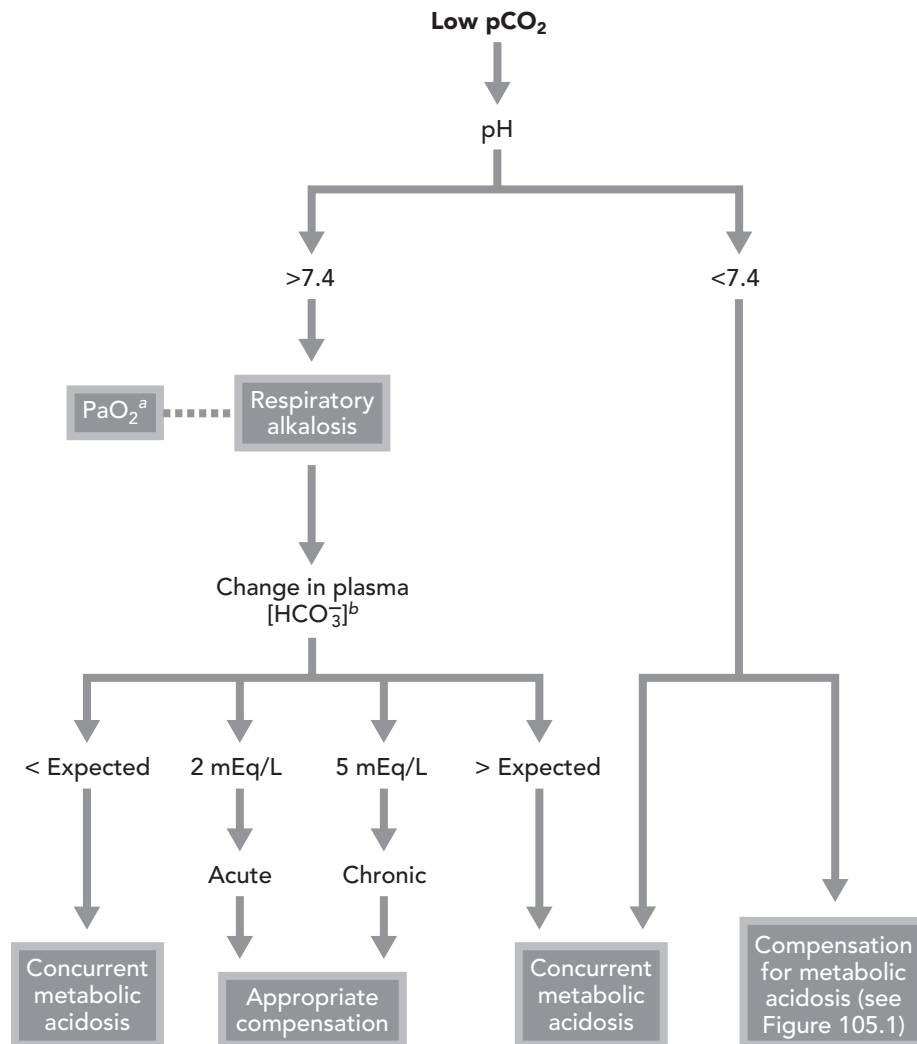

Figure 105.5 Approach to the patient with low pCO_2 . ^a Use to determine etiology of respiratory alkalosis—see text and Table 105.4. ^b For each 10 mm Hg decrease in pCO_2 , in primary respiratory alkalosis one expects serum $[\text{HCO}_3^-]$ to decrease (from 24 meq/L) by 2 meq/L (in acute respiratory alkalosis) to 5 meq/L (in chronic respiratory alkalosis). PaO_2 , partial pressure of oxygen; pCO_2 , partial pressure of carbon dioxide.

which is important because mixed acid–base disorders frequently are encountered. If the fall in serum $[\text{HCO}_3^-]$ exceeds that predicted from the normal renal compensation, a superimposed metabolic acidosis should be considered. Common scenarios of *concurrent respiratory alkalosis and metabolic acidosis* include salicylate poisoning, sepsis, and advanced liver disease. If renal compensation for respiratory alkalosis appears to be inadequate, one should consider a superimposed metabolic alkalosis. For example, an individual who is hyperventilating from mountain sickness and begins to vomit may develop severe, life-threatening alkalemia.

Respiratory alkalosis can be divided into causes driven by hypoxemia, non–hypoxemia-related causes, or both (see Table 105.4). Arterial blood gases are absolutely essential in making this distinction. If tissue hypoxia is present, cardiopulmonary diseases most commonly are implicated. Although hyperventilation may be seen in patients with mild pulmonary diseases prior to the development of hypoxemia, hypoxemia is usually a more important factor. A number of disorders can produce hypoxemia through multiple mechanisms. For example, pulmonary edema resulting from left-heart failure lowers pO_2 by reducing the ventilation:perfusion ratio and increasing diffusion block, at the same time lowering venous oxygen concentration caused by low cardiac output and increased peripheral extraction (Chapter 39).

Conditions in which patients hyperventilate despite relatively normal pO_2 and tissue oxygenation include disorders with heightened ventilatory drive caused by factors other than pH, pCO_2 , or pO_2 . In *early septicemia*, respiratory alkalosis can precede the onset of fever, leuko-

cytosis, or hypotension (Chapter 26). Sudden onset of unexplained respiratory alkalosis in the hospitalized patient should prompt the clinician to consider sepsis. *Salicylate intoxication* also may cause respiratory alkalosis without hypoxemia (Chapter 121). Salicylates directly stimulate the central respiratory center, and respiratory alkalosis may be the only abnormality seen in early acute intoxication. In this instance, the alkalemia is protective against the central nervous system toxicity of salicylates because it increases the fraction of salicylate in its ionized, impermeable form. As salicylate intoxication evolves, the acid–base picture is compounded by a metabolic acidosis that aggravates the central nervous system toxicity of salicylates. Management includes general supportive measures plus alkaline diuresis and, in severe cases, hemodialysis (Chapter 121). Respiratory alkalosis also can be seen with rapid correction of chronic compensated metabolic acidosis. If the serum $[\text{HCO}_3^-]$ suddenly is raised to normal and plasma pH rises, the peripheral acidemic ventilatory drive decreases, and pCO_2 transiently rises. The rise in peripheral $[\text{HCO}_3^-]$ is followed by a slow rise in cerebrospinal fluid $[\text{HCO}_3^-]$, but the rise in plasma pCO_2 is transmitted rapidly to the cerebrospinal fluid, providing a strong drive for ventilation. This is of particular concern if the acidosis is overcorrected rapidly; the combination of metabolic and respiratory alkalosis may generate severe alkalemia.

Treatment Issues

In addition to correcting hypoxemia (if present), the most important therapeutic consideration when respiratory alkalosis is present is to treat the underlying cause(s), as outlined above. Rarely does alkalemia warrant therapy unless a metabolic alkalosis is also present.

TABLE 105.4
CAUSES OF RESPIRATORY ALKALOSIS

Associated with tissue hypoxia
Decreased pO_2 of inspired gases: e.g., high-altitude exposure
Reduced ventilation/perfusion ratio: e.g., pneumonia, pulmonary edema
Shunt
Anatomic: e.g., congenital heart disease
Physiologic: e.g., pulmonary embolus with reperfusion
Diffusion block: e.g., pulmonary fibrosis
Decreased venous pO_2 : low cardiac output, anemia
Not related to tissue hypoxia
Anxiety-related psychogenic hyperventilation
Primary central nervous system diseases: e.g., stroke, infection, malignancy
Hormonally induced: e.g., progesterone in pregnancy
Pharmacologic: e.g., salicylates
Fever/septicemia
Liver disease
Rapid correction of metabolic acidosis

KEY POINTS

- The establishment of acid–base diagnoses often reveals previously unrecognized diseases and provides an index of their severity. Therapy is usually directed at the underlying condition.
- Plasma electrolytes alone often can establish an acid–base diagnosis. However, if there is any uncertainty, arterial blood-gas measurements are invaluable. Arterial blood-gas levels should be obtained in all situations in which a respiratory or mixed acid–base disorder is suspected.
- Metabolic acidosis should be approached in terms of whether there are accumulated unmeasured anions in the plasma. If the anion gap is not elevated, renal and extrarenal causes can be distinguished by measur-

ing the urinary anion gap, which assesses renal acid excretion.

- Metabolic alkalosis can result from effective arterial volume contraction or heightened mineralocorticoid activity. The latter represents the most frequently encountered form of curable secondary hypertension and can be divided into primary disturbances in renin secretion, aldosterone secretion, and mineralocorticoid effect.
- Respiratory acidosis and alkalosis are disorders of alveolar hypoventilation and hyperventilation, respectively. Mixed acid–base disorders are common in patients with pulmonary disease.
- Chronic respiratory acidosis with stable renal compensation should not be corrected acutely. Always look for and correct concurrent metabolic alkalosis in patients with chronic respiratory acidosis.
- Respiratory alkalosis is usually secondary to tissue hypoxemia, and management should be directed at improving oxygenation. If alveolar hyperventilation is not associated with hypoxemia, it may be a harbinger of other important systemic diseases.

- Laboratory Assessment of Hypopituitarism 1076

INTRODUCTION

Clinical endocrinology encompasses an extensive range of disorders. The majority of these begin insidiously and progress gradually, with the result that their evaluation and management are largely based in the ambulatory setting. Thus, endocrine disease is seldom the principal admitting diagnosis in the hospital setting. Rather, it either presents as a comorbid condition or is first detected clinically or through abnormal laboratory test findings as an ancillary disorder during hospitalization. On the other hand, non-endocrine disease and certain medications can lead to profound abnormalities in some laboratory values that might normally indicate the presence of endocrine disease.

This chapter addresses certain clinical signs that suggest endocrine disease and offers recommendations for their cost-effective evaluation and management. In addition, the

chapter considers the interpretation of abnormal results of thyroid laboratory tests during acute illness and discusses some laboratory tests for assessing pituitary function.

GOITER

When Presenting at the Time of Admission

Description and Differential Diagnosis

The term *goiter* refers to enlargement of the thyroid gland (*thyromegaly*). The enlargement may involve the gland diffusely (*diffuse goiter*) or may comprise one or more nodules (*uninodular* or *multinodular goiter*). In a patient who presents with a goiter, the palpatory characteristics of the gland, such as size, consistency, nodularity, and the presence or absence of tenderness, should be determined, as they may shed light on the cause. Movement on swallowing should be assessed, as this is a characteristic feature of the thyroid gland, distinguishing it from other neck masses. Movement is lost when the gland is fixed to adjacent structures, such as may occur with thyroid carcinoma or Riedel thyroiditis. Auscultation of the goiter should be performed, as it may disclose a systolic or continuous bruit, usually

signifying the hypervascular gland of Graves' disease. The presence of a retrosternal goiter may be revealed by the arm-raising test, which leads to further narrowing of the thoracic outlet and results in facial congestion and inspiratory stridor (*Pemberton's sign*).

Goiter may lead to hyperthyroidism, be associated with hypothyroidism, cause obstructive manifestations, or harbor a malignant neoplasm (Table 106.1). A diffuse goiter that is softer than normal and has a bruit is characteristic of *Graves' disease*, and the patient will be thyrotoxic and may display other features of *Graves' disease*, such as infiltrative ophthalmopathy. A diffuse goiter that is firmer than normal and has a finely irregular surface is highly suggestive of chronic autoimmune thyroiditis (*Hashimoto's thyroiditis*), and the patient may be hypothyroid. A multinodular goiter is found in older patients, has usually been present for many years, and may cause obstructive manifestations if it is very large or plunges retrosternally, or it may lead to hyperthyroidism, especially if the patient has received large quantities of iodine (*Jod-Basedow disease*). A dominant nodule in a multinodular goiter or a solitary nodule in a normal thyroid gland may be the seat of thyroid carcinoma, especially if it is hard or adherent to adjacent structures or if there is a history of radiation exposure, recent growth, or dysphonia. Tenderness of the thyroid gland indicates either acute or subacute thyroiditis or hemorrhage into a pre-existing nodule.

Evaluation

The clinical characteristics of the goiter and the metabolic state of the patient should delimit the type and extent of evaluation. For example, a diffuse goiter in a patient with thyrotoxicosis, confirmed with an undetectable value for serum thyroid-stimulating hormone (TSH) and a high level of serum free thyroxine (FT₄) or free triiodothyronine (FT₃), requires no additional evaluation, as the patient almost certainly has *Graves' disease*. Similarly, a firm, diffuse goiter in a euthyroid or hypothyroid patient is in all likeli-

hood a manifestation of chronic autoimmune thyroiditis, and this diagnosis can be confirmed by the demonstration of thyroperoxidase (antimicrosomal) antibody in serum. On the other hand, in a patient with a multinodular goiter, scintigraphic scanning with radioactive iodine should be undertaken, as it will define the functional nature of the nodules and may reveal retrosternal extension. Furthermore, it will serve to identify a hypofunctional, dominant nodule from which a specimen should be obtained by *fine-needle aspiration biopsy* (FNAB). In the evaluation of a solitary nodule in an otherwise palpably normal gland, FNAB is the only procedure that should be performed, as it will empty a cystic lesion and provide a cytologic diagnosis of a solid lesion with an overall diagnostic accuracy of approximately 95%. Ultrasonographic examination of the thyroid provides a very accurate assessment of goiter size and morphology and is sometimes needed to direct FNAB. However, its principal utility is to complement physical examination in monitoring goiter size and morphology over time.

Management

When goiter is accompanied by thyroid dysfunction, management is primarily directed at restoring the patient to a eumetabolic state. In the case of a thyrotoxic patient, endocrinologic consultation should be sought, as management entails various therapeutic considerations concerning antithyroid drugs, radioiodine, and surgery. Similarly, management of a goiter that is producing obstructive manifestations or a nodule that yields a malignant cytologic diagnosis on FNAB is the province of the endocrine surgeon. The management of a benign solitary nodule or multinodular goiter has customarily involved long-term suppression of TSH with levothyroxine, but prospective studies have not consistently demonstrated shrinkage (1). Moreover, the doses of levothyroxine required over the long term may be associated with reduced bone mineral density and an increased risk for atrial fibrillation.

TABLE 106.1
TYPES OF GOITER AND ASSOCIATED DISORDERS

Palpatory features	Cause	Clinical picture
Diffuse goiter	Graves' disease	Hyperthyroidism; infiltrative ophthalmopathy common
Multinodular goiter	Chronic autoimmune thyroiditis	Hypothyroidism common ^a
	Idiopathic, iodine deficiency, goitrogens, genetic defect	Hyperthyroidism common ^b ; thoracic outlet syndrome uncommon
Uninodular goiter	Follicular adenoma	Hyperthyroidism uncommon
	Carcinoma ^c	Cervical lymphadenopathy common

^a Spontaneous or induced by iodine excess or lithium.

^b Spontaneous or induced by iodine excess.

^c May also present as a dominant nodule in a multinodular goiter.

When Presenting During Hospitalization

Description and Differential Diagnosis

A goiter that is predominantly retrosternal in location may present during hospitalization with episodes of acute ventilatory insufficiency. These episodes are characterized by inspiratory stridor and are precipitated or aggravated by the supine position and promptly alleviated by endotracheal intubation.

Imaging of the neck for indications unrelated to the thyroid may reveal the presence of a *nonpalpable* thyroid nodule (thyroid “incidentaloma”).

Evaluation

Magnetic resonance imaging (MRI) or computed axial tomography (CT) of the mediastinum will reveal the presence of a retrosternal goiter. A thyroid “incidentaloma” should be subjected to FNAB under ultrasonographic guidance if the patient has a history of radiation exposure or a family history of thyroid carcinoma (as these are risk factors for thyroid carcinoma), or if it displays suspicious ultrasonographic features (2).

Management

A retrosternal goiter that is obstructing the airway or a thyroid “incidentaloma” that yields a malignant cytologic diagnosis on FNAB requires surgical excision. In the case of a thyroid “incidentaloma” that does not meet the criteria for ultrasonographically-guided FNAB or is benign, ultrasonographic surveillance is currently recommended.

CLINICAL SIGNS OF CUSHING SYNDROME

When Presenting at the Time of Admission

Description and Differential Diagnosis

Cushing syndrome is characterized by a constellation of clinical and biochemical manifestations that are caused by cortisol excess. Clinical signs that might suggest the presence of Cushing syndrome at the time of admission include facial rounding and plethora, truncal obesity with prominent dorsal cervical and supraclavicular fat deposition, thin skin with violaceous abdominal striae, and proximal muscle wasting in a patient with moderate hypertension. None of these physical signs is specific, but together they increase the likelihood of Cushing syndrome.

The causes of Cushing syndrome are manifold, but in the absence of exogenous glucocorticoid excess, pituitary adrenocorticotropin (ACTH)-dependent Cushing syndrome (*Cushing disease*) accounts for at least 70% of cases (3) (Table

TABLE 106.2
SPECTRUM OF CUSHING SYNDROME

Cause	Prevalence (%) ^a
ACTH-dependent	
Pituitary ACTH (Cushing disease)	70
Ectopic ACTH or, rarely, CRH	15
ACTH-independent	
Adrenal adenoma or carcinoma	15
Bilateral micronodular or macronodular hyperplasia	Rare
Pseudo-Cushing	
Alcohol-induced	Rare
Megestrol-induced	Rare

^a In absence of exogenous glucocorticoid.

ACTH, adrenocorticotropin hormone; CRH, corticotropin-releasing hormone.

106.2). The underlying cause of Cushing syndrome may modify the clinical presentation greatly. For example, in contrast to Cushing disease, the *ectopic ACTH syndrome*, which is caused by a small-cell carcinoma of the lung or other neuroendocrine neoplasms and accounts for about 15% of cases, is usually found in older men rather than in women. Moreover, it is usually characterized by extreme elevations of ACTH and cortisol secretion. These lead to a much more rapid evolution of clinical manifestations, accompanied by hyperpigmentation (secondary to the extremely high ACTH concentration) and by features of mineralocorticoid excess, such as hypokalemia and metabolic alkalosis (secondary to the extreme cortisol excess). Similarly, in contrast to patients with Cushing disease, those with adrenal carcinoma often display the additional features of adrenal androgen excess, such as hirsutism, acne, and other signs of masculinization, in addition to mild polycythemia.

Several other conditions, apart from exogenous glucocorticoid excess, may mimic spontaneous Cushing syndrome. They include the rare alcohol-induced pseudo-Cushing syndrome and the pseudo-Cushing syndrome that can be associated with the use of megestrol acetate (Megace) (4), which has glucocorticoid-like activity, for the management of cancer or wasting states. In the alcohol-induced syndrome, liver function is deranged, and the syndrome resolves with abstinence.

Evaluation

The most reliable test for detecting Cushing syndrome is measurement of cortisol in a 24-hour urine collection (along with creatinine to assess completeness of collection) as it most closely reflects the cortisol secretion rate (5). A normal value essentially rules out Cushing syndrome, but mildly increased values for urinary cortisol may occur during major stress and in alcohol-induced pseudo-Cushing syndrome. A clearly increased value confirms the presence

of Cushing syndrome but does not indicate its cause. Thus, the most efficient and cost-effective manner for evaluating the patient is to measure serum cortisol and ACTH during the evening of the 24-hour urine collection so as to exploit the normal circadian depression of both, which is lost in Cushing syndrome (Figure 106.1). Under these conditions, an increased serum ACTH level accompanying increased values for serum and 24-hour urinary cortisol would indicate ACTH-dependent Cushing syndrome, whereas a subnormal serum ACTH would indicate adrenal adenoma, carcinoma, or bilateral nodular hyperplasia. Moreover, patients with the ectopic ACTH syndrome usually display extremely high values for cortisol and ACTH. Tests based on the suppressibility of serum or urinary cortisol with large doses of dexamethasone have been used in an attempt to differentiate between Cushing disease, in which cortisol is usually suppressible, and the ectopic ACTH syndrome, in which it is usually not suppressible. However, these tests may give misleading results, as their overall diagnostic accuracy (~80%) is less than the pretest probability of Cushing disease (>90%) in patients with ACTH-dependent Cushing syndrome (5). Rather, the con-

sideration of variables such as age, sex, rate of progression, presence of hypokalemia, and magnitude of elevation of urinary cortisol and serum ACTH together yield an overall diagnostic accuracy of 90% or greater in the differential diagnosis of ACTH-dependent Cushing syndrome. (In contrast to Cushing disease, the ectopic ACTH syndrome usually occurs in older men rather than in women and is characterized by a much higher cortisol secretion rate that leads to hypokalemia and metabolic alkalosis and to more rapid clinical progression.) This issue of differentiation is highly important, as both the pituitary adenoma causing Cushing disease and the ectopic ACTH-secreting neoplasm may be small and difficult to localize using imaging techniques. It is at this juncture in the patient's evaluation that endocrinologic consultation should be sought.

Once a functional diagnosis of Cushing syndrome has been established, localization of the cause needs to be undertaken. In ACTH-independent Cushing syndrome, thin-section CT of the abdomen will reveal an adrenal mass or bilateral hyperplasia. A pituitary-dedicated MRI study will detect a pituitary adenoma in most, but not all, patients with Cushing disease. The majority of patients with the

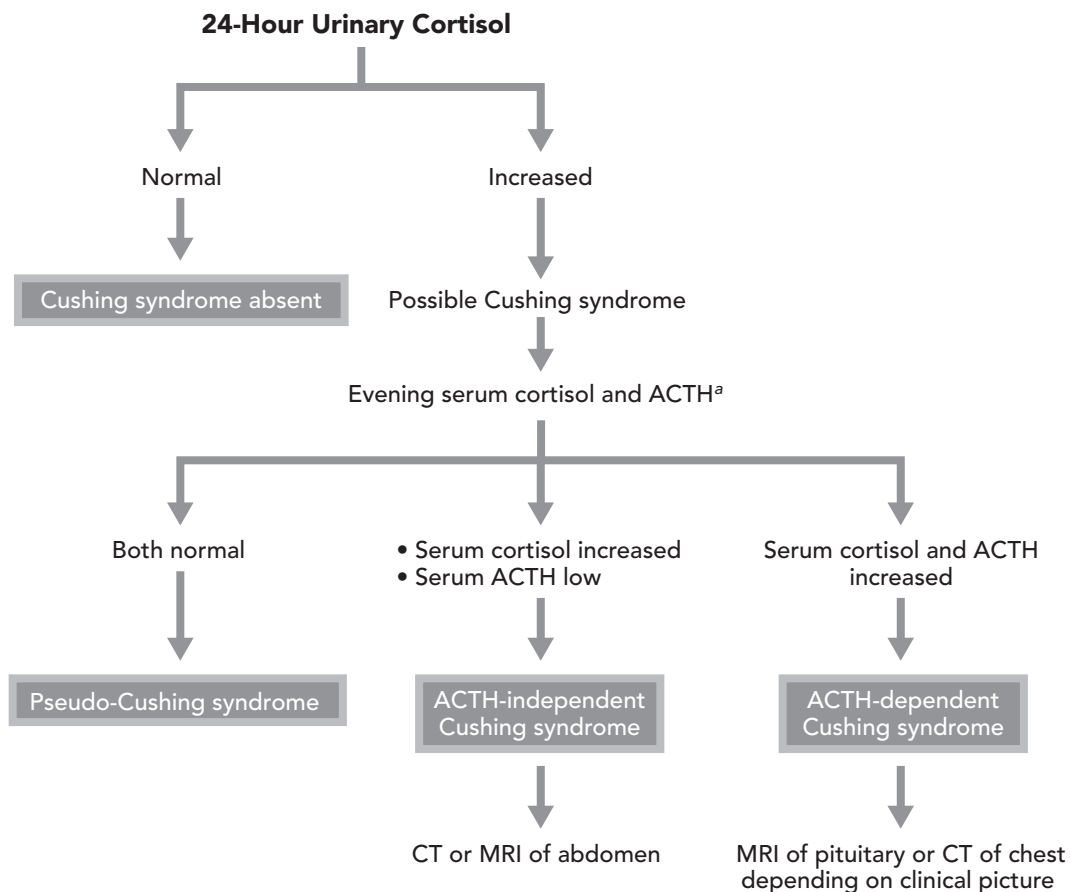

Figure 106.1 Laboratory investigation of Cushing syndrome. ^aSerum cortisol and adrenocorticotropic hormone (ACTH) should be measured during the evening of the 24-hour urine collection. CT, computed axial tomography; MRI, magnetic resonance imaging.

ectopic ACTH syndrome will harbor a small-cell carcinoma of the lung, and CT of the chest, therefore, will usually provide the necessary confirmation. If the aforementioned imaging studies are unrevealing and the functional diagnosis is not entirely consistent with Cushing disease, inferior petrosal venous sinus sampling with determination of central-to-peripheral serum ACTH ratios before and after intravenous administration of corticotropin-releasing hormone (CRH) is indicated, as Cushing disease is still the most likely cause.

Management

The treatment of choice for patients with Cushing disease is transsphenoidal pituitary microsurgery, which results in a 10-year remission rate of approximately 75%. For those patients in whom surgery is unsuccessful or who relapse, pituitary irradiation is indicated. In Cushing syndrome with an adrenal cause, unilateral or, in the rare case of bilateral nodular hyperplasia, bilateral adrenalectomy (which can now be performed through a laparoscope) is the appropriate treatment. The management of patients with the ectopic ACTH syndrome, which is usually caused by a small-cell or other neuroendocrine carcinoma or by an adrenal carcinoma, involves the use of adrenal enzyme inhibitors, such as ketoconazole or mitotane. Glucocorticoid replacement therapy will be required for a short time in some patients after pituitary surgery or unilateral adrenalectomy and permanently in all patients who have undergone bilateral adrenalectomy.

When Presenting During Hospitalization

Description and Differential Diagnosis

During hospitalization, the appearance of certain clinical signs should lead one to entertain a diagnosis of Cushing syndrome. Thin skin and an increased fragility of the tissues predispose to the formation of ecchymoses after phlebotomy and to decubitus ulceration, and these are especially noteworthy findings when they occur in a younger patient. A fracture with little or no antecedent trauma, reflecting the loss of bone mass in Cushing syndrome, may be the presenting manifestation and reason for admission. Difficulty in rising from the lying or sitting position may point to wasting and weakness of the limb-girdle musculature in Cushing syndrome. In a hypertensive patient, the presence of hypokalemia and metabolic alkalosis, suggesting a disorder of mineralocorticoid excess, may be the presenting manifestation of the ectopic ACTH syndrome, especially if there is a history of recent darkening of the skin.

Evaluation

This is undertaken in the same manner as described in the corresponding previous section.

Management

This is the same as described in the corresponding previous section.

ABNORMAL RESULTS OF THYROID LABORATORY TESTS

When Presenting at the Time of Admission

Description and Differential Diagnosis

Because of its sensitivity, measurement of serum TSH is the test used first to screen patients for thyroid dysfunction. This sensitivity resides in the approximate negative logarithmic-linear relationship between serum TSH and FT₄ concentrations, with the result that small changes in FT₄ result in large changes in serum TSH. Current second-generation (sensitive) and third-generation (ultrasensitive) TSH assays have approximate functional sensitivities of 0.1 and 0.01 mU/L, respectively, with an approximate normal range of 0.5–5.0 mU/L (6).

The finding of low or undetectable serum TSH in a patient at the time of admission suggests the presence of thyrotoxicosis. However, a low serum TSH may also be found in about 15% of patients with various systemic nonthyroid illnesses (*euthyroid sick syndrome*), in calorically-deprived patients, or in the occasional patient with hypopituitarism. In these circumstances, serum TSH, although low and sometimes undetectable with a sensitive assay, is rarely undetectable with an ultrasensitive assay. By contrast, in patients with thyrotoxicosis, serum TSH is virtually *always undetectable* (6).

The finding of an increased serum TSH in a patient at the time of admission is highly suggestive of primary hypothyroidism, especially if the value exceeds 10 mU/L. On the other hand, values between 5–10 mU/L may revert to normal on follow-up testing in some patients.

Evaluation

Measurement of serum FT₄ and sometimes FT₃ will provide the necessary discrimination among the various causes of an abnormal serum TSH (Figure 106.2). These measurements have replaced the older measurements of total T₄ and total T₃, which reflect alterations in hormone binding in serum in addition to alterations in hormone production.

In patients with nonthyroid illness, serum FT₄ is usually normal, even when serum total T₄ is reduced (7). A high serum FT₄ will confirm the diagnosis of thyrotoxicosis in a patient with an undetectable serum TSH. Uncommonly, an undetectable serum TSH with an ultrasensitive assay will be accompanied by a normal serum FT₄. In this circumstance, measurement of serum FT₃ should be

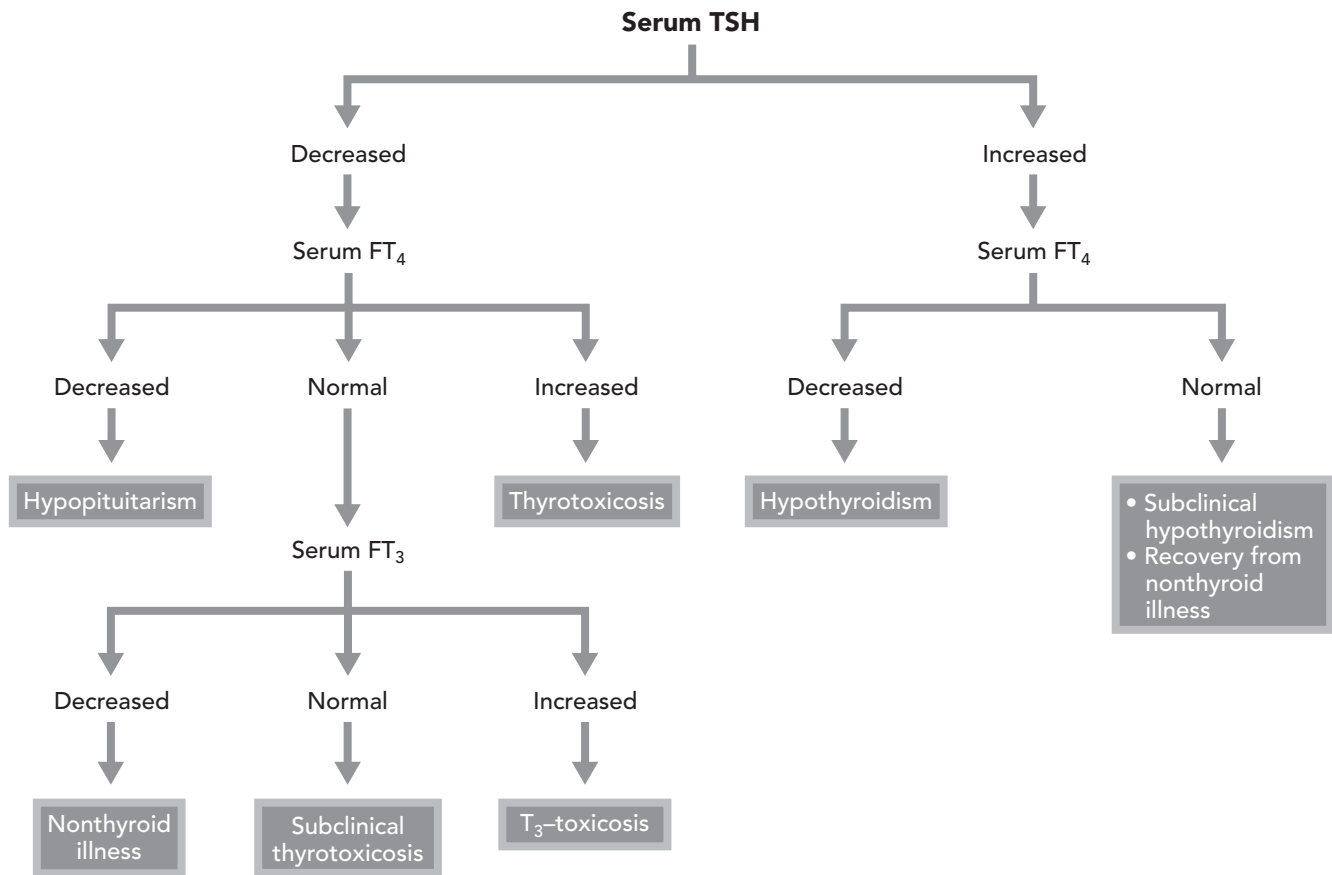

Figure 106.2 Evaluation of abnormal serum values of thyroid-stimulating hormone (TSH). FT₄, free thyroxine; FT₃, free triiodothyronine.

undertaken, as an increased value would establish a diagnosis of *T₃ toxicosis*, whereas a normal value would indicate the presence of *subclinical thyrotoxicosis*. A low serum FT₄ in conjunction with a subnormal serum TSH is virtually diagnostic of *hypopituitarism*. On the other hand, a low serum FT₃ is much less specific, as it is often found in patients with nonthyroid illness (7).

In a patient with a high serum TSH, a low serum FT₄ will establish the diagnosis of *primary hypothyroidism*. If the serum free T₄ is normal and the serum TSH is above 10 mU/L, the patient has *subclinical hypothyroidism*, and progression to overt hypothyroidism is very likely. In a patient with a serum TSH between 5–10 mU/L, measurement of serum thyroperoxidase (antimicrosomal) antibody should be undertaken because its presence, indicating chronic autoimmune thyroiditis, would be an independent risk factor for the eventual development of overt hypothyroidism (8).

Management

In patients with non-thyroid illness, a low value for serum TSH will eventually revert to normal during convalescence, and no specific treatment is indicated. In a patient with

clinical or subclinical thyrotoxicosis, endocrinologic consultation should be sought, as management will entail various considerations concerning choice of therapy. Similarly, endocrinologic consultation is required in a patient with suspected hypopituitarism, as assessment of the functional integrity of the pituitary–adrenal axis becomes critical.

In a patient with established primary hypothyroidism, replacement therapy with levothyroxine should be initiated, as hypothyroid patients tolerate anesthesia and surgery less well than euthyroid patients. In an elderly patient or a patient with pre-existing heart disease, treatment should be initiated with smaller than usual doses of levothyroxine (e.g., 25 mcg daily) and careful monitoring. As there are no outcome data to support therapeutic intervention in patients with subclinical hypothyroidism, management should consist of surveillance with monitoring of serum TSH.

When Presenting During Hospitalization

Description and Differential Diagnosis

The interpretation of abnormal values for thyroid laboratory tests in patients during hospitalization is the same as

that described in the corresponding previous section, except that the potential confounding effects of certain drugs also need to be considered (Table 106.3).

Dopamine or pharmacologic doses of glucocorticoids acutely suppress pituitary TSH secretion and lead to decreases in serum TSH and FT₄ in patients with nonthyroid illness, resulting in a laboratory profile that might suggest hypopituitarism. Moreover, in a patient with primary hypothyroidism, these drugs, when administered concurrently, may suppress the serum TSH into the normal range, with the result that the diagnosis of hypothyroidism can be overlooked. By contrast, amiodarone acutely increases pituitary TSH secretion through inhibition of the conversion of T₄ to T₃ within the pituitary and reduces the peripheral uptake of T₄ and its conversion to T₃, thereby leading to increases in serum TSH and FT₄ and a decrease in serum FT₃. Sodium iopanoate and ipodate, which are non-water-soluble radiographic contrast agents, produce effects similar to those of amiodarone.

Drugs that increase the hepatic uptake and metabolism of T₄, such as phenytoin, rifampin, and carbamazepine, may lead to a decrease in serum FT₄ with little or no change in serum FT₃ or TSH. Lithium interferes with the secretion of hormone by the thyroid and may lead to an increase in serum TSH, sometimes accompanied by a decrease in serum FT₄, if the patient has an underlying chronic autoimmune thyroiditis that limits thyroid functional reserve.

During recovery from nonthyroid illness, serum TSH may rebound from a normal or suppressed value to a value as high as 20 mU/L in euthyroid patients, mimicking primary hypothyroidism, before reverting to normal levels over several days.

Evaluation

The evaluation of abnormal results of thyroid laboratory tests in hospitalized patients is the same as that described in the corresponding previous section, except that the interpretation of the values must take into account the potential confounding effects of certain drugs.

Management

In patients with nonthyroid illness who are being treated with any of the aforementioned drugs, abnormal values for thyroid laboratory tests will revert to normal after the drug has been discontinued during convalescence, and no specific treatment is indicated. With the long-term administration of amiodarone, even though the values return to normal, patients with chronic autoimmune thyroiditis or multinodular goiter are at risk for later development of iodine-induced hypothyroidism or iodine-induced thyrotoxicosis, respectively, as a result of the iodine released during the degradation of amiodarone. Similarly, the long-term administration of lithium may unmask hypothyroidism in some patients with chronic autoimmune thyroiditis. On the other hand, the long-term administration of phenytoin, carbamazepine, or rifampin, although accompanied by a decrease in serum FT₄, does not lead to hypothyroidism, because a normal serum TSH concentration is maintained. For patients in whom thyroid dysfunction has been established through an appropriate profile of abnormal laboratory values, management is the same as described in the corresponding previous section.

TABLE 106.3

NONTHYROID CAUSES OF ABNORMAL THYROID LABORATORY TEST RESULTS

	Serum TSH	Serum FT ₄	Serum FT ₃

LABORATORY ASSESSMENT OF HYPOPITUITARISM

When Presenting at the Time of Admission

Description and Differential Diagnosis

Prompt assessment of the functional integrity of the pituitary is critical in a patient with suspected hypopituitarism so as to avoid overlooking the secondary cortisol deficiency, which can lead to shock and death (9). The clinical presentation of hypopituitarism depends on the nature of the pituitary insult. Thus, hemorrhagic necrosis of a pituitary adenoma (*pituitary apoplexy*) presents dramatically with severe headache, visual field defects, oculomotor palsies, and hypotension. In contrast, more gradual destruction by a slowly growing adenoma or other infiltrative lesion or following radiation therapy for head and neck carcinoma presents with nonspecific manifestations, such as lethargy, pallor, loss of sexual hair, and orthostatic hypotension. In the presence of severe stress, however, ACTH deficiency may emerge as symptomatic hyponatremia, mimicking the syndrome of inappropriate antidiuretic hormone secretion (SIADH) (Chapter 104). Finally, hypoglycemia for which there is no ready explanation may be the presenting manifestation of hypopituitarism.

Measurement of serum cortisol under stressful conditions imposed by acute illness or during hypoglycemia is the single most helpful test because a serum cortisol level below 20 mcg/dL—that is, an inappropriately normal or low value—points to a defective pituitary–adrenal axis (9) (Chapter 109). Similarly, the absence of an increased serum growth hormone level in these circumstances also points to pituitary hypofunction. Measurement of serum follicle-stimulating hormone in a postmenopausal woman is helpful, as in this circumstance an increased value is expected, and consequently an inappropriately normal or low value suggests the presence of hypopituitarism. Finally, the finding of a low serum FT₄ that is accompanied by a subnormal serum TSH is characteristic of hypopituitarism (Table 106.4).

Evaluation

Functional evaluation of the pituitary–adrenal axis is of paramount importance in a patient with suspected hypo-

pituitarism, and endocrinologic consultation should be sought. Although the absence of an increased serum ACTH level in a patient with a low serum cortisol level indicates pituitary ACTH deficiency, some patients with hypopituitarism display values for serum cortisol under basal conditions that are within the normal range. Accordingly, various tests have been devised to provoke the hypothalamic–pituitary–adrenal axis. Of these, the stimulation test with synthetic ACTH (Cortrosyn) is undertaken first; a normal serum cortisol response (i.e., a value exceeding 20 mcg/dL at 60 minutes following an intravenous bolus of 250 mcg of synthetic ACTH) excludes the presence of hypopituitarism unless it is of such recent onset that adrenocortical atrophy has not yet occurred (9). On the other hand, a subnormal serum cortisol response is also found in patients with primary adrenocortical insufficiency. Tests that evaluate pituitary ACTH secretion directly include the insulin-induced hypoglycemia test, the metyrapone tartrate stimulation test, and the CRH stimulation test. These tests are associated with some risks, and their selection, performance, and interpretation are the province of the consulting endocrinologist.

The most common cause of hypopituitarism is a *pituitary adenoma*, often a prolactin-secreting macroadenoma. Accordingly, measurement of serum prolactin and a pituitary-dedicated MRI study should be performed.

Management

Cortisol is essential for survival under stressful conditions. Accordingly, once hypopituitarism has been recognized, replacement therapy with hydrocortisone must be instituted promptly, in stress doses if indicated by the clinical circumstance (Chapter 109). Replacement therapy with levothyroxine should also be instituted, but *not before hydrocortisone*, as the increase in metabolic rate may aggravate the cortisol deficiency. At this juncture, treatment of a pituitary adenoma or other potentially remediable cause of hypopituitarism can be undertaken. Finally, replacement therapy with gonadal steroids, although not essential for survival, will preserve bone mass and restore vitality. With full hormone replacement therapy and appropriate surveillance, patients with hypopituitarism should be able to lead normal lives.

When Presenting During Hospitalization

Description and Differential Diagnosis

This is the same as described in the corresponding previous section.

Evaluation

This is undertaken in the same manner as described in the corresponding previous section.

TABLE 106.4

LABORATORY TEST RESULTS THAT SUGGEST HYPOPITUITARISM

- Normal or low serum cortisol during severe stress
- Normal serum FSH (<20 U/L) in a postmenopausal woman
- Low serum FT₄ in association with subnormal TSH

FSH, follicle-stimulating hormone; FT₄, free thyroxine; TSH, thyroid-stimulating hormone.

Management

This is the same as described in the corresponding previous section.

KEY POINTS

- In the evaluation of a solitary nodule in an otherwise palpably normal thyroid gland, or a dominant nodule in a multinodular thyroid gland, fine-needle aspiration biopsy is the initial procedure of choice, as it empties a cystic lesion and provides a cytologic diagnosis of a solid lesion with an overall diagnostic accuracy of 95%.
- A nonpalpable thyroid nodule discovered incidentally by nonthyroid imaging of the neck should be subjected to fine-needle aspiration biopsy under ultrasonographic guidance if the patient has a history of radiation exposure or a family history of thyroid carcinoma, or if the nodule displays suspicious ultrasonographic features.
- The overall diagnostic accuracy of the collective use of variables such as age, sex, rate of progression, presence of hypokalemia, and magnitude of elevation of urinary cortisol and serum ACTH exceeds that of high-dose dexamethasone suppression testing in differentiating between pituitary ACTH-dependent Cushing syndrome and the ectopic ACTH syndrome.
- In a hypertensive patient, the presence of hypokalemia and metabolic alkalosis, suggesting a disorder of mineralocorticoid excess, may be the presenting manifestation of the ectopic ACTH syndrome.
- In hospitalized patients, abnormal results of thyroid laboratory tests are more often the consequence of nonthyroid illness or the effects of drugs than of intrinsic thyroid disease.
- In nonthyroid illness, serum TSH may be low but is rarely undetectable with an ultrasensitive assay, whereas in thyrotoxicosis, serum TSH is virtually always undetectable.
- During recovery from nonthyroid illness, serum TSH may transiently increase to values as high as 20 mU/L in euthyroid patients, mimicking primary hypothyroidism.
- In severe illness or during hypoglycemia, a normal serum cortisol value is inappropriate and indicates a defective pituitary–adrenal axis.

The Management of Hyperglycemia and Diabetes Mellitus in Hospitalized Patients

Harold E. Lebovitz

INTRODUCTION

It has long been recognized that patients with diabetes mellitus are at increased risk for morbidity and mortality when they are stricken with an illness that requires hospitalization. Special attention must be paid to many aspects of their illnesses in order to maximize health care benefits and minimize health care costs. A relatively new area of concern is the hospitalized patient who does not have diabetes mellitus but presents with significant hyperglycemia during the acute phase of a general medical or surgical illness. Several major studies show that careful management of the hyperglycemia has profound effects in decreasing both morbidity and mortality. These findings mandate that physicians extend their intensive efforts to control metabolism from the diabetic hospitalized patient to the hyperglycemic, nondiabetic patient as well.

Diabetes mellitus encompasses many disorders, the phenotypic expression of which is hyperglycemia occurring in the fasting and/or postprandial state. Approximately 12.1 million patients in the United States (4.1% of the U.S. population) have clinically diagnosed diabetes mellitus. It is estimated that an additional 30%–40% have undiagnosed diabetes mellitus. Those clinically diagnosed diabetic patients consume 91.8 billion dollars per

year in direct health care costs and an additional 40 billion dollars per year in indirect costs such as lost wages. The clinically diagnosed diabetic patient costs the health care system 2.4 times more per year than comparable nondiabetic patients, and their aggregate costs consume 10.1% of the entire U.S. health care budget. In 2002, patients with diabetes utilized 16.9 million inpatient hospital days (43.9% of direct costs) and 82.35 million nursing home bed days (15.1% of direct costs). It is noteworthy that 61% of diabetics' inpatient costs were for the management of general medical conditions, 24% were for cardiovascular disorders, and only 5% were for uncontrolled diabetes.

Newly diagnosed hyperglycemia in a patient hospitalized for an acute illness may represent stress-induced hyperglycemia or diabetes mellitus in a previously undiagnosed individual. Frequently it is not possible to make the differentiation at presentation, and the outcome appears to depend on the effectiveness of treating the hyperglycemia rather than its cause. In patients with acute myocardial infarction, admission plasma glucose level is an independent predictor of nonfatal reinfarction, hospitalization for heart failure, and death. In one large intensive care unit (ICU) study, 70% of patients presented with blood glucose >110 mg/dL, yet only 13% had a history of diabetes mellitus (1).

In such patients, morbidity and mortality are directly correlated to the extent of the increase in plasma glucose values above 110 mg/dL. Several randomized prospective studies indicate that treating hyperglycemia in hospitalized patients with acute illnesses by insulin infusion can reduce morbidity, mortality, and hospital costs by approximately 30%–50%. The treatable detrimental effects of excess hyperglycemia (>110 mg/dL) in acutely ill hospitalized patients has opened an important new therapeutic window for the hospital-based physician.

Rational management of hospitalized patients with diabetes or excessive hyperglycemia requires an understanding of the metabolic consequences of hyperglycemia. Hyperglycemia increases oxidative stress, alters the coagulation pathway, and activates the inflammatory cascade. Clinically, these derangements result in greater susceptibility to bacterial infections, poorer responses to treatment of bacterial infections, increases in thromboembolic events, weight loss and negative nitrogen balance, depressed tissue anabolism, and poor wound healing.

The impaired host resistance to infection in diabetes has been known for decades (2). One significant component of this impaired response is deficient polymorphonuclear leukocyte function. Polymorphonuclear leukocytes from patients with diabetes mellitus demonstrate impaired adherence, chemotaxis, phagocytosis, oxidative activity, and bactericidal activity (3). These disturbances become evident when plasma glucose levels exceed 130–175 mg/dL and become increasingly more severe as the plasma glucose rises to 300–400 mg/dL. Impaired function of polymorphonuclear leukocytes renders patients particularly susceptible to *Staphylococcus aureus* and *Escherichia coli* infections.

In a prospective, randomized, controlled clinical trial in a surgical ICU, patients admitted with a plasma glucose ≥ 140 mg/dL were randomized to standard insulin treatment (target glucose levels 180–220 mg/dL) or strict insulin therapy (target glucose levels 80–120 mg/dL) throughout their ICU stay (1). The “strict control” group (mean plasma glucose 125 ± 36 mg/dL) had significantly fewer bloodstream and surgical site infections than the standard treatment group (mean plasma glucose 179 ± 61 mg/dL). Another prospective study, the Portland Diabetic Project, assessed the effects of glycemic control of 4,864 patients with diabetes who underwent cardiovascular surgery (4). Tight perioperative diabetes control (150–200 mg/dL in the early years of the trial, later further tightened to 100–150 mg/dL) was achieved by continuous intravenous administration of insulin. In diabetic patients whose mean perioperative blood glucose averaged 175 mg/dL or less, deep sternal wound infections occurred in about 0.5%, comparable to the risk in the nondiabetic population. Diabetic patients whose mean blood glucoses exceeded 175 mg/dL had rates of 1.1%, while those with glucoses above 250 mg/dL had rates of 3.7%, a sevenfold increase over the base rate. Length of

hospital stay increased from 8.2 days in diabetic patients with tight control to 11.0 days in those with poorly controlled perioperative blood glucoses.

Short-term hyperglycemia increases the glycosylation of many proteins and may interfere with their function. Such effects have been demonstrated with circulating immunoglobins. Additionally, acute hyperglycemia has been shown to increase mediators of both coagulation and adhesion. Uncontrolled hyperglycemia is also associated with proteolysis and impaired protein synthesis (5). This leads to delay and deficiencies in tissue repair and regeneration. In an active wound, hyperglycemia increases collagenase activity and decreases collagen content. In diabetic patients with medical or surgical disease, these processes may prolong hospitalizations and impair recovery.

The above data suggest that these untoward acute and subacute consequences of hyperglycemia can be minimized by maintaining plasma glucose levels below 175 mg/dL. As will be discussed in subsequent sections, new data indicate that the glycemic target should probably be even tighter: *blood glucoses between 80 and 110 mg/dL in hospitalized acutely ill patients.*

The treatment goals for diabetic ketoacidosis and nonketotic hyperosmolar state are somewhat different because they change with the stage of treatment. Moreover, in such patients, clinicians must attend to the management of dehydration, acidosis, and electrolyte balance in addition to the glucose level.

HOSPITAL-BASED TREATMENT REGIMENS FOR GLYCEMIC CONTROL

Most hospitalized diabetic patients require some type of insulin regimen to maintain their glucose in the target range of 80–175 mg/dL. Acute illnesses are associated with a significant stress response, inadequate nutritional intake, and increased tissue requirements for energy. As a consequence, secretion of catecholamines, cortisol, growth hormone, and glucagon is increased. These hormonal changes both inhibit insulin secretion and increase insulin resistance, rendering oral antihyperglycemic agents ineffective in most hospitalized patients. Maintaining tight glycemic control (blood glucose 80–110 mg/dL) in hyperglycemic, acutely ill hospitalized patients who may or may not have diabetes mellitus generally requires continuous intravenous insulin with frequent blood glucose monitoring.

Table 107.1 outlines insulin treatment regimens that are effective for hospitalized diabetic patients. Diabetic or nondiabetic hyperglycemic patients who are severely ill and not taking oral nutrients are best managed with intravenous (IV) regular insulin. This includes virtually all patients admitted to an ICU and undergoing surgery and most patients in the first 48–72 hours following surgery or an acute myocardial infarction (5). The

TABLE 107.1**INSULIN TREATMENT REGIMENS FOR HOSPITALIZED DIABETIC PATIENTS**

Patients	Insulin administration	Glucose administration	Monitoring and dose adjustments
Acute glucose regulation by intravenously administered regular insulin			
Acutely ill patients not on oral nutrition	Regular insulin is administered intravenously at 0.5 to 5.0 units/h by infusion pump.	Glucose is administered simultaneously through the same port, either by a separate glucose infusion ("piggyback") or by mixing glucose with insulin in the same solution but varying the ratio of glucose to insulin.	Blood glucose is monitored every 1–2 hours, with adjustments of insulin and glucose infusions based on results.
Subacute glucose regulation by subcutaneously administered regular and intermediate-acting insulin			
Hospitalized patients on oral nutrition	Regular and intermediate-acting insulins are administered subcutaneously 2–4 times a day (three times is preferable).	None	Blood glucose is monitored by finger-stick before meals and at 10 PM. Insulin doses are adjusted every 1–2 days based on results.

advantages of IV regular insulin are its immediate delivery to the tissues and its rapid disappearance from the plasma (half-life of five minutes). IV insulin delivery is independent of adipose tissue perfusion, which may greatly alter the uptake of subcutaneously administered insulin. Because the cellular effects of insulin are short-lived (20–60 minutes), changes in the delivery rate of IV insulin are reflected in the glucose concentration within 30–60 minutes. *IV insulin must be administered together with a glucose solution*, which can be independently regulated but is delivered through the same portal as the insulin. The glucose is not only necessary to prevent hypoglycemia but also essential to maintain caloric intake and reduce catabolism. The regular insulin and glucose infusions should not be administered through separate portals, as unrecognized infiltration of the glucose infusion can lead to severe hypoglycemia. Concurrent administration can be accomplished by "piggybacking" the glucose infusion into the insulin line or by administering the glucose and insulin from the same container but changing the glucose-to-insulin ratio as necessary. Monitoring of blood glucose and subsequent adjustment of the insulin and glucose infusion rates must always be performed frequently (every one, two, or four hours as dictated by the specific circumstances). Supplemental potassium is generally necessary because insulin and glucose administration facilitate the intracellular movement of potassium.

Hospitalized diabetic patients who are taking oral nutrition and are not in a rapidly fluctuating state can be managed with one of several subcutaneous insulin treatment programs (6), shown in Table 107.2.

The initial doses of insulin are determined by the body weight, severity of hyperglycemia, and knowledge of a previous history of diabetic treatment and its effectiveness. The calorie distribution among the meals will influence the amount of insulin given at each specific time. A general guideline is to start with a total daily insulin dose of approximately 0.50 units/kg, with about 75% of the dose used to

TABLE 107.2**SUBCUTANEOUS INSULIN MANAGEMENT PROGRAMS****Regimen 1**

Regular insulin and intermediate-acting insulin before breakfast

control meal-mediated glycemia and 25% to control the overnight plasma glucose. The initial insulin dose will need to be modified based on the patient's degree of insulin resistance. The insulin dose then is adjusted every day or two based on the results of blood glucose monitoring (which should be performed before breakfast, before lunch, before the evening meal, and at 10 PM). Table 107.3 presents the time courses of action of human insulin, and Table 107.4 details the use of finger-stick blood glucose monitoring to adjust the insulin. Many insulins are available for subcutaneous use. These include basal insulin (such as glargine insulin), intermediate-acting insulins (such as NPH and Lente insulin), and regular soluble insulin and rapid-acting synthetic insulin analogs (such as lispro insulin, aspart insulin, and glulisine insulin). The rapid-acting synthetic analogs have the advantage that their onset of action when administered subcutaneously is 10 or 15 minutes and their duration of action is approximately 3–4 hours. One of them might be used in those infrequent cases in which these attributes are important. Glargine insulin is attractive in that it is a basal insulin with a 24-hour duration of action, it maintains a peakless plasma level, and it gives a reproducible profile from day to day. Premixed combinations of NPH and regular insulin, and NPH and a rapid-acting insulin, are available as 70/30 and 50/50 preparations. These can be used in twice-a-day treatment regimens but are of limited utility in the hospital because of the fixed proportion of intermediate-acting and regular or rapid-acting insulins.

Hospitalized patients on a subcutaneously administered insulin treatment program must receive their meals on time, and the quantity consumed must be noted. When a meal is to be held or missed for a study, the appropriate insulin dose should be held or reduced accordingly.

The time course of action of the human insulins (Table 107.3) makes it difficult to achieve glycemic levels

between 110 and 175 mg/dL with only two daily injections of mixed insulins (regimen 4, Table 107.2) because the action of the intermediate-acting insulin peaks during the early morning hours (approximately 2–3 AM) and is effectively over by 5–7 AM. Thus, it is common for a patient to be hypoglycemic at 2–3 AM and hyperglycemic at 7 AM. The administration of regular insulin before the evening meal and intermediate-acting insulin at 10 PM solves this problem and generally leads to good glycemic control when coupled with administration of regular plus intermediate-acting insulin before breakfast (regimen 1). Regular insulin and mixtures of regular and intermediate-acting insulin should be administered 30–45 minutes before the meal. A treatment program in which regular insulin is given before each meal and intermediate-acting insulin is given at 10 PM (regimen 3) is necessary only for patients whose meal pattern is totally erratic or in whom fever or stress is fluctuating rapidly. Insulin doses should be adjusted every 1–2 days based on the results of blood glucose monitoring, not according to a "sliding scale" protocol.

The treatment of hospitalized patients with oral antidiabetic agents is generally ineffective. Patients taking oral agents before hospitalization should discontinue them and then restart them after their acute problem has resolved. This is particularly true for metformin (which can cause lactic acidosis in the presence of impaired renal or hepatic function or congestive heart failure) and sulfonylureas (which have prolonged durations of action and rarely allow for consistent glycemic control in acutely ill diabetic patients).

The only instance in which oral antidiabetic therapy may be indicated in the hospitalized patient is during an admission for an uncomplicated diagnostic procedure or minimally invasive surgery under local anesthesia.

TABLE 107.3**TIME COURSE OF ACTION OF HUMAN INSULIN PREPARATIONS ADMINISTERED SUBCUTANEOUSLY**

Insulin preparation	Onset of action (h)	Peak action (h)	Effective duration of action (h)
Lispro insulin	0.15–0.33	1–3	3–5
Aspart insulin	0.15–0.33	1–3	3–5
Glulisine insulin	0.15–0.33	1–3	3–5
Regular (soluble)	0.5–1	2–4	5–8
NPH (isophane)	1–2	5–7	13–18
Lente (insulin zinc suspension)	1–3	4–8	13–20
Glargine insulin	1.5	no peak	up to 24
Combination 70/30 (70% NPH, 30% regular)	0.5–1		10–16
Combination 50/50 (50% NPH, 50% regular)	0.5–1		10–16
Combination (70% NPH + 30% aspart or lispro)	0.15–0.33		10–16

TABLE 107.4**ADJUSTMENT OF SUBCUTANEOUSLY ADMINISTERED INSULIN DOSE BY MEASUREMENT OF BLOOD GLUCOSE BY FINGER-STICK****Regimen 1**

Regular and intermediate-acting insulin before breakfast
 Adjust regular insulin dose from results of pre-lunch blood glucose
 Adjust intermediate-acting insulin dose from results of pre-evening meal blood glucose
 Regular insulin before the evening meal
 Adjust dose from results of 10 PM blood glucose
 Intermediate-acting insulin at 10 PM
 Adjust dose from results of next morning's fasting (pre-breakfast) blood glucose

Regimen 2

Basal insulin (glargine insulin) once a day
 Dose can be given anytime and is adjusted based on fasting blood glucose
 Regular or rapid-acting insulin before each meal
 Adjust dose by results of pre-meal blood glucose

Regimen 3

Regular insulin before each meal
 Adjust dose from results of next pre-meal blood glucose
 Intermediate-acting insulin at 10 PM
 Adjust dose from results of next morning's fasting blood glucose

Regimen 4

Regular and intermediate-acting insulin before breakfast
 Adjust regular insulin dose from results of pre-lunch blood glucose
 Adjust intermediate-acting insulin dose from results of pre-evening meal blood glucose
 Regular and intermediate-acting insulin before the evening meal
 Adjust regular insulin dose from results of 10 PM blood glucose
 Adjust intermediate-acting insulin dose from results of next morning's fasting blood glucose

In these instances, the oral medications are held the morning of the procedure and restarted after the procedure is finished.

MANAGEMENT OF THE DIABETIC PATIENT HOSPITALIZED FOR ORDINARY MEDICAL ILLNESSES OR POOR GLYCEMIC REGULATION

The majority of diabetic patients are hospitalized for ordinary medical illnesses or poor glycemic control. In either event, the major symptoms related to their diabetes are weakness, fatigue, polydipsia, polyuria, weight loss, and blurry vision. The hyperglycemic patient invariably shows signs of dehydration.

The goal of therapy is to bring the glucose into the target range of 110–175 mg/dL. A tradition among attending physicians and house staff is to place the diabetic patient on “sliding scale” coverage. Placing the patient on a treatment algorithm that stops insulin treatment when

glycemic control is good and treats with insulin after severe hyperglycemia and its consequences have developed is both irrational and counterproductive (7). Figure 107.1 illustrates the results of sliding scale coverage versus a planned insulin treatment regimen taken from a typical consultation at our medical center. Panel A (left) shows the clinical course of a 69-year-old man admitted to the surgical service for treatment of a hand abscess. On the surgical and rehabilitation services, he was treated with sliding scale coverage, which led to numerous blood glucose levels between 200 and 350 mg/dL, with wide excursions and no improvement in his glycemic control. After consultation, he was placed on the three-injection insulin treatment program (regimen 1 in Table 107.2), with the results shown in Panel B (right).

Effective hospital management of the diabetic patient cannot be achieved with “sliding scale” coverage. A carefully planned and adjusted insulin treatment regimen that is based on an understanding of the pathophysiology of hyperglycemia and the pharmacology of insulin treatment is essential for achieving adequate glycemic control.

Figure 107.1 Blood glucose levels, by hospital day, in a patient who was initially covered with a “sliding scale” (Panel A) and later switched to a three-injection subcutaneous insulin treatment program (Panel B). NPH, isophane insulin; R, regular insulin.

MANAGEMENT OF THE DIABETIC PATIENT HOSPITALIZED FOR SURGERY

The management of diabetic patients who are hospitalized for surgery should be thought of as encompassing three distinct phases of care: preoperative, intraoperative, and postoperative management.

Preoperatively, glucose control should be optimized to levels between 110 and 175 mg/dL. Long-acting antihyperglycemic agents and metformin should be stopped and insulin treatment regimens initiated if necessary. Cardiac, renal, and peripheral vascular function should be assessed and optimized.

Intraoperative management should be coordinated with the anesthesiologist. During surgery, regular insulin, glucose, and potassium should be administered intravenously. The goal of treatment is to maintain plasma glucose between 110 and 175 mg/dL. Several techniques of administration have been recommended. Gill and Alberti (5) infuse a glucose, potassium, and insulin (GKI) solution (15 units of regular human insulin and 10 mEq of potassium chloride in 500 mL of 10% glucose) at 100 mL/h. The GKI solution is started on the morning of surgery (subcutaneous insulin and food are withheld) and is continued during and after surgery until both the diet and subcutaneous insulin can be safely restarted. Blood glucose is monitored frequently by finger-stick. If the glucose is too high, a fresh GKI solution, this one containing 20 units of insulin, is started. A blood glucose level that is too low requires a reduction to 10 units of insulin per bag of GKI solution. If necessary, further adjustments in insulin can be made in increments of 5 units. With this approach, at least 80% of diabetic patients can maintain plasma glucose levels between 100 and 200 mg/dL during and immediately after surgery. This technique is particularly useful when insulin requirements during the operative and postoperative period are reasonably constant.

For patients in whom fluid overload is a concern, the glucose concentration can be doubled to 20% and the rate of infusion decreased to 25 or 50 mL/h. Serum potassium needs to be monitored every 4–6 hours because the potassium chloride content of the infusion may need to be altered. Prolonged GKI administration can lead to dilutional hyponatremia, which may require simultaneous administration of 0.9% saline solution. The ordinary ratio of insulin to glucose is 0.30 units of insulin per gram of glucose. Conditions such as severe obesity, major infections, liver disease, or steroid therapy may increase the requirement to 0.4–0.8 units of insulin per gram of glucose.

Another approach is to administer the insulin and glucose by separate infusion pumps in “piggyback” fashion. This allows independent regulation of the insulin and glucose infusion rates while a single entry portal is maintained. The glucose can be given as a 5%, 10%, or 20% solution. Insulin can be given at a rate of 0.5–10.0 units/h. Adjustments are made as necessary. Again, the goal is to maintain plasma glucose between 110 and 175 mg/dL and provide enough glucose to minimize catabolism. This approach is strongly preferred over the GKI solution approach in patients undergoing extensive surgery, especially in cases in which insulin requirements vary during different parts of the procedure and postoperative period. For example, insulin requirements during cardiac surgery average 1.6 units/h during the preoperative period, 3.0 units/h from the time of the skin incision to the onset of bypass, 5.0 units/h while the patient is on bypass, 8.3 units/h immediately after bypass, and 12.3 units/h postoperatively.

The importance of glucose control during cardiac surgery has been emphasized by Zerr and colleagues (8) and subsequent publications from the Portland Diabetes Program (4). As noted earlier, they treat their diabetic patients undergoing open heart surgery with IV insulin and glucose by “piggyback” during surgery and through the first 48 postoperative hours to maintain a plasma glucose below 175

Figure 107.2 Deep infection rate in 1,585 diabetic patients undergoing cardiac surgery, as a function of mean 48-hour postoperative glucose levels. (Redrawn from Zerr KJ, Furnary AP, Grunkemeier GL, et al. Glucose control lowers the risk of wound infection in diabetics after open heart operations. *Ann Thorac Surg* 1997;63:356–361, with permission.)

mg/dL. In assessing the relationship between glucose control and the development of deep wound infections in the first 1,585 diabetic patients undergoing cardiac surgery from 1987 to 1993 (595 of whom were treated with this intensive glucose control program), Zerr and colleagues reported a significant relationship between the mean 48-hour postoperative plasma glucose level and the development of serious wound infections (Figure 107.2).

During minimal surgery under local anesthesia, diabetic patients can frequently be managed by withholding food and oral antihyperglycemic agents on the morning of surgery, avoiding glucose-containing IV fluids, monitoring blood glucose every two hours and treating with a single insulin bolus if necessary, and restarting oral antihyperglycemic agents with the first postoperative meal.

MANAGEMENT OF THE DIABETIC PATIENT HOSPITALIZED FOR ACUTE MYOCARDIAL INFARCTION

The management of the diabetic patient with an acute myocardial infarction is analogous to that of the diabetic patient with any acute severe illness who can have nothing by mouth. Here, too, the philosophy of diabetes management has often been to treat only severe hyperglycemia, usually through the use of the “sliding scale.”

The Diabetes Mellitus Insulin Glucose Infusion in Myocardial Infarction (DIGAMI) study has refocused attention on the role of good glycemic control in reducing both the short-term and long-term mortality of diabetic patients with acute myocardial infarction (9). This study randomized 620 diabetic patients with acute myocardial infarction to either standard diabetes treatment or intensive treatment. The latter consisted of IV insulin and glucose for the first 24–48 hours, followed by subcutaneous regular insulin four times daily for at least three months. Twenty-four hours after randomization, the intensive treatment group had a mean blood glucose level of 173 mg/dL (vs. 211 in the standard treatment group). Whether because of the improved acute glucose control or the improved control during the next three months, the intensively treated patients experienced a 28% (and statistically significant) relative reduction in three-year mortality. Although still controversial, the results of the DIGAMI study and other similar efforts support the concept that plasma glucose levels should be maintained between 110 and 175 mg/dL in acutely ill diabetic patients.

THE ROLE OF INTENSIVE GLYCEMIC CONTROL BY INTRAVENOUS INSULIN IN CRITICALLY ILL PATIENTS

It has been recognized for many years that acutely ill hospitalized patients have a high incidence of hyperglycemia (blood glucose ≥ 110 mg/dL). The past approach was to attribute this hyperglycemia to stress and not to treat it unless the blood glucose values exceeded 220 mg/dL. In fact, many believed that the “stress hyperglycemia” might even be beneficial by providing extra glucose to the tissues. As evidence accumulated that severe stress inhibits insulin secretion and causes marked insulin resistance, with all its detrimental metabolic abnormalities, investigators began to hypothesize that the hyperglycemia and/or related metabolic abnormalities might actually contribute to increased morbidity and mortality. This was tested in a surgical ICU population of 1,548 mechanically ventilated patients. Patients were randomized to intensive insulin treatment (continuous intravenous insulin with frequent blood glucose monitoring, with maintenance of blood glucose throughout their ICU stay in the range of 80–110 mg/dL) or conventional treatment (with insulin infusion only if their blood glucose exceeded 215 mg/dL and blood glucose levels maintained between 180 and 200 mg/dL) (1). Mortality among patients who were in the ICU five days or more was reduced from 20.2% in the conventional treatment group to 10.6% in the intensively treated group. Intensive treatment reduced overall in-hospital mortality by 34%, bloodstream infections by 46%, acute renal failure by 41%, and critical illness polyneuropathy by 44%. The clinical benefits were present *whether or not the patients had previously diagnosed diabetes*. *Post hoc* analysis showed that patients with even modest

hyperglycemia (mean blood glucose levels of 110–150 mg/dL) in the conventionally treated group had a higher mortality rate than those in the intensively treated group. The relationship between glycemic control and mortality was linear, with a 75% increase in mortality for each 50 mg/dL increase in mean blood glucose. While the clinical benefits correlated with blood glucose control, they also correlated with other improvements in metabolism, such as normalization of dyslipidemia, suppression of inflammation, and improvement in macrophage function.

Other benefits of intensive insulin treatment were a decrease in number of required blood transfusions, reduced duration of ICU stay, and a yearly cost savings of at least \$40,000 per patient.

Tight glucose control was not without risks. Intensive insulin therapy was associated with an increased risk of hypoglycemia (5.2% versus 0.8%). However, because of the frequent blood glucose monitoring, these episodes were always rapidly diagnosed and treated and were not associated with any serious adverse events.

Protocols for intensive intravenous insulin treatment can be found in two recent references (10, 11).

DIABETIC KETOACIDOSIS AND HYPEROSMOLAR HYPERGLYCEMIC NONKETOTIC SYNDROME

Issues at the Time of Admission

Definition and Epidemiology

Diabetic ketoacidosis (DKA) and hyperosmolar hyperglycemic nonketotic syndrome (HHNS) represent the extremes of the metabolic derangements that occur in patients with diabetes mellitus. Early recognition and appropriate treatment of these life-threatening illnesses are essential. The incidence of DKA is reported to be 4.6–8.0 per 1,000 diabetic patient-years, and the incidence of HHNS is approximately 0.6–1.0 per 1,000 diabetic patient-years. These two entities are not distinctly different syndromes but represent variants of the disturbed metabolism that occurs in unregulated diabetes mellitus. DKA is characterized by hyperglycemia, ketosis, and acidosis (arterial pH \leq 7.30; plasma anion gap \geq 16 mmol/L; serum bicarbonate \leq 15 mmol/L). HHNS is characterized by plasma glucose above 600 mg/dL, plasma osmolality above 320 mOsm/L, little or no ketonemia, and arterial pH above 7.30 (Table 107.5). The patient who presents with HHNS usually has type II diabetes, is over the age of 50 years, and has some underlying impairment of renal function. The patient with DKA is more likely to have type I diabetes and to be younger and free of other chronic diseases not related to diabetes. It is important, however, to emphasize that DKA is a relatively common presentation for newly diagnosed type II diabetes in African-

TABLE 107.5

TYPICAL LABORATORY FINDINGS IN PATIENTS WITH DKA OR HHNS

	DKA	HHNS
Plasma glucose (mg/dL)	200–600	\geq 1,000
Osmolality (mOsm/L)	300–320	360
Plasma ketones (positive)	1:16	Trace or negative
Blood pH	$<$ 7.30	\geq 7.30
Plasma anion gap (mEq/L)	Usually $>$ 20	Usually $<$ 20
Serum HCO ₃ ⁻ (mmol/L)	Usually $<$ 15	Usually $>$ 15

DKA, diabetic ketoacidosis; HHNS, hyperosmolar hyperglycemic nonketotic syndrome.

American and Latino patients. As many as one in four cases of DKA occur in patients with previously undiagnosed diabetes. Many patients present with features of both syndromes (i.e., marked hyperosmolality and ketoacidosis). Mortality from DKA in the United States ranges from 2%–5%, whereas that from HHNS is reported to be as low as 12% and as high as 42%.

Pathophysiology

Table 107.6 summarizes the pathophysiology of DKA and HHNS. The primary abnormality is *markedly deficient insulin secretion*. Insulin deficiency at the level of adipose tissue results in an increase in lipolysis and the release of large quantities of free fatty acids into the circulation. Insulin deficiency also causes an increase in β -oxidation of free fatty acids in the liver, which generates increases in ketone bodies (acetoacetate and β -hydroxybutyrate). Moreover, decreased insulin action increases gluconeogenesis and glycogenolysis, which leads to markedly excessive hepatic glucose production. Insulin deficiency in muscle results in a profound fall in glucose uptake and utilization.

TABLE 107.6

METABOLIC ABNORMALITIES IN DKA AND HHNS

Organ	DKA	HHNS
Adipose tissue		
Lipolysis	↑↑↑	↑
Liver		
Glucose production	↑	↑↑↑
Ketone production	↑↑↑	↑
Muscle		
Glucose uptake	↓	↓
Proteolysis	↑↑	↑↑↑

DKA, diabetic ketoacidosis; HHNS, hyperosmolar hyperglycemic nonketotic syndrome.

It also stimulates muscle proteolysis, which in turn increases lactate and alanine release into the circulation.

The alanine and lactate provide the substrate, and the free fatty acid oxidation provides the energy for hepatic gluconeogenesis. As a result of the exaggerated glucose production by the liver and the decreased ability of muscle to take up glucose, hyperglycemia develops. Once the plasma glucose level exceeds 200 mg/dL, glucose is excreted by the kidneys, and the ensuing osmotic diuresis causes electrolyte loss and dehydration. The markedly increased levels of ketone bodies (which are weak acids) exceeds the buffering capacity of plasma. The efforts to compensate for the acidosis lead to further losses of electrolytes and to Kussmaul respiration. Table 107.7 describes the relationship between the metabolic abnormalities that occur in DKA or HHNS and the symptoms and signs with which patients present.

Diagnosis

The diagnosis of DKA must be considered in any patient who presents with symptoms of diabetes mellitus (polydipsia, polyuria, weight loss) and who shows signs of dehydration, acidosis, or both (12). The patient who presents with drowsiness, mental obtundation, or coma should raise particular concern. The diagnosis is confirmed by demonstrating a plasma glucose level above 200 mg/dL and the presence of urinary ketones, increased plasma ketones, and an arterial pH of 7.30 or less. The anion gap is increased, and the serum bicarbonate is below 15 mmol/L. The degree of hyperglycemia is not a reliable indicator of the severity of DKA. Euglycemic DKA has been well docu-

mented and usually results from factors that decrease hepatic gluconeogenesis (alcohol ingestion, starvation with decreased substrate available for gluconeogenesis, sepsis, or parenchymal liver disease). Appropriate therapy must focus on the treatment of ketonemia and acidosis.

The diagnosis of HHNS should be suspected in any patient who presents with mental obtundation and is severely dehydrated. Patients with HHNS tend to be older than those with DKA. The onset of symptoms is often more insidious, and patients more commonly have precipitating illnesses. The diagnosis of HHNS is confirmed by demonstration of plasma glucose above 600 mg/dL, a plasma osmolality above 320 mOsm/L, and minimal or no ketosis and acidosis.

A diabetic patient presenting with significant hyperosmolality, dehydration, or acidosis should be hospitalized unless adequate outpatient facilities for management and monitoring are available.

Management

The major principles in managing DKA or HHNS are as follows (12):

1. Make a rapid diagnosis, and initiate treatment immediately.
2. Maintain organ perfusion by restoring blood volume and supporting blood pressure.
3. Administer IV insulin to decrease free fatty acid release and excess ketone body and glucose production by the liver and to increase peripheral tissue glucose uptake.

TABLE 107.7

RELATIONSHIP BETWEEN METABOLIC ABNORMALITIES AND SIGNS AND SYMPTOMS OF DKA AND HHNS

Metabolic abnormality	Symptoms	Signs or ECG changes
Hyperglycemia	Malaise Tiredness	Decreased muscle mass
Catabolic state	Weight loss Muscle weakness	
Osmotic diuresis	Polyuria Polydipsia Thirst	Dehydration Dry mucous membranes Decreased skin turgor Tachycardia Hypotension
Hyperosmolality	Sleepiness Mental obtundation Coma	Multiple aspects of cerebral dysfunction
Ketoacidosis	Shortness of breath Abdominal pain Nausea and vomiting	Tachypnea Kussmaul respiration
Electrolyte loss	Muscle cramps Cardiac arrhythmias	Various ECG abnormalities

DKA, diabetic ketoacidosis; ECG, electrocardiographic; HHNS, hyperosmolar hyperglycemic nonketotic syndrome.

4. Replace electrolytes to prevent fatal hypokalemia and relieve severe symptomatic acidosis.
5. Prevent cerebral edema.
6. Minimize thromboembolic events.
7. Look for and treat concurrent illnesses, such as infections, that may have contributed to the development of ketoacidosis or hyperglycemia.

Fluid Replacement

The average patient with DKA has a deficit of 5–8 L of body water, 300–1,000 mEq of potassium, 400–700 mEq of sodium, and significant but variable amounts of phosphate and magnesium. Fluid replacement should begin immediately to maintain organ perfusion. Even though patients with DKA or HHNS are more water deficient than sodium deficient, it is best to start IV fluid replacement with 0.9% saline solution to replenish blood volume rapidly. One liter of 0.9% saline solution per hour for the first hour or two is usually adequate to maintain circulatory dynamics. This can be followed by 0.9% saline solution at 500 mL/h for the next four hours and 250 mL/h thereafter. If the serum sodium exceeds 150 mEq/L, 0.45% saline solution is administered instead of the 0.9% concentration. Faster infusion of saline solution leads to more protracted acidosis and no more rapid correction of hyperglycemia. If the patient presents with circulatory insufficiency (hypovolemic shock), 1–2 L of colloidal plasma expanders can be given.

Rehydration itself lowers blood glucose by increasing renal perfusion and glucose excretion and by decreasing the plasma levels of counterregulatory hormones. Once the plasma glucose has been reduced to 250 mg/dL, infusion of 5% or 10% glucose should replace the infusion of normal saline to allow for continued administration of insulin to correct the ketosis and metabolic acidosis. If the patient is still dehydrated at this stage, saline solution and glucose can be simultaneously administered.

A similar scheme of fluid replacement is used to correct the dehydration and fluid abnormalities in HHNS. Note that hypernatremia is more common in HHNS, and one should consider switching to hypotonic solutions after the first 1–2 L of 0.9% saline solution has been infused. Patients with extreme hyperosmolality (>350 mOsm/L) are at risk for thromboembolism, and prophylactic low-dose heparin is generally appropriate.

Insulin Administration

Low-dose soluble (regular) human insulin administered as a continuous IV infusion is the ideal treatment for DKA or HHNS. The usual starting dose is between 5 and 10 units/h in DKA; patients with HHNS often need less insulin (1–5 units/h). Intramuscular soluble human insulin can be used if tissue perfusion is good. This requires a loading dose of

10–20 units followed by 5 units/h. Subcutaneously administered insulin has no place in the treatment of DKA or HHNS.

Blood glucose should be monitored hourly and the insulin infusion rate adjusted up or down as necessary. A reasonable goal for treating the hyperglycemia is to decrease the glucose level by 75–90 mg/dL per hour until it reaches 250 mg/dL, at which time that level should be maintained with insulin (approximately 2–4 units/h) and glucose infusion (5% or 10%) until the ketosis and acidosis are resolved. At that time, the intravenous administration of insulin can be replaced with subcutaneous administration, provided the patient has recovered and is taking oral nutrition.

Potassium Replacement

Serum potassium levels at presentation of DKA may be high, normal, or low despite the total body potassium deficiency. Death can occur from hypokalemia or, rarely, from hyperkalemia, so the management of potassium levels in DKA is of critical importance. *Treatment of DKA is invariably associated with a fall in plasma potassium concentrations.* This fall results from rehydration of intracellular and extracellular fluid compartments, a direct effect of insulin on intracellular potassium transport, correction of acidosis, and excretion of urinary potassium with restoration of renal function.

If urine flow is adequate and the presenting plasma potassium level is normal or low, potassium replacement should begin when insulin therapy is started. If the initial plasma potassium is high (≥ 6 mEq/L) or urine flow is markedly decreased, it may be necessary to delay the start of potassium replacement by one or two hours until the plasma potassium begins to decrease. Potassium should be replaced at 20–30 mEq/h. If hypokalemia is present or bicarbonate is administered, then 40–80 mEq/h may be needed (Chapter 104). The plasma potassium should be monitored and maintained between 3.5 and 5.0 mEq/L. Potassium chloride is preferred initially but may be converted to potassium phosphate once the serum phosphate falls. Electrocardiographic monitoring is useful but is no substitute for frequent laboratory measurements of serum potassium.

Bicarbonate Treatment

The routine use of bicarbonate in the treatment of DKA is not beneficial and can actually increase ketone production and cause detrimental effects such as hypokalemia, paradoxical worsening of cerebrospinal fluid acidosis, and impaired oxyhemoglobin dissociation. Bicarbonate should be considered in patients with DKA only if their acidosis is so severe that they are in imminent danger of cardiovascular collapse. If the arterial pH is less than 7.0 or if bicarbonate levels are extremely low (<5 mEq/L), 50–100 mmol of

sodium bicarbonate in 250–1,000 mL of 0.45% saline solution, with 10–20 mmol of potassium added, can be given over 30–60 minutes. This can be repeated until the arterial pH exceeds 7.0.

Replacement of Other Electrolytes

Total body phosphate, magnesium, and calcium are depleted in DKA and HHNS, and plasma phosphate and magnesium fall significantly during fluid replacement. Low plasma phosphate or magnesium rarely causes untoward effects during treatment of DKA, and so replacement of these electrolytes is not routinely needed. However, serum phosphate levels below 1.0 mg/dL are associated with rhabdomyolysis, hemolysis, and cardiac dysfunction, so it is reasonable to replace phosphate if plasma levels fall below 1.5 mg/dL. Intravenous administration of phosphate (1–2 mmol/L per kilogram of body weight) during 6–12 hours is the usual treatment. Magnesium therapy is indicated only for ventricular arrhythmias that are not attributable to hypokalemia.

Complications of Treatment

The major complications of treatment for DKA and HHNS are associated with fluid overload: pulmonary edema, hypoglycemia, thromboembolism, cerebral edema, and acute respiratory distress syndrome. *Fluid overload* and *hypoglycemia* are prevented by proper monitoring of fluid intake and output, central venous pressure monitoring if indicated, and bedside blood glucose monitoring. *Cerebral edema* is a rare but well-recognized complication of treatment. It usually occurs 2–24 hours after treatment begins, is characterized by severe headache and deterioration in the level of consciousness, and is rapidly progressive and fatal if not treated aggressively (Chapter 117). The pathophysiology is poorly understood but is thought to be associated with rapid hydration and quick reduction of plasma osmolality. Treatment, which must be initiated immediately, consists of 0.5–2.0 g of IV mannitol per kilogram of body weight. The complication is best prevented by limiting the pace with which both dehydration and plasma hyperosmolality are corrected. *Acute respiratory distress syndrome* is characterized by the sudden onset of dyspnea and hypoxemia, decreasing lung compliance, and the presence of diffuse pulmonary infiltrates on chest radiography (Chapter 24). Mortality is high, and treatment consists of ventilatory support. As with cerebral edema, the cause of this rare complication is unknown. One possibility is a rapid decrease in oncotic pressure; another is a specific alveolar capillary defect induced by acidosis and hyperventilation.

Thromboembolic complications of DKA and HHNS are related to the hypercoagulable state caused by hyperglycemia and increased viscosity resulting from severe

hyperosmolality. Prophylactic heparin therapy seems appropriate in severe cases, but there are no studies to support this practice.

Issues During the Course of Hospitalization

Initial therapy should result in resolution of DKA or HHNS within the first 24–36 hours of hospitalization. Careful attention to metabolic regulation should avoid the complications of treatment. On hospital days 2 through 4, any problems that contributed to the development of DKA or HHNS (e.g., infections) should be addressed. Patients in whom DKA or HHNS has resolved and who are taking oral nutrition can also be converted to a subcutaneous insulin treatment regimen (in the case of DKA) or to either a subcutaneous insulin or oral antihyperglycemic treatment regimen (in the case of HHNS).

When a patient is switched from an IV to a subcutaneous insulin regimen, it is important to recognize that the effects of IV insulin generally last for less than an hour. Subcutaneous soluble (regular) human insulin achieves peak levels 2–4 hours after injection, and subcutaneous NPH or Lente human insulin achieves such levels 6–9 hours after injection. Therefore, the subcutaneously administered insulin program (Table 107.2) should be initiated 1–3 hours before IV insulin is discontinued.

Discharge Issues

The major issues at discharge are ensuring that the patient receives adequate diabetes education and planning appropriate outpatient management for glycemic, lipid, and blood pressure control. Diabetes education is essential if the patient is to learn how to prevent recurrent episodes of DKA or HHNS. It can also help the patient achieve target goals for metabolic control as an outpatient. In addition to receiving inpatient education, the patient should be referred to a diabetes education center staffed by diabetes educators and dietitians.

Most patients with DKA are discharged on a subcutaneous insulin treatment regimen, usually consisting of 2–4 injections per day. Adjustments to target glycemic controls are made in the outpatient setting. Patients with type II diabetes presenting with DKA are discharged on a subcutaneous insulin treatment program and can frequently be switched to oral antihyperglycemic agents after several months of good outpatient glycemic control. Many patients with HHNS can be switched from insulin-based regimens to oral antihyperglycemic agents within several weeks of discharge.

Patients being discharged after admission for DKA or HHNS should monitor their blood glucose regularly and their urine for ketone bodies when they feel ill. Such monitoring enables them to recognize early ketosis and take appropriate steps to prevent DKA.

HYPOGLYCEMIA

Issues at the Time of Admission

Although hypoglycemia is common, it rarely justifies hospitalization in and of itself. Hypoglycemia is caused by either inadequate production of glucose by the liver and kidney or excessive peripheral utilization of glucose. Both these processes are influenced by insulin and counterregulatory hormones. Excessive administration or secretion of insulin increases peripheral glucose utilization and decreases hepatic glucose production. Counterregulatory hormones increase hepatic glucose production and gradually decrease peripheral tissue sensitivity to insulin. In the normal person, a falling blood glucose level triggers an autonomic response that increases hepatic glucose production, decreases insulin secretion, and causes hunger (resulting in increased food intake). Diabetic patients treated with insulin or insulin secretagogues are not able to compensate for hypoglycemia by decreasing insulin secretion, and the autonomic nervous system function of these patients may be impaired, which hampers the counterregulatory responses to hypoglycemia.

Clinical Presentation

Symptoms of hypoglycemia are attributable to activation of the autonomic nervous system (sweating, tachycardia, tremor, and hunger) or to cerebral glucose deficiency (decreased cognitive function, mental obtundation, and coma). Ordinarily, autonomic nervous symptoms occur first and warn the person that hypoglycemia is occurring so that food can be sought. Neuroglycopenic (cerebral glucose deficiency) symptoms may render a person incapable of combating the hypoglycemia. Unfortunately, in patients with tightly controlled type I diabetes or in diabetic patients with autonomic neuropathy, hypoglycemic unawareness (i.e., lack of the autonomic response) results in the loss of these autonomic warning signs. In such persons, the sudden occurrence of neuroglycopenic symptoms must be treated by someone other than the patient.

Diagnosis

A history of classic symptoms accompanied by a blood glucose level below 50 mg/dL confirms the diagnosis of hypoglycemia. All patients who present with cognitive disorders, personality changes, or disturbed consciousness should have their blood glucose measured. If hypoglycemia is found, a history of diabetes with insulin or insulin secretagogue administration should be sought. Other causes of hypoglycemia to be considered in a person without diabetes include islet cell tumors, liver disease, adrenal insufficiency, and mesenchymal tumors.

Indications for Hospitalization

Most episodes of severe hypoglycemia in type I diabetic patients can be managed in the emergency department. Prolonged severe hypoglycemia can lead to temporary or permanent neurologic damage, and patients exhibiting such signs and symptoms require hospital admission for evaluation.

Any diabetic patient taking insulin secretagogues (sulfonylureas) in whom hypoglycemia sufficient to cause severe neuroglycopenic symptoms develops needs to be hospitalized for treatment. Drugs such as chlorpropamide, glyburide, and glipizide may continue to cause hypoglycemia for periods as long as 24–72 hours. Therefore, treatment requires not only acute IV glucose administration but also longer infusions for 24–72 hours.

Initial Therapy

The usual treatment of hypoglycemia is immediate administration of 50 mL of 50% glucose in water. This is followed by an infusion of 10% glucose administered at a rate of 100 mL/h. The infusion rate is adjusted based on the blood glucose determination.

Intravenous or intramuscular administration of 1 mg of glucagon can facilitate the treatment of hypoglycemia in diabetic subjects but is effective only if the patient is well nourished and liver glycogen stores are adequate. In the hospital setting (where IV glucose is available), there is no indication for glucagon administration. In the event that IV access is not possible or is delayed, intramuscular glucagon administration can temporarily relieve the hypoglycemia until other measures can be instituted.

In a patient who develops severe hypoglycemia secondary to insulin secretagogues and is partially resistant to treatment with intravenous glucose, the addition of octreotide 50 mcg subcutaneously every eight hours for 2–3 doses can help ameliorate the hypoglycemia. The octreotide inhibits endogenous insulin secretion. In patients with hypoglycemia secondary to insulin-producing tumors, either octreotide or oral diazoxide can reduce insulin secretion and improve hypoglycemia.

Issues During the Course of Hospitalization

The major issue for the diabetic patient during hospitalization is to identify the precipitants of hypoglycemia and educate the patient about measures to modify them. Usually, precipitants involve inadequate meal planning, not preparing for strenuous exercise, excessive ingestion of alcohol, or an inappropriate diabetic treatment program.

Discharge Issues

The primary discharge issues are educational. Persons with type I diabetes who have had a severe hypoglycemic episode are at increased risk for additional episodes. The treatment plan of each patient should be reevaluated.

COST CONSIDERATIONS AND RESOURCE USE

In one survey, 23.8% of all adults with diabetes reported being hospitalized in the previous year (13). The majority of these patients were hospitalized for the care of chronic complications or for other medical or surgical illnesses. A one-day extension of hospital stay for each diabetic patient would result in an increase of approximately 2.3 million hospital bed-days. It is obvious that efficient regulation of glycemia during hospital admissions could yield enormous savings in health care resources.

Approximately 50%–75% of DKA episodes are caused by a lack of appropriate care, either attributable to the patient or the health care system. Diabetes education for patients and their families can have a major impact in reducing episodes of ketoacidosis.

The cost of long-term diabetes care has been shown to correlate well with the quality of glycemic control. Costs of medical care were calculated for a cohort of diabetic patients in a health care plan during the three-year period from 1992 to 1995 (14). The costs for patients with a hemoglobin A_{1c} of 7%, 8%, 9%, and 10% were 4%, 10%, 20%, and 30% higher, respectively, than the costs for comparable patients with a hemoglobin A_{1c} of 6%. For a patient with diabetes, hypertension, and heart disease with a hemoglobin A_{1c} of 10%, the three-year cost of care was \$49,673; the cost for a comparable patient with a hemoglobin A_{1c} of 6% was \$38,726. Thus, appropriate management of hospitalized patients with diabetes mellitus can result not only in better outcomes but also in huge reductions in health care costs and utilization.

KEY POINTS

- The clinical management of diabetic patients includes appropriate hospital management in addition to long-term metabolic control in the outpatient setting.
- Optimal glycemic control (in the range of 110 to 175 mg/dL) has been shown to improve outcomes and lower costs in hospitalized diabetic patients.
- Hyperglycemia in acutely ill ICU patients should be normalized by an intensive insulin treatment program.
- Acute metabolic complications of diabetes (diabetic ketoacidosis and hyperosmolar hyperglycemic nonketotic syndrome) can be life threatening. Appropriate management includes rapid correction of glycemia and electrolyte and fluid imbalance, treatment of any precipitants, and a coordinated transition to outpatient care.
- Hypoglycemia is managed acutely with glucose infusion, which may need to be continued for days if the precipitant was a long-acting oral hypoglycemic agent. Hypoglycemia often represents a failure of diabetes education, which should be addressed before the patient is discharged.

Acute Presentations of Thyroid Disease

108

Leonard Wartofsky

INTRODUCTION

Although most disorders of the thyroid gland present subacutely or chronically and can be managed safely in the office setting, acute presentations of profound hyperthyroidism and hypothyroidism are dramatic and life threatening and require rapid action on the part of the hospital physician. This chapter discusses the entities of thyrotoxic storm and myxedema coma; refer to Chapter 106 for a discussion of thyroid function test abnormalities in hospitalized patients.

THYROTOXIC STORM

The syndrome of thyrotoxic "storm" or "crisis" is a life-threatening complication of severe hyperthyroidism. Thyroid storm is a state of disordered homeostasis resulting from acute decompensation of the cardiovascular, central nervous, gastrointestinal, and hepatorenal systems. A clinical suspicion of worsening thyrotoxicosis with a threat of storm may prompt hospitalization, or, perhaps just as frequently, storm will occur in a thyrotoxic patient who is already hospitalized for another medical or surgical problem. Historically, thyrotoxic storm after thyroidectomy, thoracoabdominal surgery, or obstetric procedures in thyrotoxic patients ("surgical storm") was a common complication and major cause of mortality. Early diagnosis and modern improvements in preoperative medical treatment of the thyrotoxic patient have led to a decline in the incidence of surgical storm. Today, thyrotoxic storm develops most frequently in the setting of systemic illness such as infection ("medical storm"), although surgical storm remains a potential problem. Awareness of the precipitant of storm, whether medical or surgical, helps guide the selection of therapy.

Issues at the Time of Admission

Etiology of Storm

In a patient hospitalized with nonthyroid systemic illness or operative stress, thyroid hormone binding to its carrier proteins in blood is altered, which leads to increases in the tissue-active free hormone concentration. This process may convert a previously stable patient with uncomplicated thyrotoxicosis into one with storm. Therefore, values for total thyroxine (T_4) or total triiodothyronine (T_3) determined by radioimmunoassay may be no different in thyroid storm than in uncomplicated thyrotoxicosis because it is the concentration of free or unbound thyroid hormone that is generally responsible for clinical decompensation. Indeed, Brooks and Waldstein (1) demonstrated a twofold increase in the percentage of dialyzable T_4 and concentration of free T_4 in storm in comparison with these values in uncomplicated severe thyrotoxicosis. Storm can also occur as a result of T_3 toxicosis, with normal serum total and free T_4 but elevated levels of total and free T_3 . Increased thyroid release of T_4 and T_3 has not been directly implicated in the development of thyrotoxic storm. In some instances, however, storm appeared after vigorous gland palpation, therapy with radioactive iodine (^{131}I), and iodine administration, which suggests that augmented glandular hormone release was responsible, at least in part.

Clinical Presentation

The clinical presentation of thyroid storm is often dramatic, with classic signs of severe thyrotoxicosis together with manifestations of multiple organ system failure. The diagnosis should be considered in the thyrotoxic patient with fever, marked tachycardia, congestive heart failure,

diarrhea, and central nervous system signs that may vary from confusion to coma. The importance of making an early and correct diagnosis and of initiating immediate vigorous therapy relates to the extremely high potential mortality rate. Although storm occurs in only 1%–2% of all hospitalizations for thyrotoxicosis, the reported mortality rates in large inpatient series have ranged from 30%–100% (2). Because the perioperative and postoperative periods (after both thyroid and nonthyroid surgery) are common settings for storm, surgeons and hospital physicians must maintain a heightened awareness of the potential for storm in patients with known or suspected thyroid disease.

Issues During the Course of Hospitalization

Diagnosis

Successful therapy for thyrotoxic storm begins with early and accurate diagnosis. Unfortunately, it is not possible to differentiate storm from severe, otherwise uncomplicated thyrotoxicosis on the basis of laboratory test findings. The diagnosis is most obvious with a classic and dramatic presentation of fully developed storm, which includes fever ($>38.5^{\circ}\text{C}$), altered mental status, congestive heart failure, and frequent, watery stools. However, by the time the patient manifests such a presentation, opportunities for early therapy have passed, and the mortality is significantly increased. Burch and Wartofsky (2) have proposed a scoring system to assist in the distinction between severe thyrotoxicosis and thyrotoxic storm (Table 108.1).

Patients with thyroid storm usually have some degree of alteration in central nervous system function. Although symptoms of tremor, restlessness, irritability, and emotional lability are characteristic of thyrotoxicosis, confusion, lethargy, and psychosis culminating in stupor and coma are quite typical of storm but unusual in uncomplicated thyrotoxicosis without premorbid psychopathology. Indeed, central nervous system dysfunction is so common in storm that preservation of normal mentation in a febrile thyrotoxic patient is strong clinical evidence against impending storm and may suggest a superimposed infection.

The gastrointestinal system is often involved in patients with storm. Diarrhea is the most frequent complaint, although abdominal pain, nausea, and vomiting are not uncommon. Hepatic function is variably affected; mild degrees of liver dysfunction are the rule, and frank hepatic failure is seen occasionally. Malnutrition can be profound, with weight loss often exceeding 20 kg, reflecting the underlying catabolic state. Additionally, hypoglycemia and hypoalbuminemia may be seen in storm and reflect longstanding severe caloric deficits.

Having made a diagnosis of thyroid storm, the clinician is required to search carefully for and treat an event or illness that led a case of uncomplicated thyrotoxicosis to evolve into storm (Table 108.2). Infection, often occult, is the most common precipitating event.

TABLE 108.1
DIAGNOSTIC CRITERIA FOR THYROID STORM

	Points
Thermoregulatory dysfunction	
Temperature: 99–99.9°F	5
100–100.9	10
101–101.9	15
102–102.9	20
103–103.9	25
≥ 104	30
Central nervous system effects	
Absent	0
Mild agitation	10
Delirium, psychosis, lethargy	20
Seizure or coma	30
Gastrointestinal dysfunction	
Absent	0
Diarrhea, nausea, vomiting, or abdominal pain	10
Unexplained jaundice	20
Cardiovascular dysfunction	
Tachycardia: 90–109 beats/min	5
110–119	10
120–129	15
130–139	20
≥ 140	25
Congestive heart failure	
Absent	0
Mild (edema)	5
Moderate (bilateral basilar rales)	10
Severe (pulmonary edema)	15
Atrial fibrillation	
Absent	0
Present	10
History of precipitating event (surgery, infection, other)	
Absent	0
Present	10

Points are assigned as applicable and the scores totaled. When it is not possible to distinguish a finding caused by an intercurrent illness from one of thyrotoxicosis, the higher point score is given so as to favor empirical therapy of storm. Under cardiovascular dysfunction, separate points are given for the findings of tachycardia, atrial fibrillation, or congestive heart failure. Interpretation: Based upon the total score, the likelihood of the diagnosis of thyrotoxic storm is as follows: unlikely, <25 ; impending, 25–44; highly likely, >45 .

From Burch HB, Wartofsky L. Life-threatening thyrotoxicosis: thyroid storm. *Endocrinol Metab Clin North Am* 1993;22:263–277.

Management

Successful therapy requires management directed toward four therapeutic goals: (a) reducing hormone synthesis and release from the thyroid; (b) antagonizing peripheral actions of existing excesses of circulating hormone; (c) providing supportive care and avoiding homeostatic decompensation; and (d) defining and treating any precipitating or complicating underlying conditions.

Therapy Directed Against the Thyroid Gland

The inhibition of thyroid hormone synthesis and release is the cornerstone of acute treatment. The *thionamides*,

TABLE 108.2
CLINICAL DISORDERS THAT CAN
PRECIPITATE THYROTOXIC CRISIS

Infection (bronchopneumonia, pharyngitis, meningitis, sepsis)

Hypoglycemia
Parturition
Trauma (including vigorous and repetitive thyroid palpation)
Therapy with ¹³¹ I
Emotional stress
Thiourea withdrawal

propylthiouracil (PTU) and methimazole (Tapazole), are potent inhibitors of organification of iodine. Provided that adequate dosages are used, thionamides profoundly reduce hormone synthesis in virtually all patients. Although their onset of action is relatively rapid after oral administration, it may take weeks to see clinical improvement. Therefore, other, more rapidly-acting therapies should be added (see below). In addition to blocking iodine organification, PTU inhibits the peripheral conversion of T₄ to the much more active T₃, thereby facilitating a more rapid fall in serum T₃ concentration than does methimazole, which lacks this property. Initially, PTU is administered in a dosage of 1,200–1,500 mg/d (200–250 mg given orally every 4 hours); alternatively, methimazole in a dosage of 120 mg/d (20 mg given orally every 4 hours) may be used. Although the use of a thionamide in a patient with previous thionamide-related hepatocellular dysfunction or agranulocytosis cannot be recommended, a history of minor rash or urticaria with these agents should not prevent their use in storm. Unfortunately, no suitable intravenous (IV) preparation of either PTU or methimazole is available. Rectal administration of either PTU or methimazole suppositories can achieve therapeutic blood levels in the patient for whom oral agents are contraindicated or impractical (3).

Although further synthesis of iodothyronines in the thyroid may be effectively blocked by thionamides, continued release of preformed hormone from glandular stores will persist unabated during thionamide treatment. Addition of another agent, such as *stable iodine* or *lithium carbonate*, is necessary to inhibit thyroid release of preformed hormone. Because Lugol iodine solution as sole therapy will augment and enrich hormonal stores in the thyroid, organification should be blocked with a thionamide before iodine therapy is begun. If organification has not been blocked, the iodine treatment can result in worsening of thyrotoxicosis. Although Lugol solution (0.5 mL orally every 6 hours) is ef-

fective, an IV infusion of sodium iodide (1 g every 24 hours) is equally effective and eliminates potential concerns related to variable gut absorption. Commercial preparations of the latter are no longer available in the United States but may be specifically formulated. In contrast to the slow decline in serum levels of T₄ and T₃ seen with sole thionamide therapy, levels fall rapidly after iodine therapy is added (with nearly normal values often reached in 3–5 days).

Iodinated radiographic contrast dyes such as ipodate (Oragrafin) have been used increasingly in the management of thyrotoxicosis. Iodate is effective in inhibiting glandular iodine release because of the large amount of stable iodine present in this compound (approximately 65% by weight). Iodate is also a potent inhibitor of the conversion of T₄ to T₃ in many tissues. The efficacy of ipodate for thyrotoxic storm has not been extensively studied, but a rapid decline in circulating T₄ and T₃ levels is typically seen in thyrotoxicosis with a daily dose of 1–3 g orally (in addition to adequate thionamide treatment). Another iodine-rich compound, amiodarone, should be equally effective but has not yet been studied in this setting. It could be used in an urgent situation if no other iodine source were available, but only in combination with a thionamide. A 200 mg tablet (containing 74 mg iodine) once or twice daily should suffice.

Occasionally, a patient with thyrotoxic storm will also have a clear history of iodine allergy. In such patients, *lithium carbonate*, which has been used successfully in the treatment of thyrotoxicosis, should be considered. At an initial dosage of 300 mg every 6 hours, lithium is usually effective in inhibiting thyroid hormone release. To avoid lithium toxicity, serum levels must be monitored daily with doses titrated to maintain a plasma lithium level of approximately 1.0 mEq/L. Regardless of which agent is chosen, the most important thing is to start therapy to inhibit hormone release as early as possible after initiation of thionamides. In the absence of comparative trials, the author's preference is to use Lugol iodine, ipodate, or amiodarone. If none of these is readily available, lithium carbonate would be started.

Although ¹³¹I may be considered for definitive therapy after storm has resolved (see below), *radioactive iodine should not be administered during the acute phase of thyroid storm*. This is because the associated destruction of thyroid follicular cells would release more T₄ and T₃, thereby potentially aggravating the thyroid crisis.

Therapy Against Ongoing Effects of Thyroid Hormone in the Periphery

The activity of the sympathetic nervous system is greatly enhanced in thyrotoxic storm. *β-adrenergic receptor antagonists*, especially propranolol (40–80 mg every 6 hours orally), have become the drugs of choice to counteract this hyperadrenergic state. Frequently, larger doses are required to reduce sympathetic nervous system activity in storm

because serum levels are variable after customarily employed doses. In the critically ill patient, IV propranolol in doses of 1–2 mg may be used initially until effective serum levels are achieved after oral administration. The ultra-short-acting β -adrenergic blocker esmolol can also be used for the perioperative management of thyroid storm. A loading dose of 0.25–0.5 mg/kg, followed by a continuous infusion at a rate of 0.05–0.1 mg/kg per minute, has been shown to be effective. The role of β -adrenergic blockade when congestive heart failure is present in storm is arguable, but it can be beneficial if the agent is titrated with careful hemodynamic monitoring.

Occasionally, adequate control of clinical thyrotoxicosis is not achieved despite massive doses of propranolol. In addition to β -adrenergic blockade, other more aggressive means of reducing hormone concentrations in the periphery are dialysis and plasmapheresis. Hemoperfusion through a resin bed or charcoal columns may be similarly employed (4). Finally, some removal of circulating T_4 and T_3 can be achieved safely by the use of cholestyramine resin; this agent binds thyroid hormone entering the gastrointestinal tract via enterohepatic recirculation.

Two other issues related to the use of β -blockade are worth mentioning. First, several cases of storm have been reported in patients being treated with β -blockers unaccompanied by antithyroid drug blockade (5). Therefore, one cannot rely on therapy with β -blockers alone and assume either that storm cannot supervene or that such monotherapy is adequate in severe thyrotoxicosis. Second, in the patient allergic to thioureas, surgery can be performed under β -blockade, albeit more safely with simultaneous administration of iodine, ipodate, or lithium carbonate (6).

Therapy Directed Against Systemic Decompensation

The serious prognosis of thyrotoxic storm mandates admission or transfer to a critical care unit for careful monitoring. Aggressive treatment of fever is mandatory. Acetaminophen is the preferred antipyretic agent because salicylates can increase free hormone levels by displacing thyroxine from serum protein binding sites. Aggressive cooling measures, including alcohol washes, cooling blankets, and ice packs, may be required. Fever, especially if accompanied by diarrhea and vomiting, can lead to large fluid losses, and fluids must be vigorously replaced to prevent cardiovascular collapse. Volume status must be monitored carefully because excessive fluid depletion is also a threat in storm. Congestive heart failure may be precipitated by atrial tachyarrhythmias, impaired myocardial contractility, or volume overload. Therapy with digitalis and diuretics is beneficial, although the required dose of digoxin is often high because of the altered distribution and metabolism of digitalis. Depleted hepatic glycogen and water-soluble vitamins must also be replaced. Typically, 10% dextrose supplied in hypotonic saline solution at a

rate of 3–4 L each day with vitamin supplementation is adequate.

Prompted by concern over potentially impaired adrenocortical reserve, clinicians have long used glucocorticoids empirically in patients with thyrotoxic storm. Although no controlled trials have proved its efficacy, this practice has a scientific rationale, as plasma clearance rates for cortisol in patients with thyrotoxicosis are twice those of euthyroid controls. Furthermore, the response of urinary 17-hydroxycorticosteroids to infusions of adrenocorticotrophic hormone (ACTH) may be blunted in thyrotoxicosis. An additional benefit of steroids is that they inhibit the conversion of T_4 to T_3 , as do PTU and ipodate. An initial dose of 300 mg of hydrocortisone followed by 100 mg every 8–12 hours should be adequate (2) (Chapter 109).

Therapy Directed Against the Precipitating Illness

The precipitating cause of thyrotoxic storm is often readily apparent, as in cases presenting after trauma, thyroidectomy, and parturition. No specific therapy need be administered for these causes once the initial insult has passed. Hypoglycemia, ketoacidosis, pulmonary emboli, or stroke complicating storm will require the same specific therapy generally reserved for these conditions in the absence of storm. With a stuporous patient, a high index of suspicion for these (often occult) precipitating events must be maintained.

Although fever may occur in thyrotoxic storm in the absence of infection (presumably representing the “hypermetabolic” state), it is vitally important to exclude underlying infection. Cultures of blood, urine, and other appropriate fluids (including spinal fluid in the obtunded patient) are mandatory. In many cases, it is wise to initiate broad-spectrum antibiotics, with administration guided by the clinician’s best impression of the most likely site of infection. The antibiotics can then be subsequently tailored or discontinued based on culture results.

Issues at Discharge

Definitive Therapy of Thyrotoxicosis

The rapid clinical diagnosis of early thyrotoxic storm and aggressive therapeutic intervention provide the best chance for successful resolution. Discharge should not be considered until all vital signs have been stable for 48 hours and cardiovascular and mental status have returned to baseline. As the patient begins to improve clinically, the various therapeutic measures can be gradually withdrawn. Steroids should be rapidly tapered. Whether or not to continue antibiotic treatment is guided by standard recommendations based on site of infection and etiologic agent. The withdrawal of thioureas, stable iodine, and β -blockers may be more difficult clinical decisions. If storm has occurred in the postthyroidectomy setting, it should be self-limited, because the source of thyroid hormone has been ostensibly excised. In the event that only a lobectomy or a lobectomy and

isthmusectomy were performed, medical therapy with thioureas and β -blockade will have to be continued and gradually tapered, with monitoring per standard recommendations for medical therapy in the postoperative patient.

Once the acute danger is past, attention can be directed to the long-term management of thyrotoxicosis. In cases of storm occurring outside the perioperative period, definitive treatment of the underlying thyroid disorder is strongly recommended to prevent another episode of storm. The traditional titration regimen of slowly withdrawing thioureas in the hope of maintaining a long-term remission is usually inappropriate in a patient whose thyrotoxicosis was severe enough to result in storm. Rather, *definitive therapy with radioactive iodine or surgery is indicated*. The large doses of stable iodine administered during the episode of storm will flood the body pool of iodine, diminish thyroid uptake of radioactive iodine, and thereby limit the possibility of employing ablation with radioactive iodine as definitive therapy, at least until some future date when the iodine load has cleared. Thus, in the majority of such cases, it seems preferable to consider surgical treatment 2–4 weeks after resolution of the episode of storm, and to continue aggressive therapy in the meantime with thioureas, iodine, and β -blockers.

MYXEDEMA COMA

Myxedema coma is a rare syndrome that represents the extreme expression of severe hypothyroidism. The syndrome most often is seen in hospitalized, elderly women with longstanding hypothyroidism, and the classic features of that disease usually are present. Most patients have an underlying disorder of the thyroid gland itself; fewer than 10% have hypothalamic or pituitary disease as the basis of hypothyroidism. Once considered, the diagnosis should be easy to establish on both clinical and laboratory grounds, but the disorder can still be associated with a mortality rate as high as 60% despite appropriate and vigorous therapy (7).

Issues at the Time of Admission

Clinical Presentation

Precipitating Events

Myxedema coma is most often encountered during the winter months, which suggests that external cold may be an aggravating factor. Other events associated with myxedema coma include pulmonary infections, cerebrovascular accidents, and congestive heart failure (Table 108.3). Pulmonary infection also can occur as a secondary event in the comatose, hypoventilating patient, as can aspiration pneumonia. Similarly, it can be difficult to determine whether other abnormalities, such as hyperglycemia, hyponatremia, hypercapnia, and hypoxemia, which often are associated

Acidosis

with myxedema coma, contributed to the coma or are secondary consequences. Drugs often initiate or compound the downward spiral of the hypothyroid patient into coma. Common culprits include anesthetics, opiates, sedatives, antidepressants, and tranquilizers, and the mechanism appears to be related to depression of the respiratory center.

Clinical Appearance

Two of the cardinal features of myxedema coma are *hypothermia* and *unconsciousness*. It is not unusual for the syndrome to present in patients with previously undiagnosed hypothyroidism whose illness has become complicated by infection or other systemic disease. There may be a history of antecedent thyroid disease, thyroid hormone replacement therapy that was discontinued for no apparent reason, or therapy with radioactive iodine. Examination of the neck may reveal a surgical scar and nonpalpable thyroid tissue, or a goiter may be present. The course often is one of lethargy progressing to stupor and then coma, which can be hastened by the use of sedatives or opiates, which leads to respiratory failure and retention of carbon dioxide. The usual features of dry, coarse, and scaly skin, delayed deep tendon reflexes, sparse or coarse hair, carotenemic pallor, puffy facies, large tongue, and hoarseness may be present, in addition to moderate-to-profound (e.g., 80°F) hypothermia.

Respiratory System

The most important factor underlying the ventilatory abnormality in myxedema is a *depression of the hypoxic respiratory drive*, which can be accompanied by a depressed ventilatory response to hypercapnia. The resulting decrease in alveolar ventilation leads to progressive carbon dioxide narcosis and coma, and impaired respiratory mus-

cle function may compound the hypoventilation. Muscle function is usually reduced enough that mechanical ventilation is required, especially if opiate or sedative drugs are playing a role in the depressed ventilation. Several other physical or anatomic factors can impede ventilation in the hypothyroid patient, such as pleural effusions or ascites. In addition, swelling of the tongue and tissue of the upper respiratory tract with a myxedematous infiltrate can cause partial obstruction that may progress during superimposed infection (e.g., laryngeal obstruction caused by marked edema of the vocal cords) to an acute respiratory emergency.

Cardiovascular Manifestations

The findings considered typical of hypothyroid heart disease also are observed in myxedema coma, including enlargement of the cardiac silhouette, bradycardia, decreased quality and intensity of the heart sounds, and minor electrocardiographic abnormalities. The latter consist of varying degrees of block, low voltage, prolonged QT interval, and flattened or inverted T waves. Although enlargement of the cardiac silhouette may partly represent ventricular dilatation, it is usually caused by pericardial effusion secondary to accumulation of fluid rich in mucopolysaccharide. The fluid tends to accumulate over a long time, and as a consequence, cardiac tamponade is rare.

Stroke volume and cardiac output are reduced on the basis of impaired cardiac contractility, but frank congestive heart failure is very rare. The abnormalities in left ventricular function and the pericardial effusion gradually normalize with thyroxine replacement. The lactate dehydrogenase isoenzyme pattern in severe hypothyroidism can mimic that of myocardial infarction, and creatine kinase levels also are elevated (troponins have not been studied). To add to the potential confusion, myocardial infarction (from atherosclerotic disease) can be the precipitating event for myxedema coma, and patients with hypothyroidism are at risk for myocardial infarction during injudicious overreplacement of thyroid hormone. Nevertheless, the mortality of untreated myxedema coma demands vigorous treatment with thyroid hormone, as discussed below.

Although total body water and extracellular fluid volume may be increased, intravascular volume is reduced, and this contributes to the propensity for hypotension. Increases in blood pressure regularly follow replacement with thyroid hormone. Cardiovascular collapse and shock may supervene in myxedema coma before there is adequate time for thyroid hormone to act, in which case the use of pressors (along with thyroid hormone) is mandatory. In this situation, the potential for fatal arrhythmias is extremely high, and careful monitoring in an intensive care unit (ICU) is essential.

Gastrointestinal Manifestations

Decreased intestinal motility is common in hypothyroidism, and its most severe expression, paralytic ileus, is

frequent in myxedema coma. Impaired peristalsis may be a consequence of both neuropathic changes related to thyroid deficiency and myxedematous infiltration of the gut wall. Accompanying problems include constipation and obstipation, both of which improve with replacement therapy. Gastric atony in myxedema coma is a particularly troublesome problem because absorption of oral medications is affected. Because of this, parenteral administration of T₄ or T₃ may be preferable, as discussed below.

Renal and Electrolyte Manifestations

Abnormalities noted in severe hypothyroidism include increased body water, decreased plasma volume, decreased serum sodium and osmolality, increased urine sodium and osmolality, and reduced glomerular filtration rate and renal plasma flow. Bladder atony with retention of large residual urine volumes is not unusual. Hyponatremia, if present, is likely to compound the patient's confusion and, when severe, may be largely responsible for precipitating coma. Treatment with thyroid hormone promotes water diuresis, with a resultant decrease in edema and total body water and an increase in serum sodium.

Neuropsychiatric Manifestations

The patient with the full-blown syndrome of myxedema coma manifests or complains of few neuropsychiatric signs or symptoms other than the coma itself. There may be history of disorientation, depression, paranoia, or hallucinations ("*myxedema madness*"). The subjects demonstrate poor memory or frank amnesia, varying degrees of somnolence and lethargy that progress to coma, and cerebellar signs, such as clumsy movements of the hands and feet, ataxia, and adiadochokinesia. Minor seizures or frank convulsions occur in about 25% of patients with myxedema coma, but hyponatremia may be responsible for most of these. In these usually elderly patients, decreased cardiac output combined with arteriosclerotic cerebrovascular disease is likely to produce decreased perfusion and cerebral hypoxia. All functional parameters improve gradually with thyroid hormone replacement.

Hypothermia

Hypothermia is present in about three-fourths of patients, often is dramatic (<80 °F), and may be the first clinical clue to the diagnosis. Underlying hypoglycemia may serve to decrease body temperature further. A careful history and physical examination in the hypothermic patient usually serve either to confirm the diagnosis of myxedema or to render it sufficiently unlikely to justify awaiting the results of serum T₄ and thyrotropin (TSH) determinations before initiating treatment. The presence of any appreciable hypothermia implies a poor prognosis, and the immediate initiation of thyroid hormone therapy is mandatory. With treatment, the hypothermia gradually improves in parallel with increments in serum T₄ and T₃ levels.

Diagnosis

The importance of making the diagnosis cannot be stressed strongly enough because the unnecessary administration of relatively large doses of thyroid hormone to an elderly euthyroid patient clearly can be fatal. On the other hand, when the likelihood of myxedema coma is reasonably high, treatment should not be delayed pending laboratory confirmation. It may be difficult to distinguish severe fatigue and somnolence in a patient with uncomplicated hypothyroidism from true myxedema coma. Although overzealous treatment in such a patient is discouraged, diagnostic aggressiveness is mandatory to determine whether carbon dioxide retention, hypoxia, hyponatremia, or infection is present.

Of great interest is the observation that coma frequently occurs in hypothyroid patients while they are hospitalized for other problems or for diagnostic studies. In these cases, precipitating factors may include the stress of diagnostic procedures, administration of IV fluids, or, more importantly, the all-too-common routine hospital use of sedative and hypnotic drugs. In many patients, the clinical features can be so overwhelming (for example, the comatose elderly woman with a history of hypothyroidism who has coarse skin, macroglossia, hypothermia, bradycardia, hyponatremia, ileus, and an enlarged silhouette) that thyroid function tests are necessary only for retrospective confirmation of the diagnosis. *The urgency of the diagnosis should be stressed to the laboratory, which often can perform a serum T₄ determination within 1 hour and a TSH determination within 3 hours.* Although an elevated serum TSH concentration is the most important laboratory evidence of the diagnosis, one must be alert to the possibility that pituitary disease is causing the hypothyroidism, in which case both T₄ and TSH levels will be low. Until pituitary disease is ruled out, corticosteroid therapy, in addition to thyroid hormone, is required. On the other hand, a low serum T₄ and normal serum TSH would suggest that the patient may be exhibiting the euthyroid sick syndrome (Chapter 106) and is not hypothyroid.

Issues During the Course of Hospitalization

Infection

The possibility of occult pneumonia leading to worsening respiratory status has been mentioned. Pneumonia and other infections can be overlooked because of the frequent absence of fever, diaphoresis, and tachycardia in the hypothyroid patient. Respiratory tract infection may be more common because of the risk for aspiration in a stuporous patient, particularly one with seizures related to hyponatremia. Because of these considerations and the fear that undiscovered infection can lead to vascular collapse and death, some authors advocate the routine use of antibiotics in patients with myxedema coma. This approach is most defensible if limited to the delicate period during the initial

24–48 hours of management. An alternative approach is to remain alert to the possibility of infection and institute specific antibiotic therapy only when indicated on the basis of appropriate specimen smears and cultures.

Therapy

In view of the extremely high mortality rate in untreated patients with myxedema coma, *it is essential that treatment be instituted promptly and vigorously as soon as the diagnosis is made.* The entire treatment team should be made aware that it is dealing with a medical emergency, and meticulous interdisciplinary care in a critical care setting with modern electronic monitoring equipment is essential.

Ventilatory Support

Hypoventilation resulting from a number of factors may cause carbon dioxide retention and respiratory acidosis and aggravate the comatose state. Appropriate diagnostic and therapeutic measures must be instituted when any suspect infiltrate is apparent on the chest radiograph, with the understanding that fever and cough may not be prominent. Death from respiratory failure is not unusual, and hence the maintenance of an adequate airway to prevent hypoxemia is the single most important supportive measure. Mechanical ventilatory support is usually required during the first 48 hours, particularly if the hypoventilation partly represents drug-related respiratory depression. Although the patient may become alert by the second or third day of therapy, complicated cases can require mechanical ventilation for as long as 3 weeks. Arterial blood gases must be monitored regularly until the patient is fully recovered. Numerous reports have cited the danger of relapse with premature extubation. Hence, weaning should be approached conservatively and should never be attempted until the patient is fully conscious.

Hyponatremia

Total body sodium is probably normal-to-increased, and impaired water excretion is the major underlying reason for hyponatremia. Therapy with IV fluids in general, and saline solution in particular, must be approached cautiously because cardiac reserve is often decreased. If hypoglycemia is present, sodium chloride should be added to any fluids given to correct the low blood glucose, or a concentrated glucose solution should be used. Otherwise, fluid restriction may be all that is necessary to correct mild (120–130 mEq/L) hyponatremia. If severe (<120 mEq/L) hyponatremia is present, it may be appropriate to administer a small amount of hypertonic saline solution (50–100 mL of 3% or 5% sodium chloride) early in the course of treatment; this can be followed by an IV bolus of 40–120 mg of furosemide to promote a water diuresis. A central venous pressure line should be used to monitor fluid therapy, and placement of a Swan-Ganz catheter is justifiable in the presence of significant cardiovascular decompensation.

Hypothermia

Administration of thyroid hormone ultimately is essential to restore body temperature to normal. Until that effect is achieved, some physical means of keeping the patient warm is advisable; ordinary blankets or an increase of room temperature can be used, but *great caution must be exercised in external warming*. The use of electric warming blankets can cause vasodilation and a precipitous fall in peripheral vascular resistance. The resultant augmentation in peripheral blood flow is accompanied by an increase in oxygen consumption, which can aggravate hypotension or even lead to vascular collapse.

Hypotension

Like hypothermia, hypotension should improve with thyroid hormone replacement. Because this can take several days or longer, profound hypotension requires additional therapy. Initially, fluids can be cautiously administered as 5%–10% glucose in half-normal sodium chloride solution or as isotonic sodium chloride if hyponatremia is present. Administration of hydrocortisone (100 mg IV every 8 hours) may be justified until the tendency toward hypotension is corrected and adrenal insufficiency is excluded. In rare patients, pressor agents may be required to maintain a blood pressure sufficient to sustain adequate perfusion, notwithstanding the risk for inducing ventricular tachyarrhythmias, especially in patients with underlying ischemic heart disease. An agent such as dopamine is generally preferable to norepinephrine to maintain coronary blood flow (Chapter 25), but in any event, an effort should be made to taper the dose and wean the patient from any pressor agent as soon as possible. An adverse interaction between administered catecholamine and thyroid hormone is possible, and the physician must weigh this risk against the known high mortality in myxedema coma associated with refractory hypotension.

Corticosteroids

The coexistence of adrenal insufficiency in patients with myxedema coma is suggested by the presence of hypotension, hypothermia, hypoglycemia, hyponatremia, and hyperkalemia (Chapter 109). The ACTH response to stress may be impaired in these patients, and, given the potential risk to the patient undergoing the stress of acute illness versus the relative safety of short-term steroid therapy, there should be no reluctance to administer corticosteroids until the patient is stable and the integrity of the pituitary–adrenal axis is determined. With the institution of thyroid hormone therapy, there is an additional theoretical basis for supplemental corticosteroids: the accelerated metabolism of cortisol that follows T_4 replacement in hypothyroidism, which can theoretically precipitate adrenal crisis from relative adrenal insufficiency. Hydrocortisone is usually given in a dosage of 50–100 mg every 6–8 hours during the first 7–10 days and is then tapered on the basis of clinical response and plans for further diagnostic evaluation.

Thyroid Hormone Therapy

The most controversial aspect of the management of myxedema coma is the selection of the optimal method for restoring the low serum and tissue concentrations of thyroid hormone to normal. Differences of opinion largely relate to whether to administer T_4 , which is then converted to T_3 by the patient, or T_3 itself. Secondary issues include dosage and route of administration (of either compound). Different approaches to management are based on balancing concerns for the high mortality of the untreated disease and the obvious need for attaining effective thyroid hormone levels against the risks of precipitating a fatal tachyarrhythmia or myocardial infarction. The optimal mode of therapy remains uncertain because of the relative rarity of this condition and the consequent paucity of controlled studies.

Those who advocate T_4 as the therapeutic choice point out that it provides a steady, smooth onset of action with less risk for adverse effects. Oral forms of T_4 (and T_3) can be given by nasogastric tube (8), but this route is fraught with risks for aspiration and uncertain absorption, particularly because gastric atony may be present. Preparations of T_4 for parenteral use are available in ampules of 100 and 500 mcg, and the latter dose has been advocated as a single IV bolus to restore near-normal hormonal status as rapidly as possible. After the initial loading dose, a daily maintenance dose of 50–100 mcg is given (IV or by mouth when the patient becomes alert). This method results in increases in serum T_4 to within the normal range within 24 hours and significant decrements in serum TSH. Larger doses of T_4 probably have no advantage and may, in fact, be more dangerous. The major potential drawback to the total reliance on generation of T_3 from T_4 is that the rate of conversion of T_4 to T_3 is reduced in a variety of systemic illnesses (*low T_3 syndrome* (9)). Therefore, T_3 generation may be reduced in myxedema coma as the consequence of an associated illness. In view of this potential problem, it seems prudent to add small supplements of T_3 to the T_4 during the initial few days of therapy, especially if significant associated illness is present. Regardless of which type of therapy is selected, all patients should have continuous electrocardiographic monitoring so that the dosage of thyroid hormone can be reduced if arrhythmias or ischemic changes are detected.

In addition to the problem of failure to generate T_3 from T_4 in the sick patient, advocates of T_3 point to its much quicker onset of action. T_3 (Triostat) is available in 1-mL vials containing 10 mcg/mL. Therapy with T_3 alone may be given as a 20-mcg bolus followed by 10 mcg every 4 hours for the first 24 hours, with the dosage dropped to 10 mcg every 6 hours for the second and third days, by which time oral administration should be feasible. Increases in body temperature and oxygen consumption may occur 2–3 hours after intravenous T_3 , compared with 8–14 hours after IV T_4 . This rapid onset of action may come at the cost of a greater risk for cardiac complications. Indeed, high serum

levels of T_3 during treatment with thyroid hormone have been associated with fatal outcomes.

For these reasons, *combination therapy with both T_4 and T_3* is a rational approach until better data on which to base a decision become available. Instead of a dose of 300–500 mcg of T_4 given IV initially, a dose of 4 mcg per kg of lean body weight (or about 200–300 mcg) is given, and an additional 100 mcg is given 24 hours later. By the third day, the dose is reduced to a daily maintenance dose of 50 mcg, which can be given by mouth as soon as the patient is stable and conscious. This dose subsequently is adjusted on the basis of clinical and laboratory results, as in any other hypothyroid patient. The author would also give a bolus of 20 mcg of T_3 at the same time as the initial dose of T_4 and continue IV T_3 at a dosage of 10 mcg every 8 hours until the patient is conscious, taking maintenance T_4 , and achieving physiologic levels of T_3 . Sensitivity to thyroid hormone in terms of cardiac risk varies, depending on age, cardiac medications, and the presence of underlying hypoxemia, coronary artery disease, congestive failure, and electrolyte imbalance. No general guide to management can take all these factors into account, and hence it is wise to consult an endocrinologist and monitor the patient carefully for any untoward effects of therapy before each dose of thyroid hormone is administered.

In addition to the specific therapies outlined, general supportive measures are indicated, as in all elderly, cachectic patients. These measures include treating any underlying problems with specific medications (e.g., appropriate therapy for congestive heart failure), with the understanding that the dosage of other drugs may need to be modified based on their altered distribution and metabolism in myxedema. Unfortunately, the prognosis for myxedema coma remains grim even with vigorous therapy, and patients who have severe hypothermia and hypotension fare the worst. Perhaps further elucidation of thyroid economy in health and disease will point the way to more effective approaches to therapy. Until then, early recognition and treatment, with meticulous attention to the details of management during the first 48 hours, remain critical.

Discharge Issues

Patients may be ready for discharge when their cardiovascular status and vital signs are stable, their serum electrolytes have normalized, they are taking oral nutrition and medications, and ventilatory assistance has been discontinued for 48 hours with maintenance of normal oxygen saturation or stable and acceptable values for arterial blood gases. Discharge medications (in addition to thyroid hormone) may include appropriate antibiotics to complete a course of treatment for any underlying infection. Corticosteroids can be rapidly tapered if adrenal insufficiency is no longer a consideration. Because adrenal insufficiency coexisting with primary hypothyroidism is almost always a consequence of primary adrenal disease (rather than pituitary disease), a

short stimulation test with ACTH (Cortrosyn) can be performed before discharge (while the patient is maintained on dexamethasone, a synthetic steroid that will not interfere with the measurement of cortisol) (Chapter 109).

In regard to thyroid hormone therapy, if T_3 has been administered during the acute phase of the myxedema coma, it can generally be discontinued in favor of levothyroxine by the time of discharge. Once vital signs are stable, there is no longer any urgency to increase the levothyroxine dosage rapidly to full physiologic replacement. A discharge dosage of as little as 50–75 mcg per day will be safe and preclude recurrence of myxedema coma. The dosage can be titrated to appropriate physiologic replacement on an outpatient basis according to the results of serial measurements of serum TSH, with the target TSH level in the range of 0.5–1.5 mU/L. Patients and their caregivers should be educated regarding the need to remain on *lifelong thyroid hormone replacement*, with annual follow-up once the maintenance dose has been determined.

KEY POINTS

- Thyroid storm, a potentially lethal complication of hyperthyroidism, presents with classic signs of thyrotoxicosis, accompanied by fever, diarrhea, altered mental status, and tachycardia.
- Myxedema coma, a potentially lethal complication of hypothyroidism, presents with classic signs of hypothyroidism, along with hypothermia, hypoventilation, and unconsciousness.
- Both patients with thyroid storm and those with myxedema coma should be admitted to the intensive care unit.
- Therapy for thyroid storm requires a four-pronged approach and includes the following:
 1. Therapy directed at the thyroid gland (use iodine only after thioureas have been started)
 2. Therapy for the systemic decompensation (fever, fluid losses, congestive heart failure, hypotension)
 3. Therapy directed at the ongoing effects of thyroid hormone in circulation
 4. Treatment of the precipitating illness
- Therapy for myxedema coma should be started immediately (i.e., without waiting for results of thyroid function tests) if clinical suspicion is high. Initial therapy requires intravenous administration of relatively high doses of T_4 , T_3 , or both, and attention to the key role of hypoventilation.

Adrenal Insufficiency and Crisis

109

David G. Gardner

INTRODUCTION

Adrenal insufficiency (AI), although uncommon in its native form, has become increasingly prevalent with the use of exogenous corticosteroids in the management of pulmonary, rheumatologic, and allergic disorders. This has engendered a need for increased vigilance on the part of clinicians caring for patients with these disorders as well as for other patients at risk. AI can be insidious in presentation and devastating in outcome if it remains untreated. This chapter covers the diagnosis and management of AI in the hospitalized patient.

ADRENAL PHYSIOLOGY AND PATHOPHYSIOLOGY

The adrenal gland can be divided into functional zones. The outermost zone, the *zona glomerulosa*, is responsible for the production of mineralocorticoids (e.g., aldosterone). Aldosterone promotes sodium retention and potassium excretion in the kidney. Angiotensin II and extracellular potassium levels govern the synthesis and release of aldosterone.

The *zona fasciculata/reticularis* is positioned between the *zona glomerulosa* and the adrenal medulla. It is responsible for the production of glucocorticoids (i.e., cortisol) and adrenal androgens. The *zona fasciculata/reticularis* is under the trophic control of adrenocorticotropin (ACTH), which is produced and released from corticotropes located in the anterior pituitary gland. ACTH is responsible for producing an adequate level of cortisol to meet tissue needs. ACTH secretion is pulsatile in nature and under the control of corticotropin-releasing hormone (CRH) and, to a lesser extent, vasopressin. These peptides are produced in the hypothalamus.

Circulating cortisol levels are regulated through a negative feedback mechanism in which the steroid controls the synthesis and release of ACTH. Thus, as circulating cortisol levels rise, plasma ACTH levels fall and cortisol secretion declines. At some point, circulating cortisol levels fall below the threshold for suppression of ACTH release, and levels of the latter once again increase. Administration of exogenous glucocorticoid leads to suppression of ACTH release and loss of the trophic drive for endogenous steroid production. Typically, this results in both functional and anatomic atrophy of the adrenal glands, which can take months to recover following discontinuation of the steroid. Prolonged impairment of endogenous glucocorticoid production (e.g., through autoimmune destruction of the adrenals) results in significant elevations in circulating ACTH levels without commensurate increments in adrenal steroid production.

Adrenal insufficiency can result from defects at a number of points in the neuroendocrine and endocrine cascade. Bilateral lesions of the adrenal glands themselves reduce secretion of mineralocorticoids, glucocorticoids, and adrenal androgens because the anatomic substrate for the manufacture of these steroids is lacking. Defects that are intrinsic to the adrenal glands are said to result in *primary AI* or *Addison's disease*. Table 109.1 presents some of the known causes of primary AI. Most cases in adults are caused by *autoimmune adrenalitis*, a disorder that may or may not be accompanied by other autoimmune endocrinopathies (e.g., thyroiditis, diabetes mellitus, gonadal disease, hypoparathyroidism) and associated findings (e.g., vitiligo or mucocutaneous candidiasis). In the past, tuberculosis was the leading cause of primary AI, but it is now less common. This should be considered in indigent patients, in recent immigrants from areas where tuberculosis remains endemic, and in HIV-infected patients with a history of exposure to

TABLE 109.1
CAUSES OF ADRENAL INSUFFICIENCY

Primary AI	Secondary AI
Autoimmune adrenalitis	Exogenous steroid administration
Tuberculosis	Pituitary adenoma
Fungal infection	Metastatic disease in hypothalamus or pituitary
Malignancy	Ischemic necrosis/pituitary apoplexy
Hemorrhage	Infiltrative disease
Infiltrative disease	Empty sella
Genetic	Lymphocytic hypophysitis

AI, adrenal insufficiency.

tuberculosis. The question of AI is frequently raised in the setting of HIV disease. Although the incidence of cytomegalovirus adrenalitis is high in the AIDS population, the incidence of true AI is probably less than 5% (1). This incidence likely increases with end-stage disease. When AI occurs in this setting, it is typically associated with disseminated mycobacterial disease, fungal disease, bilateral adrenal hemorrhage (as a manifestation of antiphospholipid antibody syndrome), or malignancy (e.g., lymphoma or Kaposi sarcoma). Drugs that impair steroidogenesis (e.g., ketoconazole) or increase the turnover of steroids (e.g., rifampin) also warrant consideration.

Adrenal insufficiency may also arise through loss of the trophic influence of ACTH on adrenal steroidogenesis. Thus, intrinsic hypothalamic–pituitary disease or functional suppression of corticotropes with exogenous steroids may lead to what has been termed *secondary AI*. Table 109.1 also presents potential causes of secondary disease.

ADRENAL INSUFFICIENCY AT THE TIME OF HOSPITALIZATION

Issues at the Time of Admission

Clinical Presentation

The presentation of AI can be subtle, which makes it difficult to diagnose, particularly when it represents a single component of a multifactorial illness, such as sepsis, or develops insidiously over a protracted period of time.

Chronic AI, such as that associated with autoimmune adrenalitis or chronic tuberculosis, presents primarily with constitutional symptoms. Patients complain of weakness, fatigue, general malaise, anorexia, and weight loss. The latter is often of sufficient magnitude to raise the possibility of malignant disease. Patients also complain of vague abdominal discomfort, nausea with or without vomiting, and diarrhea. Hypotension, often with orthostatic signs and symptoms, is seen frequently, particularly in patients with primary AI. Although glucocorticoids are thought to be

important in the maintenance of hepatic glucose production during periods of fasting, hypoglycemia in AI is rare except in children. The most typical diagnostic finding in chronic primary AI is *skin hyperpigmentation*. This is thought to reflect increased levels of melanocyte-stimulating hormone (MSH) and perhaps ACTH itself. The pigmentation is diffuse but can be accentuated in sun-exposed regions. Most notably, it tends to be found in areas where normal pigmentation is typically sparse (e.g., buccal or vaginal mucosa, gums, nail beds, extensor surfaces of the elbows and knees, and creases of the palms). Hyperpigmentation is absent in secondary AI; skin pallor is more typical of this disorder. Loss of axillary and pubic hair may be seen in female patients, reflecting loss of adrenal androgen production.

Acute AI can arise as a result of rapid destruction of adrenal tissue (e.g., during bilateral adrenal hemorrhage) or of acute intercurrent illness in a patient with otherwise “compensated” chronic AI. The clinical presentation of acute AI is more compressed than that of chronic AI. Symptoms of cortisol deficiency may be intensified and accompanied by symptoms referable to the underlying precipitant (e.g., flank, abdominal, or chest pain with acute adrenal hemorrhage). Precipitous loss of adrenal function or exhaustion of adrenal reserve in the setting of heightened stress can result in *adrenal crisis*. This is characterized by hyperthermia, hypoglycemia, intravascular volume contraction, altered mental status, and cardiovascular instability. Responsiveness to vasoconstrictors is compromised by glucocorticoid deficiency. Pressor-resistant hypotension in the appropriate clinical setting should raise suspicion of underlying AI and prompt a trial of steroids. Such a trial engenders little risk to the patient and may be life saving in persons with adrenal compromise.

Differential Diagnosis and Initial Evaluation

The presentation of chronic AI can be confused with that of many chronic wasting disorders, including disseminated malignancy. Acute AI with or without adrenal crisis can be mistaken for sepsis, intracranial disease, myocardial dysfunction, or intra-abdominal catastrophe. In each instance, consideration of the possibility of AI often leads to the correct diagnosis. The combination of hyponatremia and hyperkalemia seen in primary AI also occurs in hypoaldosteronism secondary to diabetes mellitus, interstitial nephritis, and administration of drugs (e.g., heparin, non-steroidal anti-inflammatory drugs). The same electrolyte abnormalities in AIDS patients more often represent a combination of inappropriate secretion of antidiuretic hormone (SIADH) secondary to pulmonary or central nervous system disease and administration of high doses of trimethoprim-sulfamethoxazole (1). The latter agent has a triamterene-like effect in the distal nephron that leads to impaired potassium excretion.

Laboratory studies are the mainstay of the diagnosis of AI. Typically, these studies are designed both to document

the presence of AI and to provide some information regarding the location of the structural or functional lesion (i.e., differentiate primary from secondary AI). Clues to the presence of impaired adrenal function can sometimes be obtained from routine laboratory studies. Eosinophilia or increased numbers of lymphocytes in peripheral blood counts suggest a relative deficiency of circulating glucocorticoids. Increased blood urea nitrogen may be seen as a consequence of volume contraction in primary AI. Hyponatremia can be seen with either primary or secondary AI and appears to reflect increased antidiuretic hormone secretion. Hyperkalemia, reflecting mineralocorticoid deficiency, is suggestive of primary AI.

Random cortisol levels are not particularly helpful in identifying patients with AI unless they consistently fall below 3 mcg/dL (5 mcg/dL in the setting of acute illness) (2). Urinary free cortisol levels are similarly of little use in establishing the diagnosis because they reflect only a small percentage of the total adrenal secretory product during a given 24-hour period.

When AI is suspected, the first step should be to carry out a *rapid ACTH (Cortrosyn) stimulation test* (see Figure 109.1). A basal blood sample is drawn to assess pre-ACTH cortisol levels. Then 250 mcg of synthetic ACTH is administered intramuscularly or intravenously, and additional blood samples are collected 30–60 minutes later. A normal

response requires an increase in cortisol levels to above 18 mcg/dL following ACTH administration. The older criteria requiring an increment of more than 7 mcg/dL have largely been abandoned because of the lack of specificity in identifying patients with structural lesions causing true AI.

In general, patients with plasma cortisol levels above 20 mcg/dL at any point during the test can be regarded as having a functionally adequate hypothalamo–pituitary–adrenal axis. An exception to this rule may exist in patients with established septic shock. In one recent study (3), 300 medical and surgical patients were treated with a combination of 200 mg of hydrocortisone and 50 mcg of fludrocortisone daily for 7 days. Those patients who demonstrated a synthetic ACTH-dependent increment in plasma cortisol of less than 9 mcg/dL from baseline to peak level and were treated with the hydrocortisone/fludrocortisone combination showed both decreased mortality (53% vs 63% in the placebo-treated group) and a reduction in the duration of vasopressor therapy. Those with increments greater than 9 mcg/dL showed no benefit from steroid therapy. While this area remains controversial, the threshold for providing supplemental steroid therapy in patients with septic shock and diminished response to ACTH should probably be low, particularly if suspicion of functional adrenal insufficiency is high (e.g., hypotension poorly responsive to fluids and conventional vasopressors).

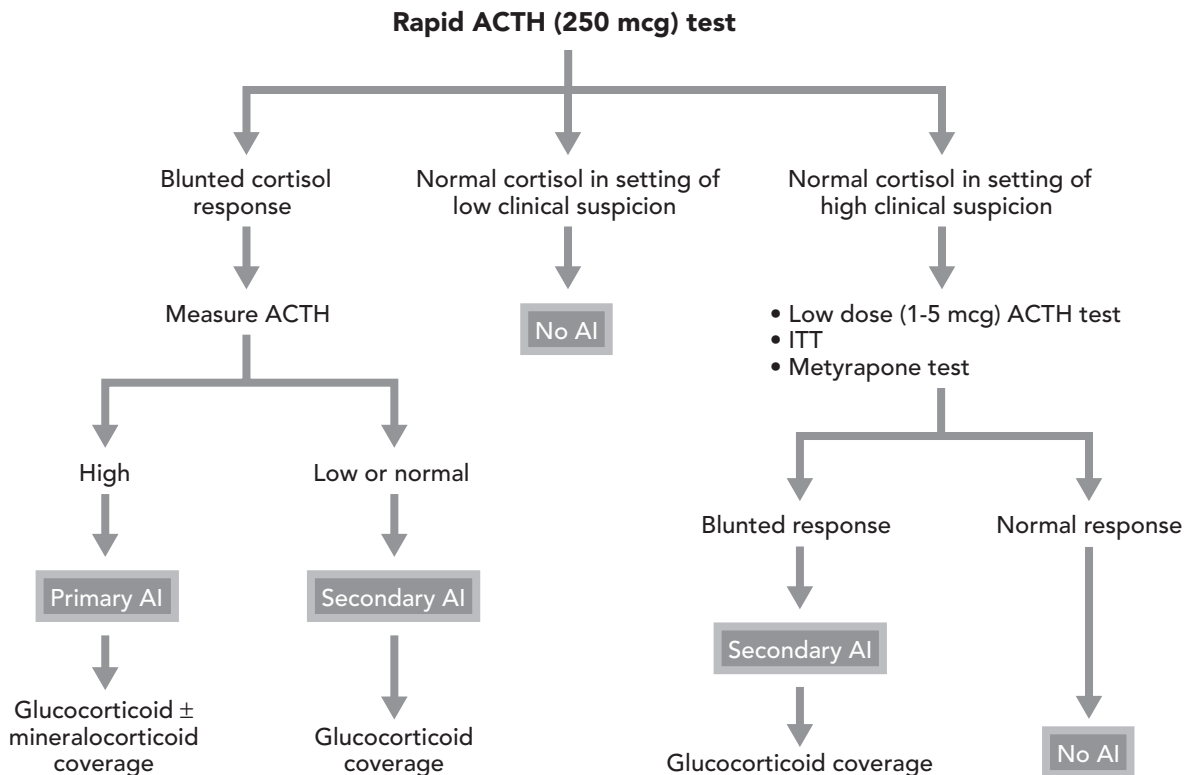

Figure 109.1 Algorithm for the evaluation of adrenal insufficiency. AI, adrenal insufficiency; ITT, insulin tolerance test. (Modified from Felig P, Baxter JD, Frohman LA, eds. *Endocrinology and Metabolism*. 3rd ed. New York: McGraw-Hill, 1995:555–712, with permission.)

The characteristics of abnormal responses to the ACTH test vary, depending on the nature and duration of the AI. Long-standing primary AI is typically associated with low-normal or frankly suppressed basal cortisol levels that do not increase or increase only modestly following ACTH administration (4). Patients with secondary AI may have normal basal levels, but the increment following ACTH administration is truncated, and the requisite cutoff of 18 mcg/dL is not reached. This truncated response reflects the functional adrenal atrophy that develops with long-term ACTH deficiency. Acute or subacute loss of ACTH secretion can be associated with a completely “normal” rapid ACTH test result despite the presence of profound secondary AI. In this instance, the duration of ACTH deficiency has not been adequate to effect the degree of adrenal atrophy required for the abnormal response.

Measurement of plasma ACTH levels is often helpful in differentiating primary from secondary AI. These levels are typically elevated in the former and either normal or frankly depressed in the latter. When findings are equivocal, a more extensive evaluation of the hypothalamic–pituitary–adrenal axis may be warranted later in the hospitalization or after discharge (Figure 109.1 and below).

Performance of the rapid ACTH test adds only 30 minutes to the initial evaluation, and if possible, it should be completed before cortisol replacement is administered. If the presentation suggests adrenal crisis, dexamethasone (2–4 mg) can be substituted for cortisol replacement. Dexamethasone does not interfere in conventional cortisol assays and thus will not impair interpretation of the ACTH test in the acute setting. Measurement of serum aldosterone levels before and after ACTH administration may provide additional information to aid in the evaluation. A normal aldosterone response (peak >5 ng/mL) is preserved in secondary but not in primary AI.

The utility of the rapid ACTH (250 mcg) test in excluding AI, particularly in the setting of acute illness, has sparked an ongoing debate. Data has been put forward suggesting limited adrenal secretory reserve and/or resistance to endogenous glucocorticoids in this setting (perhaps related to excessive cytokine production), neither of which is addressed by the conventional ACTH test. More refined testing (e.g., with the more physiological 1 mcg ACTH test) may help resolve this issue in the future. In the meantime, clinical judgment should play a role in guiding the decision to provide or withhold glucocorticoid coverage. If clinical suspicion is high, yet the patient shows a normal ACTH (250 mcg) test, short-term treatment with steroids is justified until the patient stabilizes and more definitive testing can be carried out (5).

Therapy

Appropriate therapy of AI is dictated largely by the anticipated glucocorticoid requirements of the patient in a given

clinical setting. Thus, management of chronic AI differs considerably from that of acute AI.

Once a diagnosis of chronic AI has been established, the patient should be started on a replacement dose of glucocorticoid. Typically, 20 mg of cortisol in the morning and 10 mg in the evening provides sufficient replacement for the average patient, but this may need to be titrated to minimize overtreatment or undertreatment. Weight gain is frequently one of the first signs of cryptic glucocorticoid excess in this setting. Other glucocorticoids, such as prednisone, can be substituted in bioequivalent doses.

In patients who display clinically significant *mineralocorticoid deficiency*, 9 α -fluorocortisol (Fluorinef) at a dosage of 0.05–0.2 mg daily can be used to control hyperkalemia, orthostatic hypotension, or other symptoms of intravascular volume depletion. Excessive mineralocorticoid levels can result in hypertension and hypokalemia, so the dose should be adjusted empirically. When high doses of cortisol are administered in the acute setting, supplemental mineralocorticoid is usually not required, even in primary AI, because of the intrinsic mineralocorticoid properties of the glucocorticoid.

As noted earlier, acute AI and adrenal crisis represent medical emergencies requiring immediate attention. A rapid ACTH test should be carried out and cortisol given intravenously as soon as the diagnosis is suspected. The dosage should be 100 mg every 8 hours. This is probably in excess of the endogenous glucocorticoid response to stress but guarantees adequate coverage in the acute setting. If the ACTH test fails to confirm the diagnosis and clinical suspicion is low, steroids can be withdrawn. If suspicion remains high despite a normal ACTH test result or if the diagnosis is confirmed, stress-dose steroids should be continued as long as the patient remains unstable. If the clinical situation improves, the hydrocortisone dose can be reduced by half on the second hospital day and then gradually tapered to replacement doses during the next 3–4 days. Dose reduction should be carried out only after careful examination of the patient indicates that the crisis is resolving. Attention should also be directed toward early correction of the sequelae of acute AI. This includes restoring intravascular volume, correcting anemia secondary to adrenal hemorrhage, and correcting hyperkalemia and hypoglycemia if present. Adrenal crisis in a patient with otherwise stable chronic AI and good medication compliance usually arises in the setting of acute physiologic stress. The source of this stress (e.g., sepsis, myocardial ischemia, pulmonary embolus, cerebrovascular accident) should be investigated, but this should not delay the initiation of steroid therapy.

Issues During the Course of Hospitalization

When the results of the rapid ACTH test are equivocal or “normal” but the suspicion of secondary AI remains high, additional testing may be warranted (Figure 109.1).

The low-dose (1–5 mcg) ACTH stimulation test is often useful in identifying subtle deficiencies in adrenal secretory reserve that are not apparent with the standard test (6). The metyrapone test and insulin tolerance test, which examine the entire hypothalamic–pituitary–adrenal axis, are useful in evaluating situations in which borderline or equivocal responses to ACTH stimulation have been identified (7). Nevertheless, they are fraught with potential hazards, such as precipitation of AI or myocardial ischemia, and deaths have been recorded. They are best carried out in consultation with an endocrinologist.

Once the diagnosis of AI has been established and the probable locus of the defect identified, imaging studies may be indicated to provide additional diagnostic information and assist with management. Both computed tomography (CT) and magnetic resonance imaging (MRI) have been used effectively to study the adrenal glands. The choice of one over the other hinges on the availability of radiologic consultants experienced in evaluating adrenal lesions, the type of lesion suspected, and the expense. Typically, one looks for evidence of (a) *adrenal atrophy* suggestive of autoimmune adrenalitis or chronic granulomatous disease, (b) *adrenal enlargement* compatible with metastatic disease, active granulomatous inflammation, hemorrhage, or rarely congenital adrenal hyperplasia, and (c) *parenchymal calcifications* suggestive of chronic granulomatous disease or old hemorrhage. When secondary AI is suspected in a patient who has not received exogenous steroids, MRI of the sella contents and hypothalamus is indicated, particularly if there is evidence of other pituitary hormone deficiency.

Approach to the Incidental Adrenal Mass

Autopsy studies suggest that the frequency of adrenal adenomas approaches 6% in unselected adult populations. Most of these are clinically silent. Increased use of high resolution imaging studies such as CT and MRI have resulted in more frequent detection of adrenal masses during investigation for unrelated intra-abdominal pathology (8, 9). The overwhelming majority of these so-called “adrenal incidentalomas” are nonfunctional cortical adenomas. The remainder are aldosteronomas, pheochromocytomas, cortisol-secreting adrenal adenomas, adrenocortical carcinoma, or metastases originating from malignancies outside the adrenal.

Typically the goals in approaching the incidental adrenal mass are to mitigate morbidity attendant to hormone overproduction by the lesion if it exists and to identify malignancies sufficiently early in their development to allow interventions that will prolong survival. Workup for these lesions should include: (1) measurement of urinary metanephrines and fractionated catecholamines to exclude pheochromocytoma, (2) performance of a 1 mg overnight dexamethasone suppression test to exclude Cushing syndrome, and (3) measurement of serum K^+ and plasma aldosterone concentrations, and plasma renin activity (for

calculation of Aldo:PRA ratio) if the patient is hypertensive. Functional adenomas, lesions that are more than 4 cm in diameter, lesions that are less than 4 cm in diameter but that increase more than 1 cm over a 12-month period, or lesions that have malignant characteristics on CT or MRI should be removed through a laparoscopic approach (9). *Fine needle aspiration (FNA) is not indicated for most primary adrenal lesions* and, in fact, is contraindicated if a pheochromocytoma or adrenal cortical carcinoma is suspected. FNA may have limited utility in diagnosis of a suspected metastases or adrenal involvement with tuberculosis or other infections. Each of these typically presents with manifestations outside the adrenal glands.

Discharge Issues

Patients with chronic AI should be instructed to increase their glucocorticoid dose in the setting of physiologic stress. With mild-to-moderate stress (e.g., viral syndrome or minor trauma), doubling the glucocorticoid dose for several days followed by a return to the basal dose as the stress resolves is often sufficient to provide the requisite increase in coverage. With more serious illness, patients should receive 100 mg of intravenous cortisol every 6–8 hours. This typically takes place in a hospital setting. For potentially serious stress outside the hospital, the patient should be instructed to take 100 mg of cortisol and come to the emergency department for further evaluation. Patients who do not live in close proximity to medical aid should be provided with parenteral steroid preparations for use in emergency situations. MedicAlert bracelets should be obtained for all patients with known or suspected AI. These bracelets should include information regarding the diagnosis, the patient’s medications, and the physician to contact in case of an emergency.

ASSESSMENT AND MANAGEMENT OF THE PATIENT PRESENTING WITH ADRENAL INSUFFICIENCY DURING A HOSPITALIZATION

This scenario is best subdivided into anticipated and unanticipated AI. The former would include patients admitted for deliberate reduction in exogenous steroid dosage, bilateral adrenalectomy, or transsphenoidal resection of an ACTH-producing pituitary tumor. In each instance, AI is anticipated, and appropriate steroid coverage is provided. The appearance of unanticipated AI several days into a hospitalization should raise the possibilities of exogenous steroid administration before admission, administration of drugs such as rifampin or ketoconazole (which unmask limited adrenal secretory reserve), or bilateral adrenal hemorrhage secondary to ongoing sepsis, thrombotic disorders, or anticoagulant administration. As explained above, patients should receive immediate steroid coverage

and undergo a rapid ACTH stimulation test followed by more definitive characterization of the functional and anatomic location of the defect.

Management of the patient with AI in the perioperative period warrants special consideration. Relatively minor surgery in the outpatient setting may not require more than the usual replacement coverage. Procedures likely to cause an intermediate level of physiologic stress (e.g., limb revascularization) should prompt the prescription of additional steroid coverage. One hundred milligrams of intramuscular cortisol, or its equivalent, on call to the operating room, and 50 mg every 8 hours for the ensuing 24 hours, should provide adequate perioperative coverage. The intramuscular dose provides a depot of steroid to cover the possibility of missed or delayed steroid doses in the immediate postoperative period. If the patient is stable, the parenteral dose can be reduced by half on the second or third postoperative day. The oral daily replacement dose can then be reestablished when the patient is able to resume oral intake. For patients undergoing major surgical procedures that are likely to lead to near-maximal physiologic stress, 100 mg of intramuscular cortisol should be given on call to the operating room, and 100 mg should be given intravenously every 8 hours, or 75 mg every 6 hours, through the day of surgery. The dose of cortisol can be reduced in stepwise fashion beginning on the second or third postoperative day while the physician watches for possible early signs of AI. It can then typically be tapered to replacement levels by the seventh postoperative day, provided postoperative complications do not develop.

KEY POINTS

- Adrenal insufficiency in either the chronic or acute form may present in such a nonspecific manner that the diagnosis is overlooked initially.
- Recognition of the appropriate clinical setting and compatible clinical manifestations are the most important factors leading to a successful diagnosis.
- In the acute setting, administration of exogenous glucocorticoid should be initiated after completion of a rapid ACTH stimulation test.
- If therapy cannot be delayed, the ACTH stimulation test can be carried out while the patient is treated with dexamethasone.

- Patients with chronic adrenal insufficiency require additional steroid coverage during periods of moderate-to-severe physiologic stress.
- Early diagnosis of adrenal insufficiency and careful attention to the details of patient management are the keys to long-term survival in this disorder.

INTRODUCTION

The rheumatic diseases constitute a heterogeneous group of illnesses with correspondingly heterogeneous clinical signs and symptoms. At one end of the spectrum are diseases manifested exclusively by musculoskeletal signs and symptoms (e.g., joint or muscle pain), the presence of which immediately suggests a rheumatologic problem. At the other end of the spectrum are the systemic rheumatic diseases, which can present with virtually any sign or symptom (e.g., fever, chest pain, rash, confusion, deafness, and countless others). Because many of these signs and symptoms do not immediately suggest a rheumatologic problem, the suc-

cessful identification of the systemic rheumatic diseases requires a thorough differential diagnosis and a systematic approach to the clinical workup.

This chapter provides guidelines applicable to the broad spectrum of rheumatology. It begins with a strategy for approaching patients with the most common musculoskeletal signs and symptoms. It then proceeds to a discussion of the approach to patients with systemic rheumatic diseases and the significance of specialized laboratory tests in their evaluation.

JOINT PAIN

When Joint Pain Presents at the Time of Admission

Description and Differential Diagnosis

It is common for patients to complain of joint pain when in fact the pain is arising from elsewhere. Therefore, the first challenge in evaluating a patient with joint pain is to determine whether the pain truly originates from within a *joint* (arthralgia, arthritis) or whether the source is actually within the *periarticular structures* (e.g., bursitis, tendinitis), *underlying bone* (e.g., fracture, osteomyelitis, tumor), or

overlying skin (e.g., cellulitis). For example, virtually all patients with greater trochanteric bursitis report the problem as hip pain, even though the hip joint is anatomically distinct from the site of the pain and may well be normal. This distinction can only be made with a careful physical examination of the joints, including inspection, palpation, and assessment of the range of motion. Inspection and palpation may demonstrate swelling and synovial thickening and thereby confirm the presence of arthritis. (This will be further discussed under “Joint Swelling.”)

Evaluation

Although physical examination is the most important step in determining the source of joint pain, radiographic studies may be required to establish the precise nature of the problem. As a general rule, if physical examination does not establish the cause of the pain, radiography is warranted. This may show fracture, infection, or tumor in bone, hypertrophic pulmonary osteoarthropathy in the periosteum, calcification in a periarticular tendon, or some other definitive finding that identifies the source outside the joint. When evaluating nontraumatic, acute joint pain (less than 2–3 weeks’ duration), bear in mind that the process may not have persisted for sufficient time to develop abnormalities detectable by plain radiography. Alternatively, for many of the chronic rheumatic diseases, the roentgenogram may reveal a characteristic pattern of bony erosions within the joint that suggests the correct diagnosis. For example, rheumatoid arthritis (RA), the seronegative arthritides (reactive arthritis, psoriatic arthritis, ankylosing spondylitis), and gout each can cause distinctive erosive damage.

Management

The management of joint pain is determined by the precise diagnosis. Immobilization may be appropriate in some instances (e.g., intra-articular hemorrhage), whereas physical therapy and range-of-motion exercises may be appropriate in others (e.g., frozen shoulder). Ice may be appropriate for acute injuries, but heat may be more effective for chronic joint pain. Anti-inflammatory medications may work well in gout but are no substitute for systemic antibiotics in treating a septic joint. The only generalization is that *there is rarely any harm in providing analgesia*, in whatever form is effective, to make the patient more comfortable while more definitive measures aimed at treating the cause of pain are instituted.

When Joint Pain Appears During Hospitalization

Almost by definition, joint pain that appears during hospitalization represents an acute problem and therefore should be approached according to the guidelines de-

scribed in Chapter 113. It is worth emphasizing here, however, that certain joint problems are more likely to occur during hospitalization than at other times. Both gout and pseudogout commonly develop in hospitalized patients, particularly in the postoperative setting. In this case, the joint pain is accompanied by dramatic signs of inflammation, including warmth, redness, and swelling. Fluxes in uric acid levels associated with changes in diet (including being without oral intake prior to a procedure) can contribute to this predisposition. Gout during hospitalization is particularly common in alcoholics, who may enter the hospital with lactic acidosis or ketoacidosis, both of which interfere with uric acid excretion. Fluxes in uric acid concentration that occur as these metabolic disturbances are corrected can contribute to an acute attack of gout. Joint problems that stem from prolonged immobilization, sometimes in awkward positions, during procedures or surgery are also more likely to develop in hospitalized patients. Accordingly, mechanical back pain, bursitis, or nerve and tendon compressions are seen commonly in hospitalized patients.

JOINT SWELLING

When Joint Swelling Presents at the Time of Admission

Description and Differential Diagnosis

The detection of joint swelling during physical examination localizes the pathology within the joint and should trigger a straightforward, almost invariably informative approach to differential diagnosis. This approach is based on the answers to three simple questions:

1. *Is the problem acute or chronic?* This question is answered by the history.
2. *How many joints are involved?* This question is best answered by a complete musculoskeletal examination. Just as the careful clinician reads the entire chest radiograph before focusing on the lobar infiltrate, the clinician evaluating arthritis must consider even asymptomatic joints. Reliance on the history can sometimes be misleading, especially when the intensity of pain in a single joint distracts the patient from more subtle symptoms in other joints.
3. *Are there hints of systemic involvement?* Unintended weight loss, pronounced fatigue, subjective fevers, or new skin rashes hint at a systemic process, cuing the clinician to consider an evaluation for systemic infections, neoplasms, or a systemic connective tissue disease.

The appeal of this approach to differential diagnosis is the ease with which the data can be gathered—a history of the present illness and a musculoskeletal exam are sufficient to

TABLE 110.1
COMMON CAUSES OF MONARTICULAR ARTHRITIS

Acute	
Noninflammatory	Inflammatory
Trauma Hemarthrosis Sickle cell anemia	Infection (e.g., bacterial, Mycobacterial, fungal, viral) Gout (monosodium urate crystals) Pseudogout (calcium pyrophosphate dihydrate) Trauma Sickle cell anemia
Chronic	
Noninflammatory	Inflammatory
Osteoarthritis Neuropathic joint Hemarthrosis Sickle cell anemia	Infection (e.g., Mycobacterial, <i>Borrelia burgdorferi</i> , <i>Coccidioides immitis</i>)

craft an excellent differential diagnosis. Further refinement of the differential can be made if the clinician has access to the results of a diagnostic arthrocentesis. Synovial analysis will suggest whether the process is inflammatory or noninflammatory. A detailed description of synovial fluid evaluation is provided in Chapter 113. For the purposes of this approach to differential diagnosis, it is sufficient to rely on the number of white blood cells in the joint fluid to determine whether the fluid is inflammatory ($>2,500/\mu\text{L}$) or

noninflammatory ($<2,500/\mu\text{L}$). The differential diagnosis is further refined by a complete physical exam with careful attention to physical signs of systemic illness. Like all strategies that are designed primarily to detect common problems, this approach requires vigilance to recognize when the common diagnoses seem not to fit and unusual explanations must be sought. It is summarized below and in Tables 110.1 and 110.2.

Common Causes of Acute Monarticular Arthritis

If the joint fluid is *noninflammatory*, the most likely diagnoses are trauma, nontraumatic hemorrhage (e.g., as a result of hemophilia, thrombocytopenia, or some other coagulopathy), or sickle cell anemia (Table 110.1). These are easily distinguished by history or, when necessary, by blood tests. If the joint fluid is *inflammatory*, the most likely diagnoses are a bacterial joint infection (septic arthritis) or crystal-induced arthritis. Either process can cause high fevers and similar findings on physical exam: gout may mimic cellulitis, while septic joints in gouty patients have frequently been ascribed to “just another gouty flare.” Both can trigger extremely high synovial and peripheral blood cell counts. Thus arthrocentesis with Gram stain, synovial bacterial culture, and microscopic crystal analysis are crucial components in the evaluation of this patient population. Sickle cell anemia is an occasional confounder because the joint fluid may be inflammatory or noninflammatory, the pattern of joint involvement may be monarticular or polyarticular, and the presentation may be acute or chronic. However, a known history of sickle cell anemia (Chapter 97) almost invariably accompanies these presentations, so the diagnosis is rarely difficult.

TABLE 110.2
COMMON CAUSES OF POLYARTICULAR ARTHRITIS

Acute	
Infection Hepatitis B, Parvovirus B19 Neisseria gonorrhoea Subacute bacterial endocarditis ^a Acute rheumatic fever ^a Crystal-induced arthritis (e.g., monosodium urate) Acute onset rheumatic condition (RA, SLE) Sickle cell crisis ^a	
Chronic	
Noninflammatory	Inflammatory
Osteoarthritis	Infections (<i>Borrelia burgdorferi</i> , hepatitis C, Parvovirus B19) Rheumatic condition (RA, SLE, seronegative arthritis) Paraneoplastic syndrome

^a These diseases may be characterized by inflammatory or noninflammatory joint fluid. RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

Common Causes of Chronic Monarticular Arthritis

If the joint fluid is *noninflammatory*, the diagnosis is likely to be osteoarthritis, neuropathic arthropathy (Charcot joint), trauma, hemophilia, or sickle cell anemia (Table 110.1). Roentgenograms and, if necessary, appropriate laboratory tests generally make distinguishing among these possibilities quite straightforward. If the joint fluid is *inflammatory*, the index of suspicion for infection, particularly pathogens such as *Mycobacterium*, endemic fungi, or *Borrelia burgdorferi* should be high. In these cases, signs and symptoms of systemic disease—e.g., weight loss, sweats, or fatigue—will be particularly important to elicit.

Common Causes of Acute Polyarticular Arthritis

Acute polyarthritis is usually caused by infection, polyarticular gout, or sickle cell crisis. Infections to consider include diseases of viral origin (e.g., rubella, hepatitis B, parvovirus, or HIV infection), gonococemia, bacterial endocarditis, and acute rheumatic fever (Table 110.2). Detection of new or changing cardiac murmurs or observation of pustular skin lesions would significantly move the differential diagnosis toward endocarditis or disseminated gonococcal infections, respectively. Polyarticular gout can be diagnosed definitively by detection of crystals in the joint fluid and should be strongly considered only in the patient with prior bouts of gout. Though uncommon, patients who are ultimately diagnosed with a connective tissue disease may present with acute onset of symptoms. A small fraction of patients with rheumatoid arthritis, for example, can recall the very day they awoke with multiple swollen joints.

Common Causes of Chronic Polyarticular Arthritis

The patient with chronic polyarticular arthritis and *noninflammatory* joint fluid is quite likely to have osteoarthritis (Table 110.2). This impression can generally be confirmed by roentgenograms. The chronic *inflammatory* polyarthritides are most likely to be caused by the classic rheumatic conditions (e.g., rheumatoid arthritis; seronegative arthritis; connective tissue diseases). The differential, however, still includes chronic infections with viruses such as hepatitis C and bacteria such as *Borrelia burgdorferi*. Paraneoplastic syndromes such as hypertrophic osteoarthropathy can cause arthritis even when the cancerous process is occult. Sometimes, associated signs and symptoms provide critical clues to one of the chronic inflammatory arthritides from the outset. For example, the presence of urethritis and conjunctivitis may suggest Reiter disease; psoriatic plaques may be the key to diagnosing psoriatic arthritis; chronic bloody, loose stools point to inflammatory bowel disease. RA and systemic lupus erythematosus (SLE), on the other hand, rarely can be diagnosed with certainty on the first visit. When these diagnoses are suspected, specialized serologic tests are often required to establish the diagnosis. The use of these tests is described under "Laboratory Abnormalities."

Evaluation

The simple approach to differential diagnosis described above should not be a substitute for a thorough history and physical examination, either of which may provide critical clues to the correct diagnosis. Particularly helpful aspects of the history are the following:

Age and Gender

Most common causes of arthritis can affect persons of either sex at any age. However, age and gender strongly influence the likelihood of many diagnoses and can help prioritize the differential diagnosis and workup. For example, acute rheumatic fever is seen almost exclusively in children, gonococcal arthritis most commonly in young adults, and osteoarthritis most frequently in the elderly. Most patients with RA, SLE, or scleroderma are women, whereas most with ankylosing spondylitis or gout are men.

Duration of Symptoms

The duration of symptoms provides a highly important clue to the diagnosis and is the basis for one of the three key questions described in the previous section.

Past Medical History/History of Present Illness

The setting in which arthritis occurs often shapes the differential diagnosis. A history of trauma, intravenous drug use, or exposure to hepatitis, for example, could each be the key to a correct diagnosis. Similarly, the onset of joint pain in a patient with a known systemic illness (e.g., sickle cell anemia, SLE, inflammatory bowel disease) carries a different implication than the onset of joint pain in someone who was previously healthy.

Review of Systems

Because joint pain is often one manifestation of a systemic infection or connective tissue disease, a careful review of systems is important in all patients. Has the patient had fever, iritis, pleurisy, diarrhea, or urethritis? Each of these associated symptoms influences the differential diagnosis.

Just as the details of the history shape our perception of a patient with arthritis, so, too, do all the elements of the physical examination. It is not at all uncommon for the physical examination to alter the approach to a patient with unexplained joint pain or swelling. Particularly crucial elements of the examination are the following:

Vital Signs. Temperature is especially important to document. Low-grade fever may occur in almost any inflammatory arthritis (e.g., gout, RA), but high-grade fever strongly suggests infection (Chapter 62).

Skin. Many diseases that involve joint pain are associated with characteristic rashes. Valuable findings include urticaria in patients with hepatitis B prodrome, a photosensitive malar rash in those with SLE, gonococcal pustules, psoriatic plaques, rheumatoid nodules, and gouty tophi.

Eyes. Ocular manifestations of rheumatic diseases are common. These include conjunctivitis in reactive arthritis or gonococcal disease, uveitis in ankylosing spondylitis, and scleritis in RA.

Oropharynx. Presence of palatal or buccal ulcers could suggest SLE, a seronegative arthritis, or Behçet disease.

Cardiopulmonary Examination. Several cardiopulmonary abnormalities may be informative. For example, bacterial endocarditis (Chapter 71) presents with joint pain in about 15% of cases. Therefore, detection of a murmur in a patient with joint pain can be a critical finding. Similarly, the discovery of a pleural or pericardial rub in a patient with joint pain may point toward RA or SLE.

Genitourinary Examination. Evidence of venereal infection (gonorrhea) or nonspecific urethritis (reactive arthritis) will likely influence the differential diagnosis.

Joint Examination. The most important aspect of the physical examination of a patient with joint pain is a thorough examination of all joints. Often, patients focus on a single “worst” joint only to have it discovered that other joints are also involved, albeit to a lesser extent. The discovery of polyarthritis can completely change the differential diagnosis. Even among patients with polyarthritis, the detection of characteristic patterns of involvement can be helpful. For example, symmetric involvement of the small joints of the hands and feet is typical of RA (or perhaps viral arthritis). On the other hand, asymmetric involvement of large joints would be more typical of one of the seronegative arthritides, such as reactive arthritis, psoriatic arthritis, or ankylosing spondylitis.

Management

Like the management of joint pain (arthralgia), the management of joint swelling (arthritis) is determined entirely by the cause of the problem. Drainage is sometimes essential, as in patients with septic arthritis; often, it is unimportant. Sometimes local corticosteroid injection is helpful, but not if multiple small joints are involved or infection is suspected. The inability to generalize about the management of joint swelling underscores the importance of the systematic pursuit of a definitive diagnosis.

When Joint Swelling Appears During Hospitalization

The development of joint swelling during hospitalization should be evaluated, just as one would evaluate acute joint swelling in any other setting (Chapter 113). However, as described earlier in the section on joint pain, certain possibilities should come to mind first when the patient is hospitalized. Crystal-induced arthritis is one of these, but not

the only one. The onset of joint swelling in an immunosuppressed patient or in a patient hospitalized for an infection or valvular heart disease mandates a careful search for an infectious etiology. New polyarthritis in a hospitalized patient may be caused by serum sickness related to a new medication.

NEW SIGNS AND SYMPTOMS IN A PATIENT WITH UNDERLYING RHEUMATIC DISEASE

Description and Differential Diagnosis

Patients with an established diagnosis of a systemic rheumatic disease (e.g., RA, SLE, Wegener’s granulomatosis) constitute a particularly challenging problem because they can present to the hospital with a myriad of signs or symptoms (Chapters 111 and 112). A patient with RA may present with shortness of breath related to a pleural effusion. A patient with SLE may present following a seizure. A patient with vasculitis may present with angina. Therefore, it is particularly important in these patients to consider virtually any new problem as a possible manifestation of the underlying disease. The differential diagnosis must not stop there, however, because patients with rheumatic diseases are susceptible to an array of other problems. Many patients with systemic rheumatic diseases are taking immunosuppressive medications, which raises the risk for infection. The dramatic success and thus widespread use of anti-tumor necrosis factor (anti-TNF) therapies for multiple rheumatic conditions, for example, has been accompanied by an increased risk for disseminated mycobacterial infections (1). Even in the absence of immunosuppressive drugs, certain infections are more likely to occur in people with rheumatic diseases. The patient with RA-induced eroded bony surfaces or joint prostheses may develop a septic joint even from transient bacteremia. Therefore, a new flare of arthritis in one joint, out of proportion to symptoms in other joints, should raise the possibility of septic arthritis and should not be casually attributed to a flare of RA. Similarly, patients with SLE are at high risk for the development of osteonecrosis of bone, either as a manifestation of the underlying disease or as a complication of corticosteroid therapy. Finally, people with systemic rheumatic diseases are often on complex medication regimens that frequently change. Therefore, it is important to immediately consider adverse drug reactions or even medication errors (see Chapter 21) whenever a new problem occurs.

Evaluation

The cardinal rule in evaluating any new complaint in a patient with an underlying systemic rheumatic disease is thoroughness. Whatever the problem, it may be a manifestation of the disease itself, a superimposed problem to

which the patient is predisposed, a medication complication, or a new and unrelated medical problem. A broad differential diagnosis and a correspondingly thorough evaluation are essential.

Management

The management of a new problem in a patient with an underlying systemic rheumatic disease depends entirely on the results of the diagnostic evaluation.

LABORATORY ABNORMALITIES

Erythrocyte Sedimentation Rate

When an Elevated Erythrocyte Sedimentation Rate Is Present at the Time of Admission

Description and Differential Diagnosis

Measurement of the erythrocyte sedimentation rate (ESR) is a technically simple test in which blood, mixed with the anticoagulant sodium citrate, is added to a 200-mm glass tube and left to “sediment” for one hour at room temperature (2). The quantitative result is the distance between the top of the tube and the meniscus of aggregated red blood cells. Acute-phase reactants such as haptoglobin, immunoglobulins, and, most importantly, fibrinogen cross-link red blood cells into large, rapidly falling aggregates that accelerate the ESR (3). Other factors that can increase the ESR include the presence of paraproteins, anemia, or the use of oral contraceptives. Androgens seem to lower the ESR; consequently, the normal range for men (<15 mm/h) is somewhat lower than the normal range for women (<28 mm/h). Importantly, the normal range increases slightly with increasing age in both men and women.

Several studies have examined the diagnoses associated with a *markedly elevated ESR* (>100 mm/h) (4). Infectious diseases are the most common cause, accounting for 35% (in academic tertiary centers) to 62% (in rural community hospitals) of all patients with the abnormality. Any infectious agent, but especially bacterial pathogens, can be associated with an accelerated ESR. The inflammatory rheumatic diseases, such as RA, SLE, and vasculitis, comprise the second most common diagnostic group in patients with an elevated ESR. Of particular note is the important role the ESR plays in diagnosing and monitoring *polymyalgia rheumatica* and *giant cell arteritis*. The ESR is greater than 50 mm/h in the vast majority of cases of *polymyalgia rheumatica* or *giant cell arteritis*, but recent studies have demonstrated that even these conditions can (infrequently) occur in patients with an ESR less than 20 mm/h (Chapter 111). Neoplasms were found to be causative in 10%–15% of patients with a markedly elevated

ESR. Because immunoglobulins can increase red blood cell aggregation, one must consider lymphoproliferative malignancies such as multiple myeloma, macroglobulinemia, and lymphoma. Finally, advanced renal disease (particularly end-stage renal disease) is typically associated with a markedly elevated ESR.

Evaluation

Because the differential diagnosis of an elevated ESR is so broad, the value of this result in isolation is limited. The practitioner must therefore incorporate the test result into the overall clinical picture by using demographics, health-related behaviors, comorbidities, review of systems, and physical examination findings to refine the probability of disease. Symptoms such as low-grade fevers, sweats, and weight loss can suggest occult infection or malignancy. New signs, such as skin lesions or swollen joints, may point to a rheumatologic condition. Alternatively, paresthesias can be the clue to multiple myeloma or a vasculitis.

Management

The management will be dictated by the initial results obtained from workup. Because infections commonly cause an elevated ESR, and because many infections can be catastrophic in the short term, clinical judgment will sometimes dictate initiation of empiric antibiotic therapy until the culture results are known (e.g., when subacute bacterial endocarditis [SBE] is being considered, after multiple blood cultures have been obtained). However, on other occasions, legitimate concerns about catastrophic complications of connective tissue diseases (e.g., blindness in a patient with suspected giant cell arteritis) will necessitate initiation of empiric immunosuppressive therapy. The challenge in these situations, therefore, is to act swiftly enough to minimize the greatest risk while being cautious enough to avoid immunosuppressive therapy in patients who are infected.

When an Elevated Erythrocyte Sedimentation Rate Appears During Hospitalization

Description and Differential Diagnosis

The new appearance of an elevated ESR during hospitalization implies an acute cause and therefore strongly suggests infection. Other acute inflammatory processes, such as gout, should also be considered, depending on the clinical context. Although neoplasms and connective tissue diseases are common causes of an elevated ESR in clinic populations, it would be unusual for these problems to be the cause of an acutely elevated ESR in a hospitalized patient.

Evaluation and Management

Proper management can be determined only after the cause of the elevated ESR has been established. However, once this has been accomplished, the ESR determination can be of value during management by providing an

objective guide to the effectiveness of therapy. Specifically, in conjunction with other clinical and laboratory parameters, the trend of the ESR can be helpful in directing the duration and intensity of therapy in patients with serious infections (e.g., osteomyelitis) or connective tissue diseases (e.g., temporal arteritis).

Antinuclear Antibodies

When the Antinuclear Antibody Test Result Is Positive at the Time of Admission

Description and Differential Diagnosis

The antinuclear antibody (ANA) test detects serum antibodies to various nuclear antigens (e.g., histones, DNA, RNA). The test result is reported as a titer, often accompanied by a pattern of fluorescence seen under microscopy. The pattern of fluorescence may provide a clue to the nature of the target antigens, but definitive identification of the target (e.g., double-stranded DNA) requires further specialized tests.

Several prospective studies of clinically healthy cohorts demonstrate that a positive ANA test result at a titer of 1:40 can be detected in 20%–30% of asymptomatic people (5). The frequency of positive test results is higher in women and in the elderly. With a titer of 1:80, the false-positive rate is closer to 10%; fewer than 5% of normal subjects will have a titer of 1:160.

Even at higher titers ($>1:160$), the differential diagnosis of a positive ANA test result is broad. The ANA test is highly sensitive for SLE (more than 95% of patients with SLE have a titer $>1:160$), but not specific. It may also be positive in people with virtually any other connective tissue disease, including scleroderma, Sjögren syndrome, polymyositis/dermatomyositis, or RA (see Chapter 112 for further information on these disorders). Moreover, many drugs stimulate the production of ANAs, a phenomenon seen most frequently with procainamide and hydralazine (6). Chronic active hepatitis, Laennec cirrhosis, and primary biliary cirrhosis are sometimes associated with a positive ANA test result. The ANA test result may also be positive in people with neoplasms or chronic infections.

Evaluation

An abnormal ANA test result should prompt a directed history with specific inquiries into the medication list and family history, in addition to the occurrence of signs and symptoms that suggest a rheumatologic disorder (e.g., photosensitive rash, oral ulcers, arthralgia/arthritis, muscle weakness, dry eyes and mouth). Although many of these signs and symptoms can occur in diverse settings (e.g., weakness with neoplasm or myositis), their presence should motivate the pursuit of a definitive diagnosis.

If, after initial evaluation, a connective tissue disease is still a consideration, further serologic testing to characterize

the auto-antibodies is indicated. For example, antidouble-stranded DNA and anti-SM are highly specific for SLE, with a high positive predictive value for the diagnosis. Though less specific, quantitative analysis of complement levels C3 or C4 can also suggest SLE. Because the pathologic processes that yield abnormal ANAs frequently involve multiple organ systems, urinalysis, complete blood count, coagulation studies, renal function tests, and liver function tests should be performed. Whereas false positive ANAs are common, the absence of an abnormal ANA is particularly valuable when excluding the possibility of SLE. With a sensitivity of 99% for SLE, the negative predictive value of a normal ANA is so high as to essentially eliminate SLE from the differential.

Management

The ANA test result rarely guides management because it does not correlate with disease activity. Therefore, once it is noted to be abnormal, the test need not be repeated. The main value of the ANA test is to refine the pretest probability for a connective tissue disease when the clinical findings already suggest this possibility. In these situations, the finding of a positive ANA test result warrants further workup to establish the correct diagnosis and initiate appropriate therapy.

When a Positive Antinuclear Antibody Test Result Appears During Hospitalization

Differential Diagnosis

An ANA test, when ordered during hospitalization, often is performed during a protracted, complicated course, when the exclusion of other diagnostic possibilities leads to the eventual consideration of a connective tissue disease. Because an abnormal ANA test result can signify either an innocuous etiology (e.g., medications or a normal variant) or an as-yet-undiagnosed connective tissue disease, it is critical to have some sense of the clinical possibilities before the test is performed.

Evaluation and Management

The acute nature of most illnesses in hospitalized patients often mandates follow-up serologic studies (e.g., anti-ds-DNA, anti-Smith antigen, complement levels) and aggressive pursuit of a tissue diagnosis when the ANA test result is positive. A review of all the primary data, including musculoskeletal and skin examination findings, and attention to indicators of multi-organ system involvement can provide important clues regarding the significance of the abnormal ANA test result. Prompt subspecialty consultation will focus the evaluation on the remaining possibilities, lower the potential for inappropriate empiric therapy, and facilitate elucidation of the diagnosis. Management will depend on the precise explanation for the positive ANA test result.

Rheumatoid Factor

When the Rheumatoid Factor Test Result Is Positive at the Time of Admission

Description and Differential Diagnosis

Rheumatoid factor (RF) is an auto-antibody (most commonly an immunoglobulin M antibody) that binds the constant portion of immunoglobulin G molecules. It is strongly associated with, but not specific for, RA. Although its presence may precede the onset of arthritis, many patients will be clinically identified as having RA before they become seropositive. Eventually, 70%–85% of people with RA have a test result positive for RF. Serologic surveys demonstrate the presence of RF in 5% of healthy young adults and 15% of healthy elderly adults. An appreciation that RF is an immunoglobulin leads to the understanding that any chronic inflammatory state may be associated with production of RF. Virtually all the systemic connective tissue diseases can be associated with the presence of RF (e.g., Sjögren syndrome, SLE, scleroderma, and cryoglobulinemia). Chronic infections, including subacute bacterial endocarditis, tuberculosis, leprosy, syphilis, and rheumatic fever, also commonly are associated with positivity for RF. Finally, RF is detected in some patients with neoplasms, especially leukemias, lymphomas, and macroglobulinemia.

Evaluation

The history and physical examination should provide hints regarding the likelihood of infectious or neoplastic etiologies. Musculoskeletal findings, if present, may focus the workup on possible connective tissue diseases. Radiography of arthritic joints can be particularly valuable because periarticular osteopenia and characteristic erosions may be diagnostic of RA.

Management

Titers for RF do not correlate well with disease activity. Therefore, the RF titer is rarely helpful in guiding the management of patients with RA. The test is primarily of diagnostic value and of some prognostic value. Patients with higher titers generally have more aggressive joint disease and are at greater risk for extra-articular manifestations of RA, including subcutaneous nodules, interstitial lung disease, scleritis, and vasculitis.

When a Positive Rheumatoid Factor Test Result Appears During Hospitalization

In the acutely ill patient, detection of RF should trigger a search for occult infection. Subacute bacterial endocarditis in particular can cause musculoskeletal complaints that may mimic the presentation of an inflammatory arthritis. Similarly, RF may be a clue to the diagnosis of vasculitis. The evaluation of RF positivity during hospitalization is similar to the evaluation that would be indicated at admis-

sion, although even more emphasis should be placed on ruling out infectious etiologies.

Antineutrophil Cytoplasmic Antibodies

When the Antineutrophil Cytoplasmic Antibody Test Result Is Positive at the Time of Admission

Description and Differential Diagnosis

The antineutrophil cytoplasmic antibody (ANCA) test detects a group of auto-antibodies that react with specific cytoplasmic antigens (7). Depending on the precise nature of the target antigen, two ANCA patterns can be seen when ethanol-fixed neutrophils are stained. The cytosolic (cANCA) pattern correlates with antibodies that recognize the proteinase-3 neutrophil protease (PR3). The perinuclear (pANCA) pattern is associated with antibodies against the myeloperoxidase enzyme (MPO) found in lysosomes. Increasingly, laboratories are directly measuring the titers of the auto-antibodies rather than relying on the fluorescent staining pattern.

The *cANCA pattern* has been heralded as a marker for Wegener's granulomatosis. In cohorts with a high pretest probability (i.e., >10%), the specificity approaches 98%, with a sensitivity of 60%–80% (5,6). The positive predictive value of the ANCA for a diagnosis of Wegener's plummets when there is a low pretest clinical probability of this uncommon disease. Of the other rheumatic disorders, only Churg-Strauss syndrome and microscopic polyangiitis have demonstrated an association with the typical cANCA pattern (7). An atypical pattern of fluorescence, often read as cANCA, that is not associated with anti-PR3 antibodies has been described with cystic fibrosis, inflammatory bowel disease, primary sclerosing cholangitis, and RA. The *pANCA pattern*, first described in patients with pauci-immune rapidly progressive glomerulonephritis, occurs in 50% of patients with microscopic polyangiitis in the setting of renal failure, with or without pulmonary hemorrhage. The antibodies are also seen in Churg-Strauss syndrome and well described in a host of autoimmune diseases, including: RA, SLE, Sjogren syndrome, poly- and dermatomyositis, reactive arthritis, antiphospholipid antibody syndrome, ulcerative colitis, and primary sclerosing cholangitis (7).

Evaluation

A positive cANCA test result requires a careful evaluation for signs and symptoms of Wegener's granulomatosis. A positive pANCA test result should trigger a search for other vasculitides involving the lungs and kidneys. This topic is covered in detail in the Chapter 111.

Management

The ANCA test is used most often to help diagnose a systemic process. The outcome of the diagnostic evaluation will dictate the direction of therapy. More than a diagnos-

tic test, clinicians have used the titer of the cANCA-related antibodies as a surrogate for disease activity, guiding ongoing therapy of patients with Wegener's granulomatosis. A rise in ANCA titers correlates with disease flare in approximately two-thirds of the cases, but this relative insensitivity makes it vital to base therapeutic decisions on both the titer and concomitant clinical changes (8). Like other monitoring tests, the titer determination is simply an adjunct to a thorough assessment of the clinical picture.

When a Positive Antineutrophil Cytoplasmic Antibody Test Result Appears During Hospitalization

The differential diagnosis, evaluation, and management of a patient with a positive ANCA test result are the same whether this finding is detected at the time of admission or during the hospitalization.

Complement

When Hypocomplementemia Is Present at the Time of Admission

Description and Differential Diagnosis

The complement system involves a cascade of 30 proteins. When activated, the proteins are catabolized into intermediates that augment the inflammatory response by attracting neutrophils, directing lysis of opsonized cells, and increasing vascular permeability. The functional integrity of the entire classic pathway can be evaluated by performing a test for total hemolytic complement (CH_{50}). Deficiencies in any of the complement proteins of the classic pathway, whether inherited or caused by consumption, will decrease the CH_{50} value. Individual complement components can also be measured. The levels of C3 and C4 are most commonly tested.

Complement levels are generally sent in two clinical scenarios: either to evaluate an inherited complement deficiency or to diagnose and/or determine the level of activity of a pathologic, inflammatory condition. In the latter group, hypocomplementemia, in the appropriate clinical setting, could indicate an SLE flare, cryoglobulinemic vasculitis, a variety of glomerulonephritides, SBE, or cholesterol emboli syndrome. Each of these disorders triggers consumption of complements, thus a reduction in number of individual complement components and an overall abnormality in the CH_{50} . Rarely, end-stage liver disease can be associated with hypocomplementemia because of reduced hepatic synthesis of complement proteins, but complement levels typically are preserved even in patients with hepatic failure.

Evaluation

The first question to address when the complement level is low is whether the cause is a hereditary deficiency of an in-

dividual component or complement consumption. This can be determined by obtaining values for CH_{50} and for two individual components (e.g., C3 and C4). If consumption is the cause, all the values should be abnormal. However, if only an individual component is absent, then the CH_{50} value will be undetectably low (reflecting the absence of a functionally important component), but the levels of all other individual components will be normal. For example, levels of both C3 and C4 will be normal in a patient with C2 deficiency, but the CH_{50} level will be undetectable; C3 will be normal in a patient with C4 deficiency, but C4 will be absent.

If the tests described above establish that consumption is the cause for hypocomplementemia, then the evaluation shifts immediately to a consideration of immunopathology, particularly SLE. Some mimickers of vasculitis must also be considered, such as the cholesterol emboli syndrome, which can cause clinical manifestations suggestive of vasculitis, low complement levels, and a high ESR.

Management

Because complement is consumed and then quickly resynthesized, complement levels can be a valuable guide for monitoring disease activity. In SLE in particular, disease activity often correlates with low complement levels. This can be extremely valuable, for example, when the clinician is trying to determine whether the febrile patient with SLE is having a disease flare (which would improve with immunosuppression) or an infection. Similarly, this relationship can provide quantitative direction for adjusting the dose of immunosuppressive drugs. When complement values are being used for this purpose, it is not necessary to follow the results of multiple tests (e.g., CH_{50} , C3, and C4). Rather, because all the complement values reflect consumption, it is sufficient to rely on the most sensitive of them. Although the C4 value is generally the most sensitive to changes in disease activity (9), some patients will demonstrate a higher correlation between the CH_{50} or C3 value and their clinical status.

When Hypocomplementemia Appears During Hospitalization

An acute decrease in any measure of complement suggests immunopathology such as SLE or a vasculitis. However, in a hospitalized patient, one must also consider severe bacterial infection. Therefore, the evaluation should focus on distinguishing vasculitis from infection.

KEY POINTS

- The first challenge in evaluating a patient with joint pain is to determine whether the pain truly originates within the joint or whether it originates instead in periarticular structures, underlying bone, or overlying skin.

- In most patients with joint swelling, analysis of the joint fluid is a crucial part of the diagnostic evaluation.
- Crystal-induced arthritis is a common cause of acute joint pain in hospitalized patients.
- In seriously ill patients with signs and symptoms suggestive of rheumatic diseases, the differential diagnosis often also includes infection. The challenge is to act swiftly to minimize the risk for catastrophic complications of rheumatic diseases while avoiding immunosuppressive therapy in infected patients.
- The erythrocyte sedimentation rate may be elevated in any inflammatory process that increases the levels of acute-phase reactants.
- The antinuclear antibody titer is most useful as a diagnostic test for SLE, because of its high sensitivity, but not as a monitoring test, because the titer does not correlate well with disease activity.
- Since the rheumatoid factor will be positive in only 80% of patients with rheumatoid arthritis, the diagnosis must still be made on clinical grounds.
- The cytosolic pattern for antineutrophil cytoplasmic antibody (cANCA) is most useful diagnostically when the clinical picture suggests a greater than 10% pretest probability of Wegener's granulomatosis.
- Hypocomplementemia may reflect either an inherited deficiency of an individual complement component or complement consumption resulting from immune complex-mediated activation of the complement cascade.

Vasculitis

111

Gary S. Hoffman **Carol A. Langford**
Leonard H. Calabrese

INTRODUCTION

When to Suspect Vasculitis

For most physicians, the recognition and treatment of the systemic vasculitides is not a routine matter. More than 20 different forms of systemic vasculitis have been enumerated. Each is uncommon and likely to be confused with other systemic illnesses that produce similar abnormalities. The hospitalized patient ultimately identified to have systemic vasculitis has often had either a toxic presentation or a clinical picture dominated by multifocal evidence of organ injury. Processes that can be confused with vasculitis include infections (particularly bacterial endocarditis), drug toxicities and poisonings (especially with agents likely to produce vasospasm), coagulopathies, malignancies, cardiac myxomas, and multifocal emboli from aneurysms of large vessels (Table 111.1). Whether critical organs are involved, together with the rate of disease progression, will determine the intensity and pace of the diagnostic evaluation and treatment choices. The physician may encounter a situation, especially early in a hospitalization, in which systemic vasculitis cannot be distinguished from endocarditis or other infections. Under such circumstances, one may be forced to treat for multiple diagnoses before a final diagnosis is achieved. To minimize the risk of such an approach, the clinician must recognize the clinical patterns of competing diagnoses, rather than depend on immunoserologic studies that may not be readily available or are inadequately specific. For example, oral and genital aphthous ulcers suggest Behçet's disease; the presence of upper and lower airway inflammation, red blood cell casts in the urine sediment, and renal insufficiency suggests Wegener's granulomatosis; and hypertension and claudication in an extremity in a young female patient suggest Takayasu's arteritis. Unfortunately, many patients with vasculitis do

not present with such recognizable features. Instead, one may have to depend on combinations of less typical clues. For example, a patient with a flat or palpable purpuric rash, fever, an active urinary sediment, and peripheral neuropathy is likely to have vasculitis. However, because these features may also be part of endocarditis, they oblige definitive evaluation for both conditions.

Proving the Diagnosis of Vasculitis

Definitive proof often depends on visualizing vasculitic lesions in affected tissue. The greatest success in achieving a tissue diagnosis comes from the *biopsy of abnormal or symptomatic sites*. Biopsy of apparently normal tissue is not recommended (1, 2) because the yield is less than 20%, even in patients with proven vasculitis. Biopsy of abnormal organs provides diagnostically useful information in more than 65% of cases (not 100%, because "skip" lesions are seen in all types of systemic vasculitis). This explains why large specimens of abnormal tissue provide a greater yield than specimens obtained by needle biopsy.

A biopsy may not be practical in certain circumstances. For example, in the patient with symptoms of visceral ischemia, carotidynia, or findings of unequal pulses or blood pressures, biopsy of large vessels and diagnostic laparotomy (in the absence of an acute abdomen) would be impractical. In this setting, *angiography* can be helpful. Vascular injury may be evidenced by areas of vascular stenosis or aneurysm that cannot be explained on the basis of atherosclerosis. Angiography is particularly useful for patients with diseases that involve large vessels (Takayasu's arteritis, giant cell arteritis of the elderly) and medium-size vessels (e.g., polyarteritis nodosa) (Figure 111.1).

Once the diagnosis of vasculitis is clearly established, based either on the strongest of circumstantial evidence

TABLE 111.1**WHEN TO SUSPECT SYSTEMIC VASCULITIS**

Consider systemic vasculitis in all patients with multisystem disease, but rule out the following processes:

Infection/sepsis; pay particular attention to endocarditis (Chapter 71)
 Drug toxicity/poisoning (Chapter 121)
 Coagulopathy (Chapter 98)
 Malignancy
 Atrial myxoma
 Multifocal emboli (e.g., cholesterol, mycotic)

(potentially including angiography, which is less specific than histopathology) or on biopsy proof of vascular inflammatory injury, one must still ask whether such lesions represent *secondary vasculitis* caused by infections (e.g., bacterial, mycobacterial, fungal, syphilitic, rickettsial, hepatitis B or C or, in immunologically compromised patients, HIV or cytomegalovirus infection). In addition, vasculitis can be associated with a variety of malignancies. Paraneoplastic vasculitis should be considered on the basis of a suggestive history or in patients who fail to respond to usually effective aggressive immunosuppressive therapy.

Figure 111.1 This renal arteriogram was obtained concurrently with a study of the mesenteric circulation in a patient with postprandial abdominal pain, hypertension, musculoskeletal symptoms, and fever of unknown origin. The diagnosis of polyarteritis nodosa was suspected. The angiogram revealed marked “pruning” of medium-sized vessels, vascular irregularities, and aneurysms throughout the renal vessels and mesenteric vasculature, confirming the diagnosis.

General Considerations for Treatment

With the exception of acute Kawasaki syndrome, in which salicylates and high-dose intravenous immunoglobulin are indicated, therapy for all other forms of severe systemic vasculitis usually begins with *high doses of a corticosteroid*. Whether the corticosteroid should be given as a single morning dose, in split doses, or as a large intravenous “pulse” or bolus (e.g., 500–1,000 mg of methylprednisolone for 1–3 days), and whether a *cytotoxic agent* should be used at the onset, have not been the subject of controlled studies. Certain forms of systemic vasculitis improve dramatically after corticosteroid therapy (e.g., giant cell arteritis of the elderly). But, most patients with generalized Wegener’s granulomatosis or severe microscopic polyangiitis with pulmonary and renal involvement usually progress to severe organ system impairment and death if not treated with a corticosteroid plus a cytotoxic agent such as cyclophosphamide. Special concerns are raised when the condition of a patient who has experienced marked improvement or remission subsequently deteriorates. If deterioration occurs before significant tapering of corticosteroids or cytotoxic agents, it is likely to be caused by events other than vasculitis; generally either comorbidities or complications of treatment (e.g., venous thromboses, pulmonary emboli, opportunistic infections, and drug toxicity).

Because most systemic vasculitides are not curable, the primary realistic goal is to diminish morbidity from both disease and treatment, in the hope that the underlying process will enter an extended treatment-induced remission or be self-limited. When treatment is indicated for systemic vasculitis, high doses should be maintained until all manifestations of active disease have abated. Tapering of prednisone should begin after about 1 month. Whether corticosteroid tapering should be accomplished by reducing the dose on every day of therapy or on every other day; or whether the interval between each dose reduction should be every 3, 5, 7, 10 or more days, etc., is controversial. Some advocate tapering to alternate-day prednisone (single morning dose), because this schedule is associated with less toxicity than daily treatment. However, even alternate-day prednisone carries a high risk for osteoporosis and fracture. All patients who receive long-term corticosteroids should be placed on bone conservation programs.

Daily cyclophosphamide has been the most thoroughly studied treatment for severe forms of vasculitis. Although the drug may be life-saving, its use requires close vigilance for bladder and bone marrow side effects, titration of doses based on blood cell counts (particularly in regard to leukopenia), high oral intake of fluids to dilute cyclophosphamide-derived bladder toxins, and urologic consultation for any sign of bladder toxicity (3). Figure 111.2 shows a sample discharge instruction form for patients being started on a corticosteroid, cyclophosphamide, or both. Specific indications for adding a cytotoxic agent will be considered in following sections on the specific vasculitides.

Medications:

- Cyclophosphamide 150 mg taken all at once in the morning with 2-3 liters of fluid throughout the day.
- Prednisone 60 mg taken all at once in the morning.
- Trimethoprim 160 mg/Sulfamethoxazole 800 mg 1 tablet on Monday, Wednesday, Friday (prophylaxis for pneumocystis)
- (Consider intervention to minimize prednisone-induced osteoporosis).

Follow-up:

- While taking these medications, it is very important that you have blood tests every 1-2 weeks
- Return to see Dr. _____ on _____

Alerts:

- Contact your doctor at phone number _____ or seek medical attention immediately for any:
 - Fever
 - Blood in your urine
 - Shortness of breath
 - Symptoms of infection
 - New symptoms that you are unsure or concerned about

Main Side Effects (discussed here or through separate written literature):**Cyclophosphamide:**

Increased risk of infection
 Lowering of blood counts
 Bladder injury
 Injury to an unborn child
 Infertility
 Nausea, vomiting
 Hair thinning or loss
 Increased risk of cancer of the bladder, blood elements, skin

Prednisone:

Increased risk of infection
 Increased appetite and weight
 Fluctuations in mood
 Acne
 Easy bruising
 Fullness of the face and body
 Osteoporosis
 Muscle weakness
 Avascular necrosis (fractures of the hips/shoulders)
 Cataracts
 High blood pressure
 Diabetes

Figure 111.2 Sample discharge instructions for patients on cyclophosphamide and prednisone therapy.

SPECIFIC VASCULITIDES

Vasculitis of Large Vessels

Takayasu's Arteritis

Issues at the Time of Admission

Takayasu's arteritis is a large-vessel vasculitis of unknown cause that involves the aorta and its major branches. It affects young women about 10 times more often than men. Morbidity results from arterial stenosis and organ ischemia (e.g., extremity claudication, transient cerebral ischemia, stroke, renal artery hypertension, congestive heart failure, angina, myocardial infarction, mesenteric vascular insufficiency), and from the formation of aneurysms, especially in the aortic root, which can result in aortic regurgitation. Mortality rates have varied widely from series to series. When mortality occurs, it is usually caused by hypertensive or primary cardiac, renal, and central nervous system (CNS) vascular disease. Symptoms of large-vessel abnormalities,

especially in young patients, necessitate careful examination of pulses and blood pressures in all four extremities, with a search for asymmetry and vascular bruits (4).

Symptoms may be specific for vascular disease (e.g., extremity or visceral ischemia) or nonspecific (e.g., malaise, arthralgias, night sweats, fever). When such symptoms occur in the setting of an elevated erythrocyte sedimentation rate (ESR), active disease is likely and should be evaluated by invasive (4) or non-invasive (5) angiography. The initial presentation may be subtle; a significant number of patients have neither constitutional nor new vascular symptoms, and up to 50% have normal ESR values despite progressive disease (4). Patients admitted with suspected active Takayasu's arteritis should be started on high-dose corticosteroids (1 mg of prednisone per kilogram daily), even as the diagnosis is being confirmed.

Issues During the Course of Hospitalization

Approximately 60% of patients with Takayasu's arteritis respond to corticosteroid therapy, with resolution of symptoms and stabilization of arteriographically demonstrable

abnormalities. However, tapering of corticosteroid therapy has been associated with disease relapse in more than 40% of patients. Corticosteroid-resistant or relapsing patients may respond to the addition of daily therapy with low doses (2 mg/kg/d) of cyclophosphamide or weekly therapy with methotrexate (15–25 mg/wk) (6).

About 40% of patients who are treated with a cytotoxic agent and corticosteroids achieve remission, but about half of these patients also relapse in time, so that long-term immunosuppressive therapy is required in at least one-fourth of all patients with Takayasu's arteritis.

By discussing only pharmacologic strategies, we would risk ignoring the important effects of the vascular lesions themselves, which cause morbidity through inflammation or vascular distortion and stenosis. Because more than 90% of patients have stenotic lesions, with the most common site of stenosis being the subclavian artery (or arteries), blood pressure recordings in one or both arms may not reflect the more worrisome pressure in the aorta. Therefore, in patients with Takayasu's arteritis, the entire aorta and its primary branches should be assessed with vascular imaging studies, including magnetic resonance angiography or invasive catheter-guided angiography. Whenever feasible, anatomic correction of clinically significant lesions should be considered, especially in the setting of renal artery stenosis and hypertension, coronary or cerebral ischemia, or enlarging aortic aneurysm or dissection.

Discharge Issues

The care of patients with Takayasu's arteritis requires management by a team that includes clinicians familiar with the proper use of immunosuppressive therapies, vascular imaging and intervention specialists, and, in the setting of critical stenoses or aneurysms, cardiovascular physicians and surgeons. For most patients, medical and surgical therapies are palliative. The acute hospitalization provides an opportunity to diagnose and treat urgent problems and to assemble a team that will follow the patient outside the hospital.

Giant Cell Arteritis of the Elderly

Issues at the Time of Admission

Giant cell arteritis (GCA) and Takayasu's arteritis are the principal diseases associated with sterile granulomatous inflammation of large and medium-sized vessels. Whereas Takayasu's arteritis has a predilection for young women, GCA favors people over 50 years of age. In fact, the mean age for patients in most series is over 70 years. Women are affected more than men, but the degree of female predominance (ranging from 2:1 to 3:1) is not as striking as in Takayasu's arteritis. The demographic characteristics of patients with GCA are the same as for patients with polymyalgia rheumatica, and in fact 30–50% of patients with GCA also have features of polymyalgia rheumatica. The most common characteristics of GCA are represented in Table

111.2. The new onset of atypical and often severe headaches, scalp and temporal artery tenderness, acute visual loss, and pain within the muscles of mastication are among the most compelling features to suggest the diagnosis (7). When such abnormalities are present in conjunction with marked elevations in the ESR (Chapter 110), a clinical diagnosis of GCA can be presumed and treatment initiated, even without the benefit of a temporal artery biopsy. The diagnosis would be thrown into question only if dramatic improvement had not occurred within 24–72 hours. In those instances in which typical features are not present but the diagnosis is suggested because of vague systemic symptoms and atypical headache in face of a normal or elevated ESR and all other reasonable diagnoses have been ruled out, a positive biopsy result is useful in guiding treatment. The yield of temporal artery biopsy in patients suspected to have GCA has been estimated to be about 50%–80%, depending in part on the pre-test (biopsy) probability of GCA, size of the biopsy specimen and whether bilateral samples have been obtained.

Giant cell arteritis produces aortitis in at least 15% of cases and involves the primary branches of the aorta in a similar number of persons (8). Recent studies have demonstrated that patients with GCA were more than 17 times more likely than age-matched controls to have thoracic aortic aneurysms (carrying a 55% mortality rate) and about 2.5 times more likely than age-matched controls to have abdominal aortic aneurysms (8). The finding of large-vessel disease, including aortic aneurysms, in elderly persons with GCA should not merely be assumed to be secondary to atheromatous disease.

Corticosteroids remain the most effective therapy for GCA. As in patients with suspected Takayasu's disease,

TABLE 111.2
GIANT CELL ARTERITIS: CLINICAL PROFILE

Abnormality	Frequency (%)
Age >50 y (mean age, ~70 y)	>90
Atypical headache	60–90
Tender temporal artery	40–70
Systemic symptoms not attributable to other diseases	20–50
Fever	20–50
Polymyalgia rheumatica	30–50
Acute visual abnormalities	12–40
Blindness	5–17
TIA or stroke	5–10

Aortic aneurysm	15–20
Dramatic response to corticosteroids	~100
Positive temporal artery biopsy result	~50+

TIA, transient ischemic attack.

prednisone therapy (0.7–1 mg/kg daily) should be started immediately in patients with suspected GCA. The biopsy result will remain positive for at least a week after corticosteroid therapy is begun. Controlled studies, designed to determine whether adjunctive therapy with cytotoxic agents is superior to corticosteroid therapy alone in patients with GCA, have yielded contradictory results (9, 10).

Issues During the Course of Hospitalization and at Discharge

Prednisone will reduce symptoms within 1–2 days and often eliminate them within a week. One month after clinical and laboratory parameters, particularly the ESR, have normalized, tapering can begin. Unfortunately, the ESR does not always normalize, even with disease control, so it should not be relied on as the only measure of remission. Occasional patients may either fail to achieve complete remission or be unable to withdraw from corticosteroid therapy. Cytotoxic or immunosuppressive agents have been recommended for such patients by some authors, but in the absence of convincing proof of efficacy, we are reluctant to endorse such approaches. Recent preliminary experience has suggested that therapies directed at blocking the pro-inflammatory and granuloma-enhancing cytokine, TNF, may be efficacious (11). Studies of this approach have just begun.

Evidence that as many as 40% of patients with polymyalgia rheumatica may have histologic proof of GCA has continued to fuel controversy over whether all patients with polymyalgia rheumatica should be treated with high doses of corticosteroids. In any case, the clinical overlap of these disorders obligates careful vascular evaluations of patients with presumed polymyalgia rheumatica.

VASCULITIDES OF SMALL AND MEDIUM-SIZED VESSELS

Issues at the Time of Admission

Clinical Presentation

The systemic vasculitides that have a predilection for involving small and medium vessels are Wegener's granulomatosis (WG), polyarteritis nodosa (PAN), microscopic polyangiitis (MPA), and Churg-Strauss syndrome (CSS).

Wegener's granulomatosis is a necrotizing granulomatous vasculitis classically thought of as involving the triad of the upper airway, lungs, and kidneys. It affects approximately 3/100,000 people and is distributed equally between men and women, with a mean age of onset of 41 years (range, 9–78 years). Although this disease can affect virtually any organ system (Table 111.3), patients most frequently seek medical attention for symptoms involving the upper and lower airways (Figure 111.3). In the hospitalized patient in whom a diagnosis of WG is being considered, it

TABLE 111.3
WEGENER'S GRANULOMATOSIS:
CLINICAL PROFILE

Abnormality	Frequency at presentation (%)	Frequency during disease course (%)
Upper airways	73	92
Lower airways	48	85
Kidneys	20	80
Joints	32	67
Eyes	15	52
Skin	13	46
Nerves	1	20

Data adapted from Hoffman GS, Kerr GS, Leavitt RY, et al. Wegener's granulomatosis: an analysis of 158 patients. *Ann Intern Med* 1992;116:488–498, with permission.

is important to recognize that the symptom of dyspnea can occur for multiple reasons, including obstruction of the upper airways resulting from involvement of the trachea, bronchi, or subglottic region. Patients with stridor or unexplained dyspnea should be emergently evaluated by an otolaryngologist. If severe tracheal narrowing is present, tracheotomy can be life-saving. Glomerulonephritis is another important disease manifestation. Because it is usually asymptomatic and may be rapidly progressive, clinicians should perform a urinalysis in patients with systemic illnesses for which the cause is uncertain. Although the presence of renal disease is helpful in narrowing the differential diagnosis and although renal disease ultimately occurs in 80% of patients, it is present at the onset of WG in only 20%.

Figure 111.3 Wegener's granulomatosis. This computed tomogram demonstrates multiple bilateral nodules with cavitation of a left posterior nodule in a patient with upper and lower airway disease and glomerulonephritis.

The description of *periarteritis* (later renamed *polyarteritis nodosa*) in 1866 was the first detailed account of a systemic vasculitis in the medical literature. Although the term polyarteritis nodosa was initially used to describe all cases of systemic vasculitis that did not include the largest vessels, it became recognized in the 1950s that certain clinical and pathologic features often allowed separation of these vasculitides into distinct entities. Under a 1993 International Consensus Conference classification, PAN was defined as a vasculitis of medium-sized arteries not associated with glomerulonephritis or vasculitis of small vessels. In contrast, *microscopic polyangiitis* was defined as a necrotizing vasculitis, with few or no immune deposits, affecting small vessels (i.e., capillaries, venules, or arterioles); it can also affect medium-sized arteries. Like WG, MPA has a predilection for the lungs (e.g., pulmonary infiltrates and hemorrhage) and kidneys (glomerulonephritis). Biopsy specimens in MPA are devoid of granulomas, unlike those in WG. MPA can pose an immediate threat to life and organ function, particularly in cases characterized by pulmonary hemorrhage and rapidly progressive renal failure. Once diagnosed, MPA necessitates aggressive treatment.

Based on its definition, PAN is probably very rare. Although several natural history and treatment studies of PAN have previously been performed, the populations analyzed included a number of patients with small-vessel disease who would now be considered to have MPA. This is reflected in the wide range of frequencies of organ involvement reported in different series (Table 111.4). It is very important to note that the phenotypes of patients with PAN, MPA, and *cryoglobulinemic vasculitis* can be the same as those of patients with viral infections complicated by

vasculitis (e.g., hepatitis B and C, HIV infection). Screening for these viruses should therefore be performed in all such presentations, insofar as antiviral therapies may be an important part of treatment for these diseases.

Churg-Strauss syndrome is a rare disease characterized by asthma, eosinophilia, and systemic vasculitis. The peak age of onset is 30–45 years (range, 15–69), and there is a slight male predominance. The course of CSS has often been divided into three phases: the prodrome, the eosinophilic phase, and the vasculitic phase. Although this separation is helpful in approaching CSS, the three phases are not clearly definable in all patients and may occur simultaneously. The prodrome is characterized by allergic disease, usually asthma and allergic rhinitis. During the eosinophilic phase, peripheral eosinophilia and eosinophilic tissue infiltrates, often involving the lung or gastrointestinal tract, may develop. The vasculitic phase may be heralded by constitutional symptoms followed by the development of more organ-specific features, such as mononeuritis multiplex or congestive heart failure. Cardiac involvement can be a significant cause of mortality in these patients.

Differential Diagnosis and Initial Evaluation

All the primary vasculitides of small and medium vessels have the potential to be systemic and evolve rapidly. Initial assessment must be comprehensive and quickly address those organ systems in which involvement carries the greatest potential for significant morbidity or mortality (airway, lungs, kidneys, nerves, gastrointestinal tract, heart, and eyes). It is important to recognize that the absence of symptoms does not rule out disease. For example, one study of patients with WG showed that 34% of radiographs demonstrated infiltrates or nodules while patients were asymptomatic. The point that glomerulonephritis, often rapidly progressive, is usually asymptomatic cannot be overemphasized.

Role of Antineutrophil Cytoplasmic Antibodies in the Differential Diagnosis of Vasculitis. Antineutrophil cytoplasmic antibodies (ANCA), novel auto-antibodies associated with certain forms of systemic vasculitis, were described in Chapter 110. The cytosolic pattern of ANCA (cANCA), combined with reactivity to Proteinase 3 (PR3), has been found to have a high degree of sensitivity and specificity for WG. Although ANCA positivity is useful to suggest the presence of WG, in almost all instances *it should not be used in place of a biopsy to confirm the diagnosis*. This is because the prevalence of WG is low in most clinical situations, and ANCA/PR3 positivity is not 100% specific for WG (12). Conversely, where there is convincing clinical evidence to suggest WG, ANCA negativity should not be a reason to eliminate vasculitis from the differential diagnosis.

Biopsy Strategy for Diagnosis. We have discussed strategies for obtaining biopsy proof of vasculitis in our introductory comments. An important aspect of these strategies

TABLE 111.4

^a Frequencies represent a compilation of data from several series.

includes selecting a suitable biopsy site when more than one organ site is involved. The decision about which site is most suitable for biopsy must be based on individual factors, such as the stability of the patient, invasiveness of the procedure, likelihood of a positive yield based on data from the literature, and urgency of beginning treatment. For example, in a stable patient, it may be reasonable to perform a biopsy at a location where the yield is lower but where the procedure is less invasive. Conversely, when beginning treatment immediately is critical, the biopsy should generally be performed on the involved tissue most likely to yield a diagnosis.

Indications for Hospitalization

The indications for hospitalizing a patient with possible vasculitis chiefly fall under three interrelated headings: diagnosis, monitoring, and treatment. Admission may be indicated so that a diagnostic procedure (e.g., bronchoscopy, surgical biopsy) or an invasive radiologic procedure can be performed safely. Hospitalization for monitoring and treatment typically go together, as it is often the patients who need to be followed closely who require more aggressive (often intravenously administered) treatment. Immediately life-threatening manifestations often dictate the need for hospitalization, but it must be recognized that stable, untreated vasculitis of small and medium-sized vessels has the potential to progress rapidly to life-threatening disease and complete renal failure. For this reason, when these forms of vasculitis are high on the list of possible diagnoses, admission should be considered if it would expedite making a prompt diagnosis and instituting therapy.

Indications for Initial Intensive Care Unit Admission

In the management of the vasculitides of small and medium vessels, indications for ICU admission may include respiratory or airway compromise, pulmonary or gastrointestinal bleeding, unstable cardiovascular parameters, or impaired central neurologic function.

Initial Therapy

The decisions regarding initial treatment will largely be based on the sites and severity of organ involvement and on individual factors. This section reviews the general approach to initial treatment, but physicians are strongly encouraged to seek further information from the literature or consultants regarding the risks, benefits, and protocols of the treatment regimens. Also of note, the following comments are confined to the treatment of small- and medium-vessel vasculitis that is not associated with hepatitis or HIV; these secondary vasculitides may warrant an approach that includes antiviral therapies.

Historical reports have demonstrated that untreated WG is almost universally fatal. Corticosteroids were the first applied therapy, and, although they slowed disease progression in some instances, they usually did not prolong survival. The introduction of treatment with a *corticosteroid*

and daily cyclophosphamide dramatically improved outcome, such that 75% of WG patients achieved complete remission and 91% showed significant improvement, with an 80% survival during a mean follow-up period of 8 years (3). This regimen is now the treatment of choice in any patient with life-threatening disease or rapidly progressive glomerulonephritis. The starting daily dose of cyclophosphamide is 2 mg/kg (Figure 111.4), administered either orally or intravenously (the latter in patients who are too ill to receive oral medications). In either setting, cyclophosphamide should be given all at once in the morning, with 2–3 L of fluid daily to lessen the risk for bladder mucosal injury. Cyclophosphamide is bone marrow-suppressive, and the complete blood cell count should be monitored every 1–2 weeks throughout treatment. An unfortunate misinterpretation of the protocol has led some to believe that the induction of leukopenia is a goal of treatment. Quite the contrary—the starting dose of cyclophosphamide should be lowered if necessary to maintain the white cell count above 3,500/ μ L. Cyclophosphamide is eliminated by the kidneys, and thus drug levels will be higher in patients with renal insufficiency. The decision about whether to begin with a lower dose of cyclophosphamide must be based on the individual circumstance. In the setting of rapidly progressive glomerulonephritis, the adequacy of initial treatment may be critical for renal salvage, and thus it is preferred to start treatment with at least 2 mg/kg daily and closely monitor for trends toward leukopenia. Use of intravenous bolus cyclophosphamide (1 g/m²) to initiate treatment is not advised in the treatment of WG, and intermittent administration is not felt to be as efficacious as daily administration.

In addition to cyclophosphamide, corticosteroids are a critical part of the regimen. The starting dose is 1 mg of prednisone per kilogram daily or the equivalent intravenous dose of methylprednisolone. This dose is continued for a full month, after which time, if there is evidence of disease improvement, it is tapered to an alternate-day schedule and ultimately discontinued, usually by 6–12 months. Splitting the corticosteroid dose (usually to every 8–12 hours) is theoretically more efficacious but also increases the potential for side effects. This is mainly indicated in hospitalized patients who have severe disease. Split doses should be consolidated to a single daily morning dose as soon as possible.

In patients with *fulminant vasculitis of small and medium-sized vessels* that poses an immediate threat to life, a more aggressive approach may be warranted (Figure 111.4). In such settings, large corticosteroid pulses with methylprednisolone (e.g., 1 g/d for three days) are frequently used. In addition, the dose of cyclophosphamide can be increased to 3–4 mg/kg daily for 3 days, then reduced to 2 mg/kg daily (3). Because such patients are uncommon and are critically ill, no controlled study has demonstrated the efficiency of higher doses. Such high-dose therapy does carry a greater risk for morbidity and mortality, and

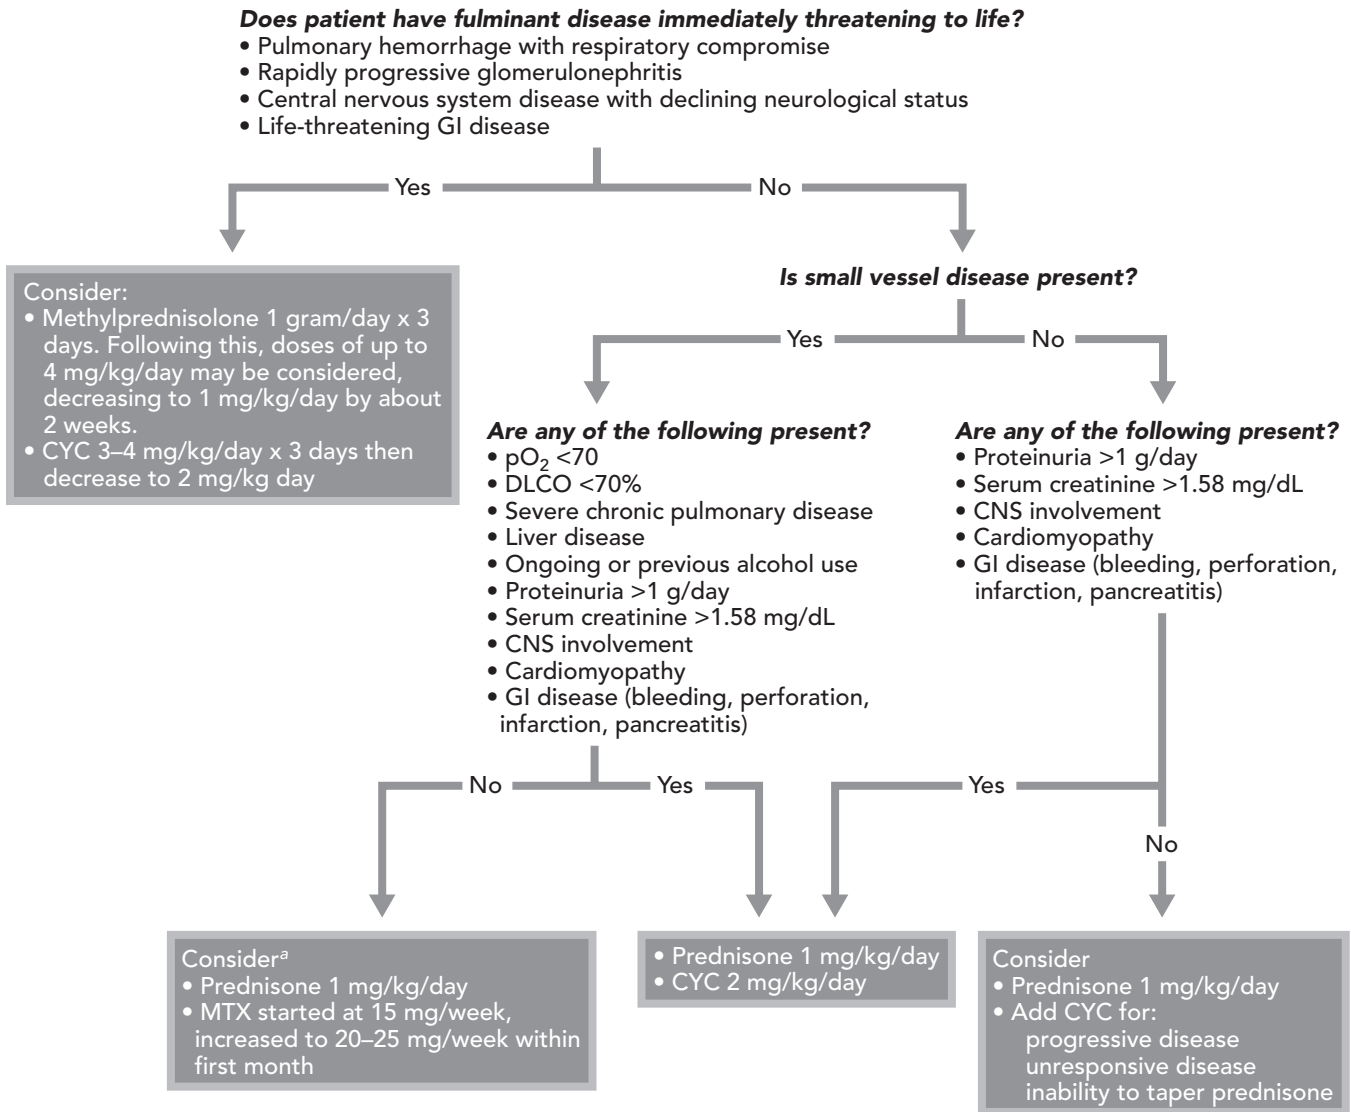

Figure 111.4 Algorithm for the initial treatment of primary vasculitis of small and medium-sized vessels. CYC, cyclophosphamide; MTX, methotrexate; CNS, central nervous system; GI, gastrointestinal; PAN, polyarteritis nodosa. Note: In addition to the listed immunosuppressive agents, therapy should include pneumocystis prophylaxis with 160 mg of trimethoprim and 800 mg of sulfamethoxazole three times weekly for all patients not allergic to sulfa drugs who are receiving a cytotoxic agent plus prednisone. Treatment to decrease steroid-induced bone loss should also be considered. ^aUse of methotrexate has been studied only in Wegener’s granulomatosis.

should be reserved for selected patients for whom the potential benefits are thought to outweigh the risks. Plasmapheresis is another intervention that is often considered in the setting of fulminant disease. Although one study did not find plasmapheresis to be of additional benefit in patients with severe PAN or CSS (13), it has continued to be used by some in the setting of severe small-vessel disease or rapidly progressive glomerulonephritis. In the absence of supportive data, the unknown benefits of this modality must be weighed against the risks of large-bore vascular catheter insertion and procedural hemodynamic lability.

Although cyclophosphamide is the cytotoxic agent of choice in severe disease of small and medium-sized vessels, it may not be necessary for initial therapy in all settings. *Low-dose weekly methotrexate* has been found to be an effective and less toxic alternative to cyclophosphamide in patients who do not have immediately life-threatening disease or in whom cyclophosphamide has been toxic (14). Although trimethoprim-sulfamethoxazole (TMP/SMX) has been advocated by some authors to treat WG affecting the upper and lower airways, progressive disease has also been noted with such treatment (3). TMP/SMX monotherapy may have a role in treating isolated disease of the upper

airway, but it is not recommended in the setting of disease involving the pulmonary parenchyma and should never be used in patients with glomerulonephritis. Finally, not all disease manifestations require or respond to systemic immunosuppression. For example, WG-related subglottic stenosis is optimally managed surgically.

At this time there are few disease-specific data for the treatment of MPA. We recommend a treatment approach similar to that used in WG because MPA can have comparably severe manifestations. Any patient with active small-vessel disease should be managed with daily cyclophosphamide and a corticosteroid at the doses discussed previously and in Figure 111.4, and at higher doses in patients with fulminant disease.

The retrospective nature of the studies and the lack of uniform definitions of disease have complicated the determination of optimal treatment for purely medium-sized vessel vasculitis (PAN). Analyses of PAN and CSS have identified five factors associated with increased mortality: renal insufficiency (creatinine >1.58 mg/dL), proteinuria (>1 g/d), gastrointestinal disease (bleeding, perforation, infarction, pancreatitis), cardiomyopathy, and CNS involvement (15). In the presence of any of these factors, initial therapy should consist of cyclophosphamide (2 mg/kg daily) in addition to prednisone (1 mg/kg daily). A corticosteroid alone can be considered in patients whose disease manifestations do not pose an immediate threat to life or critical organ systems, with cyclophosphamide added later for unresponsive or worsening disease or when the corticosteroid cannot be tapered (Figure 111.4). A simple approach (corticosteroid alone for mild-to-moderate disease; corticosteroid and daily cyclophosphamide for severe disease) is appropriate for patients with CSS, although therapeutic trials are lacking.

In addition to the immunosuppressive agents, the initial treatment regimen may also include medications aimed at preventing treatment complications. Prophylaxis for *Pneumocystis jirovecii* (formerly *P. carinii*) pneumonia with TMP/SMX (160 mg of trimethoprim and 800 mg of sulfamethoxazole three times weekly) is important because fatal infections have been observed in vasculitis patients receiving daily prednisone and a cytotoxic agent. Other interventions that are often part of the initial treatment regimen include folic acid or calcium leucovorin in the setting of methotrexate treatment, and medications directed toward the prevention of prednisone-induced osteoporosis.

Indications for Early Consultation

The vasculitides of small- and medium-sized vessels are uncommon diseases that can result in significant morbidity and mortality. For this reason, consultation with physicians who frequently care for patients with these diseases should be sought early in the course of the illness. In addition to rheumatologists, such consultants may include specialists in nephrology, otolaryngology, neurology, ophthalmology, and pulmonary medicine if these systems are involved.

Issues During the Course of Hospitalization

The main issue during hospitalization is often to provide supportive care and monitoring while diagnostic procedures are performed and treatment is instituted. The rapidity of response to therapy can be influenced by many individual factors, including sites of involvement, severity of organ injury, and the presence of other medical problems. The first 2–4 weeks are a critical time for assessing response to treatment and disease progression by following specific indicators of organ function for each involved site (e.g., renal function tests for glomerulonephritis, oxygenation and respiratory status for pulmonary disease, and changes in examination findings for disease affecting the bowel or nervous system). Some measures of disease activity (e.g., red cell casts noted on urinalysis or chest infiltrates or nodules apparent on roentgenograms) may not change rapidly. Pulmonary abnormalities usually show signs of improvement by four weeks. Improvement in urine sediment may take longer, but the serum creatinine should be stable or improving while the urine sediment is at least stable. Complete clearing of urinary abnormalities may take more than 12 months. When the clinical condition of a patient worsens at the beginning of treatment, one must determine whether the deterioration represents vasculitic disease that has had insufficient time to respond or another process that has emerged, such as infection or drug toxicity (e.g., drug-induced pneumonitis, dermatitis, or hematologic toxicity). If the deterioration is felt to represent active vasculitis and becomes life-threatening, institution of the measures discussed above for fulminant disease may be warranted. In the setting of active vasculitis of small and medium vessels, new sites of involvement can develop at any time. It is therefore essential to be vigilant for any new signs or symptoms of disease.

Discharge Issues

At the time of discharge, it is critical that patients have a clear comprehension of their medications and follow-up. Medication issues include understanding the doses, preferred times to take medications (e.g., single morning doses for prednisone and cyclophosphamide), and possible side effects. A thorough understanding of medication toxicities can most optimally be achieved through a combination of direct discussion and written materials (Figure 111.2). Patient-directed literature on immunosuppressive agents is often available from the pharmacy or support foundations.

Patients require close follow-up to assess the course of disease, adjust medication doses, and observe for therapeutic side effects. Intermittent laboratory studies are mandatory, both to monitor the disease and to ensure the safety of medications. While a patient is taking cyclophosphamide, these studies are usually performed every 1–2 weeks and should include a complete blood cell count with differential, measurement of creatinine levels and

sedimentation rate, and urinalysis with microscopic examination. In addition to these studies, methotrexate monitoring must include liver function tests and measurement of albumin levels, with laboratory values obtained every week after dose adjustments and every month thereafter. The patient may require ongoing outpatient consultation with multiple specialists, but one physician should be responsible for adjusting medication doses and monitoring laboratory parameters.

In our originally published regimen for WG, cyclophosphamide was continued for one full year after remission, at which time it was tapered and discontinued (3). Increasing evidence has supported an approach whereby cyclophosphamide is given until the patient achieves remission (about 3–6 months in most patients), after which time the cyclophosphamide is stopped and either methotrexate or azathioprine are added to maintain remission (16). During the initial hospitalization, decisions regarding such future treatment are not required and usually are not possible. In the outpatient setting, as the patient is serially evaluated for response to treatment and observed for side-effects, management options after achievement of remission can be more fully considered (16).

CENTRAL NERVOUS SYSTEM VASCULITIS

The CNS is a common target organ in many forms of systemic vasculitis. The CNS can also be the sole target of vasculitis, as in *isolated* or *primary angiitis of the central nervous system* (PACNS). The clinical manifestations of CNS vasculitis, including its pace and severity, are highly variable. The rarity of CNS vasculitis, the relative inaccessibility of CNS tissue, and the lack of specificity of noninvasive diagnostic techniques further serve to complicate the clinical approach.

Angiitis of the CNS can be classified as primary and secondary. Primary disease, or PACNS, is a relatively rare disorder in which vascular inflammation is confined to the CNS, including the brain and spinal cord and overlying leptomeninges. This disease has also been referred to as granulomatous angiitis of the CNS, but it should be noted that at least 25% of such patients have nongranulomatous pathology. Secondary vasculitis of the CNS occurs in the setting of a systemic vasculitis. CNS involvement in this setting may rarely be the presenting manifestation of an underlying systemic disease but more often occurs during the course of established systemic vasculitis. Table 111.5 displays the relative frequency of CNS involvement in the various systemic vasculitic syndromes (17).

The clinical manifestations of vasculitis of the CNS are nonspecific and primarily reflect the underlying distribution of ischemia. Diffuse neurologic dysfunction can manifest as encephalopathy affecting cognition or level of consciousness. Focal or multifocal neurologic dysfunction

TABLE 111.5

in the brain or spinal cord can manifest as stroke, seizure, subarachnoid hemorrhage, or cranial neuropathies (18, 19). The diagnosis of CNS angiitis should be considered when a neurologic deficit remains unexplained after a thorough evaluation and noninvasive imaging studies suggest that focal or multifocal ischemia may be responsible.

In the setting of an established systemic vasculitic syndrome such as PAN, CSS, or WG, the new onset of CNS dysfunction mandates an evaluation for possible CNS vasculitis. The initial priority is to determine whether the CNS symptomatology represents arteritic involvement of the CNS or (more commonly) a complication of the underlying disease (i.e., malignant hypertension), effects of drugs (i.e., steroid psychosis), or secondary infection in the setting of immunosuppressive therapy. Even more challenging is the scenario in which CNS angiitis is the initial clinical manifestation of a systemic vasculitis or the presenting finding in PACNS.

Diagnosis and Differential Diagnosis

There are no noninvasive tests or blood studies of sufficient positive predictive value to secure the diagnosis of CNS arteritis. The actual diagnosis of CNS vasculitis relies heavily on neurologic diagnostic modalities, such as cerebrospinal fluid analysis; neuroimaging studies, such as computed tomography (CT) and magnetic resonance imaging (MRI); cerebral angiography; and biopsy of CNS tissues.

Analysis of the cerebrospinal fluid is an essential part of the diagnostic process of both primary and secondary angiitis of the CNS. First, it is important to rule out infectious causes that can mimic CNS angiitis or actually produce a secondary form of CNS angiitis. A number of invasive infections of blood vessels can produce multifocal CNS vascular disease. Examples include syphilis, tuberculosis, certain fungal infections (e.g., coccidioidomycosis and aspergillosis), and infections with viruses (including herpes agents), rickettsial pathogens, and others. In PACNS, the

cerebrospinal fluid has been found to be abnormal and have features consistent with chronic meningitis in more than 90% of patients shown to have this diagnosis histologically (18, 19). Blood tests, such as the identification of acute-phase reactants and auto-antibodies, are of no value, and findings are usually normal or negative. No serologic tests have been shown to have high positive or negative predictive value for CNS vasculitis.

Findings of CT are normal in more than 50% of patients with CNS vasculitis. MRI is more sensitive than CT, but it is not specific in regards to etiology of lesions. Often, multiple bilateral infarcts of different ages are present in the cortex, deep white matter, and leptomeninges. MR angiography is a more recently developed technique for noninvasive visualization of the cerebral vasculature. Unfortunately, at the present time, its spatial resolution allows visualization only of the larger intracranial blood vessels, which are generally spared by small-vessel vasculitides. Collectively, normal cerebrospinal fluid analysis and MRI findings weigh heavily against, but do not completely exclude, a diagnosis of CNS arteritis.

Cerebral angiography is a technique often used in the diagnosis of CNS arteritis, but the findings are normal in more than 50% of cases of biopsy-proven PACNS (18, 19). The presence of alternating areas of stenosis and ectasia in multiple vessels in multiple vascular beds is the most specific finding for CNS arteritis, but unfortunately, even when present, its specificity is low. Vasospasm caused by drugs, hemodynamic changes, or degenerative vascular diseases such as atherosclerosis and fibromuscular disease can completely mimic these findings. In fact, the most important disorders to exclude are those associated with reversible segmental cerebral vasoconstriction, which may mimic completely the angiographic findings of arteritis. This type of disorder may be seen in a variety of settings, including following ingestion of sympathomimetic drugs, in the post-partum period, in association with severe hypertension, in the setting of exertional headaches, or in association with the so-called "thunderclap headache syndrome." It may also occur in an idiopathic form, referred to as *benign angiopathy of the CNS* (20). It is clinically important to recognize these mimics, since immunosuppression is to be avoided.

Biopsy of the CNS is a valuable technique that has a high degree of sensitivity and specificity. In experienced hands, CNS biopsies can be performed with minimal morbidity. Biopsy is rarely needed in suspected cases of *secondary* CNS vasculitis; however, it is often essential to secure the diagnosis of *primary* CNS angiitis (PACNS). The preferred biopsy technique is generally an open biopsy of leptomeninges and underlying cortex taken from the non-dominant tip of the temporal lobe. When CNS biopsy is performed, cultures and special stains for occult infectious agents are essential. Unfortunately, false-negative biopsy results are seen in up to 20% of patients in whom PACNS is ultimately documented pathologically.

Collectively, the clinician is left with a series of tests of varying sensitivities and specificities that must be performed serially until he or she reaches the decision of whether to treat or not to treat as CNS angiitis. Table 111.6 lists a number of conditions that can mimic either the angiographic or pathologic picture of CNS angiitis. These must be ruled out with certainty before immunosuppressive therapy is initiated.

Indications for Hospitalization and Intensive Care Unit Admission

Because the diagnosis of CNS vasculitis cannot be made on the basis of noninvasive testing, hospitalization is usually required for sequential clinical evaluations, spinal fluid analysis, and possibly angiography and CNS biopsy. Competing diagnoses that generally require therapies other than immunosuppression need to be ruled out as soon as possible. The need for ICU admission is determined by the

Indications for Consultation

The successful diagnosis and treatment of CNS angiitis require a team approach. The team should generally include a neurologist, an immunologist or rheumatologist, an angiographer with an interest in CNS angiitis, a neurosurgeon, and a neuropathologist with expertise in CNS angiitis.

Prognostic Variables

In our opinion (data are scarce), all symptoms and signs associated with vasculitic involvement of the CNS should be viewed as life-threatening and thus warrant aggressive therapy. Previously healthy young women with acute onset of headache with or without a focal neurologic deficit, normal or near-normal cerebrospinal fluid, and a high-probability angiogram for vasculitis may well have benign angiopathy of the CNS. It is important to avoid overly aggressive and potentially harmful treatments in such patients.

Treatment

Controlled data regarding treatment of either PACNS or secondary vasculitis of the CNS do not exist. PACNS that is chronic and progressive is potentially life-threatening and warrants aggressive therapy. Empirically derived, efficacious therapy includes a combination of high-dose corticosteroid (e.g., 1 mg of prednisone per kilogram daily) and cyclophosphamide (2 mg/kg daily). After convincing initial improvement has occurred or progressive illness has been arrested, corticosteroid doses are tapered. Cyclophosphamide therapy is continued for approximately 12 months after the disease has been controlled. Serial evaluations of the patient's clinical status, MRI findings, cerebrospinal fluid, and at times angiographic findings may be necessary to gauge the effectiveness of therapy. In patients with a more benign angiopathic presentation, cautious observation or a short course of high-dose corticosteroids (1 mg of prednisone per kilogram daily) for a period of 2–3 months has been advocated. Calcium channel blockers have also been recommended in such patients based on a presumed role of vasoconstriction, although evidence for efficacy is anecdotal.

COST CONSIDERATIONS AND RESOURCE USE

Because the symptoms and signs of vasculitis are often non-specific, considerable resources are frequently expended in evaluating patients before the correct diagnosis is established. Moreover, the generalist who suspects vasculitis often orders a panoply of immunologic and serologic studies ("rheumatology panel"), and patients are frequently shut-

tled from the office of one consultant to another. It is easy with vasculitis to be penny-wise and pound-foolish. The patient with suspected vasculitis is often well served by hospital admission, early consultation with the relevant specialists, rapid and focused laboratory, radiographic, and pathologic evaluation, and prompt initiation of therapy.

KEY POINTS

- Systemic vasculitis must be distinguished from other processes that can mimic the signs and symptoms of vasculitis (e.g., infections, drug toxicities, and emboli).
- The workup of patients with suspected vasculitis requires an integrated, multidisciplinary approach that focuses on patterns of organ involvement rather than a "shot-gun" set of immunoserologic studies.
- While tissue diagnosis is most satisfying in vasculitis, it may not be required in the setting of classical GCA or Wegener's granulomatosis. It is also usually impractical in the setting of clinically-typical Takayasu's arteritis, where the angiogram reveals characteristic features.
- Therapy for systemic vasculitis generally begins with high-dose corticosteroids, often supplemented with a cytotoxic agent such as cyclophosphamide.
- Large-vessel vasculitis, such as Takayasu's or giant cell arteritis (temporal arteritis), can cause hypertensive or ischemic damage to target organs and requires rapid therapy.
- The vasculitides that affect small and medium vessels tend to have unique patterns of organ-injury (e.g., lungs, upper airways, and kidneys in Wegener's granulomatosis), which provides clues for the clinician.

Acute Presentations of Selected Rheumatic Disorders

112

Kenneth H. Fye Kenneth E. Sack

INTRODUCTION

This chapter reviews the acute manifestations of five common rheumatic disorders: systemic lupus erythematosus, scleroderma, Sjögren's syndrome, polymyositis/dermatomyositis, and rheumatoid arthritis. Although their manifestations are remarkably protean (Table 112.1), certain therapeutic principles are generally applicable.

SYSTEMIC LUPUS ERYTHEMATOSUS

Systemic lupus erythematosus (SLE) is an autoimmune disorder characterized by the presence of auto-antibodies and immune complexes (1). The disease generally affects women of childbearing age; the female-to-male ratio is approximately 10:1. Among black or Asian women, the incidence of SLE is 1 in 250, and among white women, it is 1 in 1,000. SLE has a definite genetic component; the HLA antigens, HLA-DR2 and HLA-DR3, predispose to the disorder. Environmental factor(s) may trigger the disease in genetically susceptible persons, but specific factor(s) have not yet been identified. Animal studies demonstrate a direct association between the concentration of estrogens and severity of disease, supporting the hypothesis that female hormones have a role in pathogenesis.

Issues at the Time of Admission

Typical clinical manifestations of the disorder include arthritis, rash, oral ulcers, pleuritis, pericarditis, psychosis, seizures, vasculitis, pulmonary disease, anemia, thrombocytopenia, and glomerulonephritis (1, 2). Despite the protean nature of SLE, most patients can be comfortably treated on an outpatient basis. Hospitalization is, however, occasionally required. Acute SLE can resemble an acute infectious process, with hectic fevers, diaphoresis, lymphadenopathy, malaise, and lethargy. Generally, patients with acute systemic disease have an inflammatory, symmetric polyarthritis, similar to that seen in rheumatoid arthritis, and most have a rash. Life-threatening complications are listed in Table 112.1. Medication-induced side effects can complicate the initial evaluation of a patient with SLE. Most patients with active disease take prednisone or cytotoxic drugs and are therefore susceptible to severe infections with a variety of bacteria, mycobacteria, fungi, or parasites (3). In addition, the leukopenia, thrombocytopenia, or anemia encountered in the patient with acute SLE can reflect drug-induced marrow suppression and may not represent hematologic manifestations of the disease.

A high white blood cell count is consistent with ongoing steroid therapy but should raise the possibility of infection. The erythrocyte sedimentation rate (ESR) is generally elevated. In patients with nephritis, the urinalysis typically reveals proteinuria and active urinary sediment with cellular or granular casts. Antinuclear antibodies (ANA) in a

homogenous or peripheral immunofluorescent pattern are associated with elevated levels of anti-double-stranded DNA antibodies. Patients with pulmonary disease may have a speckled ANA pattern, reflecting anti-Sm (Smith antigen) antibodies. Decreased complement levels reflect a combination of increased utilization (increased amounts of circulating immune complexes) and decreased production of complement components by the liver. The combination of increasing concentrations of anti-double-stranded DNA antibodies and decreasing levels of serum complement is suggestive of increased disease activity. Measurement of serum creatinine, blood urea nitrogen, liver enzymes, and blood gases, in addition to chest radiography, help determine the extent of end-organ involvement. Admission

blood and urine cultures help rule out superimposed infection. Lumbar puncture, magnetic resonance imaging, or cerebral angiography may be necessary to evaluate central nervous system manifestations. A history of deep venous thrombosis, arterial occlusive disease, or recurrent fetal wastage in a lupus patient suggests the *anti-phospholipid antibody syndrome*. Screening studies for this potentially hypercoagulable state include the anti-cardiolipin antibody assay, Russell viper venom time, prothrombin and partial thromboplastin times, and rapid plasma reagent test. Often, only one or two of these tests are positive (Chapter 98).

Therapy of SLE depends on the extent and severity of target-organ involvement. Outpatients may require only fast-acting nonsteroidal anti-inflammatory agents for control of

arthritis. Hydroxychloroquine is effective treatment for the arthritis, rash, and pleuropericarditis of SLE. Patients with more severe disease, such as those with severe constitutional manifestations or hematologic disease, may respond adequately to high-dose corticosteroid therapy. In critically ill patients, *pulse intravenous (IV) methylprednisolone (Solu-Medrol)* (1,000 mg/d) can be administered on each of three consecutive days, following which the patient should be switched to 60–80 mg of prednisone (or the IV equivalent) per day. Life-threatening complications of disease, such as acute lupus nephritis, vasculitis, or cerebritis, require the use of cytotoxic therapy. *IV pulse cyclophosphamide* (1,000 mg/m², given once a month for 6 months and then every 3 months for an additional 18 months) is the current cytotoxic regimen of choice. However, other cytotoxic agents, such as azathioprine, mycophenolate mofetil, methotrexate, cyclosporine, and chlorambucil, have been used with success. With treatment, acute clinical manifestations of the disease should improve during a period of days to weeks. Hematologic studies, determination of the ESR, complement levels, anti-double-stranded DNA titers, and, if the kidneys are affected, creatinine and blood urea nitrogen levels and urinalysis, are helpful in monitoring the activity of disease.

Issues During the Course of Hospitalization

The major issues involve excluding infection, assessing the response to therapy, and monitoring for noninfectious complications of therapy. Occult infection is always the major concern in patients who do not respond appropriately to therapy. Subacute bacterial endocarditis, meningitis, pneumonia, pyelonephritis, and septic arthritis can all mimic acute SLE. In addition, the use of powerful immunosuppressive agents can significantly increase the possibility of nosocomial infection. Concomitant infection is particularly worrisome in patients with active disease and low complement levels who receive corticosteroid and cytotoxic therapy. In patients who initially respond to therapy but in whom fever then recurs, a leukocytosis might suggest an intercurrent infection, whereas leukopenia would be most consistent with worsening SLE. Unfortunately, high-dose corticosteroid therapy can cause a leukocytosis in the absence of infection, and cytotoxic drugs can cause marrow suppression with leukopenia even in the face of overwhelming sepsis.

Discharge Issues

Patients with SLE are not cured when they are discharged from the hospital (1, 4). Generally, they still have active disease and are typically taking oral corticosteroids or cytotoxic drugs (see Figure 111.2 for sample discharge instructions). Discharge plans must include close follow-up with the patient's primary physician. A rheumatologist should be involved in the continuing care of patients ill enough to require hospitalization.

SCLERODERMA

Scleroderma is a clinically heterogeneous disorder of connective tissue characterized by excessive fibrosis in the skin and internal organs (5). Manifestations range from skin thickening confined to the distal extremities and face, with limited internal organ involvement (*limited scleroderma*), to widespread skin thickening, often with life-threatening internal organ involvement (*diffuse scleroderma*). *Localized scleroderma* (morphea, linear scleroderma) is a benign condition that does not affect other organs.

The estimated prevalence of scleroderma is about 200 cases per 1 million population (6). The incidence is low in children and men under age 30 but increases steadily with age, peaking in the fourth through sixth decades. As with other connective tissue diseases, women are affected more often than men (female-to-male ratio of 3:1). Young black women are at highest risk.

The cause of scleroderma is unknown. Familial cases are rare, and there is no strong association with any of the major histocompatibility loci. Evidence is growing, however, for an immune-mediated process that may trigger fibroblast proliferation and collagen biosynthesis. Tissue ischemia can occur early as a result of microvascular endothelial cell injury.

Systemic scleroderma, whether limited or diffuse, has potentially life-threatening complications. Rarely, patients may present with internal organ involvement (e.g., renal crisis) without obvious skin involvement (*systemic sclerosis sine scleroderma*) (Table 112.2).

Issues at the Time of Admission and During Hospitalization

Scleroderma is usually treated in the outpatient setting. Occasionally, however, digital infarction or severe involvement of the lungs, heart, kidneys, or gastrointestinal tract necessitate hospitalization.

Severe ischemia of the digits in patients with Raynaud's phenomenon may cause gangrene of the fingers or toes. In such patients, it is essential to provide a warm hospital environment, discourage cigarette smoking, and discontinue the use of potentially vasoconstrictive drugs (e.g., β -blockers, pseudoephedrine). Control of pain, application of topical antiseptics, and protection of the digits from trauma are the cornerstones of management. There is no good evidence that vasodilating modalities (i.e., drugs or sympathectomy), anticoagulants, or platelet inhibitors improve outcome. Surgical removal of the affected digit is rarely necessary. In most instances, the ischemic area demarcates and the necrotic tissue eventually sloughs, leaving a substantial portion of viable digit.

Dry cough and dyspnea on exertion, along with bilateral basilar late inspiratory crackles, often indicate *interstitial lung disease*. Pulmonary hypertension can be an isolated manifestation of limited scleroderma or develop as a result of advanced pulmonary fibrosis (Table 112.2). A palpable

TABLE 112.2
SUBTYPES OF SCLERODERMA

Type	Clinical characteristics	Auto-antibodies	Major complications
Limited scleroderma	Raynaud's phenomenon for years; skin involvement limited to hands, forearms, face, feet; variable presence of telangiectasia, cutaneous calcifications, esophageal dysmotility	Anticentromere antibodies (ACA), 50–60%; anti-DNA topoisomerase I (Scl-70) antibodies, 10%	Pulmonary hypertension
Diffuse scleroderma	Onset of puffy or hidebound skin within one year of onset of Raynaud's; truncal and extremity skin involvement; tendon friction rubs; esophageal dysmotility	Anti-Scl-70, 30–40%; ACA, 5%	Pulmonary fibrosis, renal crisis, diffuse gastrointestinal involvement
Systemic sclerosis <i>sine</i> scleroderma	Raynaud's; no skin involvement	May have antinuclear antibodies	Renal, gastrointestinal, or myocardial disease
Localized scleroderma	Morphea, linear scleroderma	May have antinuclear antibodies	<i>Coup de sabre</i> deformity (linear scleroderma over the scalp or forehead)

parasternal heave, a split-second heart sound with a loud pulmonary component, a right-sided S₃ or S₄ gallop, and a murmur of tricuspid insufficiency are all physical findings typical of pulmonary hypertension. Hemoptysis in a patient with scleroderma should prompt a search for *endobronchial telangiectasia*.

A decreased diffusion capacity for carbon monoxide (DLCO) is an early indicator of either interstitial or vascular lung disease. A restrictive pattern on pulmonary function tests, or bilateral basilar linear, nodular, or honeycomb infiltrates on chest radiography, suggest interstitial involvement. "Ground glass" opacities on high-resolution, thin-section computed tomography correlate with interstitial inflammation and indicate the need for corticosteroids or immunosuppressive agents (i.e., azathioprine, cyclophosphamide). Advanced pulmonary hypertension unresponsive to immunosuppressive therapy can occur in patients with scleroderma. More information on the pulmonary manifestations of scleroderma can be found in Chapter 57, and the diagnosis and management of pulmonary hypertension are described in Chapter 59.

Cardiac manifestations of scleroderma include constrictive pericarditis, restrictive cardiomyopathy, arrhythmias, and small-vessel coronary artery disease. Although there are no specific treatments for the cardiac involvement, calcium channel blockers may increase myocardial perfusion.

Scleroderma renal crisis manifests as a sudden rise in blood pressure or rapid deterioration in renal function, often accompanied by hemolytic anemia. It occurs most often in patients with diffuse scleroderma, particularly those with rapidly progressive cutaneous thickening early in the course. Occasionally, renal disease develops before skin changes are clearly visible. The use of high-dose systemic corticosteroids can precipitate renal crises in scleroderma patients. Urinalysis often shows proteinuria (usually <2.5 g/24 h), microscopic hematuria, and granular casts.

Markedly increased plasma renin activity is the rule. Renal histopathology shows intimal thickening in interlobular arteries in addition to adventitial and peri-adventitial fibrosis. The prompt use of *angiotensin-converting enzyme inhibitors* in the treatment of renal crisis has dramatically improved survival and reduced the need for prolonged dialysis (7).

The *gastrointestinal tract* is involved in almost all patients with scleroderma (8). Esophageal abnormalities are common and include decreased or absent peristalsis in the distal esophagus and reduced pressure in the lower esophageal sphincter, resulting in dysphagia, chest pain, and, in severe cases, recurrent aspiration.

Involvement of the small bowel can alter peristalsis, with the development of intestinal stasis and eventual dilatation, leading to pseudo-obstruction, bacterial overgrowth, and malabsorption. Proton-pump inhibitors may also predispose to bacterial overgrowth. Radiographic studies of the small bowel typically show dilatation of the duodenum and jejunum, prolonged transit time, sacculations, and packing of valvulae (a unique radiographic finding termed "*hidebound*" *small bowel*). Large-bowel involvement manifests as a dilated colon without haustra, sometimes associated with wide-mouthed diverticula along the antimesenteric border. Anorexia, early satiety, nausea, vomiting, abdominal distention, diarrhea, or constipation should prompt imaging studies of the gastrointestinal tract. *Pneumatosis cystoides intestinalis* occasionally complicates scleroderma, possibly because excessive hydrogen production by intestinal bacteria reduces the partial pressure of nitrogen in the intestinal wall to less than that of venous blood. Thus, gas cannot be reabsorbed and accumulates in the tissues.

Prokinetic agents, such as metoclopramide, domperidone, low-dose octreotide, and erythromycin, can provide symptomatic benefit in some patients with intestinal involvement. The combination of octreotide and

erythromycin can be particularly effective. Antimicrobial agents may be necessary to treat bacterial overgrowth. Intestinal pseudo-obstruction requires bowel rest and decompression with a nasogastric or small-bowel suction tube.

Discharge Issues

Local protection and antisepsis are crucial until the necrotic tissue of gangrenous digits demarcates and sloughs. Prevention of further ischemia by controlling Raynaud's phenomenon is equally important. Treatment techniques include staying warm (gloves, hat, appropriate socks and undergarments, and hand soaks); avoiding nicotine, caffeine, and vasoconstricting medicines; and using vasodilating agents, such as calcium channel blockers. Nifedipine is one of the most effective vasodilators, but it can relax the lower esophageal sphincter and worsen reflux symptoms. Diltiazem, although not as potent a vasodilator, has little effect on the lower esophageal sphincter. Angiotensin-converting enzyme inhibitors may also be beneficial.

Evidence of active interstitial lung inflammation on high-resolution, thin-section computed tomography mandates prolonged therapy with corticosteroids and immunosuppressives. Pulmonary fibrosis will not respond to such therapy. Most vasodilators are ineffective in the long-term treatment of pulmonary hypertension, but IV prostacyclin can reduce pulmonary artery pressure over extended periods (Chapters 57 and 59). Bosentan, an oral endothelin antagonist, is also effective in the treatment of pulmonary hypertension (9).

Although aggressive treatment with any antihypertensive agent would likely prove effective in treating scleroderma renal crisis, angiotensin-converting enzyme inhibitors have become the mainstay of both the short- and long-term management of this disorder and its associated microangiopathic hemolytic anemia. The target blood pressure should be less than 140/90 mm Hg.

The long-term management of scleroderma bowel can be challenging and often requires the expertise of an experienced gastroenterologist.

SJÖGREN'S SYNDROME

Sjögren's syndrome is an autoimmune disorder defined pathologically by mononuclear cell infiltration of exocrine glands throughout the body (10). There is a strong association between Sjögren's syndrome and the HLA-DR3 gene. The female-to-male ratio is above 10:1. Environmental factor(s) may trigger the disease in genetically-susceptible persons. Manifestations of the disease reflect dysfunction of exocrine glands, with a decrease in the secretions that interface between the body and the external environment. The major complaint is that of dryness of mucocutaneous surfaces throughout the body. Half the patients with Sjögren's syndrome have no other rheumatologic problems. In others the syndrome occurs in association with some other

autoimmune disorder, such as SLE, rheumatoid arthritis, scleroderma, dermatomyositis, or autoimmune thyroiditis. Extraglandular manifestations of Sjögren's syndrome may necessitate hospitalization.

Issues at the Time of Admission

Severe pulmonary involvement by Sjögren's syndrome, including lymphocytic interstitial pneumonitis and interstitial fibrosis, can lead to restrictive lung disease and respiratory failure (Chapter 57) (11). Inadequate airway secretions increase the susceptibility of the patient to sinusitis, bronchitis, and pneumonia. Gastrointestinal manifestations include pancreatitis, malabsorption syndrome, primary biliary cirrhosis, and chronic active hepatitis. The typical renal lesion is interstitial nephritis, with decreased concentrating ability, potassium wasting, glycosuria, and renal tubular acidosis. Glomerulonephritis and renal failure can rarely occur. Central nervous system involvement in Sjögren's syndrome includes abnormalities of white matter (seen on magnetic resonance imaging) associated with cognitive defects and (rarely) a demyelinating process, reminiscent of multiple sclerosis. Peripheral neuropathies may reflect vascular occlusive disease, caused either by inflammatory vasculitis or by an obliterative vasculopathy related to the presence of anti-phospholipid antibodies. A rare patient will present with a symptom complex of fever, salivary gland enlargement, lymphadenopathy, and hepatosplenomegaly. The major differential diagnosis in these patients with the "*pseudolymphoma*" of Sjögren's syndrome is true generalized histiocytic lymphoma. The best way to distinguish pseudolymphoma from true lymphoma is through biopsy of affected tissues. The anti-phospholipid antibody syndrome is a consideration in patients with arterial or venous occlusive disease or with a history of multiple miscarriages.

Typical laboratory abnormalities include an elevated ESR, a positive rheumatoid factor or ANA assay, positive anti-SSA or anti-SSB antibody determinations, and polyclonal or monoclonal hypergammaglobulinemia. Anemia, abnormal urinalysis findings, abnormal renal or liver function, or hypoxemia may occur, depending on end-organ involvement. A prolonged partial thromboplastin time, a false-positive rapid plasma reagent test result, a prolonged Russell viper venom time, or the presence of anti-cardiolipin antibodies may reflect the anti-phospholipid antibody syndrome. Chest radiography, pulmonary function testing, magnetic resonance imaging of the central nervous system, electroencephalography, or electrocardiography can help to assess disease activity in individual patients.

Although hydroxychloroquine and fast-acting non-steroidal antiinflammatory agents may be of value in the outpatient treatment of Sjögren's syndrome, *high-dose corticosteroids* are necessary in life-threatening extraglandular disease. Pulse methylprednisolone (1,000 mg IV on each of three consecutive days) is indicated in both interstitial lymphocytic pneumonitis with respiratory failure and in acute demyelinating disease of the central nervous system.

Patients who do not respond or in whom unacceptable side effects of corticosteroid therapy develop may require therapy with cytotoxic agents such as azathioprine, mycophenolate mofetil, methotrexate, cyclosporine, or cyclophosphamide.

Issues During the Course of Hospitalization

High-dose corticosteroids and cytotoxic drugs can predispose to secondary infection, and nosocomial pneumonia can complicate the course of Sjögren's interstitial pneumonitis. Rupture of a colonic diverticulum or acute pyelonephritis might confuse the picture in patients with pancreatitis. Secondary meningitis or epidural abscesses are infectious problems that can obscure the response to treatment of the central nervous system manifestations of Sjögren's syndrome.

Patients with extraglandular disease that does not respond appropriately to therapy may have a malignancy. Generalized histiocytic lymphoma and Waldenström's macroglobulinemia both occur more frequently in patients with Sjögren's syndrome. Such malignancies may be heralded by falling ANA or rheumatoid factor titers, and by a rising ESR. Hyperviscosity syndrome in a patient with Sjögren's syndrome is also suggestive of Waldenström's macroglobulinemia. Diagnosis depends on biopsy of involved tissues (e.g., lymph nodes, salivary glands, or bone marrow).

Discharge Issues

Sjögren's syndrome is not curable, but symptoms can be controlled. The hospital physician must ensure that discharge medicines are appropriate (Figure 111.2) and that expeditious follow-up care is arranged with the patient's rheumatologist and primary care physician.

POLYMYOSITIS/DERMATOMYOSITIS

Idiopathic polymyositis is an inflammatory disease of striated muscle defined by proximal muscle weakness, elevated serum creatine phosphokinase or aldolase, typical electromyographic changes, and abnormal findings on muscle biopsy. Dermatomyositis differs histologically from polymyositis, manifests cutaneous lesions, and may have a higher association with malignancies (12). Nonetheless, we will refer to both entities in this chapter as polymyositis/dermatomyositis (PDM). The incidence of PDM in the general population is approximately 1 in 250,000. Women are affected twice as often as men. Although outpatient management suffices for most patients, certain complications of PDM necessitate hospitalization.

Issues at the Time of Admission

Overwhelming proximal muscle weakness often warrants hospital admission. A patient with severe disease may be completely bedridden, unable even to lift his or her head

off the pillow. Involvement of the striated muscles of the oropharynx and upper third of the esophagus may cause severe dysphagia and dysphonia and increase the risk for aspiration (Chapter 79). Weakness of the muscles of respiration can produce ventilatory insufficiency. Interstitial pneumonitis and fibrosis occasionally accompany PDM and can lead to restrictive lung disease and respiratory failure (Chapter 57). Cardiac involvement in PDM can cause conduction defects (with sometimes fatal dysrhythmias), congestive heart failure, and pericarditis. Systemic necrotizing vasculitis occurs in childhood PDM but rarely in adults with PDM. The incidence of cancer appears to be increased in PDM, particularly in children and in adults over 50 years of age. The initial screening evaluation for occult malignancy should be age appropriate, and include a careful physical examination, routine blood and urine studies, serial stool Hemoccult tests, and chest radiography.

In addition to elevated creatine phosphokinase and aldolase levels, typical laboratory abnormalities might include an elevated ESR and a positive ANA assay result. Anti-synthetase (Jo1) antibodies tend to be associated with severe, progressive PDM with pulmonary involvement.

High-dose corticosteroid therapy, including pulse methylprednisolone (1,000 mg IV on each of three consecutive days), is effective in treating the complications of severe PDM. Cytotoxic agents, particularly methotrexate, mycophenolate mofetil, or azathioprine, may benefit patients who do not respond to corticosteroids. Newer therapies for recalcitrant disease include IVIG or the TNF α antagonists, such as etanercept or infliximab (13).

Issues During the Course of Hospitalization

Many patients with severe disease respond slowly to therapy, so corticosteroids should be tapered gradually. Cytotoxic therapy is necessary if an adequate trial of corticosteroids has failed, if unacceptable side effects have developed, or if the patient has rapidly progressive, overwhelming disease. Failure to respond to therapy should alert the clinician to the possibility of nosocomial infection or occult malignancy. An occasional patient with PDM responds poorly to all therapies and has a poor long-term prognosis.

Discharge Issues

In general, patients with severe PDM will still be significantly symptomatic at discharge. They are usually weak and may have persistent respiratory insufficiency. Chronic dysphagia, dysphonia, and aspiration are troublesome manifestations that put the patient at constant risk for repeated hospitalization. Many patients require a vigorous program of physical therapy, ongoing home nursing, and careful monitoring by a physician. Some require alternatives to oral feeding (Chapter 15). The response to treatment is often agonizingly slow, and most patients must undergo long-term therapy with systemic corticosteroids, cytotoxic agents, or both (Figure 111.2). Persistent weakness in the

proximal lower extremities may reflect steroid myopathy rather than ongoing inflammatory disease.

RHEUMATOID ARTHRITIS

Rheumatoid arthritis is an inflammatory, symmetric, erosive polyarthritis with prominent involvement of small proximal joints of the upper and lower extremities (14). It affects approximately 7 million Americans, generally between the ages of 20 and 50, with a female-to-male ratio of 4:1. Although arthritis is the cardinal manifestation of this condition, virtually every organ system can be affected. Negative prognostic signs in rheumatoid arthritis include seropositivity for rheumatoid factor, involvement of multiple joints within six months of onset, persistent elevation of acute-phase reactants (e.g., ESR or C-reactive protein), early erosive disease, a history of tobacco abuse, and lack of formal education.

Issues at the Time of Admission and During Hospitalization

Patients experiencing a severe flare in disease activity frequently improve during hospitalization, even without a change in pharmacologic therapy, probably because of both physical and emotional rest. Although bed rest may relieve joint symptoms, early institution of physical therapy (including active range-of-motion exercises, muscle strengthening, and ambulation) is critical to maintaining joint function.

Extraarticular manifestations are common in patients with seropositive rheumatoid arthritis. Rheumatoid nodules tend to develop over the extensor surfaces of the elbows and forearms, but they can be seen over any pressure point or in internal organs, such as the heart and lungs.

Ocular involvement is common in rheumatoid arthritis. Episcleritis manifests as localized hyperemia, usually near the limbus, and is associated with only mild discomfort. Although it tends to be self-limited, some patients require topical corticosteroids to control inflammation. Scleritis and scleronodular disease involve deeper ocular tissues, tends to be painful, and can lead to blindness if untreated. Proper management includes corticosteroids or cytotoxic agents. Corneal ulcers are usually caused by obliterative vasculopathy. The management of all these serious eye manifestations requires the expertise of an ophthalmologist.

Keratoconjunctivitis sicca associated with Sjögren's syndrome is the most common ocular finding in rheumatoid arthritis. Patients typically complain of a foreign body sensation, but in severe cases photophobia and deep eye pain may occur. Symptoms are usually relieved by the liberal use of artificial tears and an ophthalmologic gel. The decreased salivary flow of Sjögren's syndrome can cause discomfort and predisposes patients to severe dental caries and oral candidiasis. The former can be managed by meticulous oral hygiene and frequent dental evaluation, and the latter re-

sponds to a nystatin vaginal tablet dissolved in the mouth for 20–30 minutes two or three times a day.

Pleuropulmonary involvement occurs in up to 50% of patients with rheumatoid arthritis. Pleural disease, which is frequently asymptomatic, occurs more commonly in men than in women and occasionally precedes the onset of arthritis. Pleural effusions are typically exudative, with high protein and low glucose concentrations (Chapter 60). Spontaneous resolution is the rule, but systemic corticosteroids are sometimes needed to treat recalcitrant pleuritis. Interstitial disease, including lymphocytic pneumonitis or pulmonary fibrosis, can lead to respiratory failure but may be asymptomatic, manifesting only as restriction or decreased diffusion on pulmonary function tests (Chapter 57). Cigarette smoking predisposes to interstitial involvement, particularly among men. Patients with active interstitial inflammation may require corticosteroid or immunosuppressive therapy. Less common pulmonary manifestations include nodular lung disease (sometimes with cavitation), obliterative bronchiolitis, bronchiectasis, spontaneous pneumothorax, amyloidosis, vasculitis, and pulmonary hypertension. Synovitis of the cricoarytenoid joints may, in addition to pain, dysphagia, and hoarseness, produce stridor and dyspnea. Pulmonary disease can also result from treatment with certain antirheumatic drugs, especially methotrexate.

Cardiac lesions are common in rheumatoid arthritis, but symptoms are unusual. Pericarditis occurs in 40% of patients, especially in those who are seropositive (Chapter 46). Tamponade and constriction are rare. Other cardiac manifestations include coronary arteritis, which is typically asymptomatic, and the formation of rheumatoid nodules, occasionally causing valvular dysfunction or conduction abnormalities.

A small-vessel vasculitis occurs in 30% of seropositive patients; a cutaneous arteritis causing malleolar ulcers occurs in 10%; and a medium-sized vessel arteritis reminiscent of polyarteritis nodosa manifests in 2%. Medium-sized artery vasculitis occurs most commonly in seropositive men who have had rheumatoid arthritis for more than 10 years and who have a history of tobacco use. Characteristic skin lesions (e.g., petechiae, purpura, necrotic ulcers), peripheral neuropathy, severe abdominal pain, and unexplained weight loss can all be the initial presenting manifestation of *rheumatoid vasculitis* (Chapter 111). Neuropathic patterns of rheumatoid vasculitis range from a symmetric sensory or sensorimotor polyneuropathy to mononeuritis multiplex. Biopsy of affected tissue may be necessary to confirm the diagnosis. Glucocorticoids or immunosuppressive agents are indicated for all but the most mildly affected patients with rheumatoid vasculitis.

Entrapment neuropathies are common in patients with long-standing seropositive rheumatoid arthritis. Such processes may result from subluxations of cervical vertebrae (particularly C-1 and C-2), impingement by proliferative synovial tissues (e.g., carpal tunnel syndrome), or amyloid deposits.

The most common *hematologic abnormality* in patients with rheumatoid arthritis is a normocytic, normochromic anemia secondary to decreased red cell production. A normal or elevated serum ferritin level helps distinguish this form of anemia from that of iron deficiency. This “anemia of chronic inflammation” responds to subcutaneous injections of erythropoietin, but such therapy is rarely necessary. Eosinophilia is sometimes seen in patients with severe extraarticular disease. A patient with rheumatoid arthritis, hepatosplenomegaly, and neutropenia (sometimes with anemia or thrombocytopenia) may have *Felty’s syndrome*. This rare but potentially life-threatening complication usually occurs in seropositive patients with severe, but often quiescent, arthritis and extraarticular disease. The major sequelae of Felty’s syndrome include cutaneous vasculitis with malleolar ulcers, recurrent infections, and, rarely, nodular hyperplasia of the liver with portal hypertension and esophageal varices. The initial treatment of Felty’s syndrome is directed at controlling the rheumatoid process with aggressive therapy—typically including corticosteroids and immunosuppressive agents. Granulocyte-macrophage colony-stimulating factor and related agents can increase neutrophil counts but have a limited duration of action, are expensive, and cause considerable side effects. Splenectomy has been advocated in patients with chronic or recurrent infections, but there is no convincing evidence that it provides any long-term benefit.

Renal disease is more commonly a result of drug toxicity than a direct consequence of the underlying rheumatoid arthritis. However, amyloidosis, a complication of long-standing rheumatoid disease, can cause proteinuria. Mesangial glomerulonephritis is a rare manifestation of the rheumatoid process and can cause proteinuria and hematuria.

Discharge Issues

Many patients will experience a mild flare in their arthritis within a few days of discharge. This is probably related, in part, to the increased stress that comes with returning to the home environment. Warning them of this phenomenon, recommending extra rest, and making appropriate adjustments in medication (Figure 111.2) will help patients deal with this flare. The patient should consult his or her primary care physician within a few weeks of discharge. The urgency of subspecialty follow-up depends on the nature and extent of the rheumatoid complications.

KEY POINTS

- In treating autoimmune disease, use aggressive therapy with corticosteroids, cytotoxic agents, or both before irreversible organ failure occurs.
- Always rule out infection in patients who present with what appears to be an autoimmune disorder and in autoimmune patients whose disease appears to be flaring.

- The side effects of immunomodulatory therapy can themselves be life-threatening.
- Corticosteroids are generally the first-line drugs in the treatment of significant autoimmune disease.
- Cytotoxic therapy is indicated for patients in whom the response to corticosteroids is inadequate or for those in whom unacceptable side effects of corticosteroid therapy have developed.
- The complications of disease need to be treated as aggressively as the primary pathogenetic process (e.g., anticoagulants are required in the treatment of anti-phospholipid antibody syndrome, and antihypertensive drugs are crucial in the treatment of scleroderma crisis).

INTRODUCTION

Acute arthritis—defined as joint inflammation developing in less than two days—presents important diagnostic and therapeutic challenges to the hospital physician. In general, the most urgent task is to determine which patients with acute arthritis have infected joints. In most forms of septic arthritis, delays in therapy threaten not only the future function of the joint, but also the survival of the patient. Acute arthritis due to causes other than infection presents different challenges. For example, the prompt diagnosis and appropriate treatment of microcrystalline disorders can alleviate pain and shorten hospital stays. Although septic arthritis and crystal-induced arthritis are the two most common causes of inflammatory joint pain seen in the hospital, a myriad of multisystem diseases (e.g., inflammatory bowel disease, adult Still's disease, leukemia, Whipple's disease, vasculitis) may also present with acute arthritis.

This chapter begins with a general approach to the differential diagnosis of acute arthritis, discusses the analysis of synovial fluid, and then describes the treatment of gout and septic arthritis.

APPROACH TO DIFFERENTIAL DIAGNOSIS

The cause of acute arthritis can usually be determined at the bedside by the history and physical examination, supplemented by a few laboratory tests. Many elements of the initial evaluation contribute to the diagnosis (Table 113.1), but the three of greatest value are usually: (1) *the pattern of joint involvement*; (2) *the presence or absence of extraarticular signs*; and (3) *the results of synovial fluid analysis*.

The *joint pattern* includes both the number and the site(s) of affected joints (Table 113.2). The number of involved joints has important implications. Most cases of

monoarthritis, for example, are caused by microcrystalline diseases (gout or pseudogout), infection, or trauma. Very few systemic diseases (infections excepted) present with monoarthritis. Acute oligoarthritis suggests reactive arthritis or occult inflammatory bowel disease. Polyarthritis is usually caused either by a systemic rheumatic disease such as rheumatoid arthritis or systemic lupus erythematosus, or by a viral infection. Because most systemic rheumatic diseases initially develop over weeks to months, the new onset of acute polyarthritis most commonly signals a viral infection. The site of the acute arthritis may be equally helpful in formulating the differential diagnosis. The first metatarsophalangeal joint or the ankle is most commonly involved by gout, whereas acute arthritis of the distal interphalangeal joints usually represents either osteoarthritis or psoriatic arthritis.

The presence or absence of *extraarticular* signs also helps narrow the differential diagnosis. Small, asymptomatic, necrotic pustules over the distal extremities, for example, strongly suggest disseminated gonococcal infection (see the section on "Gonococcal Arthritis" later in this chapter). Osler's nodes and splinter hemorrhages in a patient with acute arthritis imply endocarditis. Examples of the significance of extraarticular manifestations in the differential diagnosis of acute arthritis are listed in Table 113.3.

For patients with unexplained acute arthritis, *synovial fluid analysis* often provides crucial information. This procedure should immediately follow the history and physical examination (1) (Figure 113.1). Arthrocentesis is contraindicated if the joint has an overlying cellulitis. When possible, severe coagulopathy or thrombocytopenia should be corrected before arthrocentesis, especially if the procedure requires a needle larger than 22 gauge. Finally, arthrocentesis of some joints, such as the sacroiliac joints or the hips, requires consultation with an orthopedist or radiologist.

Synovial fluid characteristics of different conditions are shown in Table 113.4. Synovial fluid analysis answers

three questions: (1) *Is the fluid inflamed?* (2) *Is it infected?* and, (3) *Does it contain crystals?* Inflammation is present if the synovial fluid white blood cell count exceeds 3,000/ μ L. Lower synovial fluid white blood cell counts are typical of degenerative joint disease. Synovial fluid specimens with white cell counts above 50,000/ μ L are often designated “septic,” but this label is not always accurate. Acute gout, for example, often produces white cell

counts in synovial fluid of 50,000–100,000/ μ L. Conversely, some infections, especially tuberculosis, may produce relatively low white cell counts in synovial fluid (3,000–10,000/ μ L). Synovial fluid analysis utilizing a microscope equipped with polarizing lenses and (ideally) a red compensator permits the examiner to rule out microcrystalline disorders (see the section on “Differential Diagnosis and Initial Evaluation” later in this chapter). Bloody synovial fluid indicates trauma, coagulopathy, tuberculosis, or a synovial tumor, such as pigmented villonodular synovitis.

Although the joint pattern, presence or absence of extraarticular features, and synovial fluid findings are the most valuable points in evaluating acute arthritis, the patient’s epidemiologic profile, travel history, and social history may also provide important information. A careful sexual history may implicate *Neisseria gonorrhoeae* as the cause. The importance of age is emphasized by the fact that disseminated gonococcal infections rarely occur after the age of 45. The nearly 10:1 female predominance in systemic lupus erythematosus highlights the significance of gender. Closely detailing the time course of the arthritis is also crucial because systemic connective tissue diseases such as lupus, rheumatoid arthritis, and vasculitis virtually never cause acute arthritis as the very first manifestation. Most patients with these conditions have weeks of malaise, fatigue, or other symptoms before onset of the arthritis. Residence in or travel to a region in which Lyme disease is

endemic is a key point in the evaluation of patients with acute monoarthritis of the knee (the most common rheumatic manifestation of Lyme disease). A past medical history of diabetes, alcoholism, or injection drug use greatly increases the likelihood that a patient with acute monoarthritis has a bacterial infection. Serologic tests can help support the diagnosis of systemic rheumatic diseases (Chapters 110–112).

RECOGNIZING ACUTE ARTHRITIS

Acute arthritis is usually easily recognized by the cardinal signs of inflammation—swelling, warmth, redness, and pain. Most inflamed joints also demonstrate reduced motion and effusions, but in some joints (e.g., the hips), detection of swelling is difficult. The diagnosis of hip arthritis is suggested by groin pain exacerbated by weight bearing or passive internal rotation. In contrast, pain along the lateral aspect of the hip more commonly indicates trochanteric bursitis. Patients who cannot ambulate because of sudden “hip pain” but who maintain the hip in flexion are more likely to have a psoas abscess than a hip joint infection. Sep-

tic arthritis of the sternoclavicular joint is easily overlooked because the pain is often referred to the shoulder.

GOUT

Issues at the Time of Admission

Clinical Presentation

The most common presentation of acute gouty arthropathy is an exquisitely painful, swollen great toe—*podagra*. Attacks of gout develop explosively. Within several hours, a previously asymptomatic patient becomes unable to tolerate the pressure of a sheet over the toe (2). Other commonly affected sites are the ankle, instep, and knee. Gout can cause not only arthritis but also a chemical cellulitis that leads to desquamation of the overlying skin after a few days. Polyarticular gout and involvement of the upper extremity usually develop only after years of recurrent foot involvement, but exceptions occur. Fever is present in approximately 10% of patients.

Differential Diagnosis and Initial Evaluation

Patients suspected of having gout may also have pseudogout, infection, or trauma. Trauma is excluded by history. A previous history of gout, the use of drugs that impair uric acid excretion (e.g., diuretics, cyclosporine, low-dose aspirin), the occurrence of classic podagra, and the presence of tophi all increase the likelihood that the cause of an acute arthritis is gout. Acute monoarthritis of the wrist or knee favors pseudogout. A history of injection drug use, rheumatoid arthritis, or diabetes predisposes patients to infection. Because 10% of patients with gout have fever and as many as one-third of patients with septic arthritis are afebrile on presentation, fever does not distinguish infection from gout. Similarly, the serum uric acid level is difficult to interpret in the acute setting because 15% of patients with acute gout have normal values and high uric acid levels may also occur in infection (2). Thus, the crucial test is synovial fluid analysis.

Urate crystals are needle-shaped and negatively birefringent (i.e., when viewed with a red compensator, the crystals are yellow when parallel to the axis of the compensator and blue when perpendicular). Pseudogout is caused by calcium pyrophosphate dihydrate crystals, which are rhomboidal and positively birefringent (i.e., they are yellow when perpendicular and blue when parallel to the axis of the red compensator). Gout is virtually excluded if no urate crystals are present. Crystals are less numerous in pseudogout, and false-negative results of synovial fluid analysis are more common than in gout. Because microcrystalline disease and infection can coexist, Gram stain and culture of synovial fluid should be performed even in the setting of obvious crystals.

Indications for Hospitalization and Intensive Care Unit Admission

Gout is rarely the principal indication for hospitalization, and it almost never warrants ICU admission. More commonly, patients are hospitalized for another condition (e.g., congestive heart failure or surgery), and acute gout develops in the hospital. A few patients have such an explosive onset of polyarticular gout that a stroke or some other serious condition is diagnosed initially, and they are admitted for further evaluation. Even when the correct diagnosis is made promptly, hospitalization may be warranted either because the patient is bedridden with polyarticular gout or because the synovial fluid analysis suggests that the patient may have both gout and septic arthritis.

Initial Therapy

The most common mistake in the management of gout is the failure to separate the treatment of acute gouty arthritis from the treatment of hyperuricemia. It is essential to treat the acute arthritis first, and to *defer the management of hyperuricemia* until after the flare has resolved. Treatment of hyperuricemia in the acute setting alleviates neither joint inflammation nor its accompanying pain. On the contrary, if administered during a flare, a urate-lowering agent can provoke another attack.

The most commonly employed agent in treating acute gout is indomethacin, but any nonsteroidal anti-inflammatory agent (NSAID) other than aspirin can be effective (3). (Low-dose aspirin impairs renal excretion of uric acid and can precipitate gout. High-dose aspirin, in contrast, facilitates renal uric acid excretion.) We usually begin with 50 mg of indomethacin orally three times a day until the patient improves (i.e., 1–2 days) and then continue with 25 mg of indomethacin three times a day to complete a 10-day course. Unfortunately, NSAIDs are contraindicated in renal insufficiency, a common comorbidity in patients with gout. They are also relatively contraindicated in patients at risk for the development of NSAID-induced renal insufficiency, such as those with dehydration, congestive heart failure, diabetes, or whose age is greater than 60 years. A history of peptic ulcer disease is also a contraindication to the use of NSAIDs.

For patients with renal insufficiency and acute gout, corticosteroids are an effective alternative to NSAIDs. Intraarticular injection (e.g., 10–40 mg of triamcinolone, depending on the size of the joint) is very effective and especially helpful for the postsurgical patient who is taking nothing by mouth. Corticosteroids can be administered either intravenously (e.g., 40 mg of methylprednisolone IV initially, then tapered by 5 mg/d) or orally (e.g., 40 mg of prednisone once daily by mouth for 2 days, then tapered in a similar fashion). The IV and oral routes are preferable to direct joint instillation in patients with polyarticular gout. Systemic corticosteroids should be used sparingly in patients recovering

from surgery and avoided in patients with infections. Corticosteroids can cause or worsen hyperglycemia.

Colchicine, an agent once used to treat acute gout attacks, now has essentially no role in the management of this condition. Daily colchicine (0.6 mg/day or bid) is effective in the prevention of gout flares, but, in the doses required to treat acute flares of gout, it has too low a therapeutic index to be useful. Improper use of colchicine, particularly through the IV route, may lead to substantial patient morbidity (e.g., bone marrow failure). Thus, this drug is best avoided when managing acute gout attacks.

Indications for Early Consultation

Early consultation with a rheumatologist should be considered for patients who cannot be treated with NSAIDs. Orthopedic or rheumatology consultation can also be useful when a difficult joint aspiration is required.

Issues During the Course of Hospitalization

Most patients with acute gout require bed rest for the first 24 hours. Many need opiates for pain relief. Ice packs should be avoided because cold reduces the solubility of urate crystals. Consultation with a physical therapist may be indicated for elderly patients with polyarticular gout.

Discharge Issues

The effective long-term management of gout depends on follow-up with a physician who will continue to educate the patient about the disorder, prescribe an appropriate treatment regimen, and encourage compliance with treatment. Substantial long-term morbidity can result from poorly managed gout, but this can be avoided through proper care by the physician and patient compliance. More than one-third of patients with gout have hypertension or some other manifestation of cardiovascular disease, which emphasizes the importance of general medical follow-up.

The decision to begin hypouricemic agents should be made after discharge. Traditionally, the decision is based on the patient's rate of uric acid excretion during a 24-hour period. Daily urinary excretion of more than 800 mg identifies "overproducers" of uric acid. Such patients are best treated with allopurinol, which blocks the production of uric acid by inhibiting the enzyme xanthine oxidase. Xanthine oxidase also participates in the metabolism of azathioprine, an immunosuppressive drug frequently used in organ transplantation. Because organ transplant patients often suffer gout attacks (because of treatment with medications such as cyclosporine and tacrolimus, which alter urate metabolism in the kidney), clinicians may be tempted to use allopurinol in a patient already on azathioprine. This combination should be avoided, because it can

cause serious bone marrow toxicity. If gouty arthropathy, tophi, or frequent flares of acute gout become problems in a patient who has undergone organ transplantation, replacement of azathioprine with mycophenolate mofetil may be considered (3). Another point to remember is that allopurinol is excreted by the kidneys, and should be dosed according to kidney function.

Patients who excrete less than 800 mg of uric in a 24-hour urine specimen are categorized as “underexcretors” and are usually treated first with a uricosuric agent, either sulfinpyrazone or probenecid. However, uricosuric agents are ineffective in patients with creatinine clearances below 40 mL/min; patients with this level of renal insufficiency require allopurinol. Allopurinol is also indicated in patients with tophi or a history of uric acid kidney stones. Until the serum uric acid level normalizes, 0.6 mg of colchicine once daily helps reduce the likelihood of a flare of gout.

SEPTIC ARTHRITIS

In this section, we discuss the approach to the patient who may have an infected joint. We focus on the two most common types of infectious arthritis: bacterial (nongonoccal) arthritis and gonococcal arthritis. Bacterial arthritis is normally caused by an infected joint while gonococcal arthritis occurs as a result of disseminated gonococcal infection.

Issues at the Time of Admission

A cardinal rule in the evaluation of new-onset arthritis—particularly monarthritis—is that an inflamed joint is infected until proved otherwise. Arthrocentesis and thorough examination of the synovial fluid (see above) are an essential early part of the workup. During the initial assessment, however, it is helpful to consider particular patient profiles (Table 113.5), which can narrow the differential diagnosis and assist in choosing an initial empiric antibiotic regimen.

Bacterial (Nongonoccal) Arthritis

A hot joint may be the first clear sign of a potentially life-threatening disorder. Detection of an infected joint often leads to the recognition of bacteremia or the diagnosis of endocarditis. Most joint infection occurs via hematogenous seeding (4). Joints are susceptible to blood-borne bacterial pathogens because synovial tissue is well vascularized and has no basement membrane. Less common routes of joint infection include direct inoculation by trauma (e.g., penetrating injuries, human or animal bites) and arthrocentesis performed through cellulitic skin.

The most common organism associated with bacterial arthritis is *Staphylococcus aureus*, which accounts for approximately half of all such infections in adults (4). However, in many young, sexually active populations, *N. gonorrhoeae* is the most common cause of septic arthritis.

TABLE 113.5

PROFILES OF SEPTIC ARTHRITIS: CHARACTERISTICS OF ORGANISMS AND HOSTS

Organism	Distinguishing features of host
<i>Neisseria gonorrhoeae</i>	Young, sexually active adult (typically female). Arthritis associated with tenosynovitis and skin lesions.
<i>Staphylococcus aureus</i>	Injection drug user (the usual host for sacroiliac or sternoclavicular joint infections). Rheumatoid arthritis patient. The most common cause of septic bursitis.
<i>S. epidermidis</i>	Most common cause of prosthetic joint infections. Associated with an indolent presentation, constant pain (not occurring only with weight bearing), and radiographic signs of prosthetic loosening.
<i>Haemophilus influenzae</i>	Rarely occurs in adults. Formerly the most common cause (type b) bacterial arthritis in children less than 2 years old. Now less common because of the <i>H. influenzae</i> vaccine.
Gram-negative rods	Elderly, chronically ill patients at risk for Gram-negative bacteremia. Injection drug users.
Mycobacterial species	Patient with a chronic monoarticular arthritis, often associated with tenosynovitis.
Streptococcal species	No classic patient profile, but streptococcal species maintain a constant frequency as a cause of bacterial arthritis throughout the life span.
<i>Borrelia burgdorferi</i>	Residence in or travel to a tick-infested area. Classically preceded by a skin rash (erythema chronicum migrans) by weeks/months. Monarthritis, typically of the knee, develops after skin, central nervous system, and cardiac findings of Lyme disease.

In most cases of septic arthritis, the affected joint is exquisitely painful and demonstrates the classic signs of inflammation. On physical examination, arthritis of an infectious etiology is indistinguishable from that associated with a microcrystalline disorder. The majority of patients with infected joints have fevers during their course, but up to one-third are not febrile at the time of evaluation. The use of antipyretic agents can modify the presentation.

Ninety percent of patients with septic arthritis have a monoarthritis. Susceptibility to oligoarticular or polyarticular infections is dictated more by host factors (e.g., underlying rheumatoid arthritis or injection drug use) than by characteristics of the infecting organisms. With a few exceptions, the frequency of multiple joint involvement, the specific joints infected, and the responses to appropriate antibiotic therapy vary little among cases of suppurative arthritis associated with the major causative organisms. The most commonly involved joint is the knee, followed by the hip. The small joints of the hands are rarely involved by bacterial infections (except for those associated with *N. gonorrhoeae* and *Mycobacterium tuberculosis*). Sternoclavicular and sacroiliac joint infections are usually associated with injection drug use. In evaluating debilitated patients, one must carefully examine the hips (testing to elicit pain with internal rotation). Infections in these joints can be occult if patients do not bear weight on their lower extremities. Hip infections, in contrast to those in other joints, often require surgical (open) drainage to ensure completeness of therapy.

With the exception of the Gram stain and culture, the results of most laboratory tests and radiographic studies are nonspecific. The great majority of patients with acutely infected joints demonstrate elevations in the erythrocyte sedimentation rate, and a smaller majority have a peripheral leukocytosis. Many types of radiographic studies can demonstrate joint effusions, which are present nearly universally in joint infections. Scintigraphy, computed tomography, and magnetic resonance imaging are all more sensitive than plain radiography, which may not demonstrate juxtaarticular osteoporosis and bony erosions for weeks. Except for the purpose of guiding diagnostic arthrocentesis and excluding infections in joints that are difficult to examine, these studies are expensive and nonspecific, and they often contribute little to the assessment.

Most mimickers of septic arthritis present with clinical and radiographic features that are indistinguishable from those of infection. Thus, arthrocentesis should be performed as soon as possible in the evaluation. Details of the synovial fluid examination are discussed above. Although the specificity of Gram stain and culture is high, the sensitivity varies according to the organism. For most causes of bacterial arthritis, Gram stain of synovial fluid demonstrates the organism one-third of the time. In contrast, results of joint culture are positive in up to 90% of patients with bacterial (nongonococcal) arthritis. Blood cultures are also essential in the evaluation of patients for

septic arthritis. Injection drug users should be queried about the use of "street antibiotics," which can cause false-negative culture results.

All patients suspected of having a septic joint should be hospitalized for further evaluation and initial treatment with parenteral antibiotics. Because of the difficulty of performing diagnostic arthrocentesis on the hip and the rapidity with which joint destruction occurs with virulent organisms (e.g., *S. aureus*), early consultation with an orthopedist is essential if hip involvement is suspected.

Gonococcal Arthritis

Arthritis caused by *N. gonorrhoeae*, a Gram-negative diplococcus, results from hematogenous dissemination from a primary mucosal site of infection (4). Disseminated gonococcal infection develops in 1%–3% of cases of untreated gonorrhea. The initial infection precedes dissemination by days to weeks. In sexually active patients under 45 years of age, arthritis associated with disseminated gonococcal infection is the most common type of joint infection. The classic patient is a young woman infected either around the time of her menses (endocervical shedding of the organism and access to the bloodstream are both maximal during menstruation) or during the second or third trimester of pregnancy.

Women are also more likely than men to have subclinical gonorrheal infections and remain untreated, which increases the likelihood of dissemination. In addition to these host factors, certain strains of *N. gonorrhoeae*, particularly those of the protein 1-A serotype (5), are prone to dissemination because their pili permit attachment and diapedesis. Compared with strains of *N. gonorrhoeae* that remain localized in the mucous membranes, those associated with disseminated gonococcal infection have a greater sensitivity to antibiotics but are more difficult to culture. Thus, in contrast to attempts to isolate organisms in most other forms of bacterial arthritis, attempts to isolate *N. gonorrhoeae* from the synovial fluid or bloodstream are often unsuccessful; synovial and blood cultures are positive for the organism in fewer than 50% of cases of disseminated gonococcal infection (4). To optimize the yield of cultures, specimens from every possible site of infection, including the urethra, cervix, oropharynx, rectum, and blood, in addition to any involved joints, should be cultured before antibiotics are begun. The absence of symptoms at these sites should not preclude culturing specimens from them; only a minority of patients with disseminated gonococcal infection have symptoms at the mucosal site of entry.

Most cases of disseminated gonococcal infection are heralded by the acute onset of polyarthralgias, often in a migratory or additive pattern. Two overlapping presentations, the bacteremic and suppurative forms, have been identified. In the bacteremic form, patients appear more systemically ill, with fevers, chills, and malaise. Blood cultures are more likely to be positive than synovial fluid

cultures, yet the positivity rate for blood cultures remains below 50%. Tenosynovitis affecting the wrists, fingers, ankles, or toes can be a prominent feature in the bacteremic form of disseminated gonococcal infection and sometimes overshadows the arthritis. The presence of tenosynovitis distinguishes the arthritis caused by *N. gonorrhoeae* from joint infections caused by most other organisms (*M. tuberculosis* is a notable exception).

Skin lesions are also highly characteristic of disseminated gonococcal infection. The skin lesions begin as macules or papules and rapidly evolve into isolated pustules, typically resting on an erythematous base. After several days, the lesions may assume a vesicular appearance and sometimes have hemorrhagic features. The cutaneous lesions of meningococcal sepsis have an identical appearance but are usually more numerous. The presence of more than 100 discrete lesions suggests a meningococcal infection. Culture of skin lesions occasionally yields the correct diagnosis.

In the suppurative form of disseminated gonococcal infection, arthritis (most commonly of the knee) is a more prominent part of the presentation. The associated joint effusions are more purulent, with white blood cell counts rivaling those of bacterial (nongonococcal) arthritis. Joint cultures are more likely to be positive in the suppurative form but are still negative in a slight majority of cases.

For nearly all patients suspected of having disseminated gonococcal infection, hospitalization is recommended. In the hospital, the extent of the infection and sensitivities of the organism can be determined, and the patient can be monitored for a response to therapy. Once the patient demonstrates a clinical response (see "Discharge Issues"), therapy can be completed on an outpatient basis.

Issues During the Course of Hospitalization

Antibiotic therapy for septic arthritis is usually begun empirically, based on the clinical profile and guided by the results of synovial fluid Gram stain. The initial antimicrobial approach is outlined in Table 113.6. The regimen can be modified when culture results become available. Because parenteral antibiotics achieve excellent levels in inflamed joints, *intraarticular instillation of antibiotics is unnecessary*.

Although early antibiotic therapy is essential to good outcomes, adequate drainage of infected joints is also critical. In purulent joint effusions, organisms divide very slowly and are less susceptible to antibiotics. Unless an infected joint is adequately drained, the organisms may survive despite appropriate treatment. Closed drainage, performed as often as necessary to control the effusion, is sufficient for most joints. Repeated arthrocentesis is usually not required with *N. gonorrhoeae* infections, but joints infected with other organisms, especially *S. aureus* or strep-

TABLE 113.6

EMPIRIC ANTIBIOTIC REGIMENS FOR THE TREATMENT OF SEPTIC ARTHRITIS BASED ON GRAM STAIN OF SYNOVIAL FLUID^{a,b}

Gram-positive	Gram-negative
Gram-positive cocci in clusters (presumptive <i>Staphylococcus</i>): Nafcillin or oxacillin (aminoglycoside should be added if patient is an injection drug user)	Gram-negative bacilli: Nafcillin or oxacillin plus aminoglycoside
Gram-positive cocci in chains (presumptive <i>Streptococcus</i>): Nafcillin or oxacillin	Gram-negative diplococci (presumptive gonococcus): Ceftriaxone or ceftizoxime or cefotaxime

^a All patients with prosthetic joints, intravenous lines, or recent hospitalizations are at risk for infection with methicillin-resistant *Staphylococcus* species and should receive vancomycin until culture results are available, regardless of Gram stain results.

^b In the absence of definitive Gram stain results, a reasonable empiric regimen for the adult with possible septic arthritis would be the combination of nafcillin or oxacillin with a cephalosporin such as ceftriaxone or ceftizoxime or cefotaxime. An aminoglycoside should be added in the injection drug user, and (as above) vancomycin should be substituted for nafcillin/oxacillin if methicillin-resistant *Staphylococcus* is a possibility.

tococcal species, may require daily or twice daily drainage. The response to therapy is judged by the clinical examination findings, the rapidity with which joint effusions reaccumulate after arthrocentesis, and serial measures of cell counts and cultures of synovial fluid. Failure of the patient to respond to therapy, manifested by the disappearance of fever and a decrease in signs of joint inflammation after several days of appropriate treatment, is an indication for open joint drainage and lavage. In contrast to other joint infections, septic hips required immediate surgical intervention.

The majority of prosthetic joint infections originate locally, at the time of joint replacement surgery. *Staphylococcus epidermidis* rivals *S. aureus* as the most common cause of these infections. Management decisions regarding septic prosthetic joints should be made in consultation with an infectious disease specialist. If detected rapidly, early-onset prosthetic joint infections may be treated successfully by antibiotics, alone or in combination with debridement, without removal of the prosthesis. Immediate consultation with orthopedics is essential in the management of such patients. In most cases, unfortunately, the process is sufficiently advanced that the hardware must be removed. If infection in a joint abates but the patient's overall condition continues to deteriorate, another site of infection must be actively sought (e.g., another infected

joint, a splenic abscess, endocarditis, or meningitis). Patients with rheumatoid arthritis or other causes of severe debility, particularly those on corticosteroid therapy, are prime candidates for such occult infections.

Acutely infected joints require rest. As soon as the joint demonstrates clinical improvement, however, a daily program of physical therapy, designed to maintain range of motion and prevent joint contractures, should begin. Patients may begin bearing weight as soon as their pain permits, generally after several days of treatment.

Two other points are relevant to patients with disseminated gonococcal infection. First, patients with *N. gonorrhoeae* arthritis should be evaluated for the possible presence of other sexually transmitted diseases, including *Chlamydia* infection, syphilis, and HIV infection. Empiric concomitant treatment for *Chlamydia* infection with 100 mg of doxycycline twice daily for one week is often prudent. Second, the local public health department and the patient's sexual partner or partners should be notified of the infection.

Discharge Issues

Septic arthritis caused by staphylococci (*S. aureus* or *S. epidermidis*) or gram-negative rods should be treated with parenteral antibiotics for three weeks (longer courses are sometimes required, particularly if endocarditis is also present). After they are stabilized in the hospital, patients can be discharged home or to subacute facilities for the remainder of their course. Streptococcal and *Haemophilus influenzae* arthritis usually require only two weeks of parenteral treatment. *N. gonorrhoeae* arthritis should be treated parenterally for 2–4 days until clinical improvement is noted, following which several oral antibiotic regimens (for a total 2-week course) are appropriate: ciprofloxacin 500 mg twice a day, ofloxacin 400 mg twice a day, or cefixime 400 mg twice a day (6). The standard procedure for treating chronic infections in prosthetic joints is to remove the prosthesis, treat with IV antibiotics for 1 month and oral antibiotics for an additional 2–4 months (patients with *S. aureus* infections may require rifampin in addition to other anti-*Staphylococcal* antibiotics), and then implant a new prosthesis. At some centers, however, a one-stage procedure is employed, with removal of the prosthesis and implantation of another at the same time; antibiotic-impregnated cement is used and a long course of systemic antibiotics is administered.

COST CONSIDERATIONS AND RESOURCE USE

The most important strategy to reduce the cost of treating gout is to avoid recurrent attacks through patient

education and careful follow-up. The episodic nature of gout unfortunately often leads to episodic (and expensive) care.

The costs of antibiotic regimens for the treatment of septic arthritis vary widely and should be considered in choosing among regimens of comparable efficacy. The most important cost-saving maneuver, however, is to discharge stable patients to receive most of their parenteral antibiotic therapy either at home or in a subacute facility.

KEY POINTS

- Gout is the most common cause of acute arthritis in hospitalized patients, but septic arthritis must always be excluded.
- The treatment of acute gout focuses on therapy for acute arthritis; the treatment of hyperuricemia is deferred.
- Patient education and careful follow-up are vital in patients with acute gouty arthritis.
- Joint infection may be the first sign of a life-threatening condition.
- Arthrocentesis must be performed early in the evaluation of patients with possible septic joints.
- Empiric antibiotic treatment should be based on the results of Gram stain and the patient's clinical profile (Tables 113.5 and 113.6).
- Effusions associated with septic joints should be drained as often as they reaccumulate, to permit maximal antibiotic effectiveness.

INTRODUCTION

Back pain is one of the leading complaints treated in the outpatient setting. Most patients can be managed conservatively without recourse to hospitalization for inpatient care. Hospital admission rates for nonsurgical treatment of back pain, while declining, show a wide geographic variation. A variety of health resource and population characteristics, as well as physician practice patterns, contribute to this variation. It is unlikely that rates of hospital utilization for nonsurgical treatment of back pain correlate with aggregate outcomes of care, although studies have not directly addressed that question.

The majority of back problems prompting medical hospitalization involve the low back. In this chapter, we focus on those disorders that present in adults with low back pain as a cardinal symptom. Although we emphasize disorders of the lumbar and lumbosacral spine, much of our discussion is relevant to cervical disease, and certain aspects of the discussion, such as the management of osteoporotic fractures, are also applicable to the thoracic spine. There are parallels between the common lumbar and cervical spinal disorders. Both regions are affected by spinal stenosis and degenerative disease of the disks and facet joints. Such pathoanatomy, however, is commonly present in the absence of local pain, radiculopathy, or myelopathy, so clinical correlation is always important.

The causes of low back pain generally fall into three categories: *regional disorders*, *systemic disorders*, and *visceral disease*. (Some authorities refer to regional disorders as *mechanical conditions*, and to systemic disorders as *non-mechanical conditions*.) *Regional disorders*, which are by far the most prevalent, include such common pathoanatomic disorders as herniated disk, vertebral compression fracture, degenerative disease, and spinal stenosis. In many cases, no specific underlying etiology can be identified. Nearly all instances of regional back pain can be managed conservatively without hospitalization. *Systemic diseases* that can involve the spine include tumors, infections, and inflammatory

spondyloarthropathy. Rest pain and night pain are seen more commonly in systemic than in regional disorders, whereas exacerbation of pain during trunk motion is seen more often with regional pain. *Visceral disease* includes any of the non-musculoskeletal processes affecting the intra-abdominal or other nearby organs that can present with back pain. Examples include aortic dissection and pancreatic or renal diseases. Patients requiring hospitalization for nonsurgical care of back pain are a highly selected group with systemic disease, visceral disorders, or exceptionally severe symptoms of regional disorders.

The systemic causes of low back pain are uncommon. The combined prevalence of neoplastic, infectious, and inflammatory causes is around 1% among primary care patients with low back pain (1). About 2% of patients will have visceral disease (1). The *cauda equina syndrome*, in which compression of the cauda equina by a large herniated disk or other mass results in bowel or bladder dysfunction and neurologic deficits in the lower extremities, has an estimated prevalence of 4 in 10,000 patients with low back pain (2).

The appropriateness of many nonsurgical hospitalizations for low back pain is open to question. Cherkin and Deyo (3) examined hospital admissions for medical problems of the low back during 1988 both nationally and in Washington State, and they concluded that many of those hospitalizations involved diagnostic procedures (e.g., myelography) or therapies (some of questionable efficacy) that could be performed or administered in the outpatient setting. Nonspecific back pain, herniated disk, and degenerative changes accounted for 81% of nonsurgical admissions for low back pain nationwide; systemic problems such as malignancy, infection, and inflammatory conditions were excluded from their analysis. Nearly half of the admissions were for pain management; bed rest was the most common physical treatment modality (72% of patients), and opiate analgesics and sedatives were the most commonly used drugs (83% and 71% of patients, respectively). Cherkin and Deyo acknowledged that, in

addition to disease-specific indications, various other indications (e.g., difficulty ambulating, inability to prepare food or perform toileting, or the facilitation of diagnostic studies when patients are evaluated at a distance from home) can sometimes justify nonsurgical hospitalizations.

In this chapter, we discuss the diagnosis and management of selected conditions that may require inpatient management on a medical service. We assume that the patient cannot be cared for optimally as an outpatient. We also assume an evidence-based approach to diagnosis and therapy in the outpatient department, such as that proposed by the Agency for Health Care Policy and Research (AHCPR, now the Agency for Healthcare Research and Quality, AHRQ) in its 1994 clinical practice guideline for the management of acute low back problems in adults (4). A number of evidence-based guidelines have built upon the solid foundation provided by the AHCPR guideline (5). Other sources of information include recent reviews of the diagnosis and management of low back pain (1, 2, 6), as well as reviews of specific treatments in the Cochrane Database of Systematic Reviews (7).

ISSUES AT THE TIME OF ADMISSION

Clinical Presentation

Regional low back disorders commonly present with back pain alone; a subset of patients will have signs or symptoms of spinal nerve root involvement (Chapter 115). Compression or inflammation of a nerve root produces radiculopathy characterized by pain, numbness, weakness, and loss of reflexes in the distribution of the corresponding nerve. Most radiculopathy involves the L-5 or S-1 nerve root, and less frequently the L-4 root; neurologic screening should focus on these levels (4). Associated deficits may include weakness of the quadriceps (L-4), a decreased knee jerk reflex (L-4), weakness of dorsiflexion of the great toe and foot (L-5), weakness of plantar flexion of the great toe and foot (S-1), or a decreased ankle jerk reflex (S-1). Sensory deficits follow dermatomes on the medial (L-4), dorsal (L-5), or lateral (S-1) aspect of the foot.

Sciatica is the term reserved for radicular pain that radiates in a sciatic distribution down the leg beyond the knee. *Neurogenic claudication* (pseudo-claudication) is buttock and leg pain or weakness caused by standing erect or walking erect and relieved by sitting or flexing the spine. This is the classic symptom of the syndrome of "lumbar stenosis," commonly ascribed to anatomic lumbar spinal stenosis, although the pathogenesis of pain in this syndrome is debatable; anatomic stenosis is a nonspecific finding on imaging studies in the elderly and does not reliably predict symptoms. Bowel or bladder dysfunction suggests compression of the sacral nerve roots, as does sensory deficit of the perineal region ("*saddle anesthesia*"). All these features can be present in regional or systemic disease of the lumbar

spine, some even in visceral presentations. The patient who is writhing or cannot be still, however, should be assumed to have a serious underlying cause, usually a visceral disorder, until proved otherwise.

Findings from the history or physical examination may point toward a particular condition as the cause of back pain (6). A previous history of cancer is the strongest predictor of malignancy (specificity 0.98, positive likelihood ratio 14.7), but sensitivity is low (0.31). Two findings have a low sensitivity but a high specificity for vertebral compression fracture: a history of corticosteroid use (specificity 0.995, positive likelihood ratio 12.0) and age over 70 years (specificity 0.96, positive likelihood ratio 5.5). The presence of sciatica is the best predictor of herniated disk (sensitivity 0.95, specificity 0.88, positive likelihood ratio 7.9, negative likelihood ratio 0.06) (Chapter 6).

Differential Diagnosis and Initial Evaluation

Visceral Disease and Serious Spinal Disorders

The initial assessment of the patient with acute low back pain should identify those patients with a serious underlying cause requiring specific therapy. The history and examination can provide evidence of systemic or visceral disease, or of neurologic compromise that mandates surgical referral (1, 2, 6). Figure 114.1 provides a general approach to the identification of the patient with low back pain who may require hospitalization.

Back pain can be a referred symptom of a variety of nonspinal diseases, including aortic dissection or aneurysm, endocarditis, kidney stone, pancreatitis, pancreatic pseudocyst, peptic ulcer disease, urinary tract infection/pyelonephritis, perinephric abscess, prostatitis, pelvic infection, and others. As indicated in Figure 114.1, the initial workup should identify those patients with referred back pain resulting from nonspinal disease.

The search for serious spinal disorders is facilitated by a systematic evidence-based approach such as that recommended by the AHCPR practice guideline (4). This approach starts with a focused history and physical examination, with attention to certain "red flags" for possible serious conditions, including fracture, tumor, infection, and cauda equina syndrome. "Red flags" for fracture include major trauma (e.g., a fall or vehicular accident); in older or osteoporotic patients, minor trauma or strenuous lifting is of concern. Red flags for tumor or infection include age over 50 or under 20, history of cancer, fever, weight loss, pain worse in a supine position or at night, recent bacterial infection, intravenous drug abuse, and immunosuppression. Cauda equina syndrome warrants emergent diagnostic imaging and surgical consultation or referral. Red flags from the history for cauda equina syndrome include saddle anesthesia, bladder dysfunction (urinary retention, frequency, incontinence), and severe or progressive lower extremity neurologic deficit. Red flags from the physical

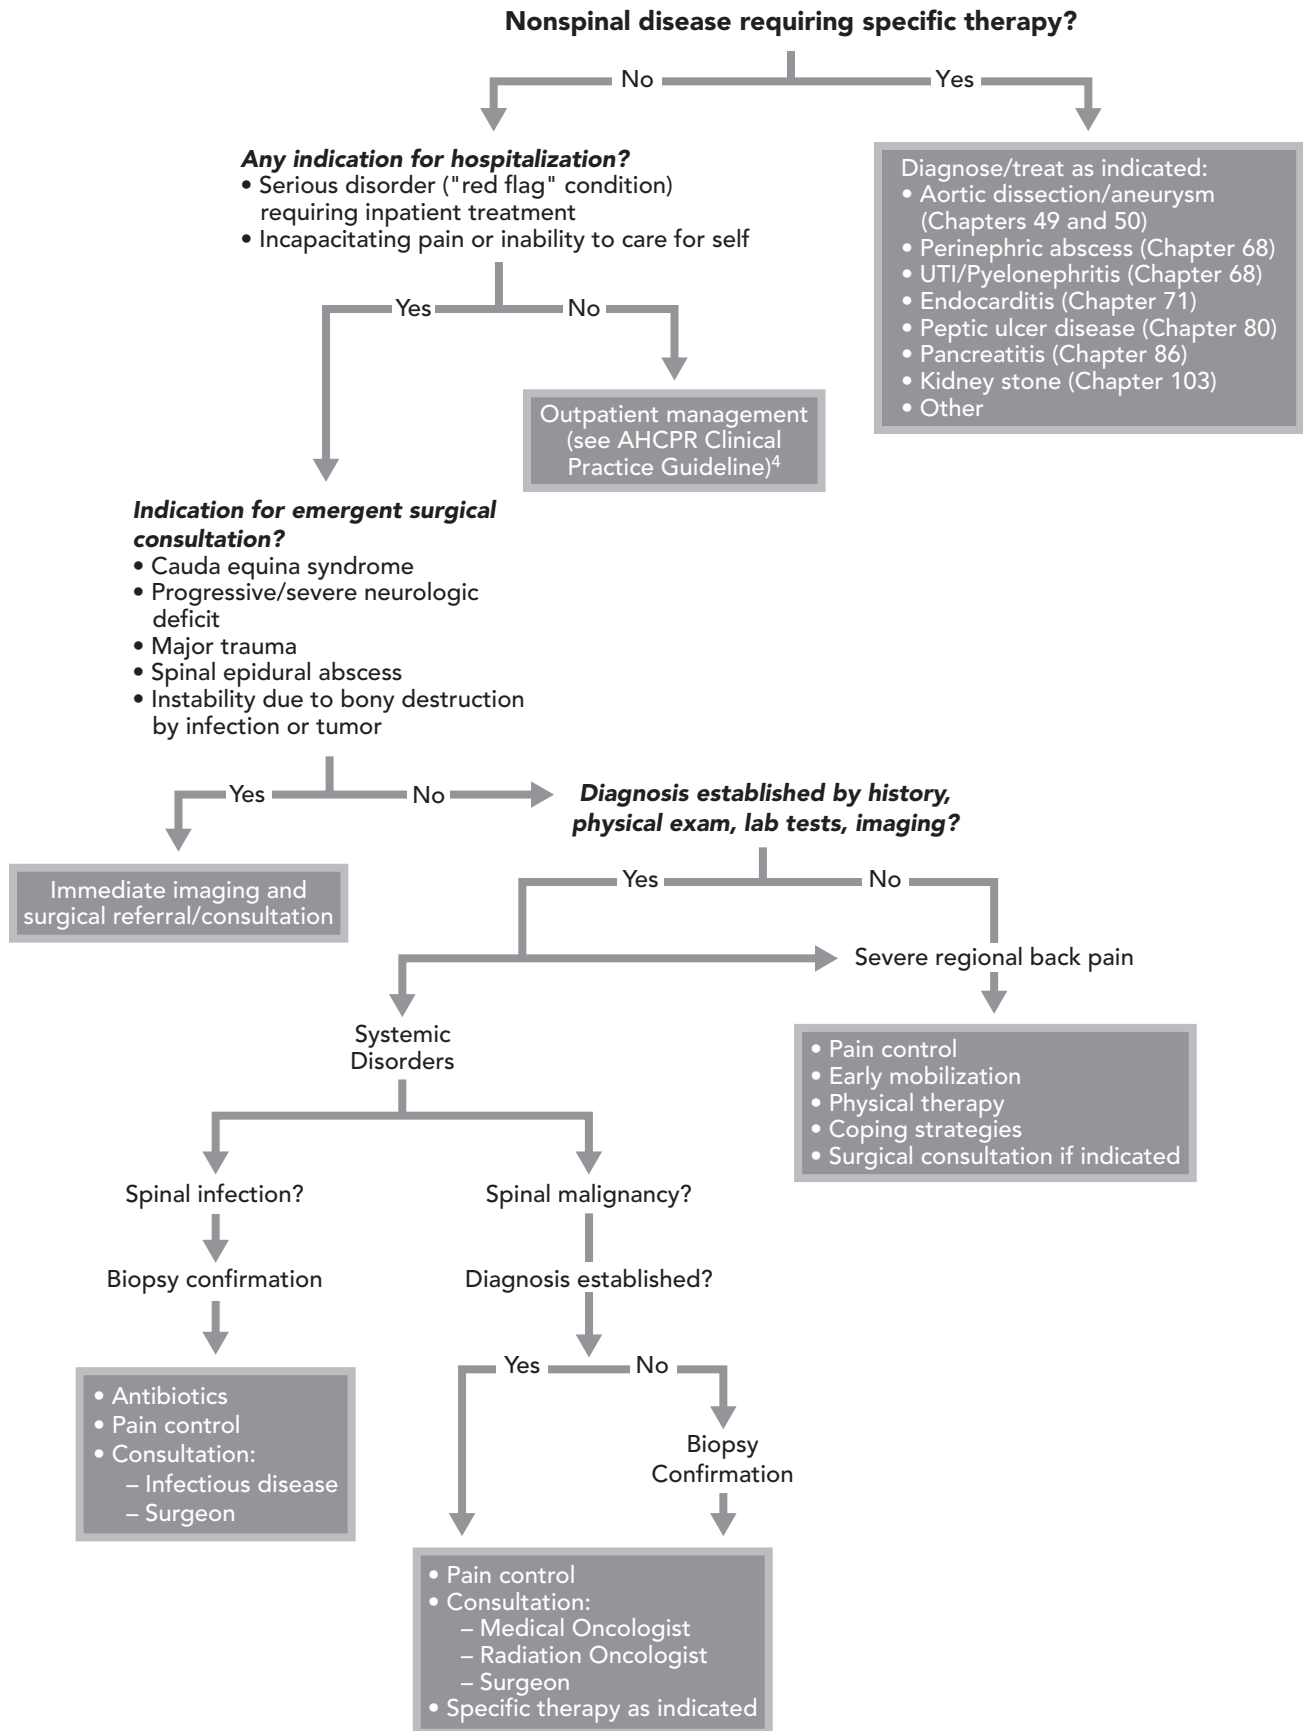

Figure 114.1 Assessment of low back pain.

examination include anal sphincter laxity, perianal or perineal sensory loss, and major weakness involving the quadriceps or the ankle plantar flexors, ankle evertors, or ankle dorsal flexors.

Although the cauda equina syndrome is the classic indication for emergent surgical evaluation, other disorders also require immediate surgical consultation or referral, including spinal epidural abscess, progressive or severe neurologic deficit, major trauma, and instability resulting from a destructive neoplastic or infectious process. As indicated in the lower portion of Figure 114.1, most patients with back pain who require hospitalization but lack an indication for urgent surgical consultation fall into the following categories of illness: severe and incapacitating regional back pain attributable to herniated disk, degenerative disease, spinal stenosis, osteoporotic compression fracture, or nonspecific causes; spinal malignancy; and spinal infections, including vertebral osteomyelitis and septic diskitis.

Most patients who are hospitalized with back pain will already have undergone diagnostic testing and imaging. Initial laboratory testing indicated for most patients hospitalized with severe back pain includes a complete blood cell count with white cell differential; measurement of serum creatinine, calcium, alkaline phosphatase, and erythrocyte sedimentation rate; and urinalysis. If infection is suggested because of fever, leukocytosis, or a markedly elevated sedimentation rate, then blood cultures are appropriate. If myeloma is clinically suspected, serum and urine protein electrophoresis should be performed.

Plain radiographs may detect destructive bone lesions and compression fractures. If rheumatic spondyloarthritis is suspected, radiographs of the sacroiliac joints are appropriate. Although radiography has a limited role in the management of outpatients with back pain, such pain of sufficient severity to prompt hospitalization justifies diagnostic imaging because the prior probability (Chapter 6) of specific lesions is so high. Plain radiographs not only may provide a working diagnosis, but also can focus the choice of additional imaging studies.

The commonly available options for radiologic imaging of the spine beyond plain radiography include computed tomography (CT), magnetic resonance imaging (MRI), radionuclide scintigraphy (bone scan), and myelography. Bone scan, although very sensitive for infectious or malignant causes of back pain, lacks specificity. It can, however, target subsequent studies that afford more specific pathoanatomic insights. Myelography is invasive and is used far less often than in the past. We would reserve its use for situations in which it is requested by a consulting surgeon. Both CT and MRI demonstrate the anatomy. MRI is probably the best overall choice for defining malignancy, infection, inflammation, and structural abnormalities of the spine and associated soft tissues. The cost of MRI varies but is typically in the range of \$1,000 (without contrast), considerably higher than that of CT or bone scan. Although

gadolinium enhancement is not necessary to detect many conditions, the added definition justifies its use in some situations.

If spinal infection or malignancy is demonstrated, further evaluation is mandatory to design specific therapy. Antibiotic therapy of *spinal infections* (vertebral osteomyelitis/septic diskitis and spinal epidural abscess) should, whenever possible, be based on identification of the causative organism. *Staphylococcus aureus* is the most common, but far from the only, cause. Other pyogenic bacteria, mycobacteria, and fungal organisms can also infect the spine. Blood cultures are mandatory when spinal infection is suspected. For processes involving the vertebral bodies or intervertebral disks, percutaneous needle aspiration and biopsy permits a specific microbiologic diagnosis. This can often be accomplished under radiologic guidance (fluoroscopy or CT) with low complication rates in the hands of experienced practitioners. Open biopsy is an alternative. Empiric antibiotic therapy pending results of these studies may be prudent, but premature institution of antibiotics without attempts to isolate the organism can result in inappropriate or unnecessary treatment. Antibiotic therapy for spinal infections is usually prolonged (e.g., 6–8 weeks); an infectious disease consultation can help guide the choice of antibiotics and the duration of therapy. Surgical debridement may be required in tuberculous (Pott's) disease, and surgical drainage is usually required for effective treatment of epidural abscess. Otherwise, surgical consultation is appropriate whenever stability is in question or when a significant neurologic deficit is present.

Metastatic disease is the most common malignant process involving the spine. Back pain can be the presenting symptom of common cancers, such as those of the breast, prostate, and lung and multiple myeloma. The prognosis varies depending on the underlying malignancy. If compression of the spinal cord or cauda equina is found at presentation, then emergent treatment is indicated in the hope of preventing paralysis or incontinence. Options include steroids, surgical decompression, radiation treatment, and in some situations hormonal therapy or chemotherapy; surgical stabilization also may be required. Consultation with a surgeon, radiation oncologist, and medical oncologist can optimize the choice of therapy in a particular situation. See Chapter 92 for a detailed discussion of the management of malignant spinal cord compression. As in spinal infection, tissue can be obtained for definitive diagnosis by either percutaneous or open biopsy. Functional outcome in patients with spinal metastasis is directly related to the degree of deficit at the time treatment is started. In cases in which pain is not controlled by oral analgesia, parenteral therapy with opiate analgesics is indicated.

For those patients with serious conditions, such as infection or malignancy, the management and expected course will depend on the particular situation. Decisions regarding immobilization with bed rest or orthopedic

braces are best made in consultation with surgical, oncologic, and other consultants. Discharge will depend on the specific therapy and response to treatment. In some cases, intravenous therapies, such as prolonged administration of antibiotics, can be completed in the outpatient setting with close follow-up and home health care.

Severe Regional Low Back Pain

Modern imaging should detect nearly all instances of infectious or neoplastic causes of back pain. For regional pain, there is a problem: abnormal findings on imaging studies are not specific. Herniated disk, degenerative spinal disease, compression fractures, and spinal stenosis are common in completely asymptomatic subjects. Therefore, a pathologic finding must be interpreted in light of the patient's symptoms and findings on physical examination (Chapter 6).

Osteoporotic vertebral compression fractures are common in older women. Population studies have shown that more than 20% of people (of both genders) over 50 years of age have radiographic Grade 1 vertebral deformities (8). These involve both the thoracic and lumbar spine, and the prevalence increases with advancing age. Most compression fractures are either asymptomatic or not memorable. In contrast, such fractures can, from time to time, cause severe pain that occasionally requires inpatient care. Symptoms may precede the development of a visible fracture on plain radiography and therefore be misdiagnosed. The impact of symptomatic compression fractures on the patient's functional status should not be underestimated. The associated pain can persist from a few weeks to a few months and be severe and incapacitating in these patients, who are elderly and often frail.

If the history, examination, and radiographic findings are consistent with an osteoporotic compression fracture and there is no neurologic compromise or suspicion of an infectious or malignant process, then further imaging may not be necessary. Caution, however, is advised in attributing such fractures to a benign process without further verification. If traumatic fracture is suspected and radiography is not definitive, then bone scan would be appropriate; CT and MRI provide additional definition in the case of a vertebral fracture that may be pathologic (i.e., resulting from metastatic neoplastic or infectious disease).

Indications for Initial Intensive Care Unit Admission

The primary indication for initial ICU admission is the presence of neurologic compromise requiring urgent intervention and close monitoring of neurologic status. Immediate surgical consultation is indicated in such cases. Other reasons for ICU admission include sepsis, hypotension, and severe comorbidity.

Initial Therapy

The remainder of this discussion focuses on the management of severe regional low back pain. Initial therapy of low back pain consists of analgesia and specific therapy when possible. Pain relief, however, is a goal with general principles that apply across the range of diagnoses (Chapter 18). Acetaminophen and the nonsteroidal anti-inflammatory drugs (NSAIDs) are the first-line analgesics used in the treatment of back pain. Well-known side effects of NSAIDs include gastrointestinal irritation and bleeding, in addition to adverse renal effects, to which the elderly are particularly prone. Opiates may be required for adequate pain control but should be used judiciously; time-limited fixed courses may avoid excessive narcotization. Constipation is likely when opiates are used and can be relieved by bowel regimens that include stool softeners and laxatives.

Effective therapies for mechanical low back pain include analgesia, limited bed rest or continuation of usual activity, mobilization, and surgery in certain well-defined situations. Evidence does not support the use of spinal traction, facet joint injection, prolonged bed rest, or transcutaneous electrical nerve stimulation (TENS). Epidural steroid injections to treat radicular pain are sometimes used in the hope of avoiding surgery. These injections, however, are not without risk, and evidence supporting their efficacy beyond temporary relief of pain is limited. "Muscle relaxants" are sedating and add little to the analgesic efficacy of NSAIDs.

Beyond analgesia, the treatment of vertebral compression fractures consists of limited bed rest and early mobilization, with a goal toward preventing debility and further bone loss. Orthopedic bracing for patient comfort is commonly used, but may not be tolerated. Assistance with the activities of daily living may be the goal of hospitalization until adequate care is available elsewhere. Opiates may be required for adequate pain control but must be used cautiously because they are often counterproductive, leading to falls and further debility. Calcitonin, in addition to its effect on bone mass, appears to have a direct analgesic effect and may therefore be of dual benefit. An intranasal form is now available.

Indications for Early Consultation

The indications for emergent consultation were discussed above. In the absence of an indication for emergent or immediate consultation, elective surgical referral for herniated disk is appropriate if the patient has persistent neuro-motor deficit, or persistent sciatica with consistent clinical and neurological findings, after 4–6 weeks of nonoperative therapy (1). The only randomized clinical trial of surgical diskectomy versus conservative treatment of patients with herniated lumbar disks and sciatica was reported by Weber in 1983 (9). In that study, 126 patients with radicular pain persisting after two weeks of conservative therapy were randomized to either surgical diskectomy or six weeks of con-

tinued nonsurgical management with analgesia and physiotherapy. It is notable that the randomization excluded two other groups of patients: those patients felt to have a definite indication for surgery, and those who improved during two weeks of initial conservative management. Among those randomized, surgical patients reported significantly less pain and incapacity at one year of follow-up, with only a trend favoring surgery at 4 and 10 years of follow-up. The Weber trial supports the early benefit of surgery in a highly selected group of patients with persisting sciatica and a corresponding and demonstrable disk herniation. There is no compelling surgical indication for the patient with nonspecific low back pain, or any patient with radiculopathy in whom there is no identifiable correlative lesion.

The indications for surgical referral of the patient with spinal stenosis are even less clearly defined. No randomized clinical trial has compared conservative management with decompressive surgical therapy. In the absence of surgery, symptoms may remain stable, spontaneously progress, or improve with time. Some patients do appear to benefit from surgery, although the duration of benefit is unclear and serious complications are frequent in this elderly population. Surgical consultation seems appropriate for those with recalcitrant, severe neurogenic claudication or with major neurologic compromise. Definitive guidelines for the management of these patients await scientific evidence defining an optimal treatment plan.

ISSUES DURING THE COURSE OF HOSPITALIZATION

For those patients with severe regional back pain, pain control, mobilization, and return to effective coping are the main goals of treatment. After that, the natural history favors a return to health. Function and independence are best preserved by early mobilization, while prolonged bed rest promotes debility and disability. An accumulation of evidence supports continuation of usual activity as tolerated rather than even a short period of bed rest in most cases. Severe pain or the presence of a motor deficit may warrant a limited period of bed rest, but early mobilization should be the goal.

Physical therapists can assist the patient with transfers and ambulation and should be an integral part of the hospital management of the patient with severe regional back pain. Occupational therapy to assist with activities of daily living and encourage independent function may also be helpful. Specific exercises are counterproductive and have no role in the management of acute back pain.

Osteoporotic vertebral fractures have typically been treated with longer periods of bed rest, up to 1–2 weeks in some cases. We would advise otherwise. Although longer periods of bed confinement may be dictated by the patient's condition, early mobilization should still be the

goal. Prolonged bed rest, which is associated with deconditioning and other risks of immobility, may actually accelerate bone resorption. The prior recommendations regarding physical and occupational therapy apply here also. Women with previous vertebral fractures are at higher risk for additional fractures, and this risk is highest (19% overall) in the first year following fracture (10). This risk underscores the importance of appropriate medical treatment of the underlying osteoporosis, with a goal of preventing recurrent fractures.

Percutaneous vertebroplasty and kyphoplasty are increasingly being used to treat painful osteoporotic compression fractures refractory to conservative management. Both procedures involve the injection of polymethylmethacrylate bone cement into the involved vertebral body using radiologic guidance with fluoroscopy or computed tomography. In kyphoplasty, the vertebral body is first expanded using an inflatable device, and then injected. Although high success rates in terms of pain relief have been reported, these procedures have not been studied in randomized clinical trials. Complication rates are reportedly low, but serious complications can occur; these include spinal cord or nerve root injury and embolism of the bone cement to the pulmonary arteries. Watts et al (11), in a review of these procedures, recommended that they be used only in carefully selected patients with severe persistent pain, by experienced operators, and ideally in centers that participate in controlled clinical trials. We would advise caution until randomized clinical trials have clearly demonstrated the efficacy and long-term safety of these procedures.

The importance of the therapeutic relationship between physician and patient in treating back pain should not be underestimated. An attitude of optimism should be maintained by the treating physician and all allied health professionals. There is no reason to feel or communicate desperation when treating any patient with severe regional back pain who has no major neurologic compromise, especially as regional back pain associated with herniated disk, spinal stenosis, compression fracture, or nonspecific causes in many cases will improve with time. The clinician should work with the patient to identify any psychological issues that might be interfering with coping. Regional back pain is a remittent and intermittent predicament of life (12). There is no substitute for a caring attitude on the part of the physician, with reassurance that the patient is not alone in facing pain.

DISCHARGE ISSUES

Discharge planning should consider patients' home and work situations and ability to function independently in those settings. Social work consultation may identify resources available to help patients cope with the functional limitations imposed by their condition. Those patients with

regional back pain for whom surgical referral is not required will be ready for discharge when their symptoms are adequately controlled on oral analgesics and they are able to function safely and adequately in the home environment.

Patients with regional low back pain should be instructed to avoid heavy lifting, prolonged sitting, and bending or twisting the back for a limited period of time. Low-stress aerobic exercise as tolerated may be beneficial (4). Temporary modifications of job-related activity may help facilitate the return to work; however, this is no substitute for addressing issues that relate to job satisfaction.

Patients with osteoporotic fractures should be followed over time for progressive deformity or neurologic compromise. Medical treatment to deter further loss of bone density and prevent subsequent fractures should be considered as an integral part of the management of osteoporotic compression fractures (13).

COST CONSIDERATIONS AND RESOURCE USE

The key to the cost-effective management of back pain is appropriate outpatient treatment that maximizes patient benefit while avoiding unnecessary hospitalizations, ineffective therapies, and unwarranted imaging procedures. Assuming optimal outpatient management with an appropriate decision to hospitalize and image the patient, the cost of inpatient medical treatment of regional back pain will largely be a function of the length of stay. The timely coordination of resources such as physical therapy, occupational therapy, social work, and home assistance will likely reap dividends in terms of earlier mobilization and discharge. Unnecessary drug costs can be reduced when generic NSAIDs are chosen over more expensive but no more efficacious alternatives.

KEY POINTS

- Back pain is a common complaint that usually responds to conservative outpatient treatment. Hospitalization for medical management is indicated in a minority of patients.
- Emergent imaging and surgical consultation are indicated for the cauda equina syndrome. Immediate surgical referral is also warranted for progressive or severe neurologic deficits, instability resulting from bony destruction by infection or neoplasm, spinal epidural abscess, and major trauma.
- Beyond these urgent indications, hospitalization for medical management is indicated when there is a serious

“red flag” condition, when pain is incapacitating and refractory to outpatient management, or when the patient is incapable of self-care and independent function and does not have adequate assistance in the home setting.

- For severe regional back pain, nonsteroidal antiinflammatory medications and early mobilization are the mainstays of therapy.
- Osteoporotic vertebral compression fractures can cause incapacitating pain and debility. Analgesia and mobilization are primary short-term goals; medical therapy to prevent further bone loss and subsequent fractures is critical.
- Serious disorders, such as infection and malignancy, should be treated in consultation with the appropriate specialists.

INTRODUCTION

The key to evaluating patients with neurologic symptoms is to obtain an adequate neurologic history. Many hospitalized patients are unable to give a full history because of an altered mental state or severe medical illness. Historical accounts by firsthand observers (family members, friends) become essential. The neurologic history informs the search for pertinent findings on the neurologic examination.

The neurologic history and examination are critical for localization of disease to the *central nervous system* (CNS), *peripheral nervous system* (PNS), or a *nonneurologic*

source. Analysis of the symptoms and signs determines the neurologic differential diagnosis, which in turn guides further history and examination. The importance of this point cannot be overemphasized, because hospitalized patients are accessible for repeated evaluations. Simply obtaining additional history and repeating the examination often spares patients from ill-directed and expensive investigations.

This chapter describes common neurologic symptoms, signs, and diagnostic tests. Symptoms and signs are organized by the order in which they appear in a typical neurologic examination. A differential diagnosis is presented whenever possible. The readings listed at the end of this chapter cover clinical evaluation and management of specific neurologic diseases.

SYMPTOMS AND SIGNS

Headache

The top clinical priority is to determine if headache reflects serious intracranial pathology that requires acute intervention. The presence of new headache increases the likelihood of a serious cause, while a change only in severity or location of pain (particularly in the setting of chronic headache) is far less worrisome from the standpoint of structural brain disease. A new headache that reaches peak intensity within one or two seconds suggests intracranial

hemorrhage (Table 115.1; also see Chapter 117). Headache precipitated by the supine position that improves with standing suggests elevated intracranial pressure. Headache precipitated by standing and relieved by the supine position suggests low intracranial pressure. Such low-pressure headaches usually are caused by a cerebrospinal fluid (CSF) leak, most commonly following lumbar puncture (LP). An LP headache typically resolves spontaneously over 4–7 days and is treated with bedrest and simple analgesics.

New headache associated with systemic signs, including fever, stiff neck, rash, or arthritis, may reflect sepsis or meningitis. If bacterial meningitis is suspected (e.g., stiff neck) and focal neurologic findings are absent, then LP can be performed without prior brain neuroimaging. Neuroimaging ideally should precede spinal fluid examination when papilledema, other evidence of elevated intracranial pressure (ICP), or focal CNS neurologic findings are present. In patients with cancer or immunosuppression, new headache may be due to brain metastasis, carcinomatous meningitis, brain abscess, or infectious meningitis. Neuroimaging may be followed by LP if midline shift of brain structures or obstructive hydrocephalus resulting in a CSF pressure differential between the brain and the spine are absent. In elderly patients with new headache, structural brain disease and temporal arteritis are important and treatable considerations. New-onset posterior cervical headache should raise the suspicion for upper cervical spine structural disease (metastatic tumor, osteomyelitis, or arterial dissection) which may refer pain to the posterior cranium.

Although headache is a common symptom among inpatients, it is not usually the primary reason for hospitalization. Many systemic disorders result in headache, including hypercapnia, hypoxia, anemia, sepsis, chronic renal failure, hypoglycemia, hypercalcemia, hyponatremia, and thyrotoxicosis. Headache also may be caused by medications (Table 115.2). Outpatients with chronic headaches treated regularly with analgesics may develop withdrawal symptoms or rebound headaches if the analgesics are discontinued during hospitalization. A methodical review of the relationship between recent medication changes and

TABLE 115.1

new headaches is important. Patients with drug-induced or withdrawal headaches should receive short-term symptomatic treatment while more significant medical issues are managed.

The approach to benign causes of headache (migraine, tension headache) requires an accurate diagnosis, followed by either nonpharmacologic or pharmacologic intervention. Acute migraine or tension headaches often respond to simple analgesics (aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs). Serotonergic agents (e.g., sumatriptan), ergots (ergotamine), or a combination of isometheptene, acetaminophen, and dichloralphenazone (Midrin), are helpful for acute-subacute headache if simple analgesics are ineffective and there are no medical contraindications. Optimal management of frequent, chronic headache is best performed in an outpatient setting where management can be tailored to the patient's activities of daily living.

Delirium and Dementia

The hospital physician must be able to distinguish delirium from dementia at the bedside. Delirium refers to an acute confusional state with a fluctuating level of alertness. Dementia is a chronic, progressive cognitive deterioration, typically with impaired recent memory but normal level of alertness. Delirium (encephalopathy) is common among patients with severe systemic illness or primary CNS disorders. The physician should begin to assess mental status (including attention, memory, insight, and abstract reasoning) during his or her initial interactions with the patient, and decide if further formal testing is necessary.

The screening bedside mental status examination tests circumscribed cognitive abilities (Table 115.3). The results must be interpreted in the cultural and educational context of the patient. For example, simple arithmetic may challenge an uneducated patient, while difficulty with complex calculations may suggest cognitive deterioration in an accountant. Initial testing of *orientation and attention* consists of eliciting the patient's name and the month, year, city,

TABLE 115.3
BEDSIDE TESTS OF MENTAL STATUS

Function	Test
Orientation	Month, year, name
Attention/concentration	Spell "world" backwards, digit span forward
General knowledge	Historical figures, current events
Memory	Recall 3 objects at 5 min Number of animals named in 1 minute
Abstract reasoning	Similarities/differences comparing common objects
Calculation	Subtraction of serial sevens

Table 16.3 shows the more detailed Short Portable Mental Status Questionnaire.

and hospital. The daily routines of the hospital frequently cause patients to confuse day of the week and date. On the other hand, nearly all unimpaired patients can recall telephone numbers and can immediately and accurately repeat a sequence of seven digits forward (e.g., digits span) or spell the word *world* backwards. Attention is a crucial determinant of recent memory. If ability to pay attention is impaired, recent memory testing becomes inaccurate. Tests of *recent memory* (e.g., recall of three objects after five minutes) should incorporate commonly used objects to avoid cultural bias. *Calculation performance* depends upon the patient's educational achievement and ability. Qualitative assessment of *mood and general knowledge* occurs during the general medical history. The widely used Short Portable Mental Status Questionnaire (Table 16.3) is useful when screening for dementia. Detailed formal neuropsychological testing is particularly helpful in differentiating dementing conditions, including depression (pseudodementia), from true dementia.

Delirious patients are disoriented and exhibit poor attention. Although drowsiness or agitation may predominate; these features often fluctuate during the examination. Visual hallucinations, restlessness, or lability of mood are common. Examination findings common in delirium are fever, tachycardia, postural tremor, asterixis, or myoclonus. Delirium must be managed promptly to prevent the consequences of poor patient judgement. Reassurance in a supportive and closely supervised environment may be adequate. The use of sedatives or restraints should be preceded by discussion with the patient and family regarding their necessity for the patient's safety (e.g., to prevent falls or inadvertent self injury). The differential diagnosis of delirium is determined by individual circumstances (Table 115.4). Delirium in hospitalized patients is often multifactorial and treatable. Care should be taken to avoid assuming that a single cause is present. Medications commonly cause or contribute to delirium. A review of the patient's medication list (Table 115.5), with special attention to the

risks of polypharmacy, new drugs, changes in drug dose, or recent discontinuation of drugs, is mandatory.

Hospitalization of an elderly patient with limited or unknown cognitive function at baseline is common, and delirium may initially obscure an underlying dementia. *Dementia* frequently complicates the medical history and examination in hospitalized elderly patients (Chapter 16). The most common type of dementia (Alzheimer's disease, or AD) is characterized by slowly progressive behavioral and cognitive deterioration, and often presents with diminished recent memory and relative preservation of alertness. Preserved social function may obscure the cognitive deficit initially. The initial clues may be limited to subtle behavioral or personality changes apparent only to friends and family. Asking family members about observed deterioration in

cognitive activities of daily living (managing finances, remembering appointments) is often useful, since the family may already have intervened to help the patient. The history from family, friends, or coworkers is extremely helpful, because these patients frequently deny that a problem exists. Tests of immediate attention (e.g., digit span) are preserved, but tests of recent memory (e.g., events of the past day) are impaired. A wide range of cognitive problems eventually appears. Insight and motivation diminish, and thought processes become less flexible. Eventually, there may be impairment of language (aphasia), recognition (agnosia), or execution of motor tasks (apraxia).

The investigation of dementia is directed at searching for potentially treatable conditions including vitamin B₁₂ deficiency, hypothyroidism, normal pressure hydrocephalus, AIDS, chronic CNS infection (i.e., tertiary syphilis), or pseudodementia (depression). Differentiating AD from other neurodegenerative diseases has become more important now that FDA-approved therapies for AD have become available. Depression is a frequent and treatable accompaniment of illness and hospitalization, and can be difficult to distinguish from dementia without formal cognitive testing (Chapter 119). Outpatient evaluation after recovery from acute illness may be needed to make this distinction clear.

Pupillary Responses

The pupillary responses are critical neurologic signs to elicit in patients with coma or an acute CNS deficit. Light directed into either eye provides the stimulus for optic nerve afferent input to midbrain nuclei. Efferent parasympathetic nerve fibers travel in the third cranial nerve to produce bilateral pupillary constriction (miosis). Sympathetic pathways in the brainstem and cervical spinal cord eventually exit at the T1 nerve roots, pass rostrally over the ipsilateral carotid arteries, and along the fifth cranial nerves to mediate pupillary dilatation (mydriasis). A history revealing use of medications or other drugs that affect pupil size, previous eye surgery, or recent mydriatic eyedrop use (atropine results in an unreactive, dilated pupil without ptosis) can easily establish an explanation for many pupillary abnormalities. *Bilaterally dilated pupils* are seen with administration of anticholinergics (atropine) or sympathomimetics (recreational stimulants, hallucinogens), in thyrotoxicosis, and in severe anxiety states. *Bilaterally constricted pupils* occur with administration of opiates, alcohol, barbiturates, phenothiazines, and pilocarpine.

The pupils are normally round and equal in size. Both pupils normally constrict in symmetric fashion in response to light directed into one eye. The *direct response* is constriction of the ipsilateral pupil. The *consensual response* is pupillary constriction in the opposite eye. Minor fluctuations in ambient light result in small and rapid physiologic variations of pupillary diameter (hippus). The normal pupils of adults are 3–4 mm in diameter, and are

larger in children and smaller in older adults (“senile miosis”). The latter may not react briskly. Physiologic anisocoria denotes a normal degree of pupillary asymmetry (up to 1 mm). Bedside examination of pupils includes inspection of pupil size, response to light (eyes looking ahead) and accommodation (eyes converging), and assessment of nearby midbrain and pontine neurologic functions (abnormalities of eye movement, corneal responses, facial sensation).

The single most important pupillary abnormality to recognize at hospital admission or during hospitalization is a new dilated (6–9 mm) pupil. This finding should always trigger consideration of early brain herniation resulting from a mass lesion (e.g., focal brain swelling, acute cerebral hemorrhage, brain abscess, brain tumor) compressing the parasympathetic pupillary fibers that mediate pupillary constriction in the third cranial nerve (Chapter 117). Subsequent dilatation of the other pupil implies further brain herniation. Immediate neuroimaging and neurosurgical consultation is necessary in the setting of a new dilated pupil. Of note, some noncompressive causes of third-nerve palsy spare the pupillary response; diabetes is the most common example. Midposition (3–4 mm), unreactive pupils may indicate further herniation involving both the midbrain and pons, and almost always carry a poor prognosis.

Dizziness and Vertigo

Dizziness is a nonspecific symptom of diverse etiology, variously described as unsteadiness, light-headedness, spinning, or blurring of vision. Vertigo is a perception of movement experienced as spinning of the surroundings or self; less commonly dysequilibrium is described as “rocking” in vertical or horizontal planes, as in a boat (Table 115.6). Vertigo is normal if there is an acute mismatch of input from visual, somatosensory, and vestibular systems that normally control balance (seasickness). Vertigo of PNS origin is sometimes associated with hearing loss or tinnitus, but is unassociated with other CNS

TABLE 115.6

findings such as hemiparesis. Vertigo of CNS origin results in milder, less specific vertigo; “spinning” vertigo is less common. Other neurologic symptoms and signs suggestive of a CNS lesion are often present.

Peripheral nervous system pathology affects the vestibulo-cochlear apparatus or the vestibular division of the eighth cranial nerve. The *Hallpike maneuver* commonly is used to assess presumptive peripheral vertigo. The patient is positioned with the shoulders at the edge of the examination table, and the head is extended and rotated to one side. Gaze is directed toward the rotated side by having the patient focus upon the examiner’s finger. An affected patient may exhibit nystagmus, report vertigo, or both. The maneuver is repeated to the opposite side after the head has been returned to neutral position and the nystagmus and vertigo have stopped. Vertigo of PNS origin exhibits fatigability (attenuation of vertigo while maintaining the triggering position) and habituation (less severe and shorter duration vertigo with repeated assumption of the triggering position). Peripheral vertigo may also exhibit a latency to onset, typically lasting a few seconds. These examination characteristics can be used to suggest a benign cause of vertigo that can be treated symptomatically. Nystagmus associated with vertigo is usually unidirectional, with the fast phase away from the involved side. Benign positional vertigo is strongly suggested by provoking nystagmus or vertigo during the Hallpike maneuver. Symptomatic treatment options for benign causes of acute or subacute vertigo of peripheral origin include bedrest, the Epley maneuver (three times per day until vertigo is gone for 24 hours [1]), or medications such as anticholinergics (scopolamine), antihistamines (meclizine), or benzodiazepines (diazepam).

Central nervous system causes of vertigo involve the vestibular nuclei or their connections in the brainstem, cerebellum, and cerebral hemispheres (less common). Individual bouts may occur spontaneously without movement as a trigger. Central vertigo often lacks habituation, fatigability, and latency to onset. Progressive unilateral hearing loss should alert the physician to a possible cerebellopontine angle tumor. Hearing loss is the most frequent presenting symptom, but vertigo is present in 20%. Vertebrobasilar artery ischemia can produce abrupt isolated vertigo, but other CNS symptoms and signs are usually present.

Dysphagia of Neurologic Etiology

Dysphagia can be caused by neurologic disease (Table 115.7) involving cranial nerves IX or X (resulting in dysfunction of the soft palate), cranial nerve XII (resulting in tongue wasting or weakness when protruded against the buccal mucosa), or bilateral upper brainstem or cerebral hemisphere disease (i.e., pseudobulbar palsy from multiple cerebral infarctions or multiple sclerosis). Dysphagia should trigger diagnostic consideration of upper motor neuron, cranial nerve, neuromuscular junction, or myopathic disorders. The history often allows the examiner to differentiate between mechanical and

neuromuscular causes of dysphagia (Chapter 79). Dysphagia resulting from oropharyngeal disease causes difficulty immediately on attempted swallowing. Weakness of muscles that elevate the soft palate may result in nasal regurgitation of liquids and nasal speech. Neuromuscular esophageal disease results in discomfort that occurs later after swallowing and is located in the lower neck or upper chest. Neurologic examination can assess the oropharynx directly but is not helpful for esophageal disease.

Movement Disorders

Involuntary movements often reflect systemic illness, drug effects, or neurologic disease. The most common movement disorders are tremor, bradykinesia, dystonia, choreoathetosis, asterixis, and myoclonus. Accurate description of the abnormal movement suggests the differential diagnosis.

Tremor is a rhythmic involuntary movement of a body part that can be classified as postural (action) or rest. The most common tremor (postural tremor) is a high-frequency (8–10 beats per second), low-amplitude, rhythmic oscillation of the hands and fingers noted readily with the upper limbs outstretched against gravity. The tremor stops if the arms and hands are supported at rest. The differential diagnosis includes essential tremor, hyperthyroidism, sepsis, and sympathetic overactivity states (often due to sympathomimetic drugs). The hands are affected first, but later involvement of the head and neck is common. Symptomatic treatment with propranolol or mysoline may be necessary if the tremor is sufficiently embarrassing in social circumstances or impairs functional activities. Postural tremor of unknown cause (*essential tremor*) is hereditary in at least one-half of patients, worsens under stressful conditions, and is relieved with sedatives. In contrast, *rest tremor* occurs while the arms are supported at rest and becomes less prominent with arm movement. The tremor is low in frequency (2–4 beats per second), higher in amplitude, and rhythmic. The best example is the

pill-rolling tremor of Parkinson's disease. *Intention tremor* is an action tremor that worsens during voluntary movement toward a target. This tremor often is detected by movement of the patient's finger alternately between the examiner's finger held at arm's length and the patient's nose (finger–nose testing). The tremor worsens as the patient's finger is moved closer toward the intended target, such that the target is missed (past-pointing) frequently. Intention tremor is specific for the cerebellum, or associated afferent or efferent pathways.

Dystonia refers to an abnormal, involuntary posture of a limb or body part due to abnormal tension in resting muscles that interferes with normal voluntary movement. Chronic antipsychotic medication use causes tardive dyskinesia, while recreational drugs tainted with phenothiazines may cause an acute dystonic reaction that remits with anticholinergic medications. *Chorea* refers to involuntary, rapid, irregular, dance-like movements that are usually focal and most prominent in the distal extremities. *Athetosis* consists of slower, snake-like involuntary movements of the proximal limbs or trunk. The simultaneous combination of these two movements (*choreoathetosis*) is common. The differential diagnosis of choreoathetosis includes both untreatable (e.g., basal ganglia cerebral infarction or hemorrhage) and treatable disorders (Table 115.8). Patient medications should always be reviewed as possible causes. Many hereditary neurodegenerative conditions also cause chorea (i.e., Huntington's disease).

Amphetamines, cocaine

Myoclonus and asterixis are often neurologic markers of systemic metabolic disease on an inpatient medical service. *Myoclonus* is a sudden, arrhythmic, asymmetric involuntary muscle contraction that produces focal or generalized jerking movements. Myoclonus can be a normal accompaniment of falling asleep. Multifocal myoclonus occurs commonly among hospitalized patients with hypoxic-ischemic encephalopathy. Other causes include electrolyte disturbances, liver failure, renal insufficiency, epilepsy, encephalitis, and neurodegenerative disease. Myoclonus that results from seizures needs to be distinguished from myoclonus resulting from other causes because treatment is different (Chapter 118). Electroencephalography (EEG) is helpful to determine if the myoclonic movements are cortical (seizures) or subcortical in origin (myoclonus). *Asterixis*, in contrast to myoclonus, consists of sudden loss of postural muscle tone rather than sudden involuntary muscle contraction. Myoclonus and asterixis can be distinguished at the bedside by instructing the patient to hold the arms outstretched with the wrists in extension, palms facing forward. The failure to maintain this wrist extension against gravity indicates either a sudden loss of forearm extensor muscle tone against gravity (asterixis) or active forearm flexor muscle contraction (myoclonus). Turning the arms over so that wrist extension is no longer against gravity eliminates asterixis, but not myoclonus. Asterixis can be caused by drug intoxication, renal failure, liver failure, or meningitis. Both asterixis and myoclonus usually resolve with correction of the underlying metabolic abnormality.

Weakness

A systematic approach is mandatory in evaluating the symptom and examination finding of weakness. Patients use the term *weakness* to describe almost any functional limitation of motor activity. The initial goal of clinical evaluation is to distinguish true neurologic from non-neurologic weakness. The distribution of weakness (e.g., hemiparesis, distal symmetric) and associated neurologic examination findings (pattern of sensory loss, muscle tone, reflexes) determines the neuroanatomic site of pathology and the differential diagnosis. The symptom of weakness can be nonneurologic and caused by generalized fatigue, impaired focal sensation, pain during attempted limb movement, or lack of effort secondary to systemic illness or depression. The physician must distinguish these forms of weakness as a symptom from weakness as a neurologic examination finding.

The examination finding of weakness can also be non-neurologic in origin. Nonneurologic weakness is observed as *breakaway weakness*, defined as variable muscle power detected by the examiner during testing of a specific muscle. When breakaway weakness is found, it is important to ask the patient if power testing of the muscle exhibiting the breakaway weakness is painful. *Painless* breakaway weakness results from poor effort and implies a behavioral

component to the observed weakness. However, it is incorrect to conclude that a behavioral disorder alone is present; many of these patients also have an underlying neurologic disorder. Patients with *painful* breakaway weakness are more difficult to evaluate because the integrity of the muscle and supplying nerve cannot be assessed by examination of muscle power. Breakaway weakness with pain occasionally is accompanied by underlying true neurologic weakness. The findings for each involved muscle should be reported as “breakaway weakness associated with pain” or “breakaway weakness unassociated with pain” given that the causes of these two observations are different and may coexist in the same patient. Electromyography and nerve-conduction studies are helpful in this circumstance to distinguish true underlying neurologic weakness from breakaway weakness.

True neurologic weakness is loss of muscle power detected as a lack of expected strength for a given muscle. The weakness appears on examination as reduced and constant muscle power during maximal muscle contraction, and arises from lesions of the CNS or PNS. *CNS weakness* has a characteristic distribution. Distal muscles are more affected than proximal muscles. Extensor muscles are more affected than flexors in the arms and dorsiflexors are affected more than plantar flexors in the legs. Power testing of finger extensors or toe dorsiflexors are excellent screening tests of muscle power when searching for CNS weakness. In contrast to PNS disorders, CNS weakness does not conform to a pattern of muscles innervated by a single nerve or nerve root. Muscle tone may be spastic, flaccid, or normal in the setting of an acute CNS injury, but nearly always becomes spastic within a few days. Spasticity is a velocity-dependent increase in resistance to passive movement of a limb, and indicates CNS injury to upper motor neurons. Testing for spasticity is best accomplished with the patient supine and limbs relaxed. The arm or leg is moved through its range of motion at slow velocity first, then at rapid velocity. Mild spasticity may be detectable only during rapid movement of a limb. Other neurologic signs are sensitive for detecting mild CNS weakness. Fast, repetitive tapping of the index finger to the thumb (“fast finger movements”) or foot tapping on the floor or against the examiner’s hand are slowed (but of regular rhythm) compared with an unaffected hand or foot. With palms facing upward, fully outstretched arms often pronate with CNS weakness (pronator drift). CNS weakness is graded as mild, moderate, or severe, depending upon the degree of motor impairment.

PNS weakness results from disease of the motor unit. The motor unit is the entire motor nerve cell, axon, neuromuscular junction, and the muscle fibers the motor nerve cell supplies. Injury along the motor unit causes weakness. Determination of where the injury is located along the motor unit narrows the differential diagnosis. For example, if sensory loss is present, injury must be to the nerves, plexuses, or nerve roots because the anterior horn cells, muscle cells, and neuromuscular junctions do not contain sensory nerve

fibers. If the weakness is accompanied by sensory loss in a distal, symmetric fashion most severely affecting the feet, then a distal symmetric sensorimotor polyneuropathy (*length-dependent polyneuropathy*) is probably present. Proximal, symmetric weakness suggests a myopathy or neuromuscular junction disorder. Reflexes are typically normal in myopathies and diminished in the distribution of the weakness in neuropathies.

Sensory Examination

Appropriate elicitation and interpretation of sensory signs is difficult at best. Extensive patient cooperation is usually necessary, the tests are qualitative and prone to technical error, and results depend upon an accurate patient description of the deficits. These limitations are more problematic among hospitalized patients. Patients with sensory deficits from peripheral nerve disorders commonly are assessed semiquantitatively with nerve-conduction studies.

The ability to distinguish sensory symptoms from sensory examination abnormalities is crucial. Common sensory symptoms unaccompanied by neurologic findings are paresthesias or pain. *Paresthesia* refers to an abnormal subjective perception of sensation, but does not include a loss or diminution of sensation. A “pins and needles” sensation is the most common description used by patients. Paresthesias are an abnormal “positive sensory” symptom that arises in the CNS or PNS. They are generated by spontaneous activation of sensory receptors or nerve fibers, or an excessive nerve fiber response to normal cutaneous receptor stimulation. Metabolic disorders, CNS or PNS injury, or mechanical distortion of nerves (e.g., Tinel’s sign seen in carpal tunnel syndrome) may trigger paresthesias. The significance of paresthesias depends upon the clinical context. The likelihood of an underlying neurologic cause increases dramatically if accompanied by neurologic examination abnormalities (i.e., weakness, focal reflex changes, sensory loss) in the same distribution. The absence of neurologic examination findings suggests a metabolic cause. The qualitative description by patients varies considerably because abnormal sensation does not reflect the normal orderly recruitment of sensory nerve cells that occurs with natural stimuli.

“Negative sensory” symptoms result from diminution or loss of sensory function. The severity and distribution of diminished sensation is more reliable in defining and localizing a neurologic deficit than positive sensory phenomena such as paresthesias or pain. Sensory modalities commonly tested are touch, position, vibration, pain, or temperature. Specific nerve, nerve root, or spinal cord syndromes associated with diminished sensation are best detected with the help of a practical examination guide or diagrams that include the distribution of nerve roots and peripheral nerves (Figure 115.1). Side-to-side comparison of analogous skin regions of the feet, hands, and face is a useful screen for touch, pain, and temperature; asymmetry of the findings is a sensitive and reliable indicator of an abnormality. If

Figure 115.1 Dermatomes of the anterior and posterior body.

sensory examination findings do not conform easily to a CNS or PNS pattern of involvement, neurologic consultation is advisable.

The sensory loss associated with a typical progressive sensorimotor polyneuropathy spreads from the toes to the knees, then simultaneously from the knees into the lower thighs and the hands in a circumferential distribution. If sensory loss has spread to the waist or upper thighs without hand involvement, the examiner should consider the possibility of a spinal cord lesion. A *spinal cord sensory level* often can be detected with a cotton swab or pin used to test posterior paraspinal sensation from the upper neck to the sacrum on both sides. The sensory level is described as the dermatomal level below which sensation is reduced or lost. As a practical matter, finding a sensory level determines the initial anatomic target for neuroimaging (i.e., a T6 sensory level will trigger a thoracic spine MRI scan).

Urinary Incontinence

Urinary incontinence is usually the result of nonneurologic disease. A precise urologic history needs to be elicited and

is volunteered infrequently by patients. *Stress incontinence* is the leakage of small urine volumes associated with increased intraabdominal pressure, and usually occurs in multiparous or postmenopausal women with pelvic relaxation. A review of medication use, paying particular attention to recent changes, is necessary (Table 115.9). Important changes from baseline habit include frequency and quantity of voiding, difficulty initiating or maintaining micturition, dysuria, urinary urgency, urinary retention,

TABLE 115.9
URINARY INCONTINENCE AND DRUGS

Class/medication	Effect on urination
Diuretics, alcohol, caffeine	Polyuria
Tricyclic antidepressants	Retention, overflow
Opiates	Retention, overflow
Anticholinergics	Retention, overflow
Antipsychotics	Stress incontinence

and nocturia. Once an initial screen for common medical causes of urinary incontinence is complete, consideration of neurologic causes is appropriate. A change in frequency of nocturia over time is often an early symptom of mechanical obstruction of the urethra or neurologic disease. Inability to sense the passing of urine or stool, or decreased perianal sensation (e.g., ability to feel toilet paper) suggest a neurologic cause of urinary incontinence.

Measurement of residual urine volume after a voluntary attempt to empty the bladder (postvoid residual) is a simple bedside test of bladder function that can help distinguish bladder dysfunction from the CNS or PNS. A high volume bladder is classically due to PNS injury of parasympathetic nerves to the bladder from bilateral S2–S4 spinal segments, either outside the spine (i.e., diabetes) or inside the spine but distal to the spinal cord (i.e., cauda equina syndrome). This PNS injury also results in reduced detrusor (bladder) muscle contractility and reduced urine flow. Chronic bladder dysfunction following CNS injury results in simultaneous contraction of the urinary sphincter and bladder detrusor muscles (*detrusor-sphincter dyssynergia*). The hyperreflexive nature of this spastic bladder results in sudden, unpredictable urges to urinate; the patient reports frequency, urgency, and sudden urinary incontinence in the setting of low postvoid residual urine volumes. Acute CNS injury (i.e., spinal cord compression from tumor or trauma) can result temporarily in a high postvoid residual urine volume; the bladder muscle may be flaccid temporarily before spasticity develops.

Bilateral spinal cord, brainstem, or brain involvement is necessary to produce urinary incontinence of CNS origin. Other neurologic examination signs of CNS involvement are almost always present. Postvoid residual is small until late in the disease. A low threshold for neurologic or urologic consultation is advisable if the cause is unclear. PNS causes of urinary incontinence (e.g., diabetic neuropathy or cauda equina syndrome) often result in diminished perianal or perineal sensation. Ankle reflexes may be absent. Reflex contraction of anal sphincter muscles can be assessed by stimulating the external anus on each side with a pin. Unilateral or bilateral absence of reflex sphincter contraction suggests a PNS lesion or a suboptimal stimulus.

DIAGNOSTIC TESTS

Cerebrospinal Fluid (CSF) Examination

CSF analysis provides data regarding changes in chemical composition of the fluid that bathes the brain, spinal cord, and nerve roots. Indications for spinal fluid evaluation include possible infectious or neoplastic meningitis, encephalitis, subarachnoid hemorrhage, papilledema, encephalopathy of unknown cause, CNS vasculitis, CNS or PNS demyelinating diseases, or postural headache. CSF analysis may lead to a specific diagnosis. Routinely exam-

ined parameters include glucose, protein, red cell count, white cell count, and differential. CSF should be analyzed immediately, or refrigerated if a delay in analysis is likely, because 40% of white cells are lysed after two hours. Typical CSF formulas seen in meningitis syndromes are discussed in Chapter 70.

Opening pressure (OP) is recorded with a manometer after the subarachnoid space has been entered and the patient's legs extended (to minimize any contribution to OP by increased intra-abdominal pressure). Elevated OP in the absence of head CT or MRI abnormalities is seen in many different diseases (Table 115.10). A low OP may indicate a spinal subarachnoid block or CSF leak. The CSF is spun in a centrifuge, then inspected for pigments. Normal CSF is clear. *Xanthochromia* is a yellow color that reflects the presence of bilirubin. Xanthochromia is detected 2–12 hours after subarachnoid hemorrhage, is at its maximum after 2 days, and persists for 2–4 weeks. It is essential to differentiate between pigmented CSF from a traumatic lumbar puncture (LP) and pathologic subarachnoid hemorrhage. Serial assessment of CSF during the LP, comparing the red cell count in an early tube with that found in a later tube, reveals visible clearing of the fluid and a significant drop in red cell count by microscopic examination in the setting of an LP-induced traumatic hemorrhage. The spun CSF supernatant is normally clear unless enough serum has entered the subarachnoid space that there are more than 100,000 red blood cells per cubic millimeter, the CSF protein level is greater than 150 mg/dL, or the CSF was examined more than two days after the first LP. In the latter circumstance, it can be difficult to differentiate pathologic from an LP-induced subarachnoid hemorrhage. Corrected white cell and protein values can be extrapolated from CSF contaminated by traumatic bleeding. For every 1,000 red cells present, subtract one

white cell and 1 mg/dL of CSF protein. Other CSF studies are helpful in specific clinical situations. Cytology can establish the diagnosis of neoplastic meningitis, and should be performed rapidly after collection of fluid to avoid cytotoxicity. Analysis of large CSF volumes (>20 mL) increases the probability of tumor cell identification. Comparison of immunoglobulin production within the CSF and in the serum (IgG index) is a marker for an active immune response within the CNS compartment. Polymerase chain reaction studies are used to detect viral pathogens in CSF (e.g., *Herpes simplex*).

Contraindications to LP are uncommon. The most feared complication, brain herniation, occurs if brain volume is increased and CSF pathways are obstructed. With hospital-based CT or brain MRI, direct visualization of the brain in the setting of papilledema or focal CNS deficits has simplified decisions about performing a spinal fluid examination. Free communication along CSF pathways, even in the presence of a mass lesion, implies that the risk of brain herniation is low. Neuroimaging findings suggesting a focal intracranial pressure differential (i.e., trapped ventricle, midline shift, or early cerebellar or uncus herniation) contraindicate LP. Severe thrombocytopenia (platelet count <20,000/ μ L), anticoagulation, or a bleeding diathesis increase the risk of spinal subarachnoid hemorrhage or spinal epidural hematoma, and are relative contraindications to LP. Use of a 22-gauge needle lowers the risk. Discontinuing heparin in advance of the procedure, or administering vitamin K or fresh frozen plasma to reverse the effects of coumadin, can be considered in selected circumstances. Introduction of infection at the puncture site rarely occurs and is caused by passage of the needle through infected soft tissue or use of an unsterile needle. If infected soft tissue is present along the anticipated needle track, consideration should be given to a C1-2 (cisternal) puncture under fluoroscopic guidance.

Other potential complications of LP include low back pain and nerve-root irritation during the procedure that results in temporary radicular pain extending from the back to the ipsilateral buttock or leg. Post-LP headache begins with standing and resolves in the supine position; it occurs after about one LP in ten. The headache begins between 15 minutes and 4 days following the procedure and lasts an average of 4–8 days. Bedrest is the treatment of choice and common analgesics are not helpful. In those few patients who develop intractable post-LP headache, installation of the patient's venous blood into the epidural space ("blood patch") by an anesthesiologist is effective treatment.

Neuroimaging

CT and MRI have simplified the diagnosis and management of many CNS disorders. These diagnostic techniques allow noninvasive localization of anatomic abnormalities in the brain, head and neck, spine, and the spinal cord. The

contour, distribution, size, and contrast-enhancement characteristics of lesions often support a specific diagnosis or a limited list of diagnostic possibilities. The choice between head CT and MRI depends upon the diagnostic question and the immediate availability of the imaging modality. If acute brain hemorrhage is the primary diagnostic consideration, then head CT without contrast is the best study. New blood is seen as a high-density lesion on the scan. The only other causes of a high-density lesion are calcium, metal, and contrast. Patient movement during CT or MRI studies degrades the images and limits diagnostic information. Patients are less likely to move during a CT scan than an MRI because image acquisition is faster and patients are unlikely to develop claustrophobia.

CT–myelography is preferred in the setting of spine disorders characterized by bony abnormalities (e.g., spinal stenosis and cervical spondylosis). Potential complications of CT include exposure of patients to low levels of radiation and contrast reactions. MRI is superior to CT in demonstrating exquisite soft-tissue anatomic detail (without radiation exposure), and results in detection of brain and spinal cord lesions missed by CT scan. These disorders include brain infection, neoplasm, cerebral infarction, neurodegenerative diseases, demyelinating diseases (i.e., multiple sclerosis), and extracranial soft tissue pathology of the head and neck. The contrast agent used for MRI (gadolinium) is not associated with renal failure, and allergic reactions are rare. Two percent of patients undergoing a brain MRI experience claustrophobia that interferes with the test. In these patients, sedation, given 30–60 minutes prior to the study, often permits an acceptable study. MRI generates a strong magnetic field that can result in injury if there are magnetic objects in the body. The induced magnetic field may inactivate cardiac pacemakers or automatic internal defibrillators.

Electroencephalography

EEG is a noninvasive, painless study that can be performed at the bedside to investigate possible seizures, focal abnormalities of brain function, and other neurologic disorders. Electrodes are pasted to the scalp and connected to amplifiers in a grid pattern that allows for the recording and display of regional brain electrical activity. The recorded waveforms have characteristic frequencies that depend on age, alertness, brain region, systemic illness, medications, focal brain disease, and technical maneuvers during the test (e.g., hyperventilation, flicker stimulation). While EEG can complement the anatomic information obtained by neuroimaging, the neurologic examination is often an adequate test of nervous system function and can be correlated with neuroimaging results. However, in severely ill patients unable to cooperate with the neurologic examination, analysis of CNS function can be assessed by the EEG. For example, persistent unconsciousness without explanation may be caused by non-

convulsive status epilepticus or a diffuse brain insult that has an EEG correlate.

Status epilepticus (Chapter 118) manifests as seizures on the EEG, whereas encephalopathy appears as diffuse slowing of EEG background rhythms. Involuntary movements can be difficult to distinguish from seizures based upon visual appearance alone, but can be clarified by an EEG study performed while the movements are ongoing. Portable EEG assessment of brain function is possible for patients who cannot be transported to a scanner because of critical illness or other logistic issues. The EEG can be helpful to suggest focal brain dysfunction when neuroimaging is normal (anatomic–functional dissociation). This circumstance may occur early in the evolution of brain pathology (e.g., herpes simplex encephalitis) and can influence the threshold for initiation of drug therapy. Depression or feigned altered consciousness manifests as a normal EEG in patients without neurologic or systemic illness. A short synopsis of the diagnostic question and a complete list of medications should be provided to the EEG laboratory when ordering the test.

Electromyography and Nerve-Conduction Studies

Electromyography and nerve-conduction studies are a sensitive extension of the neurologic examination and are useful for evaluating the functional integrity of the peripheral nervous system (PNS). These studies can offer advantages over the clinical neurologic examination by providing quantitative information, particularly if patient cooperation or effort is limited. Although they can be performed at the bedside, the electrical environment of the ICU may result in recording artifacts.

Nerve-conduction studies are semiquantitative tests of nerve function. They are performed by placing stimulating electrodes on skin overlying limb nerves and recording over nerves (sensory nerve action potentials, or SNAPs) or muscles (compound motor action potentials, or CMAPs). Slowed nerve conduction velocities or prolonged distal motor latencies are indicative of nerve demyelination. Reduced amplitude of SNAPs or CMAPs correlates best with loss of axons in the nerve.

Needle electromyography is a qualitative test of nerve and muscle function performed by insertion of a recording needle electrode into selected muscles. There is no stimulating current. Abnormal spontaneous activity at rest correlates with acute denervation (axonal injury) or muscle-membrane instability in muscle disease (polymyositis). The morphologic configuration (duration, amplitude) of individual motor units (single motor nerve cells and the muscle fibers it supplies) seen on a display screen during minimal muscle contraction can be attributed to muscle or nerve disease. The firing pattern of nerve cells during muscle contraction also may suggest muscle or nerve injury.

KEY POINTS

- The neurologic history is crucial to establish a clinical context that determines which neurologic findings on examination are likely to be pertinent.
- Historical risk factors for headache of serious cause are sudden onset, new onset in elderly or immunosuppressed patients, headache that awakens the patient, postural headache, association with focal neurologic symptoms or signs, or association with fever, rash, stiff neck, or arthritis.
- Delirium is an acute or subacute alteration of mental state characterized by fluctuating alertness and confusion; dementia is a chronic, progressive cognitive deterioration with impaired recent memory, preservation of alertness, and relative preservation of social function.
- Unilateral, new-onset pupil dilation should trigger consideration of early brain herniation resulting from a mass lesion compressing the third cranial nerve.
- Nonneurologic weakness usually is observed as variable muscle power during testing of a specific muscle (recorded as breakaway weakness with or without pain); true neurologic weakness is observed as reduced and constant resistance provided by the patient when testing muscle power during maximal muscle contraction.
- “Positive” sensory symptoms (paresthesias, pain) unaccompanied by abnormal neurologic examination signs suggest a nonneurologic cause; “negative” sensory examination signs (i.e., diminished light touch or pin sensation) suggest a CNS or PNS structural lesion.
- Disorders for which spinal fluid examination results can assist diagnosis include possible meningitis, encephalitis, subarachnoid hemorrhage, papilledema of unknown cause, CNS vasculitis, encephalopathy of unknown cause, CNS or PNS demyelination, or postural headache.
- Neuroimaging (MRI or CT) and EEG are complementary tests: MRI or CT help define the anatomy and differential diagnosis of CNS lesions (tumor vs. stroke), while EEG helps determine functional localization of brain lesions or the presence of seizures.
- Electromyography and nerve conduction studies are sensitive, semiquantitative tests of nerve and muscle function that detect, localize, and quantify PNS injury and complement the observations obtained by the neurologic history and examination.

Wade S. Smith

INTRODUCTION

Stroke, the third leading cause of death in the United States, is now considered a treatable disease. The testing and approval of tissue plasminogen activator (t-PA) for victims of acute ischemic stroke is largely responsible for this new optimism. Approval of t-PA for this use in 1996, in conjunction with aggressive hospital-based acute “stroke unit” management, has led to reduced mortality and decreased morbidity rates among stroke victims. In 2004, some hospitals began to be credentialed as primary stroke centers. These centers have the key personnel necessary to safely give t-PA, and to systematically apply the best practices for stroke victims. It is likely that these stroke centers will function much like trauma centers, with stroke patients specifically triaged to them in the prehospital setting in some communities. This chapter reviews the initial presentation, evaluation, and management of acute ischemic stroke, and is directed at the hospital physician evaluating an acute stroke patient without the benefit of a stroke center.

Despite the approximately 550,000 cases of stroke per year in the United States, few controlled prospective data exist to help guide initial management and post-stroke prophylaxis. Only in the past decade have well-designed therapeutic trials become available. Further, institutional bias and provider heterogeneity add to the complexity of individual case management. For example, neurologists, vascular surgeons, and internists vary markedly in use of anticoagulation for carotid stenosis. Many centers routinely admit all patients with transient ischemic attacks (TIAs) or minor stroke; others cite the absence of proof for the benefits of hospital management as proof of absence of benefit. Lacking are precise data on the natural history of recurrent stroke; such data are necessary to make cost-benefit decisions regarding hospitalization, timing of surgery, and use of anticoagulation.

BACKGROUND AND DEFINITIONS

Stroke is a clinical diagnosis; it is not diagnosed by radiologic study. It can be defined as the sudden onset of neurologic dysfunction produced by a presumptive vascular cause. A transient ischemic attack (TIA) is a clinical stroke that clears within 24 hours, although TIAs typically last only 10–14 minutes. Stroke is sudden or stepped in onset, and is manifested by focal neurologic findings. Approximately 85% of all hospitalized stroke victims have hemiparesis. The presence of language dysfunction or neglect coupled with facial or arm weakness is highly specific for stroke. The presence of bilateral weakness degrades this specificity. On the other hand, patients with metabolic encephalopathies can have focal neurologic findings. Therefore, the sudden onset (or new discovery) of focal neurologic findings suggests stroke, but appropriate laboratory tests are necessary to exclude potential masqueraders.

The role of early brain imaging is to define the stroke subtype. Acute stroke can be classified as *hemorrhagic* or *ischemic* by performing initial noncontrast computed tomography (CT) scan of the head (Table 116.1), based on the presence or absence, respectively, of blood seen on CT.

Hemorrhagic stroke can be defined as the sudden onset of a neurologic deficit associated with brain CT consistent with acute intracranial hemorrhage. Hemorrhage stroke can be subtyped by the anatomic space in which blood is observed: epidural, subdural, subarachnoid, or intraparenchymal. *Epidural* hematomas are typically produced by trauma, resulting in severing of the middle meningeal artery. Accumulation of blood is rapid, demanding immediate neurosurgical intervention. *Subdural* hemorrhages accumulate from a low-pressure venous source and typically are produced by tearing of bridging cortical veins.

TABLE 116.1
STROKE CLASSIFICATION, AND RELATIVE DEGREE OF URGENCY FOR EVALUATION

Stroke subtype	Frequency %	Computed tomography findings (typical)	Urgency ^a
Hemorrhage	15	Hyperdense material representing clotted blood	Moderate–High
Subarachnoid	1–2	Blood in subarachnoid space	High
Intraparenchymal	10	Blood in brain parenchyma	Moderate–High
Subdural	<1	Blood in subdural space	Low–High
Epidural	<1	Blood in epidural space	High
Ischemic stroke	85	Usually normal <6 h. Hypodensity representing edema later	Low–High ^b
Lacunar stroke	21	Hypodensity usually <1 cm ³	High ^b
Cardioembolic	17	Wedge-shaped cortical/subcortical hypodensity	High ^b
Artery–artery embolism	13	Wedge-shaped cortical/subcortical hypodensity	High ^b
Cryptogenic stroke	25	Cortical/subcortical hypodensity	High ^b
Other	8	Varies	High ^b

^a Urgency is high with depressed level of consciousness, airway instability, or hemodynamic instability.

^b High urgency if under 3 h, because patient may be eligible to receive intravenous thrombolytics.

Both severe and subtle head trauma can produce this bleeding, and patients with brain atrophy are predisposed to it. The most frequent cause of *subarachnoid* hemorrhage is closed head injury. Aneurysmal rupture into the subarachnoid space is also common. Spontaneous, non-traumatic aneurysmal subarachnoid hemorrhage is life threatening, with nearly a 50% mortality rate within the first 24 hours. Immediate neurosurgical or endovascular intervention and control of intracranial pressure are priorities that affect survival and neurologic outcome. Intraparenchymal hemorrhages are produced by both large and small vessel rupture. Chronic hypertension is the major predisposing risk factor for the genesis of most of these hemorrhages. It is unclear if an acute increase in blood pressure is responsible for the actual hemorrhage. The diagnosis and management of the hemorrhagic stroke syndromes and increased intracranial pressure are described in Chapter 117.

Ischemic stroke is produced by blockage of a cerebral vessel with resulting ischemia and later infarction within the part of the brain region irrigated by the vessel. The extent and location of infarction depends on many factors, including the presence of collateral circulation, patient age, brain temperature, serum glucose, magnitude of blood flow reduction, and the duration of ischemia. A physician may intervene to reduce duration and magnitude of ischemia (thrombolysis), reduce temperature (antipyretics or cooling), lower serum glucose to the normal range, and, perhaps, increase collateral circulation (by allowing acute hypertension). Brain tissue is the tissue most vulnerable to ischemia in the body. Death of neurons begins after approximately 4 minutes of zero blood flow. However, a core of tissue around the infarcted tissue does not infarct as

quickly. This region is referred to as the *ischemic penumbra*, which receives blood flow adequate to maintain temporary (i.e., hours) neuronal survival, but inadequate to allow normal neuronal activity. The penumbral region may infarct without intervention, so the goal of most acute stroke therapy is directed at saving this volume of brain. Perfusion to the penumbra is dependent on collateral circulation and strongly dependent on blood pressure, so *reduction in blood pressure may enlarge the infarct*. Conversely, permissive or induced hypertension may reduce infarct size. Because infarct size is critically dependent on temperature, fever should be treated aggressively with antipyretics, body exposure, and active cooling. Mild hypothermia may be beneficial but is considered investigational at this time. Thrombolytic therapy may be possible if the duration of ischemia is less than 3 hours; this is discussed subsequently in this chapter.

One-quarter of ischemic strokes results from *lacunar infarction*. This is produced by small vessel closure within the internal capsule, thalamus, pons, and cerebellum. There are many lacunar syndromes; the four most common are listed in Table 116.2. In general, lacunar strokes have a better prognosis, with a lower case-fatality rate than large vessel strokes. Hypertension and diabetes are the most commonly associated risk factors. Because lacunar strokes are caused most often by local arteriolar disease, one does not generally need to search for embolic sources.

Large vessel strokes carry a higher fatality rate and cause more significant injury. Each of the major named cerebral arteries can produce a large vessel syndrome, as listed in Table 116.2. The mechanism of large vessel occlusion is most commonly embolic closure of the vessel. The presence of such an infarct should lead the clinician

TABLE 116.2
ISCHEMIC STROKE SUBTYPES

Subtype	Clinical stroke	Mechanism
Lacunar Lenticulostriate Thalamoperforators Brainstem penetrators Cerebellar	“Lacunar syndromes” Pure motor stroke Pure sensory stroke Ataxia, dysarthria, hemiparesis Ataxia	Lipohyalinosis/thrombosis
Large-vessel Middle cerebral artery	“Large-vessel syndromes” Dominant: aphasia, gaze deviation, hemiparesis, hemisensory and visual field deficit Nondominant: neglect, gaze deviation, hemiparesis, hemisensory and visual field deficit	Typically embolic
Posterior cerebral artery Anterior cerebral artery	Visual field deficit, amnesia Leg weakness, frontal lobe syndrome	
Basilar artery	Cranial nerve deficits, quadriparesis, depressed level of consciousness

to search for an embolic source, such as the carotid artery, heart, or aortic arch. A list of common and uncommon causes of stroke is contained in Table 116.3. The search for a potential cause should be based on the clinical stroke classification and the type of stroke classified by a brain imaging study.

ISSUES AT THE TIME OF ADMISSION

Evaluation and Differential Diagnosis

Figure 116.1 summarizes the major steps followed during the initial phase of care. One first must decide if the acute onset of a focal or global neurologic deficit has been caused by stroke or TIA. Table 116.4 lists the differential diagnosis. Establishing an accurate diagnosis depends heavily on obtaining an accurate history. If the patient was not observed at the onset of his or her deficit, one falsely may attribute a generalized seizure with postictal hemiparesis (*Todd's paresis*) to stroke. Similarly, a patient with an intracranial tumor producing hemiparesis and dementia may provide an inaccurate history of sudden onset of weakness. A clear history of sudden onset rules out the stroke masqueraders.

Initial Studies and Management

The initial management of stroke and TIA is summarized in Table 116.5. Any patient suspected to have had a stroke should be evaluated for airway, breathing, and circulatory stability, followed by an assessment of serum glucose level. Laboratory assessment also should include complete

New Onset of Neurological Deficit

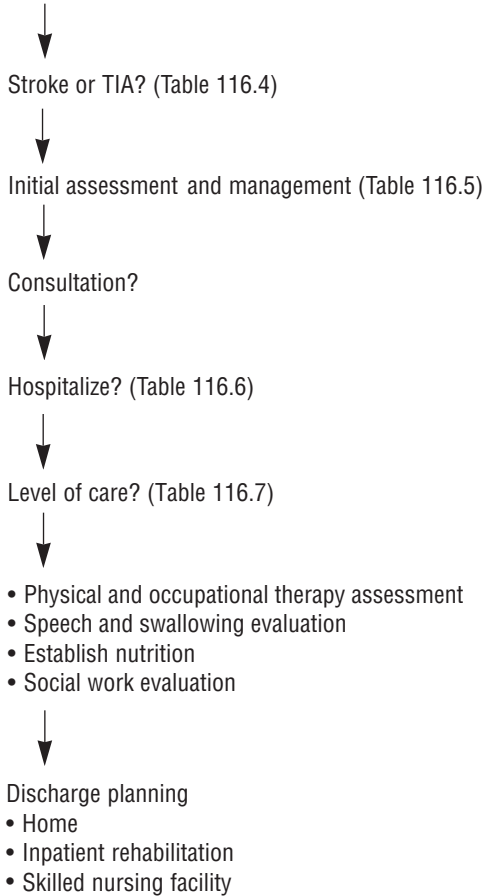

Figure 116.1 Key points in the management of acute stroke. TIA, transient ischemic attack.

blood count (CBC), platelet counts, coagulation studies, and electrolyte levels. An erythrocyte sedimentation rate is a useful screen for unexpected illness, including malignancy, arteritis, and endocarditis.

One then must determine if the stroke is hemorrhagic or ischemic using emergent noncontrast head CT (many centers now also perform CT angiography of the head and neck

TABLE 116.4
DIFFERENTIAL DIAGNOSIS OF NEW-ONSET FOCAL NEUROLOGIC FINDINGS

- Stroke/Transient ischemic attack

CNS, central nervous system.

during this time). CT is adequate to eliminate tumor and hemorrhagic stroke; it is normal in early ischemic stroke, migraine, and metabolic encephalopathies. The choice of consultants depends on the CT findings. If the CT reveals hemorrhage, neurosurgical or neurologic consultation should be sought to help with management (Chapter 117). If the CT scan does not reveal hemorrhage, or if the diagnosis or cause are unclear, emergent neurologic evaluation should be sought, because the patient may be eligible for intravenous thrombolytic therapy. The presence of hydrocephalus should prompt consultation with a neurosurgeon for placement of ventriculostomy if necessary.

Admission Decision and Level of Care

The decision to hospitalize a patient with acute stroke or TIA is controversial, and there is wide variability in practice. Table 116.6 lists certain clinical features that should

TABLE 116.6
REASONS TO HOSPITALIZE PATIENTS WITH STROKE

- Accepted
 - Hemodynamic or airway compromise
 - Depressed level of consciousness
 - Aspiration
 - Inability to walk
 - Intracranial hemorrhage
 - Atrial fibrillation
 - Myocardial ischemia
 - Crescendo TIA
 - Stroke in progression
 - Other acute medical issues
- Controversial
 - TIA
 - Minor stroke

TIA, transient ischemic attack.

be considered in making this decision. Many physicians admit patients with minor stroke and TIA to expedite the evaluation. Patients who are disabled from the event or are medically unstable should be admitted, with the level of care dictated by the clinical status (Table 116.7). Because stroke is a dynamic process, close observation of the acute stroke victim during the first few days is necessary to alert the physician to any neurologic decline that may prompt a change in therapy. Stroke centers typically maintain a “constant observation facility” or “step-down” unit with one nurse for every two or three patients to allow for frequent neurologic checks.

Specific Therapy for Stroke Subtypes

Hemorrhagic Stroke

The management of hemorrhagic stroke is described in Chapter 117.

Ischemic Stroke

Several treatments may be offered to people with ischemic stroke, including intravenous thrombolysis, aspirin, heparin, and blood pressure augmentation to enhance collateral perfusion. Neuroprotective agents are being investigated in human trials, but none are currently approved for clinical use. Similarly, the intra-arterial delivery of thrombolytic agents is a promising treatment, but there is no FDA approved drug for this indication, and only comprehensive stroke centers are offering this therapy. Referral of patients to such centers in a timely fashion is a growing trend, but this is highly specific to individual hospitals and the type of emergency transportation available.

The approval of intravenous thrombolytic agents for the treatment of acute ischemic stroke was driven by the results of a well-designed, prospective placebo-controlled trial of intravenous t-PA given within 3 hours of the onset of acute stroke symptoms (1). Patients were required to have a head CT that was free of hemorrhage, normal baseline laboratory evaluation (Table 116.8), an examination consistent with acute stroke, and the ability to receive drugs within 90 or 180 minutes. Primary outcome measures were neurologic function and disability scales that quantified residual stroke injury. All primary outcome measures reached significance and favored t-PA treatment. In the treatment group, there were 50% more patients who were neurologically normal or near-normal at three months. The mortality rate was unaffected. Three percent of patients died from treatment-associated intracranial hemorrhage. An earlier study found only slight benefit from t-PA if it was given within 6 hours of symptom onset, and there was a higher intracranial hemorrhage rate. *Streptokinase is contraindicated in the treatment of ischemic stroke* because of three intravenous trials showing increased morbidity and mortality rates in ischemic stroke patients who received this agent.

At this time, the use of thrombolytics is limited to intravenous t-PA given within the first 3 hours after stroke by the protocol listed in Figure 116.2 (2). Many hospitals have formed stroke teams headed by neurologists to administer t-PA. If a stroke team does not exist, it is helpful to obtain consultation with a neurologist who is familiar with this form of treatment or to offer immediate transfer to a stroke center. A radiologist or neurologist who has experience in interpreting the noncontrast head CT is essential, because the presence of cerebral swelling, a subtle sign on CT, predicts hemorrhagic transformation. *It is essential that no intracranial hemorrhage be present prior to administering t-PA.*

TABLE 116.7
KEY ELEMENTS TO CONSIDER IN DECIDING LEVEL OF CARE

Condition	ICU		Step-down unit		Medical ward
Need for mechanical ventilation	✓				
Airway compromise requiring tracheal intubation	✓				
Coma	✓				
Need for pressors or continuous intravenous antihypertensive therapy	✓				
Need for pulmonary artery pressure monitoring	✓				
Need for central venous pressure monitoring	✓	or	✓		
Concomitant myocardial infarction	✓				
Rule out myocardial infarction	✓	or	✓		
Need for telemetry	✓	or	✓		
Need for femoral sheath	✓	or	✓		
Need for intravenous or intra-arterial thrombolysis	✓	or	✓		
Depressed consciousness	✓	or	✓		
Hemodynamic stability ^a	✓	or	✓	or	✓
Patient able to protect airway ^a	✓	or	✓	or	✓
Intravenous heparin ^a	✓	or	✓	or	✓

^a Higher levels than medical ward may be required because of other indications.

TABLE 116.8**INDICATIONS AND CONTRAINDICATIONS FOR USE OF INTRAVENOUS TISSUE-TYPE PLASMINOGEN ACTIVATOR (t-PA) FOR ACUTE ISCHEMIC STROKE**

Indication	Contraindication
Clinical diagnosis of stroke	Sustained blood pressure >185/110 mmHg
Onset of symptoms to time of drug administration \leq 3 h	Plts <100,000/ μ L; Hct <25%; glucose <50 or >400 mg/dL
Computed tomography scan showing no hemorrhage or significant edema	Use of heparin within 48 h and prolonged aPTT, or elevated INR
Age \geq 18 y	Rapidly improving symptoms
Consent by patient or surrogate	Prior stroke or head injury within 3 mo; prior intracranial hemorrhage
	Major surgery in preceding 14 d
	Minor stroke symptoms
	Gastrointestinal bleeding in preceding 21 d
	Recent myocardial infarction
	Coma or stupor

aPTT, activated partial thromboplastin time; Hct, hematocrit; INR, international normalized ratio; Plts, platelet count.

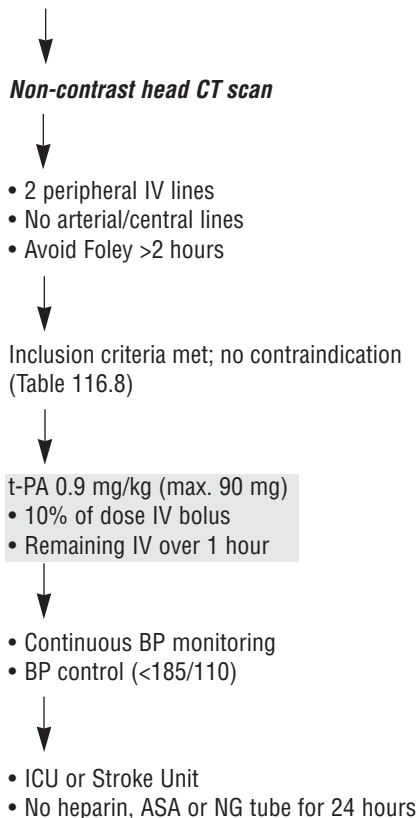

Clinical Diagnosis of Stroke

Figure 116.2 Flow sheet for administering tissue plasminogen activator (t-PA) for acute ischemic stroke. ASA, aspirin; BP, blood pressure; CT, computed tomography; IV, intravenous; NG, nasogastric.

The patient's pretreatment blood pressure should be less than 185/110 mmHg; use of topical nitrates or intravenous labetalol may be necessary to lower blood pressure. However, if the patient's neurologic signs worsen with lowering of blood pressure, the pressure should be allowed to rise again and thrombolysis should be aborted. During the infusion of t-PA and the subsequent few hours, it is also important to maintain control of the blood pressure. For these reasons, t-PA should be given only if the patient's blood pressure and clinical status can be monitored continuously, typically in an emergency department or ICU setting. Sudden neurologic decline during or within 36 hours following t-PA infusion may represent intracranial hemorrhage. If this occurs, the infusion should be discontinued, an immediate noncontrast head CT scan obtained, and a neurosurgeon consulted. Cryoprecipitate may slow bleeding and in this setting should be given presumptively and immediately; this can be discontinued if the head CT does not reveal hemorrhage. Post-thrombolytic treatment involves close neurologic observation and, for the first 24 hours, avoidance of heparin, aspirin, or nasogastric tubes.

The use of aspirin for the treatment of acute stroke has been studied in two large trials (3, 4). Both trials indicate a reduction in stroke and death by 1% within 2–4 weeks with aspirin therapy. Heparin affords no benefit and increases the extracranial bleeding rate if combined with aspirin. Thus, aspirin has a significant effect in lowering morbidity and mortality rates, but the mortality benefit is very small compared with thrombolytic treatment. It is unclear if aspirin would be more effective if given within the first few hours of stroke rather than 1 or 2 days later, as has

been studied in these trials. Current recommendations are to avoid aspirin for one day following thrombolysis (2). If thrombolysis is not performed, aspirin is safe and beneficial if given within the first 1 or 2 days following acute stroke.

Intravenous heparin is frequently used to prevent second stroke or first stroke following TIA. However, the acute effect of heparin has not been well studied, and the routine usage of heparin is being discouraged. Only one trial was large enough to allow analysis of the efficacy of heparin in acute stroke treatment (3), and it showed no benefit for unadjusted-dosage heparin (5,000–12,500 units subcutaneously twice a day). Overdosage with heparin (aPTT >100 sec) in the setting of large strokes may produce intracranial hemorrhage. However, for strokes that are evolving from progressive arterial thrombosis or from recurrent embolism, heparin may halt progression. Although no data from controlled prospective trials exist, current clinical practice of stroke management most commonly employs heparin in this setting. Most neurologists also believe that heparin is indicated for patients with arterial dissection and distal embolism, and for patient with dural sinus thrombosis. Heparin is typically given without initial bolus to avoid intracranial hemorrhage. The use of “bridging” heparin for patients who will receive warfarin is discussed below in the section on atrial fibrillation.

Treatment of acute hypertension during ischemic stroke generally is avoided unless there is coexistent cardiac ischemia, hypertensive nephropathy, or hypertensive retinopathy (Chapter 48). Blood pressure may be reflexively elevated early in the course of stroke and usually declines over the days following the acute event. *Acute reduction in arterial blood pressure may precipitate cerebral ischemia* resulting from reduction in collateral flow to the ischemic penumbra, which lacks cerebral autoregulation and can survive only if some blood flow is maintained. Even minor drops in mean arterial pressure can worsen neurologic outcome. Thus, many neurointensivists *augment* the blood pressure in patients with normal or slightly elevated pressures upon stroke presentation. In some cases, deficits may resolve with this treatment alone. No controlled data exist to support the efficacy of this aggressive treatment, but it underscores the principle that blood pressure should not be lowered.

If the patient has ischemia within the carotid artery distribution, it is important to expedite evaluation of the carotid artery for carotid atherosclerosis. This can be done with carotid ultrasonography, CT angiography (CTA), MR angiography, or conventional angiography. Combining CTA with the initial non-contrast CT scan expedites the discovery of symptomatic carotid disease. If the patient has experienced a TIA or minor stroke, carotid endarterectomy (CEA) is safe and should be offered as soon as possible to medically eligible patients. If CTA is not available, and the patient qualifies for emergent CEA, other procedures to image the carotid artery should be utilized.

ISSUES DURING THE COURSE OF HOSPITALIZATION

Figure 116.1 lists specific items to address following acute treatment. Initial consultation with physical and occupational therapists are important for patients with functional deficits. This should occur on the first or second hospital day to help with discharge planning. Speech therapy or consultation with a therapist who specializes in swallowing evaluation may be helpful to determine the safety of continued oral intake. However, acute dysphagia often resolves in the first few days, and it is common to begin nasoduodenal feeding, followed by an assessment of the need for percutaneous gastrostomy at a later date if the patient fails to improve. A social worker should be involved as early as possible to help with disposition and the financial and emotional issues that the sudden onset of stroke usually brings to bear on the entire family (Chapter 4).

Patients with dysphagia or airway compromise are at high risk for developing aspiration pneumonia (Chapter 66). Aspiration and the use of indwelling catheters increase the risk for infection. As noted previously, fever is detrimental to ischemic brain. The cause for fever should be pursued (Chapter 62), and temperature elevation should be corrected aggressively. Patients with cerebellar hemorrhage or ischemia are of special concern. Swelling from the hematoma or the ischemic brain occurs in a delayed fashion, typically 12 hours to 7 days after the initial event. Due to the anatomy of the posterior fossa, this swelling can compromise drainage of CSF through the aqueduct of Sylvius, causing hydrocephalus. It may also cause direct brainstem distortion, leading to severe hemodynamic instability and respiratory arrest. Hydrocephalus can be managed with osmotic agents and ventriculostomy. However, in both conditions definitive therapy is cerebellar hematoma evacuation or cerebellectomy. Because neurological decline (usually in the form of progressive coma or respiratory arrest) can be rapid, these patients are best managed in an ICU setting and either neurology or neurosurgery consultation should be obtained.

Stroke prophylaxis should be initiated in the hospital setting based on the exact cause of stroke. In general, patients with lacunar stroke not caused by carotid atherosclerosis, atrial fibrillation, or dural sinus thrombosis may be treated with agents that block platelet function. Aspirin at a dose of 75–325 mg/d lowers the risk of second stroke by 22%, is inexpensive, and is generally well tolerated (4). Ticlopidine has been shown to be superior to aspirin. Clopidogrel, 75 mg/d, is marginally more effective than aspirin in preventing combined end-points (stroke, myocardial infarction, and death), but it is significantly more expensive than aspirin. The combination of aspirin and clopidogrel for stroke prophylaxis is marginally better than clopidogrel alone, but also is associated with more bleeding complications (5). Aspirin and extended-release dipyridamole (Aggrenox) have been shown to be superior to

aspirin alone, and should be dosed twice a day if this combination is used. Headache is a common side effect upon initiation of therapy, but if twice a day dosing is maintained, headache clears rapidly. No algorithm for antiplatelet therapy has been studied. However, most stroke centers initiate aspirin alone if the stroke occurs in a patient not taking any antiplatelet agent. If the patient was taking aspirin, either Aggrenox is substituted or clopidogrel is added. With the exception of the settings of atrial fibrillation and dural sinus thrombosis, warfarin is no more effective than aspirin in secondary prevention of stroke (6).

All patients with stroke should have fasting lipid studies measured during hospitalization. A statin agent should be initiated to lower LDL to a target of below 100 mg/dL. Counseling for smoking cessation for smokers should be offered and documented.

Hypertension is the most significant risk factor to modify, with a long-term goal of systolic blood pressures <140 and diastolic pressures <90 mm Hg (7). Although it has never been studied systematically, blood pressure should be lowered slowly over the 3–4 weeks following the event, and it is considered good practice to discharge the patient on at least one antihypertensive. Starting a thiazide diuretic during the hospitalization followed by discharge instructions with proper blood pressure goals is prudent (8). ACE inhibitors may provide additional protection against second stroke beyond their ability to lower blood pressure (9), and therefore are commonly used with a diuretic.

Patients with stroke from atrial fibrillation are at high risk of recurrent stroke. Following a stroke, a patient with atrial fibrillation has approximately a 15% risk of second stroke in the first year if not medicated with an antithrombotic agent. Some debate exists as to the use of oral anticoagulation or antiplatelet treatment in such patients. A summary of a consensus opinion regarding the use of aspirin or warfarin is shown in Table 42.5. The decision is based on age and the presence of risk factors (10). Patients in their thirties with lone atrial fibrillation have a low rate of first stroke and TIA. However, once a patient has a cerebral ischemic event, the risk rises dramatically, favoring treatment. Whatever treatment is prescribed, it is important to educate patients about the signs and symptoms of TIA so that therapy can be adjusted if these events occur.

Heparin is frequently used while initiating warfarin therapy in patients with TIA or stroke secondary to atrial fibrillation. The recurrence rate of stroke following a single stroke or TIA secondary to atrial fibrillation is approximately 1%–2% during the first 2 weeks. Depending on how the individual physician views this risk, some physicians start heparin while oral warfarin is being initiated, while others just start warfarin without heparin. Heparin should probably be avoided during the first few days of large ischemic strokes because of risk of intracranial hemorrhage. For patients with TIA or smaller strokes from atrial fibrillation, warfarin can be initiated at the time of admission.

Patients who experience stroke or TIA with ipsilateral 50% or greater carotid stenosis carry a high risk of subse-

quent stroke or death. For example, a patient with a 70% carotid stenosis who presents with hemispheric TIA has a 26% risk of stroke or death in the next 2 years. Endarterectomy substantially reduces this risk if the surgeon has a complication rate of less than 3% (11). Patients with TIA and minor strokes should be considered for emergent endarterectomy, as discussed above. Because large strokes impair cerebral autoregulation, endarterectomy done in the first few weeks following a significant cerebral ischemic event can cause intracranial hemorrhage. Thus, many surgeons defer surgery for 4–8 weeks. Hospital management in this case should focus on defining the carotid disease, assessing the patient as a surgical candidate, and prescribing prophylaxis until elective endarterectomy is performed. Whether one should prescribe aspirin, aspirin and anticoagulation, or anticoagulation alone for symptomatic carotid disease while awaiting definitive surgery is controversial. Carotid stenting is an alternative to endarterectomy; initial data suggest that it is less morbid than CEA in high risk patients (12).

DISCHARGE ISSUES

Patients either return home, depending on home safety and functional status; transfer to an acute rehabilitation hospital; or transfer to a skilled nursing facility. The goal is to return the stroke patient home as soon as he or she is capable of returning. Assessments from physical, occupational, and speech therapists are essential in making this determination. If the patient is unable to return home but can comply with several (typically three) hours per day of active physical therapy, the patient may be eligible for acute inpatient rehabilitation. Rehabilitation units vary in their abilities to handle concomitant medical issues (e.g., adjusting anticoagulation). In general, a patient may be discharged if the neurologic examination has stabilized or is improving, adequate nutrition has been established, and arrangements have been made so that outstanding medical issues can be managed by the receiving service and adequate evaluation of the cause of stroke can be performed to guide logical stroke prophylaxis. Patients who are incapable of participating in therapy for the requisite number of hours per day or who are cognitively incapable of participating but have reached criteria for acute hospital discharge may require skilled nursing care, with later transfer to an acute rehabilitation setting if they meet appropriate criteria.

It is important to communicate several issues to the primary medical doctor in the discharge summary. These should include the cause of the stroke, the current neurological examination of the patient at the time of discharge, and the steps taken for secondary prevention. Blood pressure goals should be clarified and follow-up of blood pressure and lipid status should be assured. Finally, patients should receive comprehensive counseling on reducing stroke risk.

KEY POINTS

- Management of patients with a sudden change in neurologic status should be approached with a logical algorithm that incorporates accurate diagnosis, rapid (<3 hour) treatment with t-PA if eligible, and coordination of staff to determine patient disposition and immediate therapy. Before t-PA is administered, it is essential that blood pressure be controlled (<185/110) and hemorrhage excluded.
- In general, treatment of acute hypertension should be avoided in the patient with acute stroke.
- Patients with stroke (or TIA) and atrial fibrillation, and patients with dural sinus thrombosis, require anticoagulation, while patients with symptomatic carotid disease benefit from endarterectomy or carotid stenting. In all other stroke causes, antiplatelet agents are the favored form of prophylaxis.
- In addition, modification of risk factors following stroke is critical. Target LDL should be less than 100 mg/dL. All hypertensive patients should receive at least a diuretic prior to discharge. Long-term blood pressure goals are at least BP <140/90 mm Hg, and this is best achieved with addition of an ACE inhibitor as an outpatient. Counseling for smoking cessation should be offered and documented.
- Hospital management of acute stroke patients requires a coordinated effort of therapists and discharge planners to help institute important therapy and expedite patient transfer for more intensive rehabilitation.
- Contact with the outpatient physicians providing follow-up is essential to communicate the diagnosis, prescribed stroke prophylaxis, rehabilitation plan, and maintenance of medications.

INTRODUCTION

Anatomy and Physiology

Increased intracranial pressure (ICP) develops in many acute neurologic disorders and can have serious consequences because of the anatomy and physiology of the intracranial vault. The intracranial vault can be thought of as a compartment made up of the brain, cerebrospinal fluid (CSF), blood, and blood vessels enclosed in the rigid skull. The normal brain constitutes about 80% of the intracranial contents; blood and CSF make up approximately 10% each.

Masses, or any increase in the volume of blood or CSF in the intracranial vault, can lead to increased ICP. In addition, any process that causes an increase in brain water content (edema), such as disruption of the blood-brain barrier as seen in ischemia, infection, trauma, surgical retraction, and tumors, can lead to elevated ICP.

CSF is produced by the choroid plexus located within the lateral and fourth ventricles of the brain. It normally migrates from the ventricles, exits the brain through the foramina of Magendie and Luschka to the basal cisterns, and over the convexities, where it drains through the arachnoid granulations into the venous system. Processes such as meningitis, tumors, hemorrhage, or cerebral

edema can either obstruct the flow of CSF or interrupt the normal CSF absorption-production equilibrium, resulting in hydrocephalus.

Increases in cerebral blood volume can also lead to intracranial hypertension. As cerebral blood flow (CBF) increases, so does the cerebral blood volume (CBV). CBF is influenced by the cerebral perfusion pressure (CPP), the partial pressure of carbon dioxide ($P_a\text{CO}_2$), the partial pressure of oxygen ($P_a\text{O}_2$), and the cerebral metabolic rate of oxygen. CPP is defined as [mean arterial pressure – ICP]. Under normal conditions, autoregulation maintains the CBF over a wide range of perfusion pressures (60–150 mm Hg) (Figure 117.1A) by altering the diameter of distal arterial resistance vessels. Because more than 80% of the blood in the intracranial vault is contained within the cerebral veins and sinuses, CBV can also rise with venodilation, and drugs that alter venous tone can dramatically increase CBV and ICP.

The relationship between CBF and $P_a\text{CO}_2$ is linear (Figure 117.1B), which accounts for the fall in ICP with hyperventilation. As $P_a\text{CO}_2$ decreases, vasoconstriction occurs, decreasing CBV and thus ICP. The relationship of CBF and arterial oxygen content is also linear. However, because of the shape of the oxyhemoglobin dissociation curve, when hematocrit is normal, CBF does not increase until the $P_a\text{O}_2$ is less than approximately 50 mm Hg.

Figure 117.1 Physiologic influences on cerebral blood flow and intracranial pressure (ICP). **A.** Cerebral perfusion pressure autoregulation curve for normotensive adults. Note that cerebral blood flow remains stable over a wide range of cerebral perfusion pressures but becomes pressure passive as the limits of autoregulation are exceeded at both extremes. This curve is shifted to the right in hypertensive adults. **B.** Cerebral blood flow response to changes in P_{aCO_2} and P_{aO_2} . **C.** The relationship between ICP and intracranial volume. Note that as volume is added to the cranial vault, there is no increase in ICP as a result of compensatory mechanisms (Figure 117.2). Once these mechanisms are exhausted, however, ICP increases rapidly as volume is added. (Adapted from Diringner NM. Intracerebral hemorrhage: pathophysiology and management. *Crit Care Med* 1993;21:1593, with permission.)

Cerebral metabolism is closely linked to CBF. Any increase in metabolism, as seen with fever or seizures, results in a rise in CBF. Similarly, a decrease in metabolism, such as occurs with barbiturates and hypothermia, leads to a fall in CBF. Ischemia occurs only if CBF becomes inadequate to support cerebral metabolism.

Pathophysiology

Any process that adds volume to the intracranial vault (e.g., hematoma, tumor, edema) can eventually lead to intracranial hypertension. At first, the intracranial vault accommo-

dates the increase in volume by displacing equivalent volumes of CSF and venous blood into the spinal canal, preventing a rise in ICP (Figure 117.2). Once these compensatory mechanisms are exhausted, ICP begins to rise (Figure 117.1C).

Elevated ICP can cause injury by leading to a global fall in cerebral perfusion, causing ischemia. Initially, as CPP falls, CBF remains constant because of autoregulation. When CPP falls below its lower limit, CBF begins to fall. Initially, the amount of oxygen reaching tissues remains constant because of a rise in brain oxygen extraction. Eventually, oxygen extraction reaches a maximum, and any further decrease in CBF leads to ischemia.

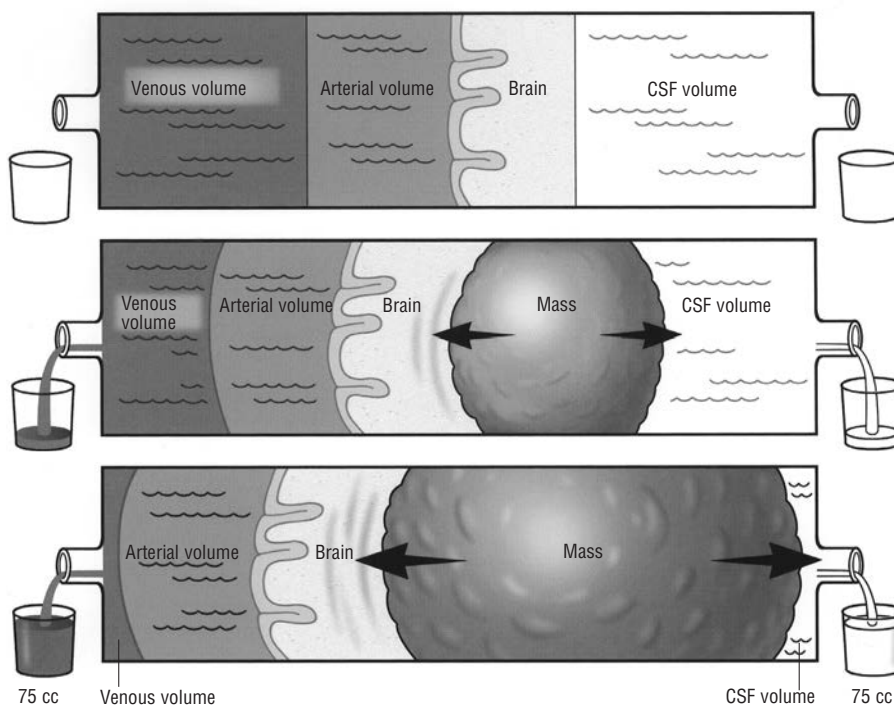

Figure 117.2 Regulation of intracranial pressure. Diagrammatic representation of the intracranial contents and their compensation for an expanding intracranial mass. Cerebrospinal fluid and venous blood occupy about 20% of the intracranial contents (**top**). Displacement of cerebrospinal fluid and venous blood is the compensation for an expanding mass (**middle**). These compensatory mechanisms are exhausted if there is no more cerebrospinal fluid or venous blood available to be displaced. Then, if the mass lesion increases further, intracranial pressure begins to climb (**bottom**). (Adapted from Kanter MJ, Narayan RK. Intracranial pressure monitoring. *Neurosurg Clin North Am* 1991;2:258, with permission.)

Intracranial hypertension can also cause brain injury by producing tissue shifts that can result in *herniation syndromes*. These shifts occur because of the division of the skull into a number of compartments by the falx cerebri and tentorium. As a mass in one compartment grows, the pressure gradients produce tissue shifts and, eventually, herniation of tissue from one compartment to another. These syndromes present with varied neurologic pictures depending on the brain region involved and the tissue shifts that ensue (Figure 117.3).

Evaluation of the Patient

The history of a patient who has suspected increased ICP usually must be obtained from a relative, friend, or witness. Relevant historical issues include the time course of the present illness, as well as prior history of cancer, bleeding

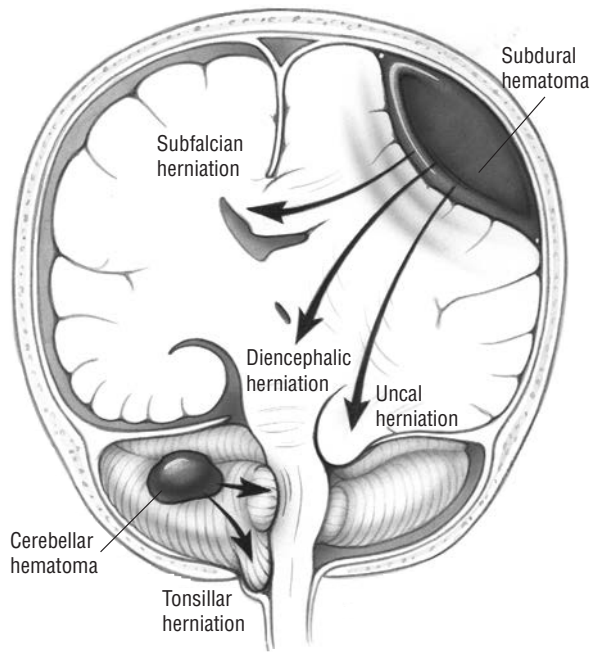

Figure 117.3 Types of brain herniation. Different types of brain herniation caused by isolated areas of increased intracranial pressure. A mass (subdural in figure) located in the cerebral hemisphere may cause a shift of the intracranial contents past midline (subfalcian herniation). Uncal herniation results from a mass in one of the parietal, frontal, or temporal lobes creating pressure on the uncus of the temporal lobe, which then herniates through the tentorium. This can cause direct pressure on the underlying midbrain and third nerve, creating a unilateral dilated pupil. Cerebellar or tonsillar herniation can occur if a mass lesion (cerebellar hematoma in figure) develops in the cerebellum, causing compression of the medulla. This can cause a rapid deterioration, abnormal breathing, flexor or extensor posturing, impaired eye movements, hypertension, and bradycardia. Finally, central herniation (not shown) occurs if the tissue shifts are directed downward through the foramen magnum. These patients usually present with a global decline in level of consciousness and may have sixth nerve palsies. (Adapted from Wijdicks EF, Diringer M, Bolten C, et al. *Essentials of management. Continuum: Lifelong Learning in Neurology*. 1997;3:51, by permission of the Mayo Foundation.)

disorders, warfarin therapy, strokes, cardiac abnormalities, rheumatic fever, oral contraceptive use, hypertension, tobacco use, or connective tissue disorders.

The clinical findings differ depending on the primary cause. For instance, lesions such as tumors or intracerebral hemorrhage (ICH) may present with focal neurologic findings including aphasia and hemiplegia; diffuse head injury may cause a global neurologic decline with loss of consciousness and motor posturing. The *Glasgow Coma Scale* (Table 117.1) is used for patients with a suspected ICP increase to quantify the level of consciousness, define prognosis, and monitor changes. It is important to note that papilledema may take several weeks to develop; therefore, its absence does not exclude elevated ICP, especially of recent onset.

Vital signs can provide early and valuable information regarding ICP. The onset of hypertension and bradycardia can indicate an acute rise in ICP (*Cushing response*), mandating immediate intervention.

Initial Patient Management

During the initial evaluation of a patient with suspected increased ICP, it is essential to ensure adequate airway, breathing, and circulation. *Early intubation* is required for comatose patients (Glasgow Coma Scale score <9) because they often develop airway obstruction, and aspiration can result from diminished pharyngeal tone and lack of adequate cough and gag reflexes. Medications utilized for intubation should be ones that decrease cerebral metabolism and ICP. A fall in blood pressure should be

avoided because this will further reduce cerebral perfusion. Etomidate (0.4–0.8 mg/kg), a non-barbiturate hypnotic, is short-acting and is least likely to cause hypotension. Thiopental (2.5–4.5 mg/kg) is effective in lowering cerebral metabolic rate but more frequently lowers blood pressure. Lidocaine (1–2 mg/kg intravenous) is a useful adjunct in this setting because it minimizes the elevation in ICP from endotracheal stimulation. Midazolam, although very sedating, may not adequately lower ICP and therefore should not be used alone. With adequate sedation, muscle paralysis is usually unnecessary and interferes with the ability to perform neurologic examinations. However, if paralysis is required for intubation, a short-acting non-depolarizing agent, such as mivacurium (0.1 mg/kg), is preferred.

Many patients with elevated ICP have increased blood pressure, which should be managed conservatively. *Lowering blood pressure at a time when ICP is elevated can cause critical reduction in cerebral perfusion pressure and produce global ischemia.* If hypertension is treated, venodilators, such as nitrates, should be avoided because of their ability to further raise ICP.

Once the patient with suspected elevated ICP is hemodynamically stable and the airway is controlled, mannitol (0.5–1.0 gm/kg intravenous) should be given. Hyperventilation to a P_aCO_2 of 25–30 mm Hg should be used only if there are signs of herniation or rapid neurologic deterioration (see later in this chapter). In patients with intracranial bleeding, coagulation status should be checked and rapidly corrected if abnormal.

Neuroimaging

After initial evaluation and stabilization, the next step is to obtain an imaging study. In an emergent situation, brain computerized tomography (CT) is preferred. A CT scan is able to determine whether the patient has an intracranial mass, hydrocephalus, diffuse cerebral edema, subarachnoid hemorrhage (SAH), or intracranial hemorrhage. Because contrast appears very similar to acute blood on CT, *a non-contrast CT should always be obtained first.*

Magnetic resonance imaging (MRI) provides an excellent anatomic image but is not the imaging modality of choice in an emergent situation. The long scan time, patient inaccessibility, and the magnetic field generated by the MRI make monitoring and treating patients difficult. In addition, MRI does not detect acute blood as well as a non-contrast CT scan.

Management of Increased Intracranial Pressure

Patients with a Glasgow Coma Scale score of ≤ 8 , an abnormal head CT scan, and suspected increased ICP require ICP monitoring and admission to an ICU. Several types of monitoring devices exist. In one, a catheter is placed

through a burr hole into a lateral ventricle, which allows for ventricular drainage of CSF as well as monitoring of ICP. However, the infection rate increases over time. A second type of device is a transducer, which is inserted into the brain parenchyma. It allows for continuous ICP monitoring but cannot drain CSF. In addition, this device cannot be recalibrated and is therefore subject to drift.

Increased ICP usually is managed medically, but sometimes it may require surgical intervention. Routine measures for patients with increased ICP include elevating the head of the bed, treating fever aggressively, and avoiding compressing the jugular veins with collars, tape, or large bore catheters. Agitated patients should be sedated to a Ramsay Scale score of 4 or 5. Cerebral metabolism suppressants such as benzodiazepines are preferred. Opiates do not suppress cerebral metabolism and can have deleterious effects on gastrointestinal motility.

Osmotic therapy is usually the next step after sedation in controlling intracranial hypertension. The goal is to produce an osmotic gradient between the intracellular space and the blood, which results in a shift of water out of the intracellular compartment (1). Mannitol is the agent primarily used in the United States. It does not cross the intact blood-brain barrier and decreases ICP in 10–20 minutes. Recently, the use of “super salt” (23.4% saline) has been introduced as an alternative to mannitol. While super salt is effective in lowering ICP, it has not been directly compared to mannitol.

Mannitol is also a potent diuretic. The most frequent error made when administering mannitol is failure to recognize and correct the resultant hypovolemia. When uncorrected, the hypovolemia can lead to a fall in blood pressure (with reduced cerebral perfusion) and renal failure. Often, large volumes of fluids are required to replace the urine output. Because the goal of this therapy is to raise osmolality, the replacement fluid should be isotonic, not hypotonic, saline. Empiric doses of a 20% mannitol solution are 1 gm/kg intravenous every six hours, or 0.25–0.5 gm/kg intravenous, every 3–4 hours. Dosing that is administered as needed when ICP exceeds a pre-determined threshold (usually 20–25 mm Hg) provides good control, often with a reduced total dose.

Mannitol can cause renal failure, although it has been difficult to define the etiology. One factor appears to be failure to clear mannitol between doses. To ensure adequate clearance, measurement of the osmotic gap (the difference between the measured and calculated osmolality) may be helpful. A rise in the gap from baseline or an absolute gap of >20 mOsm/kg is considered evidence of retained mannitol and should prompt a change in dosing. This can easily be accomplished by alternative equi-osmolar doses of mannitol and super salt. Mannitol’s ability to lower blood viscosity may increase CBF, which may be an added benefit.

Mannitol therapy must be used with caution in patients with a history of heart failure because of the initial intravascular volume expansion. In practice, this does not appear to be a significant problem because of its rapid diuretic

effect. In addition, patients with cardiac dysfunction may lose adequate preload if the intravascular space is not adequately replenished. Hypokalemia, hypophosphatemia, and hypomagnesemia are complications of mannitol therapy that can be avoided with close monitoring. Finally, as the patient improves, the hyperosmolar state must be corrected very slowly (over several days to 2 weeks) to prevent rebound cerebral edema.

Hyperventilation effectively lowers ICP, but does so by decreasing CBF. It therefore may cause cerebral ischemia. Thus, *hyperventilation should not be routinely used*, but should be reserved as a brief temporizing measure when there are signs of herniation (dilated pupil or progressive neurologic deterioration) or sudden rises in ICP. Immediately after hyperventilation is instituted, the next line of medical or surgical therapy must be initiated. If hyperventilation is used for a sustained period, its cerebrovascular effects are lost and ICP returns to baseline. At this point, a rise in $P_a\text{CO}_2$ can cause a dramatic rebound increase in ICP; therefore, hyperventilation should be slowly discontinued over several hours.

Steroid therapy (up to 20 mg of dexamethasone every four hours intravenously) may lead to neurologic improvement in patients with cerebral edema associated with brain tumors. There is no demonstrated benefit of steroids in intracerebral hemorrhage, traumatic brain injury, or stroke.

The role of *surgery* for treatment of increased ICP depends on multiple factors, including the type of injury, the condition of the patient, and the location of the injury. Lobectomy is utilized in some patients with traumatic brain injury or tumor who are refractory to medical man-

agement of intracranial hypertension. Recently, there has been increased interest in hemicraniectomy as another surgical option. Initially applied to patients with large strokes and massive edema, it is now being used in patients with head trauma, intracerebral hemorrhage, and severe encephalitis. It offers the advantage of not only increasing the size of the intracranial vault but also in reversing tissue shifts. It is currently being evaluated as primary treatment in patients with traumatic subdural hematomas and underlying cerebral edema.

SPONTANEOUS SUBARACHNOID HEMORRHAGE (SAH)

Approximately 30,000 people in the United States suffer a nontraumatic SAH each year. Rupture of an intracranial aneurysm accounts for about 80% of these hemorrhages. Other causes of non-traumatic SAH include ruptured arteriovenous malformation, bleeding disorders, mycotic aneurysms, sinus thrombosis, or idiopathic SAH. The 1-year mortality rate for untreated aneurysmal SAH is 60%, with one-third of patients dying from the initial event and another 15% dying as a result of rebleeding within 1 month. Aneurysms occur more frequently in females than males (3:2), and peak incidence of rupture is between ages 50 and 60 years.

About 80% of aneurysms are berry or saccular aneurysms found at the base of the brain at the bifurcations of the vessels that make up the circle of Willis (Figure 117.4). Approximately 20% of patients have multiple aneurysms.

Figure 117.4 **A.** Computed tomographic scan of subarachnoid hemorrhage. Subarachnoid hemorrhage (*arrows*) from an anterior communicating artery aneurysm. The amount of blood on this scan represents Fisher grade III, putting the patient at high risk for vasospasm. Also note that hydrocephalus is present, indicated by the dilation of both temporal horns of lateral ventricles. **B.** Cerebral aneurysm. An anterior communicating artery aneurysm (*arrow*) seen on the carotid injection of a cerebral angiogram.

Larger aneurysms are more likely to rupture than those smaller than 3 mm. The formation of aneurysms has been associated with fibromuscular dysplasia, Marfan syndrome, pseudoxanthoma elasticum, Ehler-Danlos syndrome, polycystic kidneys, and coarctation of the aorta. Risk factors for SAH include hypertension, smoking, and heavy alcohol use. Recently it has been recognized that genetics play a role in aneurysm formation, with a very high rate of aneurysms in certain families.

Issues at the Time of Admission

Clinical Presentation

The classic presentation of SAH is the acute onset of a severe headache, often described as “the worst headache of my life,” followed by a brief loss of consciousness in 45% of cases. Nausea and vomiting are also common, but only about 10% of patients manifest focal neurologic signs. Approximately 10% of patients have a seizure at the onset of the hemorrhage. Neck stiffness is very common but may take several hours to develop. A more atypical presentation is seen in patients who have “warning leaks” or sentinel hemorrhages. These patients may complain of generalized headache, nausea, vomiting, or malaise, all of which can develop hours to days before they present to the hospital with more typical symptoms.

The *Hunt Hess SAH classification* and the *Fisher scale* help categorize the clinical and radiographic features of SAH (Table 117.2), and they help define the risk of vasospasm. An SAH patient with a Hunt Hess grade III (or higher) or a Fisher grade III is at highest risk.

Differential Diagnosis and Initial Evaluation

A patient with acute onset of severe headache and a brief loss of consciousness has an SAH until proven otherwise (2). Other disorders that can present in a similar fashion include a ruptured arteriovenous malformation, intracranial hemorrhage, migraine, hypertensive encephalopathy, or, rarely, stroke. These disorders, however, usually have a subacute presentation and are more likely to be associated with focal neurologic signs. Cardiac syncope, seizures, and brainstem stroke can present with loss of consciousness but rarely with acute onset of severe headache.

The initial evaluation always begins with assessment of airway, breathing, and circulation. Once the patient has been stabilized, *emergent head CT without contrast* is the diagnostic study of choice. Head CT has a sensitivity greater than 90% for SAH if performed within 24 hours of symptom onset. The scan determines the patient’s Fisher grade as well as identifies associated intraparenchymal hematoma, intraventricular extension of the hemorrhage, or hydrocephalus. If the head CT is negative and the clinical suspicion is high, a *lumbar puncture* should be performed to look for bloody CSF and xanthochromia; the latter usually develops over several

TABLE 117.2
CLASSIFICATION OF SUBARACHNOID HEMORRHAGE

Grade	Signs and symptoms
Hunt Hess classification	
I	No symptoms or slight headache
II	Moderate-to-severe headache and nuchal rigidity, but no focal or lateralizing neurologic signs
III	Drowsiness, confusion, and mild focal deficits
IV	Stupor, hemiparesis, early decerebrate rigidity, and vegetative disturbances
V	Deep coma and decerebrate rigidity
Fisher scale	
I	No subarachnoid hemorrhage on computed tomography
II	Broad diffusion of subarachnoid blood, no clots, and no layers of blood greater than 1 mm
III	Either localized blood clots in the subarachnoid space or layers of blood greater than 1 mm
IV	Intraventricular and intracerebral blood present, in absence of significant subarachnoid blood

hours after hemorrhage because of the conversion of hemoglobin from lysed red blood cells to bilirubin.

A *4-vessel cerebral angiogram* should be performed quickly in order to identify the type and location of the aneurysm. Other tests that should be ordered include admission electrocardiogram, chest radiograph, prothrombin time/activated partial thromboplastin time (PT/aPTT), urinalysis, chemistries, complete blood count (CBC), electrolytes, and type and screen. An early neurosurgical consultation should be obtained regarding the timing and type of management for the aneurysm.

Indications for Hospitalization and Intensive Care Unit Admission

All SAH patients are admitted to the hospital, almost always to an ICU. Patients who are initially stable may suffer devastating early complications such as rebleeding or acute hydrocephalus and thus require close monitoring. In addition, patients with higher Hunt Hess or Fisher grades are at increased risk for cardiac arrhythmias, heart failure, and neurogenic pulmonary edema (3). Therefore, they require close neurologic and cardiac monitoring. Ideally, these patients should be cared for at specialized centers that are more familiar with the early and late complications of this disease and the treatment options.

Initial Therapy

Blood pressure control is important to prevent the aneurysm from re-rupturing; blood pressure should be maintained in the patient's usual range. If that is unknown, the mean arterial pressure usually is kept below 100 mm Hg. The preferred antihypertensive agents are labetalol or hydralazine, each given as a bolus every 15–20 minutes, as needed. Alternatively, a nicardipine infusion can be helpful.

The patient should be kept calm, quiet, and comfortable, using sedatives if necessary. Activities that could cause abrupt changes in blood pressure or ICP, such as the Valsalva maneuver or coughing, should be avoided to reduce the risk of rebleeding, which is highest in the first 24 hours. The patient is given nimodipine (60 mg po every 4 hours), a calcium channel blocker that reduces ischemic deficits from vasospasm. Phenytoin is given to prevent seizures, and some centers use dexamethasone (4 mg intravenous every 6 hours) to reduce the inflammatory response to the hemorrhage. Adequate analgesia is essential, because it not only keeps the patient calm but also helps treat elevated blood pressure. Stool softeners are given to prevent straining, and pneumatic leg compression and anti-embolic stockings are used to prevent deep venous thrombosis.

Issues During the Course of Hospitalization

Cardiac Complications Associated with SAH

SAH can cause electrocardiographic changes, cardiac arrhythmias, elevated cardiac enzymes, and wall-motion abnormalities. Electrocardiographic abnormalities include inverted T waves, prolonged QT intervals, prominent U waves, and nonspecific ST-segment changes. Cardiac arrhythmias include sinus tachycardia, sinus bradycardia, sinus arrhythmia, and, rarely, malignant arrhythmias, such as ventricular tachycardia, *torsades de pointes*, and asystole. It is believed that the cardiac complications of SAH result from either elevated systemic catecholamine levels or direct sympathetic neural stimulation of the heart, and that they are anatomically and pathologically distinct from ischemic cardiac disease (4).

Most of the cardiac disturbances are benign and resolve spontaneously. Rarely, patients have a striking clinical presentation including pulmonary edema, severe wall-motion abnormalities on echocardiogram, and pump failure. Because the pathophysiology in this situation is unclear, these patients may require prolonged cardiac monitoring and Swan-Ganz catheterization for management. These changes are generally transient, lasting 2–3 days, followed by return to normal cardiac function on follow-up evaluation.

Rebleeding

The risk of rebleeding from a cerebral aneurysm is highest (around 4%) during the first 24 hours after hemorrhage and falls to about 1.5% per day over the next 2 weeks.

Rebleeding is usually a catastrophic event, and 40%–50% of patients who rebleed die. The event is usually heralded by an acute rise in blood pressure and ICP, arrhythmias, and loss of consciousness. Airway, breathing, and circulation need to be readdressed. Repeat head CT reveals new hemorrhage in the subarachnoid space.

Management in the ICU is designed to prevent changes in pressure gradients across the aneurysm wall; thus, care is taken in patients with a ventriculostomy to avoid sudden decreases in ICP caused by draining large volumes of CSF quickly. Rebleeding is best prevented by stabilization of the aneurysm as soon as possible with either surgical clipping or endovascular treatments.

Hydrocephalus

Hydrocephalus can occur shortly after the onset of the hemorrhage (often as a result of intraventricular extension of the hemorrhage), may develop insidiously within the first 2 weeks, or occur in a delayed fashion. Hydrocephalus usually presents as a progressive decline in level of consciousness, is easily diagnosed with a CT scan, and is definitively treated with a ventriculostomy. In patients who present with SAH and acute hydrocephalus, the level of consciousness often improves considerably after ventriculostomy.

Hyponatremia and Volume Contraction

Intravascular volume regulation is impaired in SAH patients. Spontaneous hypovolemia occurs in 30%–50% of SAH patients (despite receiving what is considered to be adequate maintenance fluids), and 10%–35% develop hyponatremia. Although originally thought to be a result of SIADH (Chapter 104), the etiology of hyponatremia in SAH appears to be a complex combination of cerebral salt wasting with an additional component of SIADH. Thus, hyponatremic SAH patients are treated initially by volume expansion with isotonic saline and free water restriction. If hyponatremia persists, mildly hypertonic saline solutions (1%–2% saline) are utilized. Hypotonic solutions should be strictly avoided throughout hospitalization, as should fluid restriction, which is associated with an increased risk of stroke from vasospasm.

Repair of the Aneurysm to Prevent Rebleeding

For most patients who are Hunt Hess grades I through III, and in many centers, grade IV, *early repair of the aneurysm* (within three days of rupture) is the treatment of choice. In more severely affected patients, the location and complexity of the aneurysm, clinical grade of the patient, and difficulty of the surgery play a role in deciding when and if surgery is to be performed. Until recently, the only option for repair of a ruptured cerebral aneurysm was surgical. Recently, *endovascular repair*, in which platinum coils are placed into the dome of the aneurysm to promote thrombosis, has become

widely used. Although this technique was initially reserved for patients who were poor surgical candidates because of aneurysm location or configuration, it is now being applied to a wider range of patients. In a recently completed, randomized, controlled trial of surgery or endovascular treatment, endovascular treatment was associated with reduced morbidity and mortality (5). Early repair virtually eliminates the risks of rebleeding and facilitates the treatment of vasospasm with hemodynamic augmentation (6) (see section on Vasospasm below).

Seizures

Prophylactic anticonvulsant therapy is administered to all SAH patients because of their small, but definite risk of seizures. Phenytoin is generally used, because it is the least sedating drug and can be administered either intravenously or orally. For most patients, therapy should be continued for several days and then discontinued. Patients who have an intraparenchymal clot or focal strokes from vasospasm are at increased long-term risk for seizures, and chronic seizure prophylaxis is often administered, although its efficacy has not been established.

Vasospasm

Vasospasm is the most frequent cause of injury or death in patients who survive the initial aneurysm rupture. Although angiographic vasospasm occurs in 60%–70% of all SAH patients, it only leads to clinically detectable symptoms in about half of those cases. Angiographic vasospasm usually occurs around 3–5 days after the SAH, with maximal narrowing 7–14 days after hemorrhage. The narrowing usually resolves in 2–4 weeks. Patients who develop symptoms are said to have clinical vasospasm (also referred to as delayed ischemic deficit) and demonstrate a decline in neurologic function, including agitation, diminished level of consciousness, or new focal deficits, which frequently fluctuate. The symptoms are exacerbated by hypovolemia or hypotension. Before treating a patient for clinical vasospasm, it is important to make sure that the deterioration is not caused by other processes, such as infection, metabolic derangements, hydrocephalus, cerebral edema, or rebleeding.

Frequent neurologic examinations and transcranial Doppler ultrasound studies are the most common ways to monitor patients for delayed ischemic deficits. Patients at risk for vasospasm undergo hourly neurologic assessments. In addition, some institutions use daily transcranial Doppler studies to monitor blood-flow velocity profiles of the major intracranial vessels, although the test's clinical utility is uncertain.

Factors thought to contribute to delayed ischemic deficit after SAH include vessel narrowing, loss of cerebral autoregulation, and hypovolemia. These observations have formed the basis for the treatment of delayed ischemic deficit with *hemodynamic augmentation*, also known as

hypervolemic, hypertensive, hemodilution (“triple H”) therapy, or hypervolemic, hypertensive therapy. These treatments involve manipulation of blood pressure, intravascular volume, and cardiac output in varying combinations with the goal of increasing CBF and reversing the neurological deficit.

Measures that may be useful in preventing clinical vasospasm include administration of nimodipine, surgical removal of subarachnoid blood, and careful attention to volume status to avoid hypovolemia. With the onset of clinical signs of vasospasm, the first step is to assure that the patient is not hypovolemic. It does not appear that hypervolemia provides any additional benefit unless it results in a rise in cardiac output and blood pressure (7). Patients with cardiac disease may benefit from having therapy guided by a Swan-Ganz catheter. Elevation of blood pressure is believed to increase CBF in the setting of disrupted cerebral autoregulation. In general, blood pressure can be increased by using phenylephrine to raise systemic vascular resistance. Dopamine is sometimes effective but has a high incidence of tachyarrhythmias. In patients with poor left ventricular function, intropes may be necessary. Careful monitoring for cardiac or systemic toxicities related to vasopressor agents is essential (Chapter 25). While the therapy is guided by setting goals for cardiac index and blood pressure, it is important to emphasize that the ultimate goal of therapy is to reverse the neurological deficit. Thus, hemodynamic goals should frequently be reassessed in light of the patient's neurological response to therapy. Therapy is slowly tapered over several days after neurologic deficits stabilize and improve. If symptoms recur during the taper, therapy is increased again until the patient stabilizes. It is important to note that hypertensive therapy is generally reserved for patients whose aneurysms have been repaired by surgery or endovascular coiling.

Newly emerging treatments for vasospasm include transluminal angioplasty and intra-arterial infusion of vasodilators, such as papaverine or nicardipine. *Balloon angioplasty* can dilate vasospastic proximal intracranial vessels with long-lasting effects (8). It is not useful for diffuse distal spasm, because of the small vessel caliber, and can be associated with serious complications, such as artery rupture or displacement of aneurysm clips. *Intra-arterial papaverine* is a potent direct vasodilator. Unfortunately, the effects are short-lived, and it is not without significant risks, including increased ICP, transient neurologic deficits, and respiratory depression. Thus, its use has declined considerably. Although angioplasty has not been evaluated in prospective controlled trials, early experience has been encouraging and its use is becoming routine in many centers.

General Medical Management

Patients with severe neurologic deficits usually remain intubated until they recover a sufficient level of consciousness and their cough and gag reflexes. Although induced

coughing and rigorous suctioning should be avoided during periods of elevated ICP or when the aneurysm that bled has not been repaired, they are essential later in the hospital course. Some patients may not regain the ability to protect their airways and need to undergo a tracheostomy.

Brain-injured patients are hypermetabolic and hypercatabolic and, therefore, aggressive nutritional support is needed. If a patient's neurologic status does not allow him or her to eat safely, then enteral feedings should be initiated as soon as possible (Chapter 15). To avoid aspiration during tube feeding, it is useful to elevate the head of the bed and administer metoclopramide (10 mg every 6 hours). Agents to prevent GI bleeding should also be administered (Chapter 80). Deep venous thrombosis prophylaxis, usually with compression stockings, is also essential. The use of prophylactic subcutaneous heparin is controversial, although its use after repair of aneurysm is becoming more widespread.

Discharge Issues

About 25% of SAH patients survive with good neurologic outcomes. After stabilization and intervention, early consultation with physical, occupational, and speech therapists is critical in determining the amount and type of rehabilitation the patient needs. Social services coordinate the needs of the patient and family with their insurance companies and facilitate the transfer of the patient to the most appropriate rehabilitation facility.

INTRACRANIAL HEMORRHAGE

Intracranial hemorrhage can occur within any of the spaces of the cranium (subarachnoid, subdural, epidural, and intracerebral) and accounts for roughly 12%–15% of all strokes. This section focuses on intracerebral hemorrhage (ICH), an often devastating neurologic disease that presents with signs and symptoms similar to ischemic stroke. The symptoms are often more severe and require ICU admission. Management depends on the size and location of the hemorrhage.

Issues at the Time of Admission

Clinical Presentation

The signs and symptoms associated with an ICH vary with the location and size of the hemorrhage (9). In general, the presentation is similar to that of ischemic stroke (Chapter 116), except that the onset of symptoms is more rapid and headache, nausea, vomiting, and seizures are more common. If the hemorrhage is small, the patient may complain of an acute onset of headache with focal neurologic signs, such as hemiparesis, hemisensory loss, or difficulty speaking. With a large hemorrhage, the patient will quickly become lethargic or comatose.

The most frequent locations for hemorrhage are the putamen (35%), thalamus (10%), caudate (5%), cerebral lobes (30%), cerebellum (15%), and pons (5%). These different locations cause distinct clinical presentations (Figure 117.5). Putaminal hemorrhages present with contralateral hemiparesis, hemisensory loss, aphasia if on the dominant side, and neglect if on the nondominant side. Thalamic hemorrhages usually have prominent sensory findings and vertical eye-movement abnormalities. Patients with cerebellar hemorrhages complain of acute onset of headache, nausea, vomiting, and difficulty walking. Large pontine hemorrhages can be devastating, causing acute quadriparesis, pinpoint pupils, and coma. Lobar hemorrhages produce variable neurologic signs depending on the brain region involved. Caudate hemorrhages usually cause headache, vomiting, confusion, and decreased short-term memory. They also may cause contralateral conjugate gaze paresis, hemiparesis, or hemisensory deficits.

Differential Diagnosis and Initial Evaluation

The differential diagnosis of ICH includes SAH, hypertensive encephalopathy, ischemic stroke, meningitis, encephalitis, subdural hematoma, epidural hematoma, migraine, or arterial dissection. Usually an accurate history and CT scan can easily determine the correct diagnosis.

Figure 117.5 Intracranial hemorrhage. A large right basal ganglia hemorrhage with minimal (5 mm) midline shift. This patient presented with acute onset of lethargy, left hemiparesis, and left-sided neglect.

Multiple causes exist for ICH and vary depending on the age of the patient and location of the hemorrhage. Hypertension is the most common cause in most age groups. Putaminal hemorrhages, followed by cerebellar and pontine hemorrhages, are the most common hypertensive hemorrhages. Blood pressure is often acutely elevated after ICH, and therefore a careful history and evaluation must be performed in order to determine if premorbid hypertension existed.

One of the most common causes of lobar hemorrhages in elderly, normotensive patients is *amyloid angiopathy*. These patients often present with a series of lobar hemorrhages caused by deposits of β -amyloid in the media of the cerebral vessels. Definitive diagnosis is by brain biopsy or autopsy, and care is supportive. Other frequent causes in this age group include bleeding into a tumor, use of anticoagulation or thrombolytic agents, or hemorrhagic conversion of an ischemic stroke. The risk of a hemorrhagic complication with warfarin therapy increases with the length of time on the medication and with over-anticoagulation. Ten percent of ICHs are associated with warfarin or heparin therapy.

In younger patients, the differential diagnosis is extensive, including arteriovenous malformation, illicit-drug use (cocaine, amphetamines), sympathomimetic agents, vasculitis, trauma, cavernous angiomas, embolic stroke, neoplasm, Moyamoya disease, bleeding diathesis, and aneurysms. In general, if the patient is young and normotensive or the hemorrhage is in an unusual location, further evaluation with MRI and/or angiography is necessary to look for an atypical cause.

The initial evaluation, as with most severe neurologic injuries, begins with stabilization of airway, breathing, and circulation. Following this, a more thorough physical and neurologic examination can be performed and head CT without contrast rapidly obtained. The head CT identifies the location and size of hemorrhage, the presence of intraventricular extension, or hydrocephalus. Caution needs to be taken if looking for hemorrhages in the posterior fossa because CT scans can have unusual artifacts that may mask or mimic a hemorrhage in this location. A poor prognosis is seen in patients who are older, have a Glasgow Coma Scale score ≤ 8 , or have volumes of hemorrhage >60 mL, increased blood pressure, intraventricular extension, or hydrocephalus.

Patients who have atypical or difficult-to-delineate lesions on head CT require an MRI or a cerebral angiogram. For instance, a tumor should be considered in any hemorrhage with unusual margins located in the gray-white junction. An MRI with contrast would best define this lesion as well as an arteriovenous malformation. If there is suspicion of an aneurysm, then a cerebral angiogram should be performed as soon as possible.

All patients require routine admission laboratory tests including a coagulation panel. Any coagulopathy should be rapidly corrected.

Indications for Hospitalization and ICU Admission

All patients with an ICH should be admitted to the hospital. Hemorrhages may continue to expand, and, therefore, all patients require close neurologic monitoring. Patients who present with evolving neurologic signs, lethargy, or coma require admission to the ICU. Other criteria include the need for an intraventricular catheter for hydrocephalus, evolving hydrocephalus on scan, cerebellar hemorrhage, electrocardiographic abnormalities, difficult-to-control blood pressure, or need for intubation. Ideally, these patients should be cared for at specialized centers that are more familiar with the early and late complications of this disease and the treatment options (10).

Indications for Early Neurosurgical Consultation

Neurosurgical evaluation is essential for all patients with cerebellar hemorrhage or hydrocephalus associated with any hemorrhage. The role of surgery for hemorrhages in other locations remains uncertain and varies considerably across centers. Patients frequently considered surgical candidates are younger patients who are deteriorating and have superficial hemorrhages. The decision to intervene should be made in close consultation with a neurosurgeon, who can also provide recommendations on timing and placement of an intraventricular catheter for hydrocephalus.

Issues During the Course of Hospitalization

Continued Bleeding

It has recently become apparent that ICH is not a discrete event; many hemorrhages continue to enlarge. In one study, about one-third of hemorrhages extended during the first hour after arrival at the hospital. This occurs more frequently in patients who present early and have large, irregular-shaped hemorrhages. No relationship with elevated blood pressure has been found. The use of recombinant activated Factor VII is currently being evaluated as a means of preventing hematoma enlargement.

Blood Pressure Control

Most patients who present with an ICH have elevated blood pressure. A balance must be sought between lowering elevated blood pressure that may place the patient at risk for further bleeding, cardiac ischemia, or congestive heart failure (CHF), and decreasing the blood pressure so much that cerebral ischemia is risked. Patients with a history of hypertension have altered autoregulation such that CBF falls at "normal" blood pressures and, therefore, are at risk for ischemia if the blood pressure is decreased too aggressively. Recent studies, however, indicate that modest reduction (15%) of blood pressure in hypertensive

patients (mean arterial pressure of 120–150 mm Hg) did not lower cerebral blood flow and was therefore considered safe (11). Another report, however, pointed out that lowering blood pressure too rapidly and aggressively is harmful. With these factors in mind, blood pressure should be treated conservatively with modest reduction of pressure in hypertensive patients, but never below a mean pressure of 100 mm Hg. Labetolol, an α - and β -blocker, is ideal in this setting because it is easy to use and has no effect on ICP. Hydralazine or nicardipine may also be used. Medications such as sodium nitroprusside and nitrates should be avoided because they cause venodilation and elevate the ICP.

Hydrocephalus

Patients with ICH can present with hydrocephalus or develop it over the first few hours after presentation. Patients who are awake may complain of worsening headache, nausea, or vomiting. Signs of hydrocephalus include a decreased level of consciousness, impairment of upward gaze, and sixth nerve palsies. A head CT without contrast should be obtained and a neurosurgeon consulted if hydrocephalus is present. In patients with small hemorrhages, placement of an intraventricular catheter will allow for immediate drainage of CSF and for ICP monitoring. The need for permanent shunt placement will be determined by the neurosurgical consultant. In patients with large hemorrhage and hydrocephalus, the role of a ventriculostomy is much less certain. Mortality in this group is extremely high, and there is concern that a ventriculostomy could worsen midline shift.

Seizures

Approximately 10% of patients with ICH develop seizures, either generalized or focal. Patients with cortical hemorrhage or who present with seizures are often administered phenytoin, with levels maintained between 10–20 mg/dL. Those with posterior fossa or deep supratentorial bleeds are generally not treated with anticonvulsants unless they have a seizure. Long-term anti-epileptic therapy is determined case-by-case, weighing the risks and benefits. Patients with large cortical lesions, strokes, tumors, arteriovenous malformations, or recurrent seizures in the hospital are more likely to require long-term anti-epileptic therapy (Chapter 118).

Treatment of Elevated ICP

The guidelines outlined earlier in the chapter should be followed closely in patients with ICH and elevated ICP.

Surgical Management

Although there are several randomized studies showing no clear benefit of surgery in supratentorial ICH, the

results of these studies vary somewhat, in part because of variations in the timing of surgery and location of the hemorrhage (12). Recent attempts at very early surgery have been complicated by high rates of rebleeding (13). New interest exists in investigating early stereotactic surgery in these patients. At present, however, the neurosurgeon carefully evaluates the location, size, and timing of neurologic decline for each patient before deciding on surgery.

There is clear benefit to *surgical removal of cerebellar hemorrhages*. Patients with mild deficits initially can rapidly worsen because of the close proximity of critical brainstem structures and the fourth ventricle. Therefore, prompt removal is recommended in patients with hemorrhages greater than 2–3 cm in diameter and altered sensorium. Good recovery is often seen even if a large portion of the cerebellum is removed.

General Medical Management

Medical management for ICH patients is similar to that for SAH or other brain injured patients. Attention needs to be focused on pulmonary toilet, deep venous thrombosis prophylaxis, gastrointestinal stress ulcer prophylaxis, and nutrition. These are reviewed in the previous section.

Discharge Issues

Patients who suffer an ICH larger than 60 mL, a thalamic hemorrhage greater than 3 cm in diameter, a pontine hemorrhage greater than 1 cm in diameter, or who are unconscious on presentation all have poor prognoses and a high mortality rate. The utility of these prognostic factors is somewhat open to question because many ICH patients have life-sustaining interventions withdrawn (14), possibly resulting in a self-fulfilling prophecy (15). Patients with smaller hemorrhages or lobar hemorrhages have a better prognosis and chance for functional recovery. Therefore, as for SAH patients, the rehabilitation team and social services need to be involved early.

SUBDURAL HEMATOMA

Subdural hematomas are hemorrhages located in the space between the arachnoid membrane and dura mater. The bleeding can be caused by damage to arteries or veins and usually occurs after a low-velocity head injury. Subdural hematomas are divided into acute, subacute, and chronic, depending on the time course (Figure 117.6). Acute subdural hematomas occur in approximately 10% of all head injuries and present within the first three days after injury. Subacute subdural hematomas present between days 4 and 20 after injury; chronic subdural hematomas present after 21 days.

Figure 117.6 Head computed tomographic scan of acute-on-chronic, subacute, and chronic subdural hematomas. **A:** An acute-on-chronic subdural hematoma with significant midline shift over the right cerebral cortex. The bright signal abnormality within the lesion represents acute blood. **B:** A subacute subdural over the left hemisphere. At this stage the blood in some regions is becoming isodense with the brain parenchyma. **C:** The crescent-shaped hypodense region over the right cerebral hemisphere represents a chronic subdural hematoma. There is also a loss of cortical sulci adjacent to the hematoma and mild compression of the right lateral ventricle.

The majority of chronic subdural hematomas occur in patients older than age 50 because of damage to the bridging veins between the brain and dura mater that become more fragile with age. Thirty-five to 50% of these patients do not give a history of trauma. Predisposing factors for chronic subdural hematomas include chronic alcoholism, brain atrophy, CSF shunts, seizure disorders, coagulopathies, warfarin use, and liver disease.

Issues at the Time of Admission

Clinical Presentation

Subdural hematomas can have a variety of different clinical presentations and therefore can be easily missed; this occurs in up to 40% of patients. Patients with acute subdural hematomas often have a history of trauma. If large, the patient may experience rapid neurologic deterioration, with a decreased level of consciousness and progressive focal neurologic signs caused by the hematoma's mass effect.

Most subdural hematomas result from damage to veins, and therefore the patient may present with an insidious onset of nonspecific symptoms. Eighty percent of patients with chronic subdural hematomas complain of headache, while up to 50% present with hemiparesis and roughly 10% with seizures. Gait disturbances, nausea, vomiting, memory impairment, dysphagia, confusion, lethargy, and urinary incontinence are other common presenting symptoms. Papilledema can be found in up to 25% of patients.

Occasionally a chronic subdural hematoma may become extremely large, despite minimal neurologic signs or

symptoms. As the patient's intracranial compliance decreases, rapid onset of neurologic decompensation can occur, requiring immediate intervention.

Differential Diagnosis and Initial Evaluation

The differential diagnosis includes stroke, transient ischemic attack, meningitis, encephalitis, tumor, hydrocephalus, dementia, abscess, and other processes that may increase ICP. The initial evaluation includes assessment of airway, breathing, and circulation. Once stable, the patient who is suspected of having a subdural hematoma requires a head CT without contrast. If the hematoma is acute, the hemorrhage appears bright. Subacute lesions may have a focus of bright signal with acute blood and a surrounding isodense or hypodense area representing older blood. Occasionally, hemorrhages are entirely isodense relative to brain and very difficult to detect; a CT with contrast or MRI is required. Chronic subdurals are particularly likely to appear hypodense on head CT and therefore difficult to see (Figure 117.6). Radiographic clues include loss of cortical sulci, midline shift, or compression of the lateral ventricle. Along with appropriate imaging, patients with subdural hematomas require basic admission laboratory studies, including metabolic profiles and coagulation studies.

Indications for Hospitalization and Intensive Care Unit Admission

Patients with subdural hematomas should always be admitted to the hospital for observation, evaluation, and management, but not all need to be admitted to the ICU.

Patients with a decreased level of consciousness, rapidly changing neurologic examination, significant midline shift, hydrocephalus, electrocardiographic changes, cardiac arrhythmias, or signs of increased ICP and those requiring intubation should be admitted to the ICU. In addition, some patients undergo bedside drainage of their subdural hematomas in the ICU.

Indications for Early Consultation

All patients with subdural hematomas require a neurosurgical evaluation to address acute management and surgical options. Patients who present with acute subdural hematomas require immediate evaluation by the neurosurgeon in the emergency room; worse outcomes are seen if there is a delay between the initial incident and surgery.

Initial Therapy

Most patients with an acute subdural hematoma should have their blood evacuated immediately. Patients with elevated ICP should be treated as outlined previously. Those with stable neurologic examinations may be observed closely in the ICU or on the floor, with frequent neurologic examinations and monitoring of the vital signs. Triage of these patients should be performed in collaboration with the neurosurgical team. Any patient with a coagulopathy should have it quickly corrected.

Issues During the Course of Hospitalization

Surgical Drainage

Some patients with chronic subdural hematomas and minimal neurologic deficits can be managed conservatively, guided by serial head CT scans. Most patients with abnormal neurologic examinations require surgical intervention. The hematoma can be evacuated either through a burr hole or craniotomy in the operating room. For less complicated chronic hematomas, some surgeons may opt to perform a twist-drill craniostomy procedure under a local anesthetic. A catheter, attached to a collection bag, is placed in the subdural space for drainage of the liquefied hematoma. Patients who undergo this procedure require frequent neurologic assessments and must lie flat for the duration of drainage, which usually lasts 1–2 days. This may present a problem in patients with congestive heart failure or severe chronic obstructive pulmonary disease. Most patients treated with an indwelling drain are given prophylactic antibiotics.

Common complications of these procedures include ICH, reaccumulation of the hematoma, seizures, empyema formation, and pneumocephalus. If the patient requires ICU care or has severe neurologic deficits, they also may be at risk for nosocomial pneumonia, deep venous thrombosis, or stress ulcers.

Seizures

Seizures are relatively uncommon in patients with chronic subdural hematomas (less than 10%). However, some series show a higher risk of seizures after surgical intervention, and therefore most patients who undergo surgical evacuation of the hematoma receive anticonvulsants for at least one week. Patients with a seizure history before the subdural may suffer an increase in seizure frequency after surgical evacuation; long-term therapeutic antiepileptic treatment is recommended (Chapter 118).

Discharge Issues

Discharge issues for these patients are similar to those discussed for SAH and ICH.

COST CONSIDERATIONS AND RESOURCE USE

A financial analysis that reviewed use of hospital resources in the treatment of cerebral aneurysms found that the average cost of treatment of a patient who developed vasospasm at an academic medical center was \$38,400. The highest areas of hospital cost were identified as the ICU bed (29%) and angiography (10.3%), followed by medical supplies (9.6%) and hospital-ward bed (6%). Surprisingly, the cost of the surgery (3.7%) and the multiple CT scans (2%) were ranked relatively low. Strategies suggested to reduce the cost of treatment included (a) developing better means of predicting which patients will develop vasospasm to facilitate early transfer out of the ICU; (b) developing alternative areas outside the ICU to monitor patients for vasospasm; and (c) critically investigating the efficacy of intra-arterial infusions of papaverine to potentially reduce the utilization of angiograms. The prolonged period of risk for vasospasm precludes attempts to shorten overall length of hospital stay. The total cost of caring for patients with ICH in academic medical centers is reported to average more than \$25,000 because of long lengths of stay. One motivation for the use of bedside twist-drill craniostomy in treating subdural hematomas was to reduce the total cost by eliminating operating room and anesthesia costs. This, however, is offset by a longer ICU stay. Further study is warranted.

KEY POINTS

- Initial management of all patients with intracranial bleeding or elevated ICP should address airway, breathing, and circulation.
- If elevated ICP or intracranial bleeding are suspected, an emergent head CT should be obtained as soon as airway, breathing, and circulation have been addressed.

- All patients with suspected elevated ICP should be given immediate empiric therapy with mannitol.
- Early neurosurgical consultation is needed in all subarachnoid, subdural, epidural, and cerebellar hemorrhages and ICH associated with hydrocephalus.
- The major complications of aneurysmal SAH are rebleeding, hydrocephalus, and vasospasm.
- Patients with severe brain injury require pulmonary toilet, nutritional support, deep venous thrombosis prophylaxis, stress-ulcer prophylaxis, and a multidisciplinary approach to rehabilitation and discharge planning.

SCOPE OF THE PROBLEM

Seizures are a common neurological problem; the lifetime risk for having a seizure is approximately 10%. A seizure occurs when a group of neurons fires aberrantly, resulting in a convulsion, behavioral arrest, focal movement, or sensory disturbance—the manifestations depend upon the neural circuitry and the region of brain involved. Seizures may be caused by almost any type of brain injury and many metabolic disturbances. A diagnosis of *epilepsy* implies that a person has a chronic, inherent predisposition toward seizures rather than a transient alteration in the seizure threshold that might occur during a fever or metabolic disturbance. For example, a patient who has a seizure from cocaine toxicity can prevent future seizures by abstaining from further cocaine use, and thus does not have epilepsy. On the other hand, if a patient has a cocaine-related stroke and seizures persist despite abstinence from cocaine, epilepsy is present, and chronic treatment with anticonvulsant medications is necessary. The prevalence of epilepsy is about 0.5%, and the lifetime risk of developing epilepsy is about 3% (1). Although any given seizure typically resolves without sequelae, approximately 25% of patients with epilepsy eventually die as a direct consequence of their condition because of accidents, sudden unexplained death in epilepsy (“SUDEP”), or continuous seizures (status epilepticus). Prompt and complete seizure control is necessary to limit a person’s risk.

Because seizures are even more common in acutely ill patients and epilepsy is often exacerbated by acute illness, all hospital-based clinicians will be called on to evaluate and treat patients with these problems. In this chapter, the evaluation and treatment of hospitalized patients with seizures and epilepsy will be reviewed.

ESTABLISHING THE DIAGNOSIS

Did the patient really have a seizure? Syncope, psychogenic seizures, sleep disorders, movement disorders, stroke, and

migraine can all be mistaken for epileptic seizures. Syncope and psychogenic seizures are the most common mimics. Because the evaluation and treatment of these conditions is much different than for epileptic seizures, it is imperative that a distinction be made. This requires a working knowledge of the common clinical features of the epileptic seizures (Table 118.1), as well as the features of seizure mimics.

Clinical Features of Generalized Seizures

Generalized seizures arise diffusely over both hemispheres. The most common etiologies include metabolic disturbances, inherited disorders that affect neuronal excitability, diffuse brain injuries, and disorders of cortical development. The most commonly encountered generalized seizure type is the *tonic-clonic* seizure. During a tonic-clonic seizure, the entire brain participates in an extremely rapid discharge of neurons, leading to tonic extension of all the muscles lasting for a few seconds. The massive excitatory discharges activate inhibitory cells in the thalamus, which produces a feedback inhibition. Soon the seizure enters a phase of alternating bursts of discharge followed by synchronized inhibitory activity. Clinically this is seen as the clonic phase, in which the extremities may have rhythmic jerking with alternating contraction and relaxation. Typically, at the end of the clonic phase, there are a few final jerks, and then the patient lies unconscious, limp, and exhausted. Post-ictal lethargy and confusion may last minutes-to-days.

Diffuse cortical firing can also be modulated by different circuitry, resulting in other generalized seizure types. *Absence seizures* are most common in children but can be seen in adults. An absence seizure is a brief cessation of movement, sometimes with minor rhythmic motions, such as eyelid fluttering. The usual duration of an absence seizure is less than 10 seconds. *Myoclonic seizures* involve rapid, sudden contraction of a group of muscles, which can be in the extremities, trunk, or neck. These may be unilateral or

TABLE 118.1
MODIFIED INTERNATIONAL CLASSIFICATION
OF EPILEPTIC SEIZURES

Generalized seizures (generalized-onset)

Tonic-clonic
 Absence
 Myoclonic
 Atonic
 Tonic

Partial seizures (focal, localization-related, focal-onset)

Simple partial (no impairment of consciousness)
 Motor
 Sensory (somatic, visual, olfactory, auditory)
 Psychic (dèjà vu, derealization, fear, etc.)
 Autonomic (sweating, gastric sensations, etc.)
 Complex partial (consciousness impaired)
 Partial seizure secondarily generalized

bilateral. A patient with myoclonic seizures may have involvement on the right side on one occasion and the left side on another; however, the disorder is usually a generalized one. Tonic and atonic seizures result in sudden stiffening or loss of tone, respectively. As might be expected, the major morbidity related to these seizures is from falls.

Clinical Features of Partial (Focal) Seizures

Most adults with new seizures caused by a structural brain abnormality will have partial seizures. Partial seizures that remain confined to small brain areas and thus do not impair consciousness are called *simple partial seizures*. The symptoms of a simple partial seizure depend on the part of the brain in which it arises. Simple partial seizures arising in the motor cortex produce rhythmic jerking of the face or an arm or leg. Simple partial seizures arising in the occipital (visual) cortex produce visual hallucinations. Although these simple partial seizures are easy to identify as such, seizures that arise from multimodal or association brain areas give rise to more complicated symptoms. Simple partial seizures arising from the temporal lobes are the most heterogeneous and can produce a wide range of symptoms, including dèjà vu, a sudden unexplained fear of impending doom, or a poorly defined feeling of altered thinking. Frontal lobe simple partial seizures may be even more bizarre and can include features such as asymmetric bilateral posturing and pelvic thrusting. Since many physicians are unfamiliar with these symptoms, partial seizures of temporal or frontal lobe origin often are misdiagnosed as psychogenic seizures.

A partial seizure that spreads to involve enough brain tissue to produce impairment of consciousness is called a *complex partial seizure*. Generally, this requires involvement of bilateral areas of the brain, most often in the temporal lobes. There may or may not be a simple partial phase (aura) to the

complex partial seizure, so the seizures may begin with or without a warning sensation. The most common behaviors seen during complex partial seizures are a brief blank stare, an arrest of motion, and failure to respond meaningfully to surrounding events. Automatic, stereotyped behaviors (automatisms) are common. Partial seizures can spread diffusely, causing a convulsion (*secondarily generalized tonic-clonic seizure*). The spread can be so rapid that the attack is clinically indistinguishable from a tonic-clonic seizure that begins diffusely. Thus, tonic-clonic seizures should still be considered possible evidence of a focal brain abnormality. In patients presenting with tonic-clonic seizures, the patient should be questioned about the presence of common warnings that might suggest a focal onset, such as an epigastric sensation, dèjà vu, an olfactory hallucination, or another sensory symptom. Todd's paralysis or other focal post-ictal dysfunction also suggest a focal onset.

Clinical Features of Seizure Mimics

Syncope is the most common seizure mimic. Although prominent motor manifestations and post-ictal lethargy sometimes allow differentiation of seizures from syncope, these features are often over emphasized. Syncope may be accompanied by behavioral arrest, myoclonic movements, or a convulsion. Seizures may be brief, without movements and post-ictal confusion. Premonitory symptoms and the clinical setting are more consistently helpful in making the distinction. In contrast to the focal symptoms that initiate a partial seizure, syncope is typically heralded by light-headedness, graying of vision, tinnitus, diaphoresis, and nausea. The importance of the clinical context cannot be overstated. When an otherwise healthy patient suffers a convulsion during phlebotomy, it is quite likely because of convulsive syncope. On the other hand, a patient presenting similarly but with acute hyponatremia most likely has had a seizure.

Psychogenic seizures can also be confused with epileptic seizures. The often-used synonym, pseudoseizures, has fallen out of favor because it may cause patients to infer that conscious "faking" is suspected by their physicians. Although the prevalence of psychogenic seizures is probably not high, disproportionate numbers of patients with psychogenic seizures will be encountered in the hospital because anticonvulsant medications fail to control the seizures. Among patients labeled as having "epilepsy" and whose seizures are not controlled with anticonvulsant medications, as many as 25% have psychogenic seizures. A history of psychiatric problems does not strongly suggest a diagnosis of psychogenic seizures, because patients with epilepsy and brain injury also have an increased incidence of psychiatric disturbances. Prolonged, asynchronous, waxing, and waning motor activity may lead one to suspect psychogenic seizures.

Often it can be determined whether a patient has had a seizure based on the clinical information. Electroencephalography (EEG) and imaging may also be helpful if the

diagnosis remains unclear. The sensitivity of the routine EEG for epileptiform discharges is about 40%. An estimated 1%–2% the general population has epileptiform abnormalities. Thus, the positive predictive value will be high if there is a reasonable prior probability of a seizure (Chapter 6). For example, in a patient being evaluated for seizure versus syncope, a positive EEG could raise the probability that the attack was a seizure from 50% to >95%. Given the low sensitivity of EEG, however, a negative study does not exclude the possibility of seizures. As with EEG, the presence of a potentially epileptogenic lesion on brain imaging strongly supports the possibility of seizure, but a negative study is not helpful.

ACUTE MANAGEMENT OF SEIZURES

Because most seizures are self-limited, *the first rule for treating discrete seizures is to do no harm*. The most important action for a health care worker is to position the person to prevent aspiration or orthopedic injury. Aspiration risk can be lowered by turning the patient on his side. Arterial blood gas studies are likely to demonstrate hypoxia and a mixed acidosis. Post-ictal hypoxia and hypoventilation are not usually indications for intubation because they resolve quickly. The acidosis also resolves spontaneously and does not require aggressive treatment. Aspiration pneumonia is a potential complication of convulsions, but there is no evidence that intubation to “protect the airway” reduces this risk.

Tonic-Clonic Status Epilepticus

In contrast to isolated seizures, *status epilepticus* is a medical emergency (2). Until recently, most experts have used an arbitrary seizure duration of 30 minutes for a working definition of status epilepticus. Recently, analysis of isolated seizures suggests that the vast majority of tonic-clonic seizures terminate spontaneously in less than two minutes (3). Therefore, a practical definition of convulsive status epilepticus might be any tonic-clonic seizure that persists long enough for intravenous medications to be prepared for injection. Status epilepticus has an annual incidence in the United States of somewhere between 40,000 and 100,000 cases. Status epilepticus can be caused by any of the factors that cause discrete seizures, and the morbidity and mortality are largely determined by the underlying cause. A long duration of seizure activity is also associated with poorer outcomes.

Systemic morbidity from *tonic-clonic* status epilepticus may be related to transient hypertension, hypotension, hypoglycemia, hypoventilation, hyperpyrexia, or rhabdomyolysis. Drugs used to treat status can cause hypotension, arrhythmias, hepatic dysfunction, and ileus. During prolonged recovery, comatose patients may develop deep venous thrombosis, decubitus ulcers, and aspiration. Neurological morbidity from status epilepticus may be exacerbated by these medical complications but may occur even

if they are not present, perhaps because of excitotoxic injury from ongoing abnormal neuronal firing.

Treatment of status epilepticus should be prompt and well-organized (4). Standard treatment protocols have been shown to result in improved outcomes. One suggested protocol is shown in Figure 118.1. The “ABCs” (airway, breathing, and circulation) come first. Routine laboratory studies should be drawn and sent at the same time that intravenous access is established. Blood glucose level should be measured using a fingerstick kit. Glucose and thiamine should be given rapidly if warranted. Computed tomography may be performed early in the course of the evaluation but should not delay anticonvulsant therapy.

Drug treatment of status epilepticus should be aimed at rapid cessation of seizure activity. Benzodiazepines are the first-line therapy, because of their broad spectrum of action, ability to be administered rapidly, and rapid onset of action. *Lorazepam* redistributes out of the brain less rapidly than *diazepam* and therefore has a more sustained anticonvulsant effect (5). The recommended dose of *lorazepam* is 0.1 mg/kg intravenously. The chief drawbacks of the benzodiazepines are a brief duration of action, sedation, and respiratory depression.

Because the benzodiazepines will not have a prolonged effect, *phenytoin* or *fosphenytoin* also should be given promptly. The recommended initial dose is 20 mg/kg intravenously. If seizures persist, an additional 10 mg/kg can be given intravenously. The “therapeutic range” quoted by laboratories is irrelevant for patients with status epilepticus; terminating the seizure is far more important than avoiding mild dose-related toxicities such as sedation, tremor, and ataxia. Levels up to 30 mg/dL may be useful. Phenytoin should be administered as *fosphenytoin*, a phenytoin prodrug, unless the preparation is not available. In contrast to phenytoin, *fosphenytoin* is water-soluble and does not require propylene glycol as a solvent. Because much of the cardiovascular toxicity of intravenous phenytoin therapy is related to this vehicle, *fosphenytoin* can be administered rapidly (up to 150 mg/min rather than 50 mg/min) with less risk of cardiovascular or local tissue toxicity. Because phenytoin has intrinsic cardiovascular effects, continuous electrocardiographic and blood pressure monitoring are recommended during administration of either preparation. *Fosphenytoin* is labeled in “phenytoin equivalents” so that there is no need to convert the dose based upon the molecular weights of the preparations. For the phenytoin-allergic patient, administration of another intravenous medication is necessary. *Phenobarbital* and *valproate* are potential candidates, with the latter having the advantage of being structurally distinct from phenytoin (making an allergic reaction very unlikely). *Valproate* is not associated with cardiovascular or respiratory side effects, thus allowing a very rapid infusion (as little as 5–10 minutes for a loading dose of 20 mg/kg).

If the seizures do not stop with the administration of first-line, intravenous anticonvulsants, general anesthesia

Figure 118.1 A protocol for management of status epilepticus. Arrows indicate the time at which the intervention should be completed. Treatment should progress until clinical and EEG seizures abate. Acceptable alternatives include: (1) IV phenobarbital before starting general anesthesia; (2) Propofol (in adults) or midazolam in place of pentobarbital

should be initiated promptly. Pentobarbital, midazolam, and propofol are commonly used in this setting. If the patient has not yet been intubated, this should be done, and a central line must be placed. Pressors are typically required to maintain blood pressure. Following a loading dose, the anesthetic agent is titrated under EEG monitoring until seizures stop and a burst-suppression pattern is achieved. The optimum depth and duration of anesthesia is unknown. Typically, deeper, more-prolonged anesthesia is tried if initial measures fail.

Unless the seizures abate promptly and the patient improves neurologically, EEG is necessary to manage patients in status epilepticus. It is also needed at times to confirm the diagnosis. Some patients with psychogenic seizures have been intubated and anesthetized, with all of the attendant risks, before clinicians confirmed the true diagnosis. EEG is also necessary to exclude ongoing seizure activity after the movements stop. Thus, EEG is always indicated in patients

who have been pharmacologically paralyzed to facilitate intubation or to treat hyperpyrexia, hypertension, or rhabdomyolysis. EEG may also provide prognostic information. Finally, as noted above, EEG is necessary to measure the depth of anesthesia when treating refractory status epilepticus.

Non-Convulsive Status Epilepticus

Tonic-clonic status epilepticus is a dramatic condition that comes to medical attention immediately. Patients may also have subtle, continuous, non-convulsive seizure activity. It is important to distinguish the different forms of non-convulsive status epilepticus because their treatments are very different. Absence status can occur in adults or children who have discrete, absence seizures. It is characterized by a prolonged twilight state with variably altered consciousness. Absence status is not clearly harmful; recovery is almost instan-

taneous after the seizure activity abates. Thus, therapy should not expose the patient to risks that would be acceptable for treating convulsive status. Simple partial status is characterized by retained consciousness with restricted continuous focal seizure activity, such as tremulous movement of one arm. Episodes sometimes are precipitated by severe hyperglycemia (*epilepsia partialis continua*) and may respond to glucose control. Simple partial status can be very resistant to treatment and may persist for months-to-years. Complex partial status may be a difficult clinical diagnosis, often presenting with fluctuating encephalopathy or behavioral disturbance. The neurological sequelae of simple and complex partial status depend largely on the amount of tissue involved and the duration of the seizure activity. Patients with simple partial status rarely have lasting consequences. Patients with complex partial status may develop mild-to-moderate neurological deficits if the seizure activity lasts for more than a few days. Although partial status should be treated aggressively with anticonvulsants, general anesthesia is typically not necessary. Another form of non-convulsive status can be seen in patients who initially have tonic-clonic seizures that eventually seem to stop. The sole clinical feature may be failure to return to baseline function. At times, subtle motor manifestations such as eye or mouth twitching may be present. EEG is necessary to confirm the diagnosis and guide treatment. The treatment in this setting is with anticonvulsants or anesthetic agents, with the goal of abolishing both clinical and electroencephalographic seizure activity.

Preventing Status Epilepticus

Given the severe consequences of status epilepticus, prevention is highly desirable. Patients at risk for recurrent seizures, especially those with a history of status epilepticus or seizure clustering, should be offered *rescue medications* to be used to interrupt seizure clusters and abort prolonged seizures. Options include lorazepam 1 mg sublingual, diazepam 10–20 mg rectal gel, and midazolam 10 mg intravenous solution (2 cc) administered by syringe into the mouth. The later two options can be administered by a family member while the patient is having a seizure. Although rescue medications clearly abort seizure clusters, the evidence that they impact status epilepticus is less direct. Nevertheless, since rescue medications have gained increased acceptance and early treatment of seizures has extended beyond the emergency room to paramedics (4), the incidence of status epilepticus as a discharge diagnosis has fallen steadily in California over the last decade (6).

EVALUATION OF THE PATIENT WITH SEIZURES

New Onset Seizures

The evaluation of a new seizure is different than for a recurrent seizure in someone who already is known to have

epilepsy. For the patient with a new seizure, the most important question is *whether the seizure is caused by an identifiable underlying cause*. Emergency diagnoses that need to be considered include acute metabolic disturbances, intoxications (including the patient's regular medications [7]), stroke, intracerebral hemorrhage, meningitis, and encephalitis. Complete blood count, glucose, electrolytes, renal function, liver enzymes, calcium, and magnesium should be checked. A urine toxicology screen should be ordered if an obvious cause is not found on the initial evaluation. Accurate diagnosis of the etiology has immediate treatment implications in some cases, as shown in Table 118.2.

If a metabolic cause for new seizures is not identified, brain imaging and EEG should be considered. While many patients will require both studies, a rational approach based on the likely causes in children and adults is possible. Because the most common definable etiology in children is a genetic seizure predisposition, EEG should be considered first in neurologically intact children with new seizures, unless there is clinical suspicion for an acute neurological process that requires immediate imaging. *Adults rarely have new seizures on a purely genetic basis*. Imaging should be ordered first, because a positive study often makes the EEG superfluous. In children and adults, the complementary study should be ordered if the initial study is unrevealing.

Magnetic resonance imaging (MRI) is superior to computed tomography (CT) for defining almost all possible structural seizure etiologies. CT is often ordered acutely in the emergency room to exclude acute neurological etiologies, such as infections or strokes. Follow-up for these patients should include MRI to define subtle lesions, including tumors and cortical malformations, that are often missed on CT.

Patients with Established Epilepsy

When a patient with epilepsy has seizures, the main concern (after the patient becomes medically stable) is determining the reason for anticonvulsant failure. The two possible reasons are an inadequate amount of medication or an inadequate medication effect.

Reasons for an inadequate amount of medication include prescribing doses that are too low, adherence problems, and altered bioavailability of the medication. A common mistake made by physicians is to base the dose of medicine on the serum "therapeutic range." In fact, many patients require higher levels to optimize protection, and they can achieve such levels without suffering side effects. Serum anticonvulsant levels are most helpful when physicians help patients find their individualized "therapeutic level" that reflects the amount of medicine that can be taken without dose-related, neurological side effects. Common reasons for patients taking less than the prescribed dose include forgetfulness, frustration with side effects, and/or lack of efficacy. Altered medication absorption, metabolism, or clearance should be sus-

TABLE 118.2**SEIZURES REQUIRING SPECIAL TREATMENT CONSIDERATIONS**

Etiology	Treatment consideration
Alcohol withdrawal Illicit drugs	Phenytoin ineffective, benzodiazepines indicated Cocaine, amphetamines, and phencyclidine commonly cause seizures; marijuana and hallucinogens rarely, if ever, cause seizures (the latter drugs should not be considered likely precipitants)
Medications	
Isoniazid	Anticonvulsants ineffective; treat with IV pyridoxine or benzodiazepines if pyridoxine not available
Theophylline, tricyclic antidepressants	Seizures may be refractory to anticonvulsants without hemodialysis
β-lactam and flouroquinolone antibiotics	Benzodiazepines likely superior to phenytoin
Flumazenil	Seizures likely in patients on benzodiazepines plus proconvulsant medicines
Cyclosporin, tacrolimus	Seizures represent dose-related toxicity, associated with posterior leukoencephalopathy
Meperidine, tramadol	Naloxone may exacerbate seizures
Foscarnet	May require calcium or magnesium
Electrolyte disturbance	
Hyponatremia	Correct hyponatremia judiciously to avoid pontine myelinolysis
Hypernatremia	Seizures occur during treatment because of cerebral edema
Hypocalcemia, hypomagnesemia	May temporize with anticonvulsants, correct imbalance
Hypo- and hyperglycemia	Partial seizures common; test fingerstick for hypoglycemia at presentation, correct imbalance
Renal failure	Free levels of protein-bound medicines (valproate, phenytoin) underestimated by standard lab tests; medicines with significant renal clearance (gabapentin, levetiracetam, oxcarbazepine, topiramate) require dose adjustment
Hepatic failure	Seizures often caused by other metabolic abnormality or medicine
Porphyria	Avoid enzyme-inducing anticonvulsants; levetiracetam and gabapentin preferred
Hypertensive encephalopathy	Short-term use of anticonvulsants may help stop seizures (thereby decreasing blood pressure)
Eclampsia	Magnesium sulfate superior to anticonvulsants

IV, intravenous.

pected when a patient who has had well-controlled epilepsy suddenly starts having seizures. This is a common occurrence in growing children. It also occurs when patients have changes in thyroid, hepatic, or renal function. Medication interactions can also lead to altered metabolism of anticonvulsants. Vomiting or diarrhea may change absorption of the medication, resulting in lowered serum levels.

If declining anticonvulsant levels do not explain a patient's seizures, other reasons for lack of medication efficacy should be considered. Most importantly, the clinician should ask if the medication is known to be effective for the patient's type of seizures. All available medications (except ethosuximide) have demonstrated efficacy for treating partial seizures and tonic-clonic

seizures. Patients with generalized, non-convulsive seizures (absence, myoclonic, and atonic seizures) often have poor seizure control or even exacerbation of their seizures with "narrow spectrum" medications such as phenytoin and carbamazepine. "Broad spectrum" medications, such as valproate, lamotrigine, topiramate, and zonisamide, can be effective for all types of seizures (1). Other reasons for lack of medication efficacy relate to patient-specific factors that make seizures more difficult to control, including sleep deprivation, drug use, seizure-inducing medications, infections, and metabolic disturbances. If a patient has had good seizure control and one of these precipitants is present but can be addressed, the patient may not need to have a change in medication to achieve good control again.

TREATMENT CONSIDERATIONS

Deciding Whether to Use Anticonvulsants

Treatment for patients with provoked seizures involves treating the causative event. The temperature should be lowered in patients with febrile seizures, glucose should be given for hypoglycemia-induced seizures, and drug detoxification programs should be considered for patients with seizures related to illicit drug use. Sometimes, the provocative factor requires transient treatment with an anticonvulsant. For example, ethanol withdrawal seizures require treatment with benzodiazepines to prevent status epilepticus and delirium tremens (Chapter 122).

The decision to treat new, unprovoked seizures is based on the risk of recurrence weighed against the potential for medication side effects. If a patient has had more than one unprovoked seizure, the risk for recurrence is extremely high and anticonvulsant medication is warranted in most cases. Thus, in a patient presenting with a “new” seizure, a history suggesting prior seizures (including unrecognized simple partial seizures) should prompt anticonvulsant treatment. When a patient has had only one unprovoked seizure, the decision to start anticonvulsants is less clear. In the past, non-randomized studies suggested little benefit in this setting. Recently, randomized studies have shown that taking an anticonvulsant decreases the risk for recurrence by half, but does not change the person’s underlying predisposition for seizures (i.e., the person has the same risk for seizures when they taper off medicine in the future) (8). This relatively modest benefit may still be worth potential side effects for some adults, especially those at high risk for recurrence (those with structural brain damage and/or EEG abnormalities).

Social considerations are sometimes important as well. Patients involved in high risk activities, such as driving or working with machinery, may choose to do everything possible to decrease the risk of a seizure recurrence. Most of these social considerations are not relevant for children. Additionally, school-aged children may be especially bothered by cognitive or behavioral medication side effects. Thus, children are rarely treated for a single seizure.

Occasionally, patients at risk for seizures may be treated with anticonvulsants, even if they have not yet had a seizure. For example, patients with acute neurological injuries are at increased risk for seizures. There is some evidence from patients with acute, closed-head injuries that short-term prophylaxis with phenytoin reduces the risk of acute seizures, though it does not change the long-term risk. Especially for patients in whom seizure-associated intracranial pressure or blood pressure elevations might be devastating (e.g., patients at risk for herniation or re-bleeding after aneurysmal rupture), short-term prophylaxis is often undertaken, despite the lack of evidence to support this choice (Chapters 116 and 117).

Patients Requiring Anticonvulsants

The bewildering number of anticonvulsants speaks to the imperfect nature of the medications. Even so, most patients with epilepsy are able to gain control of their seizures. Studies show little-to-no difference in efficacy between medications, provided that the appropriate medication is being used for a given seizure type (1). Thus, the decision to start with a given medication may be based on potential side effects, pharmacokinetic considerations, and price. A detailed description of the individual agents is beyond the scope of this chapter, but Table 118.3 lists key attributes of commonly used antiepileptic drugs.

If a patient with epilepsy has seizures caused by a drop in anticonvulsant level, care should be taken before adjusting the chronic dosage of the medicine. Low levels resulting from missed doses should be addressed by finding out why the patient misses doses, not by increasing the ordered dose. Low levels resulting from drug interactions or medical problems (e.g., diarrhea) require attention to the underlying problem. In the hospital, patients may have anticonvulsant levels fall because of the inability to take medications orally. When this becomes an issue, consideration should be given to replacing the dose with intravenous medicine until the patient can take an adequate dose of the regular medicine. If a medication change is required, a general rule is to adjust the dosage using the smallest available increment. Since phenytoin exhibits non-linear kinetics, small adjustments in dosage may result in large changes in the serum level. Large changes in carbamazepine, valproate, topiramate, and lamotrigine dosages are often poorly tolerated, producing nausea or sedation.

When a patient continues to have seizures despite treatment with an appropriate anticonvulsant, the chance that the next medication selected will render him seizure-free is about 11%. Subsequent trials are even less likely to be successful (9). When these patients are admitted with seizure exacerbations and injuries, hospital-based physicians should consider referring the patients to a tertiary care epilepsy clinic.

Patients who fail to respond completely to the first 2–3 medications should be referred for inpatient video/EEG monitoring. Recordings obtained during the attacks may suggest that the patient is suffering from a seizure mimic that will not respond to anticonvulsants. Not infrequently, a patient is found to have a seizure type that might be better treated with a different anticonvulsant. Many patients with refractory seizures will have a potentially operable seizure focus (even if not visualized by neuroimaging). Surgical treatment offers a high chance for seizure control (50%–90% chance, depending on the underlying pathology) with only a modest risk (10). Other surgical options when anticonvulsants fail to control epileptic seizures include palliative procedures, such as vagus nerve stimulation or corpus callosotomy. Finally, a ketogenic diet often helps to bring seizures under control in children (adults

TABLE 118.3
ANTICONSULSANTS

Medication	Efficacy	Greatest concern for:	Potential interactions
Phenobarbital	P, GTC	Sedation, rash, liver, blood dyscrasias, joint fibrosis	Induces hepatic enzymes
Phenytoin	P, GTC	Acute cardiovascular, rash, blood dyscrasias, liver, hyperglycemia	Induces hepatic enzymes
Carbamazepine	P, GTC	Arrhythmias, rash, blood dyscrasias, liver, hyperglycemia, hyponatremia	Induces hepatic enzymes
Sodium valproate	All	Encephalopathy, liver, blood, pancreatitis, hyponatremia	Inhibits hepatic enzymes
Felbamate	All	Liver, blood dyscrasias	Variably induces or inhibits metabolism
Gabapentin	P, GTC	None clearly associated	Renal clearance
Lamotrigine	All	Rash, blood dyscrasias, liver	Does not alter levels of other medicines but susceptible to inhibition or induction of its own metabolism
Topiramate	All	Nephrolithiasis, angle closure glaucoma, oligohidrosis, rash, cognitive dysfunction	Increases phenytoin levels, decreases contraceptive levels
Tiagabine	P, GTC	Encephalopathy, non-convulsive status epilepticus	Does not alter levels of other medicines but susceptible to inhibition or induction of its own metabolism
Oxcarbazepine	P, GTC	Rash, hyponatremia	Induces hepatic enzymes
Levetiracetam	P, GTC	Behavioral, blood	Renal clearance
Zonisamide	All	Nephrolithiasis, rash, blood, heat stroke	Does not alter levels of other medicines but susceptible to inhibition or induction of its own metabolism
Ethosuximide	Absence	Rash, blood, lupus	Inhibits hepatic enzymes

GTC, generalized, tonic-clonic seizures; P, partial seizures.

Rash includes potential for Stevens-Johnson syndrome and other severe rashes. Blood dyscrasia includes aplastic anemia, severe leukopenia, and thrombocytopenia. Enzyme inducers typically decrease levels of susceptible medications including hormone contraceptives, while inhibitors increase levels.

have much less efficacy due to difficulty maintaining consistent ketosis) (1).

DISCHARGE PLANNING

Because most epilepsy management takes place in the outpatient setting, a smooth transition from the hospital to the clinic is essential. For patients who have started new anticonvulsants, had anticonvulsant doses changed, or changed other medications that might interact with their anticonvulsants, the timing of the follow-up visit should be dictated by the pharmacology of the drug. Ideally, one should wait long enough for levels to reach steady state, but prolonged waits may put the patient at risk for either seizures or toxicity. Because much of patient's stay is likely to have been marked by encephalopathy, there may have been insufficient time to assimilate new recommendations or instructions. Written medication schedules are useful,

particularly if the medication is being titrated. Patients may need to be counseled and re-counseled about safety issues (particularly driving and other high-risk activities) and the importance of medication compliance. Whenever family or friends can be involved in the discharge planning, the chance of miscommunication is decreased (Chapter 5). For disabled patients and patients who live alone, nursing visits may be valuable. For patients who cannot drive, discharge plans should include transportation to outpatient visits.

KEY POINTS

- Careful history, EEG, and imaging are usually adequate to distinguish seizures from common seizure mimics, such as syncope and psychogenic seizures.
- Most seizures stop promptly and, in general, a minimalist therapeutic approach is warranted.

- Status epilepticus is a medical emergency that is best addressed with a protocol directed at rapid cessation of seizures.
- Patients with new seizures require prompt evaluation for the underlying cause of the seizure.
- A sizable minority of patients with epilepsy will not gain complete control of their seizures through anti-convulsant management, and these patients should be evaluated for other treatments, including surgery.

Depression in the Hospitalized Patient

119

Richard J. Goldberg

INTRODUCTION

Depression is a common problem in the medical inpatient setting. It is found in 10%–26% of general inpatients, more than 25% of patients after stroke, more than 20% of patients after myocardial infarction, about 33% of patients with HIV infection, and 25% of cancer patients (1). Because of its prevalence, its significant undertreatment, and the existence of effective therapies, depression was an early priority disorder for the development of clinical practice guidelines (Chapter 13) by the Agency for Healthcare Research and Quality (2). This chapter reviews the diagnosis of depression in medical inpatients and the use of antidepressants in that population.

CARE OF THE HOSPITALIZED PATIENT

Problems in Defining Depression in Medical Inpatients

There is no laboratory test for diagnosing major depression. Rather, the diagnosis is made by identifying a constellation of symptoms (Table 119.1). Unfortunately, in medical inpatients it may be difficult to tell whether some of the symptoms are caused by depression or by an underlying medical problem. For example, patients may have trouble sleeping because of pain, poor appetite because of nausea, fatigue because of anemia, or trouble concentrating secondary to steroids. Because of such confounding factors, some researchers have advocated relying more on the psychological aspects of depression, such as anhedonia, feelings of hopelessness, or excessive guilt.

Hospitalized patients face a number of stressors, including uncertainty, disfigurement, alienation, and possible death. They are cut off from their usual social supports and separated from their social context. If a physician is confronted with a medical inpatient with significant depressive symptoms, the problem is to determine how much of the “depression” is a result of direct medical effects, how much is caused by psychosocial distress, and how much may actually represent a major depressive episode. Although there is no way to reliably sort out these contributing factors, this chapter outlines a clinical strategy that can address them in hospitalized patients.

Strategy for Evaluating and Managing Depression in Medical Inpatients

Step 1: Biomedical Issues

It is a mistake to dismiss a depressed patient by thinking, “Wouldn’t I be depressed if I were that sick?” Instead, as a first step it is important to identify and correct, to the extent possible, every medical problem that could be contributing to depressive symptoms. This might involve treating pain, blood gas abnormalities, metabolic abnormalities (e.g., hypercalcemia or hyponatremia), or severe anemia. Psychiatric consultants often find that presumed “depression” in the medical setting turns out to be delirium secondary to medical disorders (Table 119.2) or medications (Table 119.3) (3).

The medical workup of depression is determined by the presence of specific medical conditions that potentially affect the central nervous system. For example, although neuroimaging does not play a role in the routine evaluation of depression, it may be indicated in patients with an

TABLE 119.1
DIAGNOSTIC CRITERIA FOR MAJOR DEPRESSION

Core symptoms

Depressed mood
Anhedonia

Other symptoms

Appetite change or weight change ($\geq 5\%$)
Sleep disturbance
Psychomotor agitation or retardation
Fatigue
Feeling worthless or guilty
Poor concentration
Suicidal thoughts

A total of at least five symptoms, continuously over two weeks including one of the “core” symptoms, is necessary to diagnose major depression.

underlying disease that frequently involves the central nervous system (e.g., lung cancer, breast cancer, multiple myeloma, or AIDS). In elderly patients with depressive symptoms and in those for whom dementia is a possible diagnosis, a comprehensive dementia evaluation should be performed.

Because of the high frequency of its coexistence with depression, *substance abuse* always should be considered. Sedative substances, notably alcohol and benzodiazepines, as well as stimulant withdrawal, are common causes of depressive symptoms. Because it is difficult to diagnose depression in the presence of active substance use, the latter should be regarded as the primary diagnosis and management priority.

Step 2: Psychosocial Assessment

Medical inpatients with depressive symptoms face significant psychosocial issues that need to be identified and addressed. In patients who are too medically ill, questioning about psychosocial issues may need to be deferred. However, many depressed patients feel overwhelmed, isolated, guilty, or are grieving their loss of health. Sometimes, simply allowing patients to vent such feelings and providing reassurance is sufficient to assuage distress and lower depressive symptoms. At other times, it may be necessary to arrange for the involvement of the family, a social worker, a minister, a psychologist, or a psychiatrist. The more acute the emotional distress, the more likely it is to benefit from psychosocial support or to resolve spontaneously as the medical condition improves. Although antidepressants

may help relieve some depressive symptoms, medication alone should not be substituted for the personal supportive interaction.

Step 3: Use of Antidepressants

If medical and psychosocial issues have been addressed and the patient remains depressed, the clinician needs to

TABLE 119.3
EXAMPLES OF MEDICATIONS AND SUBSTANCES CAUSING DEPRESSIVE SYMPTOMS

Alcohol	Corticosteroids
α -Methyl dopa	Interferon

Anticonvulsants	Reserpine
Barbiturates	Sedatives
Benzodiazepines	Stimulant (withdrawal)
Cimetidine	Thiazides
Clonidine	

decide whether to use antidepressant medication. This decision is made (after steps 1 and 2) on the basis of the number and severity of “target symptoms”. That is, if the patient has depressive target symptoms (e.g., impaired sleep, depressed mood, poor appetite, or low energy) that are severe enough to be impair function and cause distress, then the patient should be started on an antidepressant.

A difficult challenge is to decide whether depressive symptoms in the medically ill patient represent a “normal” adjustment to illness or so substantially impact the individual to warrant a trial of antidepressants. If depressive symptoms are severe enough and have been present at least two weeks, antidepressants may be indicated even if the symptoms are thought to represent a “reaction” to illness. The presence or absence of some “precipitating” factor does not predict whether symptoms will or will not respond to medication.

Suicide Evaluation

Because the risk of suicide is always a concern in depressed patients, the presence or absence of suicidal ideation should be evaluated and documented (4) (Figure 119.1). Because patients are often too ill to communicate or too guarded to tell the truth, the assessment is more valid if it includes other people who know the patient well. Of course, it is necessary to consider confidentiality issues and obtain patient permission unless the situation is considered a medical emergency.

Effects of Depression on Medical Outcomes and Resource Use

In hospitalized medical patients, depression has been shown to contribute to longer lengths of stay and higher re-hospitalization rates, and psychiatric interventions have been shown in some studies to contribute to shorter lengths of stay (5). Depression also can affect medical status by leading to health-impairing behaviors, such as smoking, drinking, or noncompliance with medical treatment. Moreover, other poorly understood pathophysiologic factors involving brain-end organ relationships may influence medical outcome in depressed patients. For example, patients with depression have a significantly higher 6-month mortality rate after myocardial infarction than those who are not depressed; the differences cannot be explained by noncompliance or suicide (6).

Screening for Depression

Because of problems in recognition, time constraints for clinicians, or reluctance of patients to talk about symptoms, it can be useful to screen for depression using *standardized instruments*. However, the use of many of these instruments is problematic because of the presence of possible medically based physical symptoms.

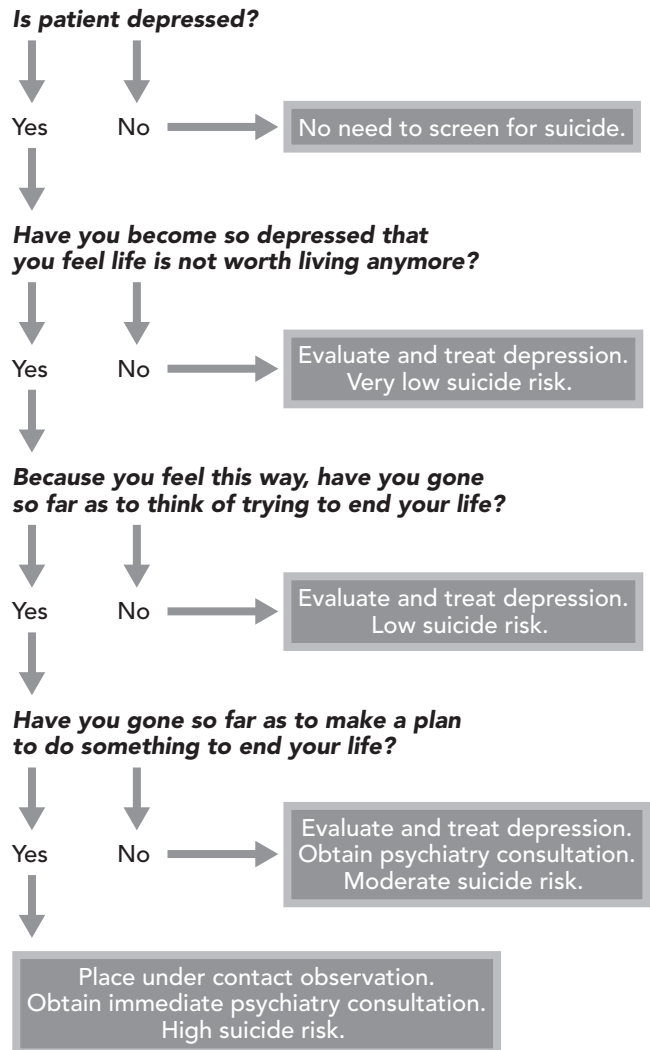

Figure 119.1 Algorithm for suicide evaluation. (From Goldberg RJ. The assessment of suicide risk in the general hospital. *Gen Hosp Psychiatry* 1987;9:1–7, with permission.)

There are a number of 20- to 30-item self-rating scales that can be used to detect depression. Commonly used scales include the Beck Depression Inventory, the Zung Depression Scale, and the Geriatric Depression Scale. The Zung and Beck scales each have problems if used in the medically ill, because somatic items may be a result of the medical disorder and not depression. The Brief Depression Scale is an 11-item, self-rated scale that factors out physical symptoms and has been shown to have reasonable sensitivity and specificity for detecting major depression (7). The single question, “Are you depressed?” also appears to be of value in screening the medically ill (8).

Treatment

Three forms of effective treatment for major depression are psychotherapy, antidepressant medication, and electroconvulsive therapy (ECT).

TABLE 119.4

Psychotherapy

Depressed patients with severe symptoms and those whose symptoms interfere with talking therapy should be started on medication. Patients with mild symptoms who seem willing to talk about their problems should first be provided with counseling or psychotherapy. Between these extremes, psychotherapy and medication can be used jointly. As a generalization, psychotherapy addresses problems and medication addresses symptoms. Psychotherapy may be the primary treatment for patients who refuse, discontinue, or cannot tolerate medications, and for situations in which medication may be dangerous, such as pregnancy, acute myocardial infarction, or unstable neurologic status. If psychotherapy is utilized in appropriate patients, its efficacy can match that of antidepressants, although there are no studies specifically addressing outcomes in medically ill depressed patients.

Antidepressant Medications

Selection

There is no clear efficacy advantage to any of the currently available antidepressants; therefore, the choice of medication generally is made on the basis of side effect and tolerability profiles (Table 119.4) and potential drug interactions (Tables 119.5 and 119.6). Past patient response and response of first-degree relatives may be predictors of drug response. Medically ill patients with concurrent depression are less likely to respond to antidepressants than patients without medical illness, who generally have a response rate of about 70%. Furthermore, guidelines for treatment of medically ill patients are based more on empirical practice than research data. A relatively small proportion of depressed older medical inpatients receives treatment with antidepressants, and those who do are usually on inadequate doses of tricyclic antidepressants

(TCAs) (9). More studies need to be performed using second-generation medications (selective serotonin reuptake inhibitors [SSRIs], venlafaxine, mirtazapine, and bupropion) instead of TCAs, which are less well tolerated in the medically ill.

Pharmacoeconomic analyses of the generic TCAs versus the second-generation antidepressants have not shown any significant cost advantage for the TCAs, because TCAs are associated with more costly treatment-related complications, such as fractures from falls associated with orthostatic hy-

potension, urinary retention, and cardiac complications (10). Overdose danger is another consideration, because TCA overdoses may be lethal (and usually require expensive ICU stays), but overdoses with second-generation antidepressants are not. Therefore, unless there is some specific reason to start a TCA, *SSRIs or other second-generation medications should be used as first-line treatment*. The use of monoamine oxidase inhibitors (MAOIs) or stimulants in medical patients should not be initiated except by psychiatric consultants.

Dosage

It is prudent to start medically ill patients, especially those with renal or hepatic impairment and the frail elderly, on low dosages (Table 119.4). Patients started too quickly on higher doses have higher rates of side effects. In general, if the patient tolerates the starting dose, the dose can be raised into the low oral dose range over the first few weeks. The response rate can often be improved by combinations or augmentation strategies, though these maneuvers are best applied by a psychiatrist. Before starting any combination, an adequate trial of single drugs should be confirmed. Plasma therapeutic levels are not established for the second generation antidepressants. All antidepressants are metabolized by the liver and are not dialyzable.

If the patient cannot tolerate the medication because of side effects, consider lowering the dose. If the lower dose would be considered ineffective, then switch to another medication that might be better tolerated. When switching, consider that drugs with long lives (e.g., fluoxetine) may be present for about 3 weeks; therefore, maintain vigilance for drug interactions during that period.

Course of Treatment

Antidepressants take *at least seven days* to exert a true neuropharmacologic effect on depression. Patients who respond earlier are showing either a placebo response or the benefit of a side effect (e.g., a sedating antidepressant may help with sleep after only one or two doses). A good trial of an antidepressant generally means using the medication at a therapeutic level for at least 4–6 weeks. In a medically ill patient in whom a low starting dose is required, the time to onset of response may be as long as 8–12 weeks. Patients who respond should remain on medication for at least 6 months, because there is a high rate of relapse associated with earlier discontinuation. Patients in their third or fourth episodes of major depression may require maintenance therapy to avoid relapse.

Antidepressant Pharmacokinetics and Withdrawal

If switching or stopping antidepressants, those with long half-lives (e.g., fluoxetine) can be stopped immediately. Those with half-lives of 1 day or less (Table 119.4) may cause withdrawal symptoms when suddenly discontinued. These medications (e.g., paroxetine) should be tapered by

halving the dose for 3–4 days. Hospital physicians should be aware of the possibility of withdrawal symptoms if a patient on antidepressants is admitted NPO. Withdrawal symptoms, which are uncomfortable but not life threatening, include dizziness, vertigo, paresthesias, flu-like symptoms, gastrointestinal activation, insomnia, nausea, and sweating. They are generally time-limited and can be relieved by restarting the antidepressant, but not by benzodiazepines (11).

Side-Effect Issues in Medical Inpatients

This section highlights a number of the medically relevant side effects of the more commonly used antidepressants (Table 119.4). It is not intended as a comprehensive list.

Anticholinergic Effects. TCAs with high anticholinergic activity can cause dry mouth. This may be merely a nuisance or may predispose patients receiving radiation or chemotherapy to stomatitis. They may precipitate narrow-angle glaucoma. Prostatic enlargement or spinal-cord problems may predispose to urinary retention. Combining anticholinergic effects with opiates in the setting of abdominal gastrointestinal surgery can lead to paralytic ileus. Anticholinergic effects can cause confusion, memory problems, or even delirium, and are augmented by other anticholinergic drugs. In general, try to avoid anticholinergic medications in the elderly and the medically ill.

Sedation. If a patient is agitated, restless, or anxious, it might be helpful to use a sedating medication. Patients who lack energy, are withdrawn, or are hypersomnic may benefit from being started on a more activating medication. Patients who become excessively activated on antidepressants should receive psychiatric consultation and discontinue the medication.

Orthostatic Hypotension. This is a result of peripheral α -adrenergic blockade as well as a central brainstem mechanism. Medical inpatients are at higher risk for orthostasis because of depleted intravascular volumes, prolonged bed rest, old age, autonomic disorders, and concurrent treatment with other medications that lower blood pressure. Orthostasis can lead to falls and injuries such as hip fracture.

Gastrointestinal Side Effects. Nausea and gastrointestinal activation are the most common side effects for the second-generation antidepressants (SSRIs). Up to 35% of patients experience nausea, and another 10%–15% have diarrhea. Nausea generally resolves after one week on a lower dosage. The TCAs decrease gastroesophageal sphincter tone, leading to symptoms of reflux. Weight loss sometimes can accompany the use of second-generation antidepressants during the first few months of treatment. However, if loss of appetite is secondary to depression,

antidepressants often help with appetite recovery and may lead to weight gain.

Cardiac Issues. There are significant potential cardiac problems associated with the use of TCAs because of their quinidine-like effects and their prolongation of cardiac conduction through the intraventricular portion of the His-bundle. This effect often requires lengthy cardiac monitoring after TCA overdose. Patients over age 40 or with cardiac histories require an electrocardiogram before starting on a TCA. TCAs should be avoided in patients with pre-existing conduction problems. Electrocardiographic and clinical studies of patients without cardiovascular disease have not demonstrated any significant arrhythmias associated with the use of SSRIs. Nevertheless, some caution may be in order in the acute post-MI period, and in those patients with severe organic heart disease and/or a history of bradyarrhythmias.

Serotonin Syndrome. The increase in peripheral serotonin caused by SSRI interference with platelet uptake may overcome the body's ability to metabolize peripheral serotonin, leading to the serotonin syndrome (10). Symptoms include confusion, agitation, myoclonus, hyperreflexia, diaphoresis, shivering, tremor, diarrhea, incoordination, fever, hypertension, nausea or vomiting, insomnia, drowsiness, and dizziness. Patients rarely develop serotonin syndrome from an SSRI alone, and most cases involve drug combinations with MAOIs or with other potent serotonin augmenters, including dextromethorphan. Symptoms of the serotonin syndrome generally abate within 24 hours after discontinuation of the causative agent. Symptoms of this syndrome have been reported to respond to treatment with cyproheptadine (a serotonin antagonist), β -blockers, or clonazepam.

Other Side Effects. A number of additional side effects may be seen in patients receiving antidepressant medications. *Sexual side effects* (anorgasmia, impaired erection or ejaculation) occur in more than 20% of patients on TCAs or SSRIs, though the incidence is about 5% on bupropion, nefazodone, or mirtazapine. The *syndrome of inappropriate antidiuretic hormone* has been seen with the use of SSRIs and TCAs. It is important to monitor serum sodium levels in elderly patients on SSRIs who develop any behavioral symptoms possibly consistent with hyponatremia (Chapter 104). Onset of symptoms may occur as early as 2 days after starting an SSRI or may emerge after many months. There also have been case reports describing *extrapyramidal side effects* and akathisia associated with SSRIs, mediated through enhanced inhibition of the dopamine system. Finally, *bleeding complications* have been reported as a rare consequence of SSRI therapy. Fluoxetine-warfarin interactions have been reported. Laboratory findings associated with SSRI-induced bleeding include prolonged bleeding time and decreased platelet aggregation in response to ADP and epinephrine.

Specific Antidepressants

Monoamine Oxidase Inhibitors. Medically important side effects of MAOIs include orthostatic hypotension, weight gain, insomnia, sexual dysfunction, and pyridoxine deficiency producing paresthesias. Hypertensive crisis is a rare (incidence <0.5% with mortality rate <0.001%) but potentially life-threatening reaction that usually is associated with mixing an MAOI with a pressor medication or food with high tyramine content. Indirectly acting sympathomimetics (such as cocaine, amphetamines, methylphenidate, pseudoephedrine, ephedrine, phenylpropranolamine, many over-the-counter cold remedies, and Sinemet) are contraindicated. Chapter 48 discusses the management of hypertensive crisis.

Stimulants. Psychiatric consultants sometimes prescribe stimulants to treat geriatric medically ill patients with depressive symptoms involving withdrawn behavior, lack of motivation and energy, and depressed mood (12). Methylphenidate or dextroamphetamine usually are started at 5 mg orally in the morning. Side effects may include overstimulation, anxiety, confusion, paranoia, tachycardia, and appetite disturbance.

Selective Serotonin Reuptake Inhibitors. Most medically ill patients receiving *fluoxetine* (Prozac) should be started on only 10 mg/d. Because of the long half-life, side effects may appear several weeks into treatment. Common side effects include gastrointestinal symptoms, tremulousness, activation, and insomnia, especially in older patients. Because of insomnia, some patients need trazodone at bedtime. The long half-life of fluoxetine can be a disadvantage in the medically ill, because the drug can take several weeks to disappear if a drug interaction or problematic side effect occurs.

The starting dosage of *sertraline* (Zoloft) in the elderly or medically ill should be 25 mg/d. There seems to be a lower tendency to activation than with fluoxetine. The major side-effect issue is generally nausea or vomiting, which should be addressed by immediate dosage reduction. Tolerance to these gastrointestinal effects usually occurs after 1 week.

A reasonable starting dose for *paroxetine* (Paxil), *citalopram* (Celexa), or *escitalopram* (Lexapro) for older or medically ill patients is 10 mg/d. Paroxetine has no active metabolites, a half-life of about 24 hours, and is often associated with a withdrawal syndrome if discontinued abruptly in younger patients. Paroxetine is the only SSRI with anticholinergic activity, which may contribute to side effects in the elderly and medically ill. Among the SSRIs, escitalopram is the least likely to cause P-450 drug interactions.

Bupropion (Wellbutrin) has a side-effect profile similar to that of stimulants (anorexia, insomnia, agitation, tremor) and is a reasonable choice for patients who need some activation. It has a greater tendency than other antidepressants to produce seizures (incidence of about 4/1,000) in

higher doses (>300 mg/d). Bupropion is also approved for use in smoking cessation.

Trazodone (Desyrel) is a weak antidepressant in dosages that medical patients can tolerate without becoming too sedated or orthostatic. It does have good hypnotic properties in doses of 50–100 mg at bedtime. Trazodone also can be used as an alternative to neuroleptics to reduce agitation in dementia patients. Trazodone rarely has been reported to be associated with heart block and ventricular arrhythmia and should be used with caution in patients with cardiac disease.

Venlafaxine (Effexor) in doses over 150 mg/d inhibits both norepinephrine and serotonin reuptake and is therefore classified as a serotonin and norepinephrine reuptake inhibitor. Its side-effect profile resembles that of the SSRIs. At doses greater than 225 mg/d, about 10% of patients experience increases in supine diastolic blood pressure within the first 2 months. Blood pressure increases are generally not an issue with oral doses under 200 mg/d. Some studies have shown better efficacy with venlafaxine than SSRIs for hospitalized patients with severe major depression (13).

Nefazodone (Serzone) acts as a 5-HT₂ antagonist and a serotonin uptake inhibitor. Although the SSRIs may cause insomnia, nefazodone causes a decrease in light-stage sleep and decreased frequency of awakenings. Because of cases of hepatic failure in patients on nefazodone, this drug should not be started in patients with active liver disease or elevated serum aminotransferases. Visual trails are an unusual side effect (seen in about 2% of patients) and may be reported as “double vision” or even hallucinations.

Mirtazapine (Remeron) is a nonadrenergic and specific serotonergic antidepressant. It has a low incidence of sexual dysfunction and GI side effects. In keeping with its antihistamine effects, its most frequent adverse effects are sedation and weight gain.

P-450 Drug Interactions

P-450 system activity is inhibited by SSRIs and nefazodone (14). Because the clearance of many drugs involves multiple enzyme pathways, a potential drug interaction listed in Table 119.6 does not necessarily mean that the combination always results in a significant interaction. Nevertheless, caution needs to guide co-prescribing if interactions are possible. Enzyme inhibition may begin immediately (or more often within the first week), increase over time until a drug reaches a steady state, and persist for as long as the drug is circulating (i.e., for weeks after terminating long-acting drugs such as fluoxetine).

Electroconvulsive Therapy

A full review of ECT is beyond the scope of this chapter. It should be noted, however, that ECT often is neglected as a treatment option by nonpsychiatrists because of the lack of knowledge of its modern applications and technology

(15). ECT is generally not a first-line treatment but should be considered if a patient has failed or cannot tolerate medication or if there is a need for an immediate response because of suicidal behaviors, malnutrition, severe psychosis with agitation, or prolonged catatonia. ECT also may be effective in refractory epilepsy, neuroleptic malignant syndrome, and Parkinson's disease.

There are no absolute and few relative contraindications for ECT, and significant complications occur in less than 1 in 200 patients. There is a substantial increased risk associated with a rise in intracranial pressure, recent myocardial infarction, recent intracerebral hemorrhage, unstable vascular malformation, retinal detachment, pheochromocytoma, anesthetic risk rated at American Society of Anesthesiologists physical status 4 or 5, or ventricular arrhythmias. ECT may be used in all trimesters of pregnancy, in consultation with the patient's obstetrician. Medical conditions that require special techniques to avoid complications include chronic obstructive pulmonary disease, asthma, severe hypertension, cardiac arrhythmia, history of stroke, advanced coronary artery disease, significant osteoporosis, or major bone fractures. Nevertheless, careful medical management makes ECT a reasonably safe option for geriatric depressed patients even with concurrent cardiovascular disease.

Pre-ECT medical assessment should include a physical and neurologic examination to rule out any risk factors. Routine laboratory studies should include complete blood count, electrolytes, renal function, and electrocardiogram. The need for neuroimaging, EEG, or chest radiograph depends on the clinical condition.

KEY POINTS

- Depression is a common problem in the medical inpatient setting and is found in a significant proportion of general inpatients.
- The first step in the evaluation of depression is to identify and correct, to the extent possible, every medical problem that could be contributing to producing depressive symptoms.
- The second step in the evaluation of depression is to address significant psychosocial issues.
- The decision to use antidepressants is made (after the first 2 steps) on the basis of the number and severity of “target symptoms.”
- The presence or absence of suicidal ideation should be assessed and documented.
- The choice of medication generally is made on the basis of side-effect and tolerability profiles (Table 119.4) and potential drug interactions (Tables 119.5 and 119.6).
- It is prudent to start medically ill patients on low dosages. This is especially true for the frail elderly and those with renal or hepatic impairment.

Allergic Reactions and Anaphylaxis

120

Neil Winawer Mark V. Williams

INTRODUCTION

A patient with initial complaints of pruritus and mild dyspnea can rapidly develop airway obstruction, respiratory failure, and circulatory collapse. This dramatic and life-threatening presentation of anaphylaxis challenges the physician to act quickly and thoughtfully to avert death. Anaphylaxis represents the extreme example of a constellation of adverse reactions to medications, food, insect venoms, and other substances. Patients, and most physicians, typically describe such acute adverse reactions as "allergic reactions." However, allergic reactions are defined strictly by the immune system's production of specific IgE antibody in response to an offending antigen. Re-exposure to the particular agent causes cross-linking of antibodies that in turn results in the release of histamine, prostaglandins, leukotrienes, tryptase, and other inflammatory mediators from mast cells. In addition to this specific IgE mast cell response, allergic reactions also are mediated by a subset of CD4 (+) T-cells, called T-helper type 2 cells, which preferentially produce interleukin 4 and 5. Mast cell and basophil-bound IgE contribute to the early (or immediate) phase of allergic response; interleukin 5 recruits and activates eosinophils, contributing to the late (or chronic) phase of allergic inflammation. The interaction between these substances and end-organ receptors determines a patient's clinical presentation.

Clinicians should distinguish allergic from nonallergic reactions because this distinction may affect diagnosis and treatment. For example, substances such as radiocontrast dyes, aspirin products, and angiotensin-converting enzyme (ACE) inhibitors produce *nonallergic reactions* (i.e., not induced by a specific IgE antibody). In these reactions, the pathogenesis may be related to direct mast

cell activation, prostaglandin inhibition, bradykinin elevation, complement activation, or other unknown mechanisms.

Anaphylaxis is defined as a potentially fatal allergic reaction characterized by cross-linking of IgE antibodies leading to systemic mast cell activation. Patients with *anaphylactoid reactions* present with symptoms clinically indistinguishable from anaphylaxis; however, the reaction is mediated by mechanisms other than IgE antibody interaction with the offending agent.

Although 15%–30% of inpatients experience adverse reactions to drugs, only 6%–10% of these are caused by allergic and other immunologic mechanisms (1, 2). Allergic drug reactions are common, but they are fatal in only 1 of 10,000 cases (3). Two epidemiologic studies documented that anaphylaxis plays a role in 1 out of every 2,700 to 5,100 hospital admissions (4, 5). Life-threatening adverse dermatologic reactions, such as toxic epidermal necrolysis (TEN), are even less common, occurring in only about 1 in 1 million people.

ANAPHYLAXIS OR SEVERE ALLERGIC REACTION PRESENTING AT THE TIME OF ADMISSION

Issues at the Time of Presentation

Clinical Presentation

Patients requiring hospitalization for adverse reactions may be suffering from a variety of entities ranging from anaphylaxis or angioedema to vesiculobullous reactions that denude the skin.

Signs and symptoms of anaphylaxis or anaphylactoid reactions usually begin within 5 minutes of exposure to the offending agent and include flushing, pruritus, urticaria, angioedema, shortness of breath, wheezing, chest tightness, nausea, vomiting, diarrhea, and lightheadedness. Patients also may develop life-threatening angioedema of the airway. Early in anaphylaxis, patients may have noticeable hoarseness or stridor. Further swelling of the larynx, tongue, epiglottis, or oropharynx may cause complete obstruction, leading to asphyxiation. Anaphylaxis also may affect the lower airways, causing bronchospasm, wheezing, and pulmonary edema. Further progression results in severe hypoxemia, which can precipitate altered mental status and seizure activity.

Anaphylactic reactions also may be associated with peripheral vasodilatation, reflex tachycardia, and subsequent cardiovascular collapse. The resultant hypotension can induce myocardial ischemia and ventricular arrhythmias. Involvement of the gastrointestinal tract with swelling of the bowel wall may present as nausea, vomiting, abdominal cramping, or diarrhea.

Adverse reactions with primarily dermatologic manifestations that require hospitalization include *Stevens-Johnson syndrome* (SJS) and *TEN*. These bullous and necrolytic reactions to drugs or infections can be life-threatening. SJS, the most severe form of erythema multiforme, involves blistering lesions, with epidermal loss occurring over less than 10% of the patient's body surface area. Patients often develop painful erosions of the oral mucosa and lip (90%), as well as conjunctivitis (85%). *TEN* is characterized by fever and epidermal loss of 30% or more of body surface area. Mucosal erosions are also a prominent feature of *TEN*, often making it difficult to clinically distinguish from SJS.

Differential Diagnosis and Initial Evaluation

The diagnosis of anaphylaxis usually is self-evident when exposure to a specific agent results in the classic constellation of symptoms. However, other diseases may have similar presentations. Initial evaluation follows the Advanced Cardiac Life Support protocol. The patient's airway should be assessed immediately, followed quickly by a thorough assessment of the patient's ability to ventilate. The patient should have frequent blood pressure checks and be connected to a hemodynamic monitor. After this rapid assessment, other organ systems can be surveyed, with particular emphasis on the skin and gastrointestinal tract. Little initial diagnostic testing is needed, because the diagnosis of anaphylactic shock relies mainly on the patient's clinical presentation and history. A serum tryptase level may be helpful in determining whether the reaction was mast cell mediated. A significantly elevated level would imply systemic mast cell degranulation but does not provide information on whether the reaction was immune mediated (i.e., anaphylaxis versus anaphylactoid reaction).

Once the patient is stabilized, a thorough history should be performed in the hope of revealing an underlying cause of the reaction, although 30%–40% of the time a definitive cause is not found. Nonetheless, patients should be queried about exposure to several well-known and common precipitants of anaphylaxis (Table 120.1) because such identification may help avoid a future life-threatening exposure. Many medications, especially penicillins and the cephalosporins, can be responsible for IgE-mediated anaphylaxis. However, anaphylactoid drug reactions are more common than IgE-mediated ones. For example, aspirin can induce severe bronchospasm by inhibiting prostaglandin synthesis and may allow the unregulated production of leukotrienes via the lipoxygenase pathway. ACE inhibitors also produce potentially fatal drug reactions by causing laryngeal, oropharyngeal, tongue, and lip edema. This reaction occurs in up to 1% of all patients taking the medication for 10 years and may be three times as common among African-Americans (6). The underlying mechanism

TABLE 120.1

DIFFERENTIAL DIAGNOSIS OF ANAPHYLACTIC/ ANAPHYLACTOID REACTIONS

Allergic (IgE-mediated)

Drugs (penicillin, cephalosporins)
Foods (shellfish, peanuts)
Contacts (latex, animal dander)
Insect stings (*Hymenoptera* spp. bees, hornets, yellow jackets, wasps)
Infections (parasitic, fungal, viral, bacterial)
Aeroallergens (pollen, dust mites)
Transfusion reactions (in patients with an IgA deficiency)

Direct Mast Cell Activation

Radiocontrast dyes
Drugs (opiates, polymixin)

Physical Stimuli

Exercise
Food-induced
Cold
Heat
Solar
Pressure

Aspirin/Nonsteroidal Anti-inflammatory Drugs

Angiotensin-converting enzyme inhibitors

Medical Conditions

Hereditary/acquired angioedema
Mastocytosis
Carcinoid syndrome

Pseudoallergic Reactions

Vasovagal reactions
Hypoglycemia

of this reaction partly relates to the drug's inhibition of bradykinin degradation.

Other disease entities can present with signs and symptoms suggestive of anaphylaxis. Hereditary angioedema is an autosomal dominant disorder characterized by low or nonfunctioning C1 esterase inhibitor. These patients often present with episodes of angioedema involving the extremities, genitalia, abdomen, lips, face, and larynx, and they relate histories of prior bouts of angioedema and positive family histories. Though rare, it is crucial for the clinician to recognize this entity, because its treatment is drastically different from that of anaphylactic reactions. In hereditary angioedema, the complement cascade produces kinin proteins that have significant vasoactive effects; mast cells are not activated. Thus, treatment with epinephrine, steroids, and antihistamines has little or no effect. Acute episodes are managed with supportive care and the administration of heat-vaporized C1 esterase inhibitor concentrate (7). Attenuated androgens such as danazol and stanozolol are effective for prophylaxis.

Patients with *mastocytosis* often have reactions that mimic anaphylaxis. This rare disease is characterized by an overabundance of mast cells in the bone marrow, liver, spleen, lymph nodes, gastrointestinal tract, and skin. Some patients may have the characteristic lesions of urticaria pigmentosa. If suspected, a 24-hour urine histamine level, coupled with a skin or bone-marrow biopsy, establishes the diagnosis. As with many mast cell-mediated processes, treatment is aimed at blocking the histamine response.

Patients with vesiculobullous reactions such as TEN and SJS require hospital admission and immediate evaluation. SJS usually is associated with medications or infection (*herpes simplex*, *Mycoplasma pneumoniae*, *Streptococcus* spp.), whereas the causative factors for TEN are most often drugs or graft-versus-host disease. Both TEN and SJS may be misdiagnosed as other processes that involve exfoliation, desquamation, or blistering. Exfoliative dermatitis presents with erythroderma and scaling. If the reaction is extensive, large amounts of scale may detach from the skin, giving the clinical appearance of full-thickness epidermal loss. Other acute drug-induced eruptions, such as exanthematous pustulosis, also can cause extensive superficial exfoliation. Primary bullous diseases (e.g., pemphigus vulgaris) also may be confused with TEN or SJS, because they can produce similar mucocutaneous findings. Other entities such as phototoxic reactions, thermal burns, and pressure blisters can clinically and sometimes histologically resemble SJS or TEN (8). Skin biopsy and immunofluorescence studies often help differentiate these vesiculobullous skin disorders.

Indications for Hospitalization and ICU Admission

The triage of patients with anaphylaxis varies depending on the severity of the reaction and the initial response to treatment (Figure 120.1). Patients who present with

anaphylaxis but respond to therapy should be observed for 24 hours. Anaphylaxis unresponsive to initial emergency-department therapy requires ICU admission. Often these patients develop laryngeal edema that necessitates intubation for airway control. Severe bronchoconstriction may lead to hypoxemia, hypercapnia, and respiratory acidosis requiring mechanical ventilation (Chapter 56). Cardiovascular collapse may result in severe hypotension requiring vasopressor support (Chapter 25). Patients with severe dermatologic reactions may require admission to specialized burn units for optimal treatment.

Initial Therapy

Initial assessment should focus on securing the patient's airway and monitoring his or her cardiopulmonary status. If there is evidence of significant airway edema or stridor, the patient should be intubated immediately. Patients with severe upper-airway obstruction, bronchospasm, or hypotension should receive intravenous doses of aqueous epinephrine 1:1000, 0.1–0.3 mL in 10 mL normal saline (1:100,000 to 1:33,000 dilution) over several minutes. This may be repeated as necessary. Patients still recalcitrant to therapy can be placed on a continuous epinephrine infusion (1.0–10 mcg/min) and titrated to response. In less severe cases, aqueous epinephrine 1:1000 dilution, 0.3–0.5 mL (0.01 mg/kg in children; max dose 0.3 mg) can be given intramuscularly. Administration in the anterolateral thigh produces higher and more rapid peak plasma levels compared to subcutaneous injections or intramuscular injections in the arm (9).

An intravenous line should be placed and fluid resuscitation begun if the patient is hypotensive. An antihistamine such as diphenhydramine 50 mg intravenous can be administered and repeated in 4–6 hours. Treatment with H₂-receptor antagonists may provide additional benefit. Systemic glucocorticoids (e.g., methylprednisolone 1–2 mg/kg per 24 h), while not acutely affecting symptoms, may help abort prolonged reactions and minimize relapses. Supplemental oxygen should be administered and bronchospasm treated with aerosolized β -agonists (albuterol 2.5 mg in 2.5 mL normal saline via nebulization every 20 minutes for three doses, then every 2–4 hours). Patients taking β -blockers may be refractory to treatment. If this is suspected, glucagon can be administered at a dose of 1 mg in 1 L of D5W at a rate of 5–15 mL/min. If the patient still remains hypotensive, intravenous vasopressors such as norepinephrine should be started (Chapter 25).

Treatment for SJS or TEN focuses on meticulous skin care, fluid and electrolyte repletion, nutritional support, pain control, and evaluation for superimposed infection. Adhesive tapes should be avoided. The patient's list of medications must be thoroughly reviewed (see Table 120.2), and all non-essential medicines discontinued. Prompt withdrawal of the offending drug has been shown to decrease

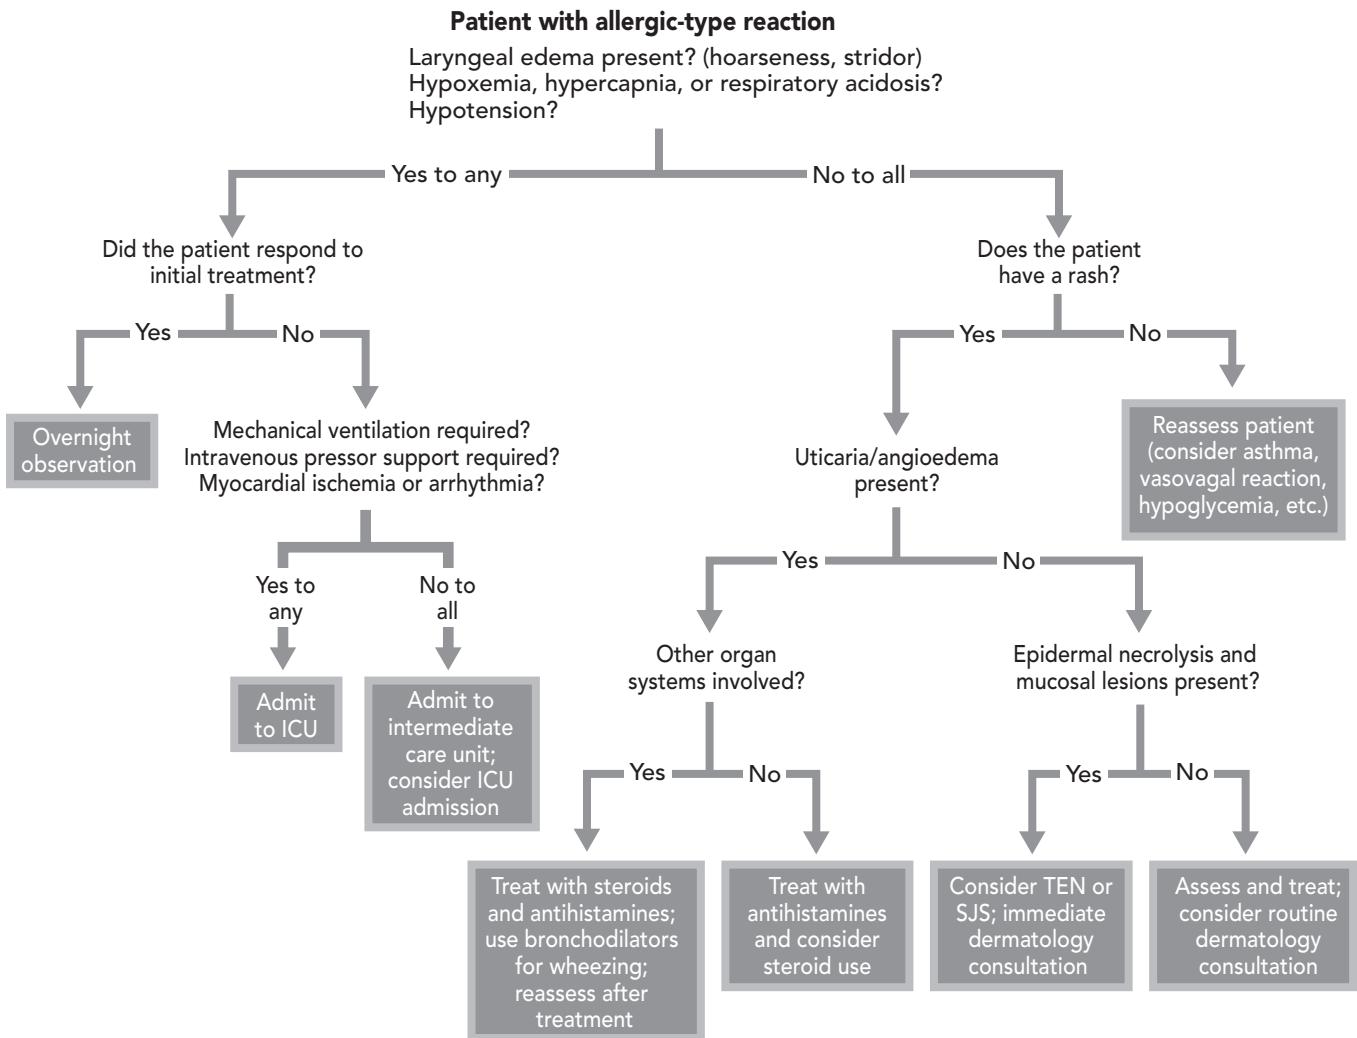

Figure 120.1 Evaluation and disposition of patients with adverse allergic-type reactions. ICU, intensive care unit; SJS, Stevens-Johnson syndrome; TEN, toxic epidermal necrolysis.

mortality in SJS or TEN by approximately 30% per day (10). The use of corticosteroids is controversial and more likely to be of benefit early in the disease process. While not of unequivocal proven benefit, the administration of high-dose intravenous immunoglobulin to patients with TEN has been effective in multiple studies (11).

Indications for Early Consultation

Most patients who experience anaphylactic reactions should be evaluated by an allergist prior to discharge. Aside from eliciting potential triggers, consultation with an allergist may help to exclude other processes with similar presentations (Table 120.1). If the causative agent is documented, an allergist can help advise the patient and the primary physician about possible cross-reacting antigens, in the hope of avoiding future events. A typical example would be patients who are allergic to sulfonamide antibiotics but have cross-reactivity with other

sulfa-containing drugs such as furosemide or dapsone. Skin testing is of no utility in the hospitalized setting, as mast cells will be refractory to an antigen challenge for several weeks.

TABLE 120.2
DRUGS MOST COMMONLY ASSOCIATED WITH STEVENS-JOHNSON SYNDROME OR TOXIC EPIDERMAL NECROLYSIS

Sulfonamides	Allopurinol
Penicillins	Fluoroquinolones
Cephalosporins	Vancomycin
Barbiturates	Thiabendazole
Phenytoin	Rifampin
Carbamazepine	Ethambutol
Nonsteroidal anti-inflammatory drugs	Chlormezanone
Phenylbutazone	

Patients with severe dermatologic reactions such as TEN or SJS require emergent allergic and dermatologic consultation, and possibly consultation with a specialist in burn care.

Issues During the Course of Hospitalization

Patients with anaphylaxis who experience rapid resolution of their symptoms can be discharged after 24 hours of observation. A critical care pathway for patients admitted to the ICU must be tailored to their clinical responses and the various end-organs affected. Critically ill patients who improve with aggressive treatment can be transferred out to the medical floor in 24–48 hours. However, patients taking β -blockers often require a longer length of stay in the ICU because of persistent hypotension. Patients who are difficult to wean from the ventilator need to have other diagnoses, such as status asthmaticus, considered (Chapter 56). Patients who experience myocardial ischemia or arrhythmias require stabilization and consideration of further risk stratification (Chapters 37, 38, 42, and 43).

Rarely, it may be necessary to initiate or continue therapy with a medication to which a patient has a history of anaphylaxis. In this situation, the patient can be desensitized by administering increasing increments of the drug orally or intravenously. This procedure needs to be performed in an ICU setting with emergency resuscitation equipment available and in consultation with an allergist or immunologist.

Mortality rates for SJS and TEN are 5% and 30%, respectively (8). The duration of disease progression is usually 3–4 days. Poor outcomes are associated with increased age, extensive epidermal detachment, visceral involvement, and dehydration (12). Steroids improve the clinical course of some patients with SJS if administered early. The effectiveness of corticosteroids on morbidity and mortality rates in patients with TEN has not been demonstrated in clinical trials, and their routine use is not recommended. Again, consultation with an allergist or dermatologist as well as a burn specialist aids the management of these patients.

ANAPHYLAXIS OR SEVERE ALLERGIC REACTION DEVELOPING IN THE HOSPITAL

A wide spectrum of adverse reactions may occur among hospitalized patients. Although treatment of severe reactions is no different whether the reaction developed inside or outside the hospital, a variety of less severe reactions can develop and must be managed in the hospital setting. The onset and manifestations of allergic reactions depend on several factors. These include the amount of antigen, its route of administration, and the relative sensitivities of the various organs to the vasoactive substances involved. Parenteral administration of antigen provokes more frequent and severe reactions than oral ingestion.

Drugs are the most common agents precipitating anaphylaxis in the hospitalized patient, with penicillins most frequent. *Patients with a history of anaphylaxis to penicillin should not receive cephalosporins*, because they share the same ring structure. The cross-reactivity with cephalosporins in this population may be as high as 50%. Most patients (80%–90%) who report a penicillin “allergy” (without anaphylaxis) do not produce specific IgE antibodies to penicillin. Therefore, the cross-reactivity with cephalosporins in these patients is significantly lower (10%–15%). Patients with a prior history of atopic diseases (asthma, atopic dermatitis, allergic rhinitis) do not have a significantly increased risk of developing anaphylaxis to drugs. However, atopic individuals have more severe reactions and an increased risk of anaphylactic reactions to radiocontrast media, food, or latex. *Latex allergy* also may pose a threat to those who have had prior or continued exposure, especially healthcare workers and patients with spina bifida or urogenital abnormalities.

Anaphylaxis also may be seen during *transfusion reactions*. Some patients who receive intravenous immunoglobulin possess an IgA deficiency and produce IgE and IgG autoantibodies against IgA. If given intravenous immunoglobulin containing IgA, such patients may experience a mast cell–mediated reaction ranging from urticaria or angioedema to anaphylaxis. The majority of transfusion reactions, however, occur through the formation of immune complexes, causing serum sickness rather than anaphylaxis (Chapter 91 contains further details regarding transfusion reactions). Food also must be considered as a precipitant. For example, peanut-induced anaphylaxis is a common problem, affecting about 1.5 million people and causing 50–100 deaths per year in the United States. TNX-901, a monoclonal antibody to IgE, has been shown to significantly increase the threshold of sensitivity to peanut antigen, hence decreasing the risk from an unintended ingestion (13).

Most severe drug reactions in hospitalized patients are anaphylactoid (i.e., not mediated by IgE antibody). Contrast material used in radiographic tests and drugs such as opiates can directly stimulate mast cell activation. These patients are treated in the exact same fashion as patients with anaphylaxis. Tryptase levels in these individuals are increased secondary to mast cell degranulation. Patients receiving aspirin or NSAIDs may have severe anaphylactoid reactions as well. Patients with a history of asthma, nasal polyps, and/or rhinosinusitis are particularly at risk.

Patients with a history of *radiocontrast allergy* often need to undergo important diagnostic radiographic tests. In these situations the prophylactic regimen should be catered to the severity of the patient’s allergy. Patients with a history of urticaria can be pre-dosed with 50 mg of oral prednisone (13, 7, and 1 hour before) and 25 mg of parenteral diphenhydramine 1 hour before the procedure. Patients with more severe anaphylactoid reactions (i.e., angioedema, hypotension) additionally can be given 25 mg of ephedrine orally and 300 mg of cimetidine orally 1 hour before the proce-

ture (14). Finally, the use of nonionic low-osmolality radiocontrast media helps to minimize the likelihood of an adverse reaction (15).

Adverse dermatologic reactions occurring among hospitalized patients range from intractable pruritus to urticaria, angioedema, or TEN. Careful history-taking and review of the medication record is essential to making the correct diagnosis. Patients presenting with urticaria have erythematous, well-circumscribed wheals (hives) that are intensely pruritic and often migratory. Urticaria also may be accompanied by angioedema. The mechanism of action is similar, but angioedema occurs in the deeper cutaneous structures. The production of urticaria or angioedema usually implies the presence of an IgE-mediated hypersensitivity reaction. Less often the drug (hapten) complexes with serum or tissue proteins, forming an immune complex that activates the complement cascade. The resulting anaphylatoxins C3a, C4a, and C5a bind to mast cells and degranulate them.

Specific classes of drugs often produce characteristic clinical syndromes involving one or more organ systems. Anticonvulsants, most notably phenytoin, phenobarbital, and carbamazepine, can cause erythematous eruptions 1–3 weeks after their administration. Clinical signs and symptoms include fever, lymphadenopathy, facial edema, leukocytosis, hepatitis, and nephritis.

Morbilliform or maculopapular rashes are the most common drug-induced cutaneous reactions. These rashes consist of symmetrical macules and papules that often are confluent. Patients may note pruritus or fever. Similar presentations have been seen in patients with acute viral infections such as measles, Epstein-Barr virus, cytomegalovirus, and acute HIV seroconversion. Patients infected with HIV are 5–10 times more likely to develop morbilliform drug eruptions than uninfected people. Trimethoprim-sulfamethoxazole, amoxicillin, and ampicillin commonly induce cutaneous reactions in such patients. It is also important to identify *erythema multiforme*, an acute inflammatory eruption of the skin and mucous membranes. In this disorder, patients may develop a variety of lesions, including maculopapular rashes. Target lesions are diagnostic, and the rash typically involves the extremities symmetrically. Fever and flu-like symptoms may precede the eruption by several days. Erythema multiforme is most commonly associated with drugs or infection (typically, *herpes simplex virus*). A variety of other adverse cutaneous reactions, such as drug-induced vasculitis, warfarin skin necrosis, and vancomycin-induced “red man” syndrome (flushing about the neck and face), may complicate a patient’s hospital course. Management of these conditions includes discontinuation of the offending drug, supportive care, and dermatologic consultation when appropriate.

Patients with *carcinoid tumors* also may develop symptoms analogous to anaphylaxis. Severe skin flushing, abdominal cramping, diarrhea, and bronchoconstriction may confuse the clinical picture. Patients suspected of having this disease should have 24-hour levels of 5-hydroxyin-

doleacetic acid measured. Treatment is based on reducing the tumor burden. The somatostatin analog octreotide has successfully reduced the severe flushing and other endocrine manifestations of the syndrome.

Other entities also may mimic anaphylaxis. For example, patients who experience hypoglycemia, asthma, cardiac arrhythmias, and vasovagal reactions can present with pallor, diaphoresis, hypotension, shortness of breath, and wheezing. These patients lack the characteristic urticaria or angioedema that is noted in 88% of individuals experiencing anaphylaxis. The role of mastocytosis as a masquerader has been alluded to previously.

Often, patients with hypertension or diabetes present to the hospital with new-onset congestive heart failure and are started on ACE inhibitors. Although this class of drugs can cause a dry cough and angioedema at any time, 60% of the adverse reactions occur immediately or within the first few days of treatment (6). If angioedema occurs, it is necessary to discontinue the drug. Lowering the dose or changing to a different type of ACE inhibitor is not effective, and similar episodes may be seen in patients switched to angiotensin II receptor blockers (16). A short course of steroids helps resolve the angioedema.

Discharge Issues

Prior to discharge, patients experiencing an anaphylactic reaction should be educated about the nature of their illness. This includes informing them to wear medical-alert bracelets and providing instructions on how to self-administer an injection of epinephrine in the event of an attack. Prevention is equally important. Patients need to be able to recognize potential triggers as well as understand substances to which they may cross-react and suffer an allergic reaction. Patients should be referred to an allergist for skin-prick testing and desensitization therapy if indicated. Finally, the primary care physician must be informed of all adverse reactions occurring in the hospital, and all such reactions should be documented clearly in both the inpatient and outpatient medical record.

COST CONSIDERATIONS AND RESOURCE USE

Patients requiring prolonged ICU admission incur significant costs. Consultation with a dermatologist early in the course of a skin reaction may expedite adequate treatment, preventing clinical deterioration and prolonged hospitalization. Consultation with an allergist or immunologist for patients with new-onset or recurring severe allergic reactions may best identify optimal therapy to shorten the hospital course and optimize patient education. Follow-up education promotes adherence and identification of the possible allergens so as to avoid them or other cross-reacting allergens. Further, utilizing protocols of premedication,

such as those utilized for radiographic contrast material, reduces costs by minimizing adverse outcomes.

KEY POINTS

- Both allergic and nonallergic reactions can produce anaphylactic symptoms.
- The differential diagnosis of an anaphylactic/anaphylactoid reaction includes several nonallergic diseases that may present with similar symptoms.
- The treatment of anaphylaxis is straightforward, but the underlying precipitant is often elusive.
- Patients with anaphylaxis usually improve if the initial therapy is administered without delay. If β -blocker therapy causes persistent hypotension, patients should receive glucagon. Other diagnoses also need to be considered.
- The most common precipitants of anaphylaxis in the hospital are drugs, radio-contrast agents, and latex products.
- Patient education and appropriate follow-up with the patient's primary care physician and an allergist are essential in cases of anaphylactic/anaphylactoid reactions requiring hospitalization.

Drug Overdoses and Dependence

121

Josef G. Thundiyil Jon K. Beauchamp Kent R. Olson

INTRODUCTION

Overdose patients are a heterogeneous group who may present with a variety of ingestions (e.g., prescription medications, over-the-counter products, and/or drugs of abuse) and reasons for their overdose (e.g., suicide attempt, accidental overmedication, or drug abuse). The overdose is often a dynamic process in which a previously healthy individual can become critically ill in a matter of minutes or hours. Frequently, clinicians must treat a drug overdose using an incomplete history, a limited physical examination, and only a few diagnostic studies. Pre-existing medical conditions can complicate the management of the overdose. Finally, the overdose may represent an intentional suicide attempt or a drug dependency that requires psychiatric or social intervention in addition to medical treatment.

The first section of this chapter discusses the general considerations pertinent to most drug-overdose patients. This includes the indications for hospitalization, initial ICU admission, early consultation, and issues during the course of hospitalization and at discharge. The subsequent sections review the clinical presentation, evaluation, and initial therapy for overdose patients with an altered level of consciousness, seizures, shock, and/or an abnormal electrocardiogram, respectively. The final section discusses the management of a drug-dependent patient during hospitalization.

GENERAL CONSIDERATIONS IN A DRUG-OVERDOSE PATIENT

Issues at the Time of Admission

Clinical Presentation

There are many different initial manifestations of an acute drug overdose. These may include an altered level of consciousness, seizures, hypotension, cardiac arrhythmias, metabolic acidosis, or gastrointestinal symptoms. Important variables in the history include the specific drug or drugs taken, the amount taken, the time between the overdose and presentation, and any underlying medical illnesses. Certain drugs (e.g., carbamazepine, salicylates, tricyclic antidepressants, sustained-release or enteric-coated preparations) may be absorbed slowly or erratically, which can delay the onset of toxicity. Some drugs (e.g., digoxin, lithium, salicylates, theophylline, metformin, verapamil) can cause toxicity after chronic, repeated overmedication or in the presence of impaired drug elimination because of kidney or liver dysfunction. The presentation and treatment of common poisonings and drug overdoses are described in Table 121.1.

Differential Diagnosis and Initial Evaluation

The symptoms and clinical manifestations may be similar for many different drug overdoses and medical

TABLE 121.1**CLINICAL ISSUES AND TREATMENT OF SOME COMMON DRUG OVERDOSES AND POISONINGS**

Drug or poison	Clinical presentation	Treatment ^a
Acetaminophen (Panadol, paracetamol, Tylenol, etc)	Potentially toxic ingestion is >7 gm. Alcoholics and patients taking anticonvulsants or INH may be at higher risk for liver injury. Initial nausea and vomiting followed by evidence of liver injury developing over 24–48 hours. Patients may be only minimally symptomatic early in the course of overdose. May lead to fulminant hepatic failure. Always consider acetaminophen as a coingestant in an opiate overdose.	Obtain STAT serum acetaminophen level and plot on nomogram (see Figure 121.1). If level is toxic or patient presents late, start <i>N-acetylcysteine</i> 140 mg/kg PO immediately followed by 70 mg/kg every 4 hours for 17 doses. Consult PCC regarding length of treatment or use of intravenous <i>N-acetylcysteine</i> if not tolerated orally. Shorter course may be used if patient has no evidence of liver injury at 36 hours. Consult regional liver transplant service for patients with rapidly rising liver aminotransferases.
Amphetamines (methamphetamine [crank, crystal meth], MDMA [ecstasy]) and cocaine (crack)	Toxicity may occur after injection, nasal insufflation, smoking, or ingestion. Delayed toxicity can occur if swallowed in drug packets. Toxicity includes agitation, psychosis, seizures, hyperthermia, tachycardia, and hypertension. Intracranial hemorrhage, rhabdomyolysis, myocardial ischemia, and cardiac arrhythmias may also occur.	Reduce external stimuli and provide calm environment. Sedation with benzodiazepines or antipsychotic agents (e.g., haloperidol). Consider whole bowel irrigation for drug packet ingestions. Treat severe hypertension unresponsive to benzodiazepines with vasodilator (e.g., nitroprusside, nitroglycerin, or phentolamine). Use extreme caution with β -blockers. Hyperthermia requires aggressive cooling measures, including neuromuscular paralysis.
Anticholinergics and antihistamines (benztropine, diphenhydramine, chlorpheniramine, etc)	Anticholinergic syndrome (tachycardia, dilated pupils, flushed dry skin, sleepiness or confusion, delirium, hallucinations). Seizures, rhabdomyolysis, hyperthermia, and QRS widening can occur. May cause delayed drug absorption. Always consider possibility of tricyclic antidepressant (TCA) overdose (see below), which has similar presentation.	Observation, supportive care. Use benzodiazepines for agitation and seizures. For non-TCA anticholinergic syndrome, consider <i>physostigmine</i> 0.5–1 mg IV. (Caution: <i>physostigmine</i> can cause seizures and bradycardia.)
Benzodiazepines (diazepam, alprazolam, chlordiazepoxide, lorazepam, oxazepam, etc)	Sleepiness, stupor, CNS depression, ataxia, slurred speech (usually arousal with strong stimulus). Relatively safe alone, although deep coma can occur with large or mixed ingestions or with newer short-acting benzodiazepines.	Supportive care. Although there is a specific antidote (flumazenil), it is contraindicated if there may be co-ingestion of a tricyclic antidepressant or other convulsant or if patient is dependent on benzodiazepines, and most toxicologists advise against empiric use. It has been reported to cause seizures and dysrhythmias in patients who are benzodiazepine dependent.
β -blockers (atenolol, metoprolol, propranolol, etc)	Severe bradycardia, atrioventricular block, hypotension, often resistant to β -adrenergic drugs. Life threatening in overdose. Lipid-soluble agents (e.g., propranolol) can also cause coma, seizures, and tricyclic-like cardiotoxicity. Bronchospasm may occur in asthmatics. Sustained release preparations may have delayed toxicity. Beta selectivity is lost in overdose.	Cardiac monitoring and close observation; consider whole bowel irrigation for sustained release preparations or massive ingestion. Use atropine, epinephrine, isoproterenol, or cardiac pacing for symptomatic bradycardia. Intravenous fluids, epinephrine infusion, or norepinephrine infusion for hypotension. For resistant bradycardia or hypotension, use <i>glucagon</i> 5–10 mg IV, followed by infusion of 5–10 mg/hr. For large or prolonged infusions, do not use supplied diluent (contains phenol). Consider sodium bicarbonate boluses if wide complex conduction defects occur.
Calcium channel blockers (amlodipine, verapamil, nifedipine, diltiazem, etc)	Severe bradycardia, hypotension, often resistant to usual agents. Junctional bradycardia and ileus are common rhythm. Sustained release products may have delayed toxicity. Hyperglycemia may occur.	Cardiac monitoring and close observation; consider whole bowel irrigation for sustained release preparations or massive ingestion if peristalsis is present. Give <i>calcium chloride</i> , 1–2 gm IV. Repeat dose as needed to raise BP and increase heart rate. Doses as high as 10 gm or more may be required. Glucagon, epinephrine, amrinone, and high-dose insulin therapy may help with refractory hypotension.

TABLE 121.1

(continued)

Drug or poison	Clinical presentation	Treatment ^a
Carbamazepine (Tegretol)	Stupor, ataxia, decreased level of consciousness, seizures, and coma occur. AV block, bradycardia, QRS, and QT widening are occasionally reported. Has some anticholinergic effects. Absorption from the gut is often slow and erratic and may lead to delayed toxicity.	For large ingestion, give extra doses of activated charcoal every 3–4 hours to ensure gut decontamination. Follow serial levels to rule out prolonged delayed absorption. Serious symptoms may occur at levels greater than 40 mg/L and if serum level >60 mg/L, consider hemodialysis or charcoal hemoperfusion.
Carbon monoxide	High index of suspicion is needed because symptoms are nonspecific: headache, nausea, dizziness, confusion, stupor, seizures, angina, and coma. After significant poisoning, permanent neurologic sequelae can occur. CT scan may show hypodense regions in central white matter. Metabolic acidosis may be present.	Give high-flow oxygen by tight-fitting mask or 100% via endotracheal tube. Obtain carboxyhemoglobin level. Recent evidence suggests that hyperbaric oxygen may reduce long-term neurologic and cognitive sequelae; but this remains controversial and HBO is not usually readily available (1).
Cocaine, crack	Toxicity can occur after nasal insufflation, smoking, injection, or ingestion. Swallowed packets may cause delayed toxicity. Symptoms include euphoria, anxiety, agitation, delirium, psychosis, tremors, seizures, hypertension, hyperthermia, myocardial ischemia, intracranial bleed, stroke, arrhythmias, and death.	Maintain close observation and cardiac monitoring; reduce external stimuli. Use benzodiazepines as the initial therapy for agitation, seizures, hypertension, anxiety, and tremors. For refractory hypertension, avoid pure β -blockers, as unopposed α effects may paradoxically worsen hypertension. Consider phentolamine as an additional vasodilatory therapy. Nitrates and calcium channel blockers may be used for cardiac ischemia.
Cyanide	Acute collapse, hypotension, severe metabolic acidosis. Symptoms can also include headache, nausea, and confusion. Smell of “bitter almonds” may be detected by about 60% of caregivers. Toxicity can also develop from high-dose intravenous nitroprusside therapy.	<i>Cyanide antidote package</i> contains amyl and sodium nitrite (300mg) (to induce methemoglobinemia) and sodium thiosulfate (12.5g) (to enhance conversion of cyanide to less toxic thiocyanate). Administer sequentially and provide supportive care. Stop or reduce nitroprusside infusion.
Cardiac glycosides (digoxin, digitoxin, oleander, and other plants)	Nausea, vomiting, visual disturbances, hyperkalemia. Bradycardia with prominent AV block. Patients with underlying atrial fibrillation may present with slowed ventricular response or a junctional rhythm. Ventricular arrhythmias, heart failure, and death may occur. Levels may be falsely elevated if drawn within 4–6 hours of ingestion.	Initiate continuous cardiac monitoring. For significant toxicity, severe hyperkalemia, and symptomatic arrhythmias, give <i>digoxin-specific antibodies</i> (Digibind or DigiFab) based on estimated body burden of digoxin (see package insert or call PCC for calculation). Note that serum digoxin levels may be falsely elevated after antibody therapy. Do not give calcium because this may worsen ventricular arrhythmias or cause asystole.
Ethanol	Common co-ingestant with other drugs that results in stupor, disinhibition, hypoglycemia, hypothermia agitation, altered level of consciousness, CNS depression, and coma. Vomiting with pulmonary aspiration of gastric contents is a common complication.	Supportive care. Examine carefully for associated co-morbidities (trauma, infections, other OD). Activated charcoal not effective. Treat alcoholism-associated ketoacidosis with glucose, thiamine, and volume replacement. Treat withdrawal syndrome with benzodiazepines (Chapter 122).
Ethylene glycol (antifreeze)	Intoxication causes gastritis, decreased LOC, stupor, and coma. Elevated serum osmolality (osmolar gap). Metabolism of EG leads to severe metabolic acidosis (non-lactate), renal failure, coma, and death. Woods lamp may reveal fluorescent urine.	Charcoal is ineffective. Block EG metabolism with <i>ethanol</i> or <i>fomepizole</i> (consult PCC for dosing). Treat acidosis with bicarbonate. Remove EG and toxic metabolites with early consideration for <i>hemodialysis</i> . Supplement with folate and pyridoxine.
Gamma hydroxybutyric acid (GHB)(2)	Drug of abuse, “date rape drug,” and used by weightlifters. Can cause rapid onset of deep coma, often with muscle twitching or occasionally seizures, bradycardia, and emergence phenomenon. Withdrawal syndrome has been described.	Supportive care. Duration usually brief, with rapid spontaneous awakening from deep coma within 2–4 hours.

TABLE 121.1**CLINICAL ISSUES AND TREATMENT OF SOME COMMON DRUG OVERDOSES AND POISONINGS (continued)**

Drug or poison	Clinical presentation	Treatment^a
Hypoglycemic agents (oral), sulfonyleureas, and other agents (3)	Sulfonyleureas can cause delayed onset of hypoglycemia that can persist for up to 48–72 hours. Symptoms can include confusion, diaphoresis, agitations, seizure, and coma. Other agents do not cause hypoglycemia but may contribute to that caused by sulfonyleureas and insulin.	Close glucose monitoring for a minimum of 24 hours. Use glucose boluses of D50 to bring glucose to within normal range; then use continuous glucose infusions and <i>octreotide</i> (50 mcg SQ every 12 hours) to maintain euglycemia. Rebound hypoglycemia may occur when dextrose infusion is stopped.
Isoniazid (INH)	After acute ingestion, nausea, vomiting, ataxia, agitation, confusion, and seizures. Seizures are often refractory to conventional therapy. Severe lactic acidosis often accompanies even a few brief seizures, due to block of lactate metabolism.	Seizures may be resistant to benzodiazepines. Give <i>pyridoxine</i> (vitamin B ₆), 5 gm IV, or if amount ingested is known, give a gm-for-gm equivalent dose.
Lithium (4)	After acute overdose, serum level may be falsely elevated if drawn within a few hours of ingestion. Chronic overmedication may cause greater toxicity. Initially, nausea, vomiting, confusion, ataxia, tremor, weakness, slurred speech, myoclonus, seizures, or coma can occur after acute or chronic intoxication. Therapeutic use or overdose can cause nephrogenic diabetes insipidus.	Activated charcoal does not bind Lithium. Consider whole-bowel irrigation for large ingestion of sustained-release products. Promote renal excretion with intravenous fluids to maintain adequate urine output. Consider hemodialysis or continuous renal replacement therapy for significant toxicity, renal failure, and severe neurologic symptoms. Symptoms may persist for days-to-weeks and do not always correlate with serum level.
Methanol (wood alcohol, solvents, glass cleaning products, paint removers)	Intoxication is similar to ethanol or ethylene glycol: gastritis, elevated serum osmolality (osmolar gap), stupor, and coma. Metabolism of methanol leads to severe anion gap metabolic acidosis (non-lactate), visual changes, blindness, seizures, coma, and death.	Block methanol metabolism with <i>ethanol</i> or <i>fomepizole</i> . Supplement with folic acid. Treat acidosis with bicarbonate and early consideration for <i>hemodialysis</i> to remove methanol and toxic metabolites.
Nonsteroidal anti-inflammatory drugs (NSAIDs) (e.g., ibuprofen, naproxen, ketorolac, etc.)	Nausea and vomiting common. After very large ingestion (e.g., >400 mg/kg) may see stupor, coma, seizures, metabolic acidosis, pulmonary edema, and renal failure. Mefenamic acid and phenylbutazone are more likely to cause seizures.	Supportive. Symptomatic treatment and observation. Monitor renal function and electrolytes.
Noncyclic antidepressants; (serotonin reuptake inhibitors: fluoxetine, fluvoxamine, paroxetine, sertraline; mixed neurotransmitter blockers: nefazodone, trazodone, venlafaxine, bupropion)	Generally safer than tricyclic antidepressants. Toxicity is increased by ingestion of other drugs. Symptoms can include ataxia, sedation, tremor, coma, hypotension, and tachycardia. Bupropion commonly causes seizures. Serotonin syndrome (confusion, myoclonus, diaphoresis, tremor, hyperthermia) can rarely be seen with overdose or medication interaction.	Close observation. Supportive care and symptomatic treatment. Some reports have suggested that oral cyproheptadine may be of benefit in serotonin syndrome.
Opioids and opiates (codeine, heroin, hydrocodone, methadone, morphine, propoxyphene, etc)	Lethargy, CNS depression, stupor, coma, respiratory depression, small pupils (often pinpoint), and noncardiogenic pulmonary edema. There may be evidence of chronic IV drug abuse. For mixed ingestions, check serum acetaminophen level (see above). Marked withdrawal syndrome.	Close observation for respiratory depression. Specific antidote is naloxone 0.4–2 mg IV. May need larger doses after codeine, propoxyphene overdose. Naloxone lasts only 1–2 hours; may need to repeat doses or give constant drip for methadone OD (can last for 2–3 days).
Organophosphate and carbamate insecticides (commonly in hydrocarbon solvent base), nerve agents (e.g., Sarin, Tabun, Vx) (5)	Poisoning can occur by ingestion, dermal absorption, or inhalation of mist. Caution must be taken by health care workers to avoid contamination by skin, vomitus, or clothing. Abdominal cramps, vomiting, diarrhea, hypersalivation, bronchorrhea, sweating, miosis, bradycardia, muscle fasciculations, and weakness. Respiratory arrest is usual cause of death. Garlicky or solvent odor may be present.	Close observation and monitoring. Perform thorough skin decontamination with soap and water. Lavage into closed (e.g., wall suction) system. Intravenous fluids for volume replacement. Antidotes include <i>atropine</i> (1–2 mg IV initially, continuous infusion may be needed) titrated to control bronchorrhea and bronchospasm. <i>Pralidoxime</i> (2-PAM) is essential for muscle weakness caused by organophosphates. Begin pralidoxime treatment early for organophosphate poisoning to prevent prolonged hospitalization.

TABLE 121.1

(continued)

Drug or poison	Clinical presentation	Treatment ^a
Phenytoin (Dilantin)	At serum levels >20–30 mg/L, ataxia, nystagmus, slurred speech, and tremor may occur. At higher levels, drowsiness, lethargy, confusion, and coma can occur. Intravenous formulation contains propylene glycol diluent, which may cause hypotension and cardiac arrest when administered rapidly IV (e.g., at a rate >50 mg/min).	Supportive care. Repeated dose activated charcoal may enhance elimination but is of little practical use and can lead to overshoot if levels drop too rapidly.
Salicylates: aspirin (prescription and OTC analgesics and cold preparations), bismuth subsalicylate (Pepto-Bismol)	Patients may become poisoned from chronic overmedication or acute overdose. Chronic overmedication can result in severe and unrecognized toxicity, and symptoms will correlate poorly with levels. Bezoar formation is not uncommon with intentional acute overdose, leading to delayed and erratic absorption. Symptoms can include nausea, vomiting, tinnitus, hyperventilation, confusion, coma, hyperthermia, pulmonary edema, cerebral edema, and seizures. Mixed respiratory alkalosis and metabolic acidosis is often seen.	Monitor closely and follow serum levels until a clear downward trend exists. With large ingestions (e.g., more than 100 pills), give extra doses of activated charcoal (every 3–4 hours) and consider WBI. Maintain serum pH above 7.4 to prevent further movement of salicylate into brain. Promote renal excretion by urinary alkalinization (sodium bicarbonate 100 mEq in 1 L of D5 quarter normal saline at 3–4 mL/kg/hr). Consider hemodialysis for severe acidosis, blood level >100 mg/dL, decreased LOC, seizures, volume overload, pulmonary edema, or chronic renal failure. Verify units of measurement when checking levels (mg/L or mg/dL).
Theophylline: (TheoDur, Theo-BID, etc.)	Poisoning can occur from acute overdose or chronic overmedication. Hypokalemia, hyperglycemia, and gastrointestinal symptoms are common after acute overdose; toxicity in chronic overdose tends to occur at lower serum drug levels. Tachycardia, anxiety, tremor, and seizures may occur with both acute and chronic overdose. Course can lead to status epilepticus, cardiovascular collapse and death. Excessive β-2-adrenergic stimulation is probable cause of cardiovascular and metabolic effects.	Close observation, continuous cardiac monitoring. Repeat doses of activated charcoal may enhance drug elimination in even mild drug overdoses. Consider whole bowel irrigation for large sustained release overdoses. For serum level >100 mg/L or multiple seizures, consider hemodialysis. Hypotension and tachycardia may respond to β-blockers (e.g., esmolol at low doses, 25 mcg/kg/min).
Tricyclic antidepressants (amitriptyline, doxepin, imipramine, nortriptyline, etc) (6)	Drug absorption can be delayed and patients may deteriorate rapidly. Anticholinergic syndrome is common. Cardiotoxicity due to sodium channel blockade leads to conduction disturbance (QRS >120 msec), tachycardia, hypotension, and ventricular arrhythmias. Seizures, coma, cardiovascular collapse, hyperthermia, and death may also occur.	Continuous ECG monitoring. Early airway management is essential because of the risk of rapid deterioration. For wide QRS complex or hypotension, give sodium bicarbonate 1–2 mEq/kg IV bolus and repeat as needed. Avoid type Ia and Ic antiarrhythmics. For hypotension refractory to intravenous fluids, consider norepinephrine infusion. Do NOT use physostigmine.
Valproic acid (Depakote, Depakene)	May cause delayed and erratic drug absorption with large ingestion. Stupor, coma, metabolic acidosis, hyperammonemia, and cerebral edema.	For large ingestions, give extra doses of activated charcoal and consider whole bowel irrigation. For serum valproate level >850mg/L, consider hemodialysis or hemoperfusion. Intravenous L-carnitine may be useful for valproic acid-induced hyperammonemia.

^a For all poisonings, appropriate, supportive care (e.g., airway management, supplemental oxygen, treating shock or cardiac dysrhythmias, correction of hypoglycemia) should be instituted. For ingestions, gastrointestinal decontamination should be performed with a single dose of an aqueous slurry of activated charcoal 50 g PO or via NG, unless an alternate method is described. GL, gastric lavage; IV, intravenous; LOC, level of consciousness; PCC, poison-control center.

conditions. Because of this, the possibility of a drug overdose should be considered in any patient who has an unexplained acute illness, particularly if he or she has an altered level of consciousness or multiple organ system dysfunctions.

The clinical condition of an acute drug-overdose patient can deteriorate quickly, and the initial evaluation should

begin with a brief assessment to determine if immediate treatment is necessary. Emergent interventions may include administration of supplemental oxygen, endotracheal intubation and mechanical ventilation, treatment of shock or cardiac dysrhythmias, control of seizures, and correction of hypoglycemia. If time permits, a more complete evalua-

tion can be done, including a physical examination, pertinent diagnostic studies (see later in this chapter), and a detailed history, including checking for routine medications, the presence of any heart, lung, liver, or kidney disease, and prior suicide attempts.

Important aspects of the physical examination of a drug-overdose patient include the level of consciousness (see subsequent discussion), a complete set of vital signs (including an accurate measurement of the respiratory rate and core temperature), pupil size and reactivity, lung sounds and an assessment of respiratory effort, the presence or absence of peristalsis (bowel sounds), and the presence of abnormal muscle activity (e.g., dystonia, fasciculations, muscle rigidity, tremors, or other abnormal movements).

The appropriate laboratory assessment of a drug-overdose patient depends on the history and clinical presentation, but should generally include serum electrolytes, glucose, blood urea nitrogen (BUN), and creatinine levels. These tests are inexpensive, quickly available, and often useful in diagnosing or managing a drug-overdose patient. Electrolyte abnormalities can result from or contribute to the toxicity of some drug overdoses. In a few cases these electrolyte abnormalities may serve as a marker of acute toxicity of a drug overdose (e.g., hyperkalemia in an acute digoxin overdose or hypokalemia in an acute theophylline overdose). The presence of an anion gap acidosis should raise the suspicion of salicylate poisoning, as well as a number of other intoxications including carbon monoxide, cyanide, iron, nonsteroidal anti-inflammatory agents, or isoniazid (Table 121.2). If there is an accompanying *osmolar gap*, one should consider the possibility of an ethylene glycol or methanol poisoning. Decreased renal

function may prolong the toxicity of a drug overdose. A serum creatine kinase level should be obtained in any drug-overdose patient at risk for rhabdomyolysis. If a drug overdose is suspected to be a suicide attempt, a rapid quantitative acetaminophen and salicylate level should be obtained and, in women of childbearing age, a rapid serum or urine pregnancy test also should be done. Additionally, an electrocardiogram should be performed to evaluate for dysrhythmias and abnormal intervals (see later discussion). Abdominal radiographs may be helpful in monitoring and the decontamination of certain radio-opaque poisons (e.g., heavy metals) or in connection with body packing or stuffing of illicit substances in plastic bags.

Comprehensive toxicologic screening of the blood and urine is costly, and the results usually are not available quickly enough to affect patient care. Because of this, it is of questionable value in the emergent evaluation of a drug-overdose patient. However, rapid urine screening for drugs of abuse (e.g., opioids, cocaine, amphetamines) may help confirm clinical suspicions and obviate the need for other workups. Urine toxicologic screens should be interpreted with caution because many common drugs (e.g., lorazepam, clonazepam, methadone, and oxycontin) frequently do not test positive for their expected assays (i.e., benzodiazepines and opiates). Meanwhile, common drugs, such as diphenhydramine and dextromethorphan, can give false positive results for such urine screening tests as phencyclidine (PCP). For some drug overdoses, quantitative serum drug levels can be helpful in deciding to hospitalize a patient, determining the acuity of care required, and guiding the use of specific treatments, such as N-acetylcysteine for acetaminophen (Figure 121.1) or digoxin-specific Fab antibodies for digoxin (Table 121.1).

TABLE 121.2
COMMON CAUSES OF AN ANION GAP^a
ACIDOSIS

Lactic acidosis

Acetaminophen (serum drug level >600 mcg/mL)	Hypoxia
β-adrenergic drugs	Metformin (rare)
Carbon monoxide	Salicylates
Cyanide	Seizures
Iron	Shock
Isoniazid	Theophylline

Nonlactic acidosis

Alcoholic ketoacidosis	Methanol
Diabetic ketoacidosis	Salicylates
Ethylene glycol	Valproic acid
Exogenous acids	

^a Anion gap: (serum sodium) – (serum chloride) – (serum bicarbonate). Normal = 8–12 mEq/L.

Indications for Hospitalization

Most patients with acute drug overdose do not need hospitalization. Typically they can be treated and released from the hospital emergency department if they remain asymptomatic or have resolution of their symptoms during a 6- to 8-hour period of observation. However, certain drugs (e.g., acetaminophen, sustained-release medication preparations, oral sulfonyleureas) may have delayed toxicity or ongoing toxicity in the absence of symptomatology. These patients, those who remain symptomatic, or those who require continuing medical treatment of their overdose or its complications require hospitalization. Patients requiring a psychiatric evaluation may need to be hospitalized unless the evaluation can be completed in the emergency department.

Indications for Intensive Care Unit Admission

An acute drug-overdose patient who has unstable vital signs, needs respiratory support, or requires close observation for medical or psychiatric reasons most likely needs to

Figure 121.1 Nomogram for prediction of acetaminophen hepatotoxicity after acute drug overdose. The upper line defines serum acetaminophen concentrations likely to be associated with hepatotoxicity, the lower line defines serum levels 25% below those expected to cause hepatotoxicity. Courtesy of McNeil Consumer Products, Inc.

be admitted to an intensive care setting. Continuous monitoring of the ECG and vital signs is recommended after overdoses involving cardiotoxic drugs or agents likely to cause seizures or altered levels of consciousness. In certain circumstances a lower acuity bed with continuous cardiac monitoring may be adequate.

Initial Therapy

The care required by hospitalized drug-overdose patients varies greatly. Most do well with observation, supportive care, and gastrointestinal decontamination with oral activated charcoal. Some patients benefit from more aggressive gut decontamination or enhancement of drug elimination (e.g., hemodialysis), and a few will require therapeutic interventions specific to the overdose drug (Table 121.1). Empiric initial therapy for most drug-overdose patients should include close observation, monitoring vital signs, establishing venous access, a single dose of activated charcoal (see later in this chapter), and, if indicated, continuous cardiac monitoring.

Emergent supportive measures include supplemental oxygen, airway management with treatment of shock or cardiac dysrhythmias, control of seizures, aggressive control of hyperthermia, and correction of hypoglycemia. More general supportive care includes the correction of fluid and electrolyte abnormalities and management of symptoms.

The goal of gastrointestinal decontamination is to reduce the amount of drug absorbed and limit the severity of the overdose. In general, it should be initiated as soon as possible and may include one or more of the following procedures: induced emesis, gastric lavage, the administration of activated charcoal, and whole bowel irrigation. *Induced emesis* poses risks of aspiration, is an inefficient method of gastrointestinal decontamination, and delays the administration of activated charcoal; it has been virtually abandoned in the hospital management of poisoning because of these limitations (7). *Gastric lavage* is commonly performed, but this procedure increases the risk of pulmonary aspiration, and its role in the routine management of an acute drug overdose remains unproven. At this time, an *aqueous slurry of activated charcoal* (1g/kg, up to 50–60 grams) given by mouth or via nasogastric tube is accepted as the best method of gastrointestinal decontamination for most uncomplicated ingestions (7). However, activated charcoal is not effective for some agents, such as iron, lithium, heavy metals, hydrocarbons, and alcohols. A cathartic agent, such as magnesium sulfate or sorbitol, can be given along with the charcoal but is of questionable value and may worsen metabolic derangements in some patients. Premixed charcoal and sorbitol products should be avoided, because the large volume of sorbitol in these preparations often causes abdominal cramps and vomiting. *Whole bowel irrigation* with a commercially available solution (e.g., GoLyte or CoLyte) may be a useful technique for gastrointestinal decontamination, especially for patients who have swallowed drugs not bound by charcoal or large numbers of sustained-release pills. The solution is administered via nasogastric tube at a rate of 1 to 2 L/h for several hours, with the intent of mechanically removing the drug via the rectum. This may be useful for an overdose of iron, lithium, or sustained-release or enteric-coated tablets, or for the ingestion of a foreign body or an illicit drug packet (7).

The potential benefit of enhanced drug elimination is reducing the severity and duration of the drug overdose. For most drug overdoses, the duration of symptoms is short and the severity is limited, so there is no benefit from enhancing drug elimination. If indicated, the most commonly used techniques include repeated administrations of activated charcoal, alkalinization of the urine, and hemodialysis. Drugs that may be more rapidly eliminated by using repeated doses of activated charcoal (based on volunteer studies) include salicylates, theophylline, phenytoin, and phenobarbital. Hemodialysis is suited for drugs that have a low volume of distribution,

low protein binding, poor intrinsic clearance, and exhibit significant toxicity. Examples include ethylene glycol, methanol, salicylates, valproic acid, and lithium. Additionally, continuous renal replacement (i.e., CVVH, CAVH, etc.) therapy has shown promise for elimination of toxins such as lithium because of its ease of implementation, avoidance of rebound levels, and applicability for hemodynamically unstable patients (4). Indications for enhancing drug elimination for some overdoses are described in Table 121.1.

Indications for Early Consultation

Consultation with a poison control system or a hospital-based toxicologist can provide useful and cost-effective information regarding the evaluation and treatment of a drug-overdose patient. It should be considered in any overdose patient who requires hospitalization, has an unknown ingestion, has an atypical presentation of a suspected overdose, or is not responding to treatment.

Issues During the Course of Hospitalization

Patients with acute drug overdose can deteriorate abruptly, particularly during the first few hours after their overdoses. Because of this, patients need to be reevaluated frequently for changes in their clinical condition. Similarly, they can have rapid improvement in their symptoms, and close monitoring allows for timely discontinuation of unnecessary interventions.

Issues at the Time of Discharge

There are several issues specific to a drug-overdose patient that should be addressed prior to hospital discharge. The ongoing medical necessity of any drug involved in the overdose should be reassessed, and consideration should be given to stopping or changing the medication. If the drug must be continued, it may be prudent to decrease the dosage or limit the amount dispensed at any one time. If an inadvertent dosage error was responsible for the drug overdose, close outpatient monitoring and patient education should be considered. A psychiatric evaluation, performed when the patient is medically stable, needs to be arranged for any patient who has attempted suicide via a drug overdose.

ALTERED LEVEL OF CONSCIOUSNESS

Issues at the Time of Admission

Clinical Presentation

An altered level of consciousness, manifested by either a decreased level of consciousness or an agitated state, is a

common presentation of a drug overdose. A patient with a decreased level of consciousness is usually easy to identify, but the terms to describe this clinical condition (e.g., somnolent, lethargic, comatose) can be confusing and inaccurate. It is generally more accurate to quantify a patient's decreased level of consciousness by her or his response to verbal and painful stimuli (appropriate, inappropriate, or no response), ability to protect their airway, and the presence or absence of cardiovascular or respiratory depression. Using this descriptive method allows a more accurate communication of the clinical condition to other health care providers and a more precise means of following changes in the patient's clinical condition. Manifestations of agitation may include confusion; psychotic, inappropriate or violent behaviors; and excessive muscle activity. Agitated patients may present dangers to themselves and others.

Differential Diagnosis and Initial Evaluation

Altered level of consciousness may be caused by a number of common drug overdoses and medical conditions (Chapter 115). Drugs and poisons that can cause a *decreased level of consciousness* include antidepressants, antihistamines, antipsychotic agents (including phenothiazines), barbiturates, benzodiazepines, carbon monoxide, clonidine, ethanol, ethylene glycol, gamma-hydroxybutyrate, isopropyl alcohol, lidocaine, lithium, methanol, opiates, other psychiatric medications, and salicylates. *Agitation* can be caused by a number of common drug overdoses, including amphetamines, antihistamines, caffeine, cocaine, ephedrine, phencyclidine, pseudoephedrine, and theophylline. Medical conditions that may present with an altered level of consciousness include head injury, central nervous system infection, systemic infection, intracranial bleeding, postictal state, and metabolic disturbances (e.g., electrolyte abnormalities and metabolic acidosis). Hypoglycemia or hypoxia are important considerations in any patient with an altered level of consciousness and may be associated with numerous drug overdoses and medical conditions. The possibility of drug withdrawal should be considered in any agitated patient.

Any patient with an altered level of consciousness should be evaluated quickly for head injury, unstable vital signs, adequacy of airway control and ventilation, hypoglycemia (bedside blood glucose determination), hypoxia (bedside room air oxygen saturation determination), hyperthermia (rectal temperature), and the presence of focal neurologic findings. Routine diagnostic studies should include electrolyte, glucose, BUN, and creatinine levels; electrocardiogram; and a urinalysis. If the screening urinalysis is positive for blood, the patient may have rhabdomyolysis, and a serum creatine kinase should be obtained. In the appropriate circumstances, a specific drug level or serum osmolality may assist in the diagnosis. Head computed tomography should be considered in any patient with focal neurologic findings or a decreased level of consciousness of unclear

cause. A lumbar puncture should be considered in any patient with suspected central nervous system infection.

Rhabdomyolysis and hyperthermia are potentially serious complications associated with drug overdoses that cause an altered level of consciousness. *Rhabdomyolysis* can occur after a prolonged period of immobilization on a firm surface, excessive motor activity (e.g., seizures, agitation), hyperthermia, direct injury to muscle tissue by trauma, certain drugs (e.g., ethanol, 2,4-dichlorophenoxyacetic acid), and toxins (e.g., snakebites) (8). Untreated rhabdomyolysis can cause myoglobinuria, hyperkalemia, and acute renal failure. The creatine kinase level invariably is elevated, and patients may have a positive urine dipstick for hemoglobin in the absence of red cells (reflecting the presence of myoglobin). *Hyperthermia* can be caused by salicylates, anticholinergic agents, inhalational anesthetics, sympathomimetic agents, serotonin antagonists, seizures, muscle rigidity, agitation with excessive muscle activity, neuroleptic malignant syndrome (from use of antipsychotic drugs), serotonin syndrome (from monoamine oxidase inhibitors or serotonin reuptake inhibitors), or malignant hyperthermia (after exposure to certain anesthetic agents). If untreated, hyperthermia may lead to rhabdomyolysis, renal failure, cardiac dysfunction, shock, and brain injury, and it probably increases the risk of death from an acute drug overdose (9).

Initial Therapy

Depending on the cause and the degree of the altered level of consciousness, initial therapy may include supplemental oxygen, endotracheal intubation and mechanical ventilation, correction of hypoglycemia, treatment of unstable vital signs, and (in the agitated patient) sedation and physical restraints to control potentially dangerous behaviors. Airway management is very important in patients with a decreased level of consciousness, because they are at risk of hypoventilation and pulmonary aspiration. Gastrointestinal decontamination should be considered but can be difficult in patients with an altered level of consciousness. When performed, great care should be exercised to prevent aspiration.

In opiate overdoses, the competitive opiate receptor antagonists *naloxone* (Narcan) or *nalmefene* (Revex) can reverse the opioid-related decrease in consciousness and respiration. They should be used primarily to reverse respiratory depression and to ensure adequate airway control and ventilation (avoiding the need for endotracheal intubation). Naloxone can precipitate acute drug withdrawal in opiate-dependent patients and can cause agitation, pulmonary edema, or cardiac dysrhythmias. The initial dosing of naloxone should be 0.2–0.4 mg intravenous, and additional doses should be titrated to reverse respiratory depression sufficiently to ensure adequate airway control and ventilation. Some opiates (e.g., propoxyphene and codeine) are resistant to usual doses of

naloxone and may require 10 mg or more to reverse respiratory depression. Naloxone's duration of action is typically shorter than those of most opiates, and repeat doses or a continuous naloxone drip may be needed. Nalmefene is longer-acting than naloxone, but its duration of action is still shorter than that of methadone. Although promising, its usefulness in an acute opiate overdose remains to be determined. On the other hand, it has begun to show increasing utility as an adjunct in the treatment of alcoholism (10).

In a benzodiazepine overdose, the specific antagonist, *flumazenil* (Romazicon), can reverse the decreased level of consciousness and respiratory depression. As with the opiate antagonists, *complete reversal of benzodiazepine effects should be avoided* in benzodiazepine-dependent patients, because this can cause acute drug withdrawal and, infrequently, seizures. Specific contraindications to flumazenil's use include known or suspected coingestion of a tricyclic antidepressant, known or suspected benzodiazepine addiction, or known use of benzodiazepines to prevent seizures. The dosing of flumazenil is 0.5–2.0 mg intravenously, and it should be titrated to the reversal of respiratory depression to ensure adequate airway control and ventilations (11). Its duration of action is typically shorter than those of most benzodiazepines, and repeat doses may be needed. Studies have not demonstrated a beneficial effect from routine administration of flumazenil, and it carries significant risks of complications including seizures and arrhythmias. For this reason, most authorities advise against empiric use of flumazenil in unknown or mixed overdose patients.

Symptomatic hypoglycemia should be treated initially with 50 mL of a 50% dextrose solution (25 g dextrose) intravenously (Chapter 107). Patients who are malnourished or alcoholic may be deficient in thiamine (vitamin B₁), and thiamine 100 mg intramuscular or intravenous also should be given to prevent Wernicke's syndrome. If vascular access is not immediately available, consider giving glucagon (1–5 mg intramuscularly) as a temporizing measure. An alert patient with adequate airway control may take juices and food by mouth. There is increasing evidence that early use of octreotide for hypoglycemia (especially when it is secondary to sulfonylurea toxicity) decreases the amount of dextrose required, decreases the rate of recurrent hypoglycemia, and may possibly shorten hospital stay (3). Dosing of octreotide is 50–100 mcg every eight hours as needed.

Placing the patient in a calm environment initially can treat agitation that is unrelated to hypoglycemia, hypoxia, hypotension, or other metabolic derangement. In the patient who remains agitated, consider sedation with a benzodiazepine (e.g., lorazepam 1–2 mg intravenously or 0.05 mg/kg intramuscularly to a maximum dose of 4 mg, or midazolam 0.05 mg/kg intravenously over 20–30 s or 0.1 mg/kg intramuscularly). If additional sedation is needed, consider haloperidol 2.5–5.0 mg intramuscularly or intravenously.

The main treatment of rhabdomyolysis is aggressive intravenous fluid hydration with an alkaline crystalloid solution (2 ampules of sodium bicarbonate in 1 L of 5% dextrose) to restore any intravascular volume depletion and to maintain a urine output of 3–5 mL/kg/h. Hyperkalemia and hypocalcemia are potential complications of rhabdomyolysis, and the patient's serum potassium and calcium levels must be monitored closely. In addition, supportive care should be provided as needed, including hemodialysis in a patient with acute renal failure. The renal function in patients with acute renal failure from rhabdomyolysis typically improves over a 2- to 3-week period (8).

Hyperthermia needs to be treated aggressively to prevent serious brain injury or death. The main goals of treatment are external cooling and reducing excessive heat production. Evaporation is usually the most efficient method of external cooling and works well for most patients. This involves undressing the patient, sponging him or her with lukewarm water, and then using a fan to circulate air over their skin. Continuous core temperature should be monitored in patients with hyperthermia to assess adequacy of treatment. Avoid ice packs or cold water immersion because these can induce shivering and vasoconstriction, which interfere with heat dissipation (9). Seizures, agitation, and muscle rigidity also must be controlled (as described elsewhere in this chapter) quickly to reduce heat production. Hyperthermia and muscle rigidity from neuroleptic malignant syndrome can be treated with bromocriptine, 2.5–10 mg orally or via nasogastric tube 2–6 times daily. The hyperthermia and muscle rigidity from serotonin syndrome may benefit from treatment with cyproheptadine, 4 mg orally every hour for 3–4 doses (12). Malignant hyperthermia should be treated with dantrolene, 1–2 mg/kg rapidly intravenously, and repeated as needed every five minutes up to a total dose of 10 mg/kg (9). If hyperthermia from seizures, agitation, or muscle rigidity cannot be controlled with these measures, consideration should be given to neuromuscular paralysis to block further heat production. (Patients will need endotracheal intubation once paralyzed.) Neuromuscular blockade is usually not effective in treating malignant hyperthermia and may even contribute to worsening of the condition.

DRUG-INDUCED SEIZURES

Issues at the Time of Admission

Clinical Presentation

Drug-induced seizures are usually brief, generalized, tonic-clonic in nature, and limited in number. For some drug overdoses, however, the seizures can be multiple, sustained, or focal. Typically, the seizure activity is associ-

ated with a decreased level of consciousness and possibly with tongue biting and incontinence. Multiple or recurrent seizures after an amphetamine or cocaine overdose suggest ingestion of a drug packet or a complication, such as intracranial hemorrhage, hyperthermia, or electrolyte disturbance (e.g., hyponatremia with MDMA intoxication).

Differential Diagnosis and Initial Evaluation

The most common causes of drug-induced seizures are tricyclic antidepressants, diphenhydramine, isoniazid, salicylates, stimulants (amphetamines and cocaine), antipsychotic agents, and newer antidepressants, especially bupropion. Medical conditions that can cause seizures include withdrawal from ethanol and sedative hypnotics, hypoxia, hypoglycemia, central nervous system infection or intracranial bleeding, or an intrinsic seizure disorder (Chapter 118). Dystonia, muscle rigidity, and dyskinesia can be confused easily with seizure activity, especially if they are associated with a decreased level of consciousness. An isoniazid overdose should be considered in any patient whose seizures do not respond quickly to conventional treatment (see later in this chapter).

A drug-overdose patient with a seizure should be evaluated for head injury, unstable vital signs, adequacy of airway control and ventilations, hypoglycemia (bedside blood glucose determination), hypoxia (bedside room air oxygen saturation determination), and the presence of focal neurologic findings. The nature of the seizures and the presence of any focal neurologic findings should be documented. Routine diagnostic studies should include electrolyte, creatine kinase, glucose, BUN, and creatinine levels. In the appropriate circumstances, specific drug levels may assist in the diagnosis or treatment. Head computed tomography or magnetic resonance imaging should be performed in any patient with focal neurologic findings or a seizure of unclear cause. A lumbar puncture should be considered in any patient with suspected central nervous system infection or subarachnoid bleeding.

Initial Therapy

Depending on the cause, duration, and number of seizures, initial therapy may include supplemental oxygen, endotracheal intubation and mechanical ventilation, correction of hypoglycemia, and treatment of unstable vital signs. Airway management is very important in these patients, because they are at risk for hypoventilation and pulmonary aspiration. Gastrointestinal decontamination should be considered but can be difficult in patients with seizures.

The approach to and treatment of seizures is described in detail in Chapter 118. The discussion here focuses on seizures in the drug-overdose patient, which are associated with significant morbidity and mortality rates and must be controlled aggressively. The drug of choice

for treating drug-induced seizures is a benzodiazepine. Lorazepam (Ativan) is given 1–2 mg intravenously every 5–10 minutes until cessation of the seizures or respiratory compromise or hypotension occurs. Alternatively, seizures can be treated with diazepam (Valium) 0.1–0.2 mg/kg intravenously every 10 minutes until cessation of the seizures or a total of 30 mg is given. If venous access is not available, midazolam (Versed) can be given, 0.1 mg/kg intramuscularly; this dose can be repeated in 10 minutes while venous access is being obtained. If the seizure activity is not controlled after a maximum dose of a benzodiazepine, then phenobarbital 50 mg/min intravenously should be given until the seizures stop or a total dose of 1,000 mg, or 15 mg/kg, has been given. Phenytoin may not be as effective as a benzodiazepine or phenobarbital in controlling drug-induced seizures (13). If a patient is thought to have a drug-induced seizure resulting from isoniazid, pyridoxine (vitamin B₆), 1 g intravenously for every 1 g isoniazid ingested, should be given. If the amount ingested is unknown, then an initial dose of 5 g of intravenous pyridoxine should be given and then repeated until the seizure activity is controlled. In addition to anticonvulsant therapy, a patient who seizes from a salicylate or theophylline overdose may require hemodialysis or hemoperfusion.

If the seizing patient develops a core temperature $\geq 40^{\circ}\text{C}$ because of prolonged, excessive muscle activity or rigidity, neuromuscular paralysis and endotracheal intubation should be considered. These abolish the motor activity and allow for better control of the temperature (as described previously) but do not stop any seizure activity within the brain. Patients who require neuromuscular blockade for temperature control may need bedside electroencephalographic monitoring or periodic removal of the neuromuscular paralysis to assess the adequacy of seizure control. Alternatively, propofol has demonstrated success in managing refractory status epilepticus and has the added benefit of rapid titratability (14).

HYPOTENSION

Issues at the Time of Admission

Clinical Presentation

Hypotension can be caused by a number of drug overdoses and medical conditions. Mechanisms of hypotension include decreased cardiac function (e.g., decreased contractility or relative bradycardia), decreased intravascular volume (e.g., blood and fluid losses or third spacing), decreased peripheral vascular tone (e.g., arterial or venous vasodilatation), or a combination of these problems. Hypotension may also accompany hypothermia (Chapter 25). Clinical findings in patients with hypotension stem from decreased perfusion of various organ systems and may include an

altered level of consciousness, cool and moist skin, tachypnea, tachycardia, nausea, and decreased urine output. Overdoses that cause a decrease in the intravascular volume or peripheral vascular tone are usually associated with some degree of tachycardia. Hypotension with a relative bradycardia is suggestive of certain drug overdoses (see later in this chapter).

Differential Diagnosis and Initial Evaluation

Drugs whose overdose can cause hypotension by *decreasing cardiac rate and/or contractility* include β -blockers, calcium channel antagonists, cardiac glycosides (e.g., digoxin, digitalis, oleander), clonidine and other α_2 -agonists, organophosphate and carbamate pesticides, procainamide, quinidine, sedative-hypnotics (e.g., alcohols, barbiturates, benzodiazepines), and tricyclic antidepressants. Those that cause hypotension by *decreasing intravascular volume* include amatoxin-containing mushrooms, colchicine, and iron. Overdoses that cause hypotension by *decreasing vascular tone* include β_2 -stimulants (e.g., metaproterenol, terbutaline, theophylline), hydralazine, nitrates, prazosin and related drugs, minoxidil, phenothiazines, and tricyclic antidepressants. Hypothermia, hyperthermia, hypoxia, and hypoglycemia also can cause hypotension. *Hypotension with a relative bradycardia* suggests an overdose of sympatholytic agents (e.g., alcohols, barbiturates, β -blockers, clonidine, and opiates), membrane-depressant drugs (e.g., propranolol, procainamide, quinidine, and tricyclic antidepressants), calcium channel antagonists, or cardiac glycosides, or the presence of hypothermia. Electrolyte abnormalities, metabolic acidosis, and other metabolic disturbances also must be considered.

A drug-overdose patient with hypotension should be evaluated for adequacy of airway control and ventilation, other abnormal vital signs, signs of blood loss (including gastrointestinal sources) or other fluid losses, myocardial ischemia or infarction (perform a 12-lead electrocardiogram), hypoglycemia (bedside blood glucose determination), hypoxia (bedside room-air oxygen saturation determination), and focal neurologic findings suggestive of a spinal cord injury. Routine diagnostic studies should include electrolyte, glucose, BUN, and creatinine levels. In the appropriate circumstances, a specific drug level may assist in the diagnosis or treatment. A chest radiograph should be considered if there is any evidence of pulmonary edema, cardiac dysfunction, or pneumonia. A sepsis workup should be considered in any patient suspected of having an infectious process.

Initial Therapy

The general treatment of hypotension is described in Chapter 25. This discussion focuses on the treatment of hypotension in drug-overdose patients, which usually responds to empiric treatment with intravenous fluids and

vasopressor agents, but occasionally is refractory to usual supportive treatment. The volume of the IV fluids given may need to be reduced in patients with pulmonary edema or a history of heart failure, but most healthy overdose patients tolerate an initial intravenous bolus of normal saline 10–20 mL/kg. Additional fluid boluses may be needed and can be given as long as there is no evidence of volume overload. In a patient who does not respond adequately to fluids, dopamine 5–15 mcg/kg/min continuous intravenous infusion, or norepinephrine 0.1 mcg/kg/min continuous intravenous infusion, should be considered. Norepinephrine may be more effective than dopamine in patients with a tricyclic antidepressant overdose. In addition, hypoxia, hypoglycemia, respiratory insufficiency, hypothermia or hyperthermia, and metabolic derangements need to be corrected. Table 121.1 contains information about more specific treatments for certain drug-related causes of hypotension.

VENTRICULAR ARRHYTHMIAS, QRS WIDENING, OR QT PROLONGATION

Issues at the Time of Admission

Clinical Presentation

Electrocardiogram abnormalities frequently are seen in drug-overdose patients, and most resolve without sequelae. The most worrisome abnormalities include ventricular arrhythmias (including polymorphic ventricular tachycardia), QRS widening (QRS duration >120 ms), and QT prolongation (QTc >420 ms) (6).

Differential Diagnosis and Initial Evaluation

Toxicologic causes of ventricular arrhythmias include amphetamines, chloral hydrate, cocaine, digitalis glycosides, phenothiazines, theophylline, tricyclic antidepressants, and many hydrocarbon solvents. Drug-related QRS widening can be caused by digitalis glycosides, diphenhydramine, procainamide, propoxyphene, cocaine, propranolol, quinidine, thioridazine, and tricyclic antidepressants. Hyperkalemia also needs to be considered as an important cause of QRS widening. Polymorphic ventricular tachycardia associated with QT prolongation can occur with therapeutic use or overdose of many drugs, including quinidine, cisapride, amiodarone, methadone, sotalol, venlafaxine, quetiapine, thioridazine, droperidol, and haloperidol. Medical conditions that should be considered in the differential diagnosis include acidosis, cardiac ischemia, hypoxia, electrolyte abnormalities (e.g., hypokalemia, hyperkalemia, hypocalcemia, or hypomagnesemia), and an intrinsic conduction defect (see also Chapter 43).

A drug-overdose patient with an abnormal electrocardiogram should be evaluated for unstable vital signs, adequacy of airway control and ventilation, hypoxia (bed-

side room-air oxygen saturation determination), cardiac ischemia, and the presence of pulmonary edema. Routine diagnostic studies should include a 12-lead electrocardiogram and electrolyte, glucose, BUN, and creatinine levels. In the appropriate circumstances, a chest radiograph or specific drug levels may assist in diagnosis or treatment.

Initial Therapy

All drug-overdose patients with any electrocardiographic abnormality need close observation, continuous cardiac monitoring, and aggressive supportive care. Gastrointestinal decontamination also should be considered but may be difficult in the critically ill patient. Ventricular fibrillation and tachycardia should be treated following the recommendations of the advanced cardiac life support guidelines (Chapter 43), with a few exceptions. First, ventricular arrhythmias associated with chloral hydrate, β -agonists, theophylline, or caffeine poisoning should be treated with β -blockers (e.g., esmolol). Patients who may have ingested a tricyclic antidepressant or other quinidine-like drugs should not be treated with procainamide or other Type-I antiarrhythmic drugs. Instead, sodium bicarbonate bolus doses should be given when the QRS duration is greater than 100 ms, or there is wide complex tachycardia, hypotension, or a terminal R wave in lead aVR (6). These boluses of sodium bicarbonate (or hypertonic saline) should be repeated as needed until QRS narrowing occurs or severe alkalosis or hypernatremia develops. For polymorphic ventricular tachycardia, administer magnesium sulfate 1–2 gm intravenous bolus, followed by 3–20 mg/h continuous intravenous infusion, and consider overdrive pacing (Chapter 43). For patients with prolonged QT intervals, close monitoring, magnesium and potassium replacement, and avoidance of severe bradycardia are indicated. Table 121.1 contains information about more specific treatments for certain drug-related causes of QRS widening or QT prolongation.

MANAGEMENT OF THE DRUG-DEPENDENT PATIENT IN THE HOSPITAL

Drug dependency or withdrawal can complicate the assessment and treatment of an acutely ill patient. They may interfere with a patient's perception of pain and make the evaluation of a painful condition difficult, cause management problems for the health care staff, and increase the risk of complications from the underlying medical condition. During a hospitalization for an acute medical illness, the symptoms of the patient's withdrawal or dependency should be alleviated while their active medical problems are treated; the issues relating to their addiction can be addressed at a later time.

Opiate withdrawal can be manifested by drug craving, agitation, dysphoria, insomnia, gastrointestinal symptoms

(e.g., nausea, vomiting, diarrhea), piloerection, diaphoresis, increased secretions (e.g., tearing, rhinorrhea), and miscellaneous symptoms (e.g., yawning, myalgias) (15). The withdrawal syndrome can be treated with routinely scheduled doses of an opiate, either orally or parenterally, depending on the patient's condition. The goals are to titrate the dosage to alleviate withdrawal symptoms, dose on a regular schedule to prevent the recurrence of symptoms, and avoid overmedicating the patient.

Withdrawal symptoms from benzodiazepines or ethanol may include agitation, dysphoria, insomnia, nausea, vomiting, confusion, hallucinations, hypertension, tachycardia, hyperthermia, sweating, or seizures (15). The withdrawal syndrome can be treated with titrated doses of a benzodiazepine (either orally or parenterally, depending on the patient's condition) or, in the case of ethanol withdrawal, phenobarbital. The goal is to titrate the dosage to alleviate the withdrawal symptoms (e.g., reduce agitation, hypertension, tachycardia); large doses of parenteral medications may be required. The approach to alcohol withdrawal is covered in more detail in Chapter 122.

Abstinence from stimulants (e.g., amphetamines, cocaine) may be manifested in a "crash" (i.e., profound fatigue and sleeping for hours-to-days) that develops within hours of the last drug dosing, followed by a withdrawal syndrome (e.g., dysphoria, irritability, insomnia, anhedonia) that begins hours or days after the crash (15). Palliative treatment of symptoms may be considered.

A withdrawal syndrome has been seen after stopping the chronic use of gamma-hydroxybutyric acid, which clinically is similar to sedative-hypnotic withdrawal. It may be associated with agitation, dysphoria, insomnia, confusion, and hallucinations, but appears to involve less autonomic hyperactivity (e.g., tachycardia, hypertension, hyperthermia, sweating) than withdrawal from other sedative agents. Symptoms may be relatively mild initially, become more severe over a few days, and then last for a week or more (2). The symptoms of gamma-hydroxybutyric acid withdrawal may be very resistant to treatment with benzodiazepines and antipsychotic agents. As with a sedative-hypnotic withdrawal syndrome, the goal is to titrate treatment to reduce the agitation, hypertension, and tachycardia if these are present. Other commonly used drugs that are known to cause a withdrawal syndrome include barbituates, carisoprodol (soma), and lioresal (baclofen).

COST CONSIDERATIONS AND RESOURCE USE

Frequent clinical reassessment is the best strategy for appropriately deploying resources in a hospitalized drug-overdose patient. This allows for the timely discontinuation of treatment modalities and high-acuity monitoring that are no longer needed. Conversely, if the patient is not improving as expected or has deteriorated, more aggressive

care, such as hemodialysis or use of a specific antidote, can be started quickly. Initiating this therapy as soon as the need arises can reduce the potential risk for an adverse outcome, decrease the total length of hospital stay, and help to optimize the resources used. If there is a possible need for a specific antidote, it is important to ensure that the hospital pharmacy has access to an adequate supply to treat an average adult for 24 hours. Antidotes that are frequently in short supply included antivenoms (snake or black widow envenomations), pralidoxime (organophosphorus agents), and pyridoxine (isoniazid). An inadequate supply of a specific antidote can prolong hospitalization and increase the overall use of resources needed to care for a drug-overdose patient.

KEY POINTS

- Supportive care is adequate for most overdose patients.
- A drug overdose is often a dynamic process with sudden changes in clinical condition, and patients need to be closely monitored and frequently reassessed.
- Adequate gastrointestinal decontamination minimizes the amount of drug or poison absorbed and reduces the severity of the overdose.
- Be aware of common toxidromes (including anticholinergic, sedative-hypnotic, sympathomimetic, and withdrawal syndromes) so that treatment may be tailored appropriately.
- Drugs that are slowly or erratically absorbed may have delayed onset of toxicity.
- Avoid treatment modalities of questionable benefit.

INTRODUCTION

Alcohol abuse and dependence are common. Surveys suggest that as many as 15 million Americans are affected adversely by their alcohol consumption. One result is almost 1 million alcohol-related hospitalizations per year in the United States. The economic cost of alcohol abuse in the United States exceeds \$185 billion annually. Between 15%–20% of patients admitted to general medical and surgical wards in community and teaching hospitals abuse alcohol, but many patients with alcohol problems are not diagnosed at admission (1). Because of the prevalence of alcohol abuse and dependence, the U.S. Preventive Services Task Force recommends screening all adolescent and adult patients as part of routine preventive services (2). All physicians providing hospital care encounter patients who manifest the signs and symptoms of acute alcohol intoxication and alcohol withdrawal syndrome (AWS).

This chapter only briefly discusses acute alcohol intoxication because this is most often treated in outpatient detoxification centers. Some patients, however, do require hospitalization because of profound central nervous system (CNS) depression secondary to alcohol intake, often in association with other ingestions. More commonly, patients are admitted with other primary medical or surgical diagnoses and develop signs of alcohol withdrawal several days after admission, when their regular alcohol consumption ceased. Screening all patients for alcoholism, recognizing the signs and symptoms of AWS, and initiating treatment using current, evidence-based approaches is emphasized.

Untreated delirium tremens and severe alcohol intoxication can be fatal, although if recognized and treated appropriately they should rarely, if ever, result in death.

ACUTE ALCOHOL INTOXICATION

Issues at Admission

Alcohol intoxication can play a role in any hospital admission and frequently is listed as a secondary diagnosis in the emergency department. This is especially true of trauma admissions. With the advent of community-based detoxification centers, it is uncommon to admit a patient with the sole diagnosis of alcohol intoxication; however, the non-habitual drinker (such as an adolescent or a college student) who binge drinks may require supportive care in the hospital or the ICU (3). The pharmacology of alcohol is complex, and our understanding of it is still evolving. Alcohol is absorbed rapidly from the stomach and small intestine and is distributed in total body water. The onset of its clinical effect is 5–10 minutes after ingestion, with peak concentrations in the blood occurring after 30–90 minutes. Metabolism is primarily (90%) by the liver; the balance is excreted by the lungs, kidneys, and in sweat.

The clinician should understand that alcohol is a *global CNS depressant*. Transmitter release and conduction are depressed throughout the CNS. In the setting of acute alcohol intoxication, patients are somnolent, with impaired reflexes, slowed respiratory rate, and eventually

coma. Patients who drink habitually can compensate for the depressant effects of alcohol through increased autonomic activity. They may appear alert and without obvious functional impairment despite high blood-alcohol concentrations (BACs). Symptoms of alcohol withdrawal result if alcohol is withdrawn or decreased, at which time compensatory autonomic hyperactivity becomes apparent. The clinical effects of alcohol depend on age, sex, comorbid conditions, dosage, and, importantly, the individual patient's drinking history. A nontolerant drinker experiences symptoms at a much lower BAC than a tolerant or habitual drinker. The spectrum of symptoms begins with mild euphoria and disinhibition, followed by slurring of speech and incoordination. Patients may become belligerent as the BAC increases, although ultimately somnolence and respiratory depression occur. Unfortunately, the BAC is not helpful in determining which patients will do well at an outpatient detoxification center and which should be admitted to the hospital. In the nontolerant drinker, high BACs correlate somewhat better with severity of intoxication. The lethal dose of alcohol for any patient is 5–8 g/kg. For children, it is approximately 3 g/kg, in part because they are generally nonhabitual drinkers.

The differential diagnosis for acute alcohol intoxication includes all diagnoses that might cause acute confusion progressing to coma (Chapter 115). The history of alcohol consumption is paramount. Other ingestions, concurrent metabolic perturbations, head trauma, infection, and acid-base or electrolyte disturbances all may present a similar picture. In addition, alcohol intoxication may be accompanied by other drug ingestions (Chapter 121). A complete history using all potential sources (especially family and friends), a physical examination, and laboratory data, including measurement of the BAC and drug screening, are critical to establishing the diagnosis.

The decision to admit the patient is based on how clinically intoxicated the patient appears, in conjunction with the BAC. One also should bear in mind that the BAC may be increasing at the time of initial evaluation; thus, continuing evaluation is important. Comorbid conditions often take precedence in determining who is admitted to the hospital and who may be discharged to a detoxification center.

Issues During Hospitalization

The treatment of a patient with alcohol intoxication is supportive. Alcohol is not adsorbed by charcoal; therefore, gastrointestinal decontamination is of no value unless some additional toxin has been ingested. Rehydration and repletion of electrolytes, maintaining perfusion and urine output, are essential. Hypoglycemia frequently occurs as a result of poor oral intake and decreased glycogen stores. Intravenous administration of fluid containing dextrose and blood glucose monitoring are especially important because the signs of hypoglycemia may be difficult to detect. Metabolizing alcohol results in increased concentrations of

acetate, pyruvate, β -hydroxybutyrate, and lactate, all of which may contribute to metabolic acidosis. Usually, adequate hydration helps to promptly clear these anions in patients with normal renal function. Patients with severe respiratory depression and hypoventilation should be considered candidates for assisted ventilation. Any patient who is unable to maintain a patent airway should be intubated. Many intoxicated patients are hypothermic because of the vasodilation that results from alcohol ingestion. Such patients should be rehydrated and rewarmed. Frequently, cardiac arrhythmias are seen in intoxicated patients. Gastritis and pancreatitis are also commonly observed with alcohol intoxication and should be treated as in any other patient (Chapters 80 and 86). Finally, hemodialysis should be considered for the patient with an extremely high BAC (greater than 5–6 g/kg) if the patient is not responding to more conservative measures.

If a patient has attained hemodynamic, metabolic, and thermal stability, transfer to an outpatient detoxification facility is appropriate. As at admission, comorbid conditions may dictate the timing of discharge. Further follow-up and counseling regarding alcohol abuse are addressed in the next section.

ALCOHOL WITHDRAWAL

Issues at the Time of Admission

The symptoms of alcohol withdrawal are nonspecific. Difficulty establishing the diagnosis is compounded by problems identifying patients at risk. Patients admitted to the hospital with virtually any primary diagnosis may develop AWS once their alcohol consumption is stopped abruptly at the time of admission. Patients with a prior history of AWS may be prone to developing it again, a phenomenon called *kindling* (4). This aspect of the past history is critically important. Many patients and families are reluctant to openly discuss their alcohol consumption and, even when asked about it directly, deny or minimize it.

Quantifying alcohol consumption (Table 122.1) is the first step in identifying patients with possible alcohol abuse and dependence. The *CAGE questionnaire* is a proven, simple screening test for alcoholism, which can be used in conjunction with quantity questions (5). The brevity and simplicity of these questions make them

TABLE 122.1
ALCOHOL CONTENT OF COMMON DRINKS

Drink	Alcohol content
1 can of beer	1 ounce of alcohol
4 ounces of wine	1 ounce of alcohol
1 mixed drink or cocktail	1.5–2 ounces of alcohol

especially useful for the busy hospital-based physician admitting multiple patients (Table 122.2). More than 2 positive responses highly correlates with a diagnosis of alcoholism and should identify patients who may develop alcohol withdrawal during their hospitalizations. All adolescent and adult patients should be screened for alcohol abuse at admission. A follow-up interview is important for suspected cases.

The *Diagnostic and Statistical Manual of Mental Disorders*, 4th ed. (6), defines alcohol withdrawal as:

1. Cessation or reduction in alcohol use that has been heavy and prolonged.
2. Two or more of the following developing within several hours to several days after No. 1: autonomic hyperactivity (e.g., sweating or pulse greater than 100); increased hand tremor; insomnia; transient visual, tactile, or auditory hallucinations or illusions; nausea or vomiting; psychomotor agitation; anxiety; and grand mal seizures.
3. The symptoms and criteria in No. 2 causing clinically significant distress or impairment in social, occupational, or other important areas of functioning.
4. The symptoms not resulting from a general medical condition and not better accounted for by another mental disorder.

The symptoms of alcohol withdrawal occur if the concentration of alcohol in the CNS decreases in habitual drinkers. The patient, over time, has developed compensation for the depressant effects that alcohol has on the CNS. The mediators of this compensation are multiple and include γ -aminobutyric acid, norepinephrine, cortisol, and others (7). If alcohol levels decrease, the compensatory mechanisms, particularly autonomic hyperactivity, become evident as symptoms and signs of alcohol withdrawal.

Presentation of AWS can be early (less than 48 hours since the last drink) or late (greater than 48 hours since last drink), as well as major and minor (Figure 122.1). It is important to understand that early findings can be similar to late findings. Alcohol withdrawal is a continuum occurring over the course of days, with increasing levels of autonomic hyperactivity. The presence or absence of delirium determines severity. The low-grade fever, tachycardia, tremu-

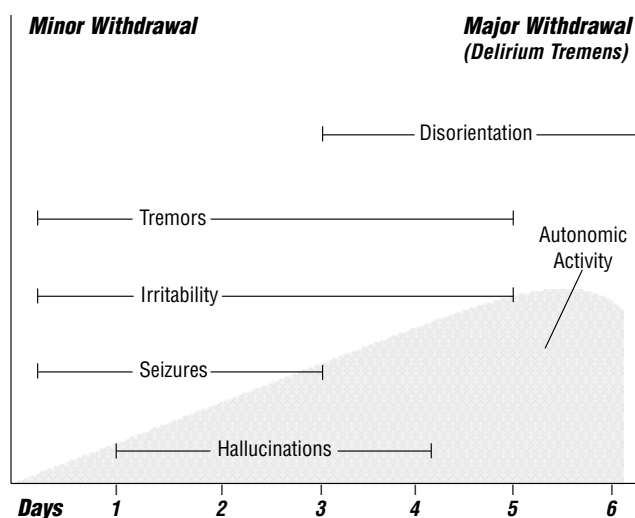

Figure 122.1 Characteristics of alcohol withdrawal. Adapted from Turner RC, Lichstein PR, Peden JG Jr, et al. Alcohol withdrawal syndromes: a review of pathophysiology, clinical presentation, and treatment. *J Gen Intern Med* 1989;4:432-444, with permission.

lousness, insomnia, and agitation of early withdrawal can proceed to delirium, complicated by profound hypertension, tachycardia, and tremors.

Some patients experience *alcoholic hallucinosis*, auditory or tactile hallucinations that occur with an otherwise clear sensorium. This might be seen in a patient with moderate withdrawal who is alert and oriented but is complaining of “things crawling under my skin.” Conversely, hallucinations of *delirium tremens* typically are visual and are never seen in the absence of disorientation.

The differential diagnosis for patients beginning to experience alcohol withdrawal is broad. Sepsis, hypoglycemia, hyponatremia, pneumonia, myocardial ischemia, pulmonary embolus, head trauma, and medication reactions are but a few of the alternative explanations for agitation, tachycardia, fever, and tremor of early AWS. If nurses or physicians note these changes during a hospitalization, a careful evaluation should ensue. As always, reviewing or augmenting the history is critical and may be the most important step. Review of the patient’s record, paying special attention to any recent trauma and medication changes, can provide valuable information, as can a focused physical and neurologic examination. Signs of trauma, focal neurologic findings, chronic liver disease, and infection can help narrow the differential diagnosis. Finally, laboratory data can help establish a diagnosis. Plasma glucose, electrolytes, renal and liver function tests, calcium, arterial blood gases, electrocardiogram, and, in the febrile patient, appropriate cultures should be performed (Table 122.3). AWS is ultimately a diagnosis of exclusion buttressed by a history of habitual alcohol consumption. Keeping the differential diagnosis broad and performing a careful evaluation is the only way to make the correct diagnosis consistently. Identification of

CAGE QUESTIONS HELPFUL FOR SCREENING ADOLESCENT AND ADULT PATIENTS

- C:** Have you felt you should **cut** down on your alcohol consumption?
- A:** Has your drinking **annoyed** your spouse/significant other/family?
- G:** Have you felt **guilty** about your drinking?
- E:** Have you ever had an “**eye opener**” (drink in the morning to “get the day started”)?

TABLE 122.3**SUGGESTED LABORATORY EVALUATION FOR PATIENTS SUSPECTED OF HAVING ALCOHOL WITHDRAWAL SYNDROME**

Plasma glucose
Electrolytes
Renal function tests (creatinine, blood urea nitrogen)
Liver function tests (aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, bilirubin)
Calcium
Arterial blood gases
Electrocardiogram
Appropriate cultures or radiographs in the febrile patient
Appropriate imaging if trauma suspected, including computed tomographic scan of the head as indicated

the patient at risk speeds this process. Increased severity of AWS has been associated with delay in making the correct diagnoses (8).

Evaluation of patients in the emergency department setting can proceed much as it would for patients already admitted to the hospital. An additional issue, however, is when and if patients should be admitted to the hospital rather than treated for alcohol withdrawal in an outpatient setting. There have been multiple attempts to identify risk factors for more severe alcohol withdrawal, although only general recommendations can be made. Patients with concomitant medical or surgical illness tend to have more severe alcohol withdrawal (8, 9). Patients who have had longer drinking histories and previous episodes of withdrawal and seizures are at higher risk for withdrawal (kindling). Although there are no strict guidelines about who to admit, objectively assessing patients can be extremely helpful in determining the severity of the withdrawal symptoms. A patient with full-blown delirium tremens merits admission. In addition, comorbid conditions complicating the alcohol withdrawal also lower the threshold for inpatient treatment. Pregnancy is another indication for admission, and patients for whom no outpatient follow-up can be arranged should be managed initially as inpatients. Objective assessment of the severity of AWS is the best way to make rational admission decisions.

Issues During the Course of Hospitalization

The goals of treatment of AWS are amelioration of symptoms and prevention of complications. Historically, decisions regarding admission, type, and level of care were empiric. Now there are tools available to allow objective assessment of patients going through AWS. The instrument most widely used is the *Revised Clinical Institute Withdrawal Assessment for Alcohol Scale (CIWA-Ar)* shown in Table 122.4

(10). This instrument facilitates reproducible scoring of the symptoms of AWS. Typically, a baseline is established, and the patient is reassessed at frequent intervals (every 1–2 hours initially, and then every 2–4 hours). The total score establishes the severity of withdrawal. A score of ≤ 10 generally merits observation or supportive treatment, such as a family member reassuring the patient in a quiet room. Scores >10 merit immediate pharmacologic intervention. Importantly, patients with previous episodes of alcohol withdrawal and previous alcohol withdrawal seizures should be treated at scores <10 because of their propensity to have severe withdrawal. The CIWA-Ar scale can be used with minimal prior experience and training in its administration. Its results are reproducible and reliable in both chemical dependency units and medical settings (11–14). As treatment progresses, the scores help direct therapy and can be used to determine if more intensive therapy and monitoring, as in an ICU, are required (Figure 122.2). Although many agents, including alcohol itself, have been used to modify the symptoms of AWS, *benzodiazepines* are the only agents repeatedly shown in multiple, randomized controlled trials to be effective (12). They are the drugs of choice and should be first-line therapy. Benzodiazepines are cross-tolerant with alcohol in the CNS. They can be given safely to substitute for alcohol and then tapered rapidly as the withdrawal symptoms abate.

The autonomic hyperactivity of AWS requires large doses of benzodiazepines at the outset of treatment, a concept called *front-loading*. Typically, up to 100 mg of chlordiazepoxide or 20 mg of diazepam is prescribed as an initial dose. Patients with AWS generally tolerate these large doses well because of underlying autonomic hyperactivity. Dosing and subsequent therapy historically have been on a fixed dose schedule (e.g., chlordiazepoxide 100 mg every 6 hours for four doses, then 50 mg every 6 hours for four doses, and so forth). Although this method is generally effective, it has been established that a *symptom-triggered approach (Symptom Triggered Therapy, STT)* (12) is just as effective and may, in fact, be advantageous. The fixed dosage regimens can potentially result in oversedation, putting patients at risk for aspiration and a prolonged treatment course. By repeatedly assessing the patient with the CIWA-Ar scale, and adjusting the benzodiazepine dosing according to the patient's response to treatment, the episode of withdrawal can be managed safely and effectively.

The body of evidence supporting the use of STT is growing. A 1994 study (13) from a chemical dependency unit found that STT was associated with a significant decrease in benzodiazepine required for treatment (100 mg, vs. 425 mg of chlordiazepoxide in controls) and duration of treatment (9 hours vs. 68 hours). A 2001 Mayo Clinic retrospective study (11) of medical inpatients treated for AWS with STT vs. usual care found similar benzodiazepine dosages and durations of treatment in both groups but significantly less delirium tremens in the STT group. Fi-

CIWA-AR QUESTIONS

Nausea and vomiting	5	3 Moderate harshness or ability to frighten
Ask: "Do you feel sick to your stomach? Have you vomited?"	6	4 Moderately severe hallucinations
<i>Observation</i>	7 Equivalent to acute panic states as seen in severe delirium in acute schizophrenic reactions	5 Severe hallucinations
0 No nausea and no vomiting		6 Extremely severe hallucinations
1 Mild nausea with no vomiting		7 Continuous hallucinations
2		
3		
4 Intermittent nausea with dry heaves		
5		
6		
7 Constant nausea, frequent dry heaves, and vomiting		
Tremor		
Arms extended and fingers spread apart.		
<i>Observation</i>		
0 No tremor		
1 Not visible, but can be felt fingertip to fingertip		
2		
3		
4 Moderate, with patient's arms extended		
5		
6		
7 Severe, even with arms not extended		
Paroxysmal Sweats		
<i>Observation</i>		
0 No sweat visible		
1 Barely perceptible sweating, palms moist		
2		
3		
4 Beads of sweat obvious on forehead		
5		
6		
7 Drenching sweats		
Anxiety		
Ask: "Do you feel nervous?"		
<i>Observation</i>		
0 No anxiety, at ease		
1 Mildly anxious		
2		
3		
4 Moderately anxious or guarded, so anxiety is inferred		
	Agitation	
	<i>Observation</i>	
	0 Normal activity	
	1 Somewhat more than normal activity	
	2	
	3	
	4 Moderately fidgety and restless	
	5	
	6	
	7 Paces back and forth during most of the interview or constantly thrashes about	
	Tactile Disturbances	
	Ask: "Have you any itching, pins and needles sensations, burning, or numbness, or do you feel bugs crawling on or under your skin?"	
	<i>Observation</i>	
	0 None	
	1 Very mild itching, pins and needles, burning, or numbness	
	2 Mild itching, pins and needles, burning, or numbness	
	3 Moderate itching, pins and needles, burning, or numbness	
	4 Moderately severe hallucinations	
	5 Severe hallucinations	
	6 Extremely severe hallucinations	
	7 Continuous hallucinations	
	Auditory Disturbances	
	Ask: "Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?"	
	<i>Observation</i>	
	0 Not present	
	1 Very mild harshness or ability to frighten	
	2 Mild harshness or ability to frighten	
		3 Moderate sensitivity
		4 Moderately severe hallucinations
		5 Severe hallucinations
		6 Extremely severe hallucinations
		7 Continuous hallucinations
		Headache, Fullness in Head
		Ask: "Does your head feel different? Does it feel like there is a band around your head?" Do not rate for dizziness or lightheadedness. Otherwise, rate severity

nally, a Swiss study recently reported (14) a randomized trial corroborating the safety and efficacy of STT in chemical dependency units (Figure 122.2).

Other agents can be used as alternatives to benzodiazepines, including phenobarbital, nitrous oxide, carbamazepine, and valproic acid. None have any distinct

advantages over the benzodiazepines (although anticonvulsants may reduce the risk of seizure), and none have been studied or used as extensively. Although all benzodiazepines can be effective in managing AWS, the short-acting preparations (e.g., lorazepam, oxazepam) may be preferable in patients with severe hepatic dysfunction or in the elderly.

CIWA Score	Chlordiazepoxide Dosage ^a	Lorazepam Dosage ^a
0–9	NONE	NONE
10–12	25mg orally	1mg orally or 0.5mg IV
15–17	75mg orally	3mg orally or 1.5mg IV
18 or greater	100mg orally	4mg orally or 2mg IV

^aUse one medication or the other, not both.

Figure 122.2. Suggested treatment protocol for patients with CIWA Score >10.

Adjunctive Treatment: Thiamine, Magnesium, Vitamins, β -Blockers, Centrally Acting α -Agonists

Wernicke's encephalopathy is a preventable, thiamine-dependent clinical complex of 6th cranial nerve palsy, ataxia, and confusion. It can be seen in any thiamine-deficient patient and thus frequently occurs in alcoholic patients. Thiamine can be given orally, subcutaneously, intramuscularly, or intravenously, typically at a dose of 100 mg/d until the patient is eating adequately. It should be given in larger doses (1000–1500 mg) to patients with oculo-lyric crisis. Dextrose solutions, especially concentrated formulations, can precipitate acute Wernicke's encephalopathy in the thiamine-deficient patient. Therefore, it is important to administer thiamine to patients receiving concentrated dextrose.

Many habitual drinkers also are *magnesium-deficient*. Hypomagnesemia lowers the seizure threshold. Thus, it is important to check the magnesium level and replace magnesium if it is low. If the magnesium level is normal, supplementation is not necessary. A malnourished patient may benefit from vitamin supplementation, although routine vitamin supplements are not necessary for most patients, especially if they are able to eat a nutritionally balanced diet.

β -adrenergic receptor blocking agents (propranolol or atenolol) have been used successfully to treat symptoms of AWS. Although β -adrenergic receptor blockers effectively treat many of the symptoms (tremor, tachycardia, hypertension) of AWS, they do not prevent progression of symptoms, seizures, or delirium. They are not recommended as monotherapy, because they may mask progressive symptoms. In selected patients who have received adequate benzodiazepine coverage but continue to have increased blood pressure or tachycardia, β -adrenergic receptor blockers may have an adjunctive role. This is especially true in patients at risk for cardiac ischemia as they progress through AWS. Contraindications to the addition of β -adrenergic receptor blockers, especially bronchospasm, should be kept in mind. *Clonidine*, a centrally acting α -adrenergic receptor agonist, also can be used adjunctively with benzodiazepines for resistant hypertension,

although, as with β -adrenergic receptor blockers, it should not be used alone. Routine use of either β -blockers or α -adrenergic receptor agonists is discouraged. Although they may have a role in selected patients, benzodiazepines should remain primary therapy, reserving atenolol or clonidine for the patient in whom blood pressure cannot be controlled or in the setting of cardiac ischemia or tachyarrhythmia (12).

Many patients in alcohol withdrawal are volume-depleted; have concurrent infection, pancreatitis, gastrointestinal bleeding, or hepatitis; or have other medical and surgical diagnoses. These conditions should be treated as in any other patients with these problems (Chapters 62, 78, 82, and 86).

Complications

Seizures

Alcohol withdrawal seizures occur infrequently, although in patients with prolonged and heavy drinking (>80–90 days), they may occur in one-third of cases. Typical alcohol withdrawal seizures occur early in the course of withdrawal, before the onset of delirium. They are usually generalized, brief, and self-limited, and, thus, they rarely require intervention. It is important, however, to evaluate patients for other contributing causes. Hyponatremia, hypoglycemia, subdural hematoma, and CNS infections all can occur in patients with alcohol withdrawal and all may predispose to generalized seizures. Patients should undergo a careful neurologic examination, assessment of the previously mentioned metabolic variables, and brain imaging. If the patient is febrile, lumbar puncture should be considered. Neurologic consultation is always appropriate in this setting, especially if seizure activity is not typical for AWS (e.g., focal, multiple, or prolonged seizures). Chapter 118 contains a general discussion of seizure management.

Seizures associated with alcohol withdrawal generally require no treatment beyond the benzodiazepines already being given for AWS itself. Patients with a known chronic seizure disorder should be continued on their usual anti-

convulsant regimen, with dosing guided by anticonvulsant blood levels. Patients with recurrent seizures during the course of AWS might be considered for anticonvulsant therapy, although recurrence is unusual enough that the diagnosis of alcohol withdrawal seizure should be considered suspect. Finally, patients with previously documented alcohol withdrawal seizures may be more likely to have recurrent withdrawal seizures. Some centers would pretreat these high-risk patients with anticonvulsant agents, although most would use only benzodiazepines aggressively at the earliest onset of alcohol withdrawal.

Delirium Tremens

Delirium tremens describes extreme autonomic hyperactivity associated with delirium and hallucinations. It occurs late in the course of withdrawal (2–4 days or more since last drink) and represents the most serious form of AWS. Early use of benzodiazepines usually can prevent progression to delirium tremens. If withdrawal progresses, though, additional treatment may be necessary. Haloperidol may be helpful in reducing hallucinations and confusion, although it should be used only adjunctively to benzodiazepines. Haloperidol therapy can lower the seizure threshold. Patients with delirium tremens can be extremely difficult to sedate, even with large doses of benzodiazepines. They may require cardiac monitoring, use of intravenous benzodiazepines and, in extreme cases, intubation and paralysis. Fluid and electrolyte status, intake and output, and renal function all must be monitored closely.

Arrhythmias

Virtually any cardiac arrhythmia can occur with AWS, although tachyarrhythmias are most common. They should be treated as in any other patient; β -adrenergic receptor blockade can be especially helpful if added to benzodiazepines. Patients at risk for myocardial ischemia should be placed in an appropriate, monitored setting with cardiac enzyme, ECG evaluation, and β -blockade (Chapters 37 and 38).

Discharge Issues

By definition, a patient recently treated for alcohol withdrawal is a habitual drinker who needs to address his or her addiction to alcohol. The resources and personnel available to help the hospital physician can range from a social worker to a complete addiction medicine or substance-abuse consulting service. Even when sophisticated hospital resources are unavailable, public health nursing, county social-service agencies, local detoxification centers, or a local Alcoholics Anonymous chapter may offer counseling services. Having just completed a course of AWS, many patients are willing to address their addictions openly and

take steps to curtail their alcohol abuse. Coexistent psychiatric diagnoses, especially depression, are common among alcohol abusers. Formal psychiatric consultation along with substance abuse counseling can be helpful. The patient should not leave the hospital without specific follow-up plans to address alcohol addiction.

Only rarely should patients be dismissed on benzodiazepines, unless they are to be followed in a detoxification center. As a patient is followed with the CIWA-Ar scale in the hospital, benzodiazepine use should continue to decrease and should be stopped once the score is ≤ 8 for 24–36 hours. The final decision regarding discharge may depend on other medical or surgical issues; however, from the standpoint of alcohol withdrawal, the establishment of a follow-up plan, stability of vital signs, and consistently low CIWA-Ar scores are the main criteria for discharge.

COST CONSIDERATIONS AND RESOURCE USE

Outpatient treatment of both acute intoxication and AWS are generally available and safe. For AWS, length of stay can be up to one-third less and cost 10-fold less in outpatient settings compared with inpatient care. The patient's overall levels of intoxication and BAC can help determine which acutely intoxicated patients can be treated as outpatients. In the case of AWS, the initial evaluation score and its trend on subsequent evaluations is helpful. For the patient admitted to the hospital, the symptom-triggered approach to alcohol withdrawal has been shown to be safe and effective in medical settings as well as chemical dependency units, and to shorten the length of stay and total amount of drug used in chemical dependency units (13).

KEY POINTS

- Screen every adolescent and adult patient for alcohol abuse and the potential for alcohol withdrawal at admission.
- Maintain a broad differential and ensure careful and thoughtful evaluation of the patient presenting with acute intoxication, as well as alcohol withdrawal.
- Use the CIWA-Ar scale to assess the patient at diagnosis and to help guide therapy for AWS.
- Use a symptom-triggered approach to dosing benzodiazepines.
- Provide for substance abuse or psychiatric consultation when the acute withdrawal phase has been completed to help design an appropriate follow-up plan.
