Most children with acute viral or autoimmune hepatitis require no nutritional supplementation. Fulminant hepatic failure requires careful management of protein to prevent hepatic encephalopathy and to reduce excess protein catabolism. Protein should be restricted only for short periods of time to treat severe encephalopathy (see above). Fluid volume can be reduced to prevent or treat cerebral edema; it is critical to maintain adequate glucose levels by infusing 6 to 8 mg/kg/minute of glucose to prevent hypoglycemia. Enteral nutrition should be continued as long as the child is conscious and in the early stages of elective ventilation. Once the requirement for liver transplantation becomes obvious, parenteral nutrition should be started to provide sufficient calories to prevent additional protein catabolism (see above).

Chronic Liver Disease

The majority of children with chronic liver disease will have cholestasis, either from biliary atresia, Alagille syndrome, or familial intrahepatic cholestasis and should be managed as indicated above. Children who are not jaundiced require similar support, although their requirement for fat-soluble vitamin supplementation will be less.

Problems can arise with children who have ascites and fluid retention; fluid restriction might be required. In these circumstances, modular feeds, which allow individual prescription of protein, sodium, and water and to which complex carbohydrate polymers, fats, vitamins, and mineral are added to produce a highly energy-dense feed, can be of value.

Inborn Errors of Metabolism

A number of inborn errors of metabolism rely on dietary modification as part of therapy. These include galactosemia, hereditary fructose intolerance, and tyrosinemia type I.

Galactosemia is an autosomal recessive disorder in which there is a reduction in the enzyme activity of galactose-1-phosphate uridyl transferase, which prevents the conversion of galactose to glucose. Dietary treatment

includes removing all products containing galactose (ie, milk and milk products).[105]

Hereditary fructose intolerance is an autosomal recessive disorder caused by a deficiency or absence of the enzyme aldolase B, which leads to cirrhosis and renal tubular disorders. Dietary management consists of elimination of fructose, sucrose, and sorbitol from the diet; this must be maintained for life. This means that all fruit and fruit juices are eliminated from the diet and only certain vegetables are permitted. Commercial products such as breads and cereals can also contain small amounts of sucrose, as can medications and toothpaste.[106]

Tyrosinemia type I is an autosomal recessive disorder caused by a defect in the enzyme fumarylacetoacetase, which leads to hypertrophic cardiomyopathy, cirrhosis, and renal tubular acidosis. For many years, dietary treatment was the only method of therapy and included restriction of phenylalanine, tyrosine, and methionine. Although restriction of these amino acids was effective in normalizing plasma amino acids, it did not prevent the progression of liver failure or the development of metabolic crises. The development of NTBC (2-[2-nitro-4-trifluoromethylbenzoyl]-1,3-cyclohexenedione) in association with dietary treatment has altered the natural history and outcome of the disease.[107]

Glycogen Storage Disease

The hepatic glycogen storage disorders are a group of autosomal recessive inherited disorders that lead to defects in the metabolism of glycogen. Liver and skeletal muscle are usually affected but heart, kidney, bones, and brain can also be involved. The presentation and biochemical features depend on the precise enzyme deficiency. Nevertheless, the treatment is dietary: to provide a continuous supply of exogenous glucose, either intravenously or enterally, to maintain normal glucose, and to suppress counterregulatory responses. In infants this is best achieved by frequent daytime feedings or continuous nocturnal enteral glucose feeding. In older children, the oral feeding of uncooked cornstarch (1 to 2 g/kg every 4 hours), which is hydrolyzed in the gut to release glucose slowly, can reduce the need for frequent daytime feedings or continuous nocturnal feeding.[106] Glycogen storage disease type III requires similar treatment but with a higher protein intake (3 g/kg). In most instances, dietary management is successful and can prevent the long-term complications of these diseases.

Preparation for Liver Transplantation

Liver transplantation is indicated for both acute and chronic liver failure. Nutritional support is of particular importance for children with chronic liver failure because malnutrition is a significant risk factor for mortality and morbidity related to liver transplantation.[64,66,67]

Chin and colleagues prospectively studied 26 children pre- and post-transplantation. They identified a significant difference in the 2-year actual survival for children with standard deviation scores (SDS) for weight of greater than –1 (57%) compared with those with scores less than –1 (95%) at the time of transplantation.[67] Similar data were obtained from Moukarzel and colleagues using height SDS. Children who were less stunted (height SDS < –1) had less morbidity and mortality (91% 1-year survival) compared with those who were more stunted (height SDS > –1), who had a 1-year survival rate of 75%.[64] These data have recently been confirmed in a study that evaluated a number of risk factors, including malnutrition, in infants undergoing liver transplantation.[66]

Children awaiting liver transplantation require intensive nutritional support, depending on the etiology of their liver failure, as documented above, but the main principle is to provide a sufficient energy intake (Table 40-6).

Effect of Liver Transplantation on Nutritional Status

Many recent studies have documented the nutritional rehabilitation achieved by successful liver transplantation.[5,67,70,108]

Following liver transplantation, surviving children experience a rapid return to normal midarm muscle area and midarm fat within 3 to 6 months.[70,108] Initial weight gain can be rapid because of the effects of corticosteroids on appetite and salt and water retention, but most children return to a normal weight once corticosteroids are reduced or discontinued. Linear growth is often delayed by 6 to 24 months, depending on the rate of hepatic complications and the withdrawal or reduction of corticosteroids.[109–111]

Preoperative nutritional status has a strong influence on post-transplantation growth. Children who were less stunted at transplantation grew slowly initially but finally achieved normal growth velocity, whereas older children who were more stunted (height SDS > –2) grew more quickly initially post-transplantation but did not achieve normal height.[112,113] There are no differences in catch-up growth between the sexes or with pretransplantation disease, apart from Alagille syndrome, which is associated with growth failure before and after transplantation in 50% of patients.[114,115]

Although successful liver transplantation reverses most aspects of malnutrition, it can be some months or years before bone density returns to normal. Persistent osteoporosis and bone fractures have been described at 3 to 6 months following transplantation[116] and were exacerbated

TABLE 40-6 Nutritional Support in Children Before and After Liver Transplantation

Requirement	*Preoperative*	*Postoperative*
Carbohydrate (g/kg/day)	Glucose polymer 15–20	Glucose polymer 6–8
Protein (g/kg/d)	Low-salt protein 3–4	Whole protein 2.5–3
Fat (g/kg/d)	50–70% medium-chain triglyceride 8	Long-chain triglyceride 5–6
Energy intake (estimated average requirement)	130–150%	120%

by the effects of corticosteroid therapy. Clinical studies to evaluate the use of bisphosphonates in the treatment of metabolic bone disease before and after transplantation are under evaluation.

Effect of Growth Hormone and IGF-I

As indicated earlier, both growth hormone and IGF-I are necessary for normal growth, and it has been shown that plasma IGF-I levels are low in children with chronic liver disease, despite elevated serum growth hormone. Although post-transplantation IGF-I and IGF-BP3 rise significantly and IGF levels return to normal, abnormalities in the IGF-binding proteins BP1, BP2, and BP3 remain for some months.[49]

Prevention of Growth Failure After Transplantation

The nutritional strategy for the prevention of growth failure before and after liver transplantation begins with intensive nutritional support preoperatively. Children who are malnourished before transplantation should be maintained with parenteral nutrition perioperatively until normal nutrition is resumed, whereas children with normal nutritional status should start enteral feeding with a rapid buildup of calorie intake 3 to 5 days following transplantation.

It is important to ensure sufficient energy intake (at least 120% of estimated average requirement) following the operation. This can be provided as a modular feed or supplemental nocturnal enteral nasogastric formula feedings in infants who refuse oral feeding and as diet in older children with calorie supplements. The energy intake should include 2.5 to 3 g protein/day and glucose polymer (6 to 8 g/kg/day), but fat can now be provided entirely as long-chain fat (5 to 6 g/kg/day) unless cholestasis secondary to chronic rejection is a complication (Table 40-6).[117]

Glucocorticoids, used to prevent organ rejection, interfere with growth hormone excretion. As growth hormone, IGF-I, IGF-BP1, IGF-BP2, and IGF-BP3 remain abnormal following transplantation, it is rational to consider whether growth hormone therapy might be helpful. Recombinant human growth hormone has been evaluated in eight growth-retarded children following liver transplantation.[118] The median growth rate increased from 3.2 to 7.1 cm/year ($p = .025$) and height SDSs increased from –2.9 to –3.1 ($p = .036$) during the first year of growth hormone treatment. Both IGF-I and insulin IGF-BP3 levels increased significantly during treatment. There was no effect on graft function, and no child developed rejection or any other complication, but growth velocity was not maintained beyond the first year.

CONCLUSION

The essential role of the liver in energy and growth has particular relevance for infants and children with end-stage liver failure. Considerable progress has been made in understanding the pathophysiology of malnutrition in liver disease, and this has improved our ability to support these children. Nutritional rehabilitation has been achieved by intensive nutritional support, and mortality following liver transplantation has been reduced. Its success depends on a multidisciplinary approach based on early intervention and prevention of malnutrition.

CHAPTER 41.1

CANCER PREVENTION

Richard S. Rivlin, MD, Susanna Cunningham-Rundles, PhD

There is increasing evidence supporting the concept that nutritional factors play a major role in the pathogenesis of several forms of cancer. Doll and Peto have estimated that, overall, about one-third of cancer cases are related to nutritional factors.[1]

Many of these studies, however, deal with cancers that generally do not occur in childhood, such as cancers of the breast, colon, prostate, and lung.[2–4] Our efforts in children need to be targeted at establishing at an early age those healthful dietary and lifestyle patterns that will form the basis for long-term reduction of risk of these cancers, as well as the risk of heart disease, diabetes, and other chronic diseases.

Chief among the concerns of prevention of adult cancer is the ominous rise of obesity in childhood.[5] Many more children are obese and even massively obese than in previous years,[6] especially in lower socioeconomic groups in the United States. Type II diabetes, previously and appropriately called adult-onset diabetes, is increasingly being diagnosed in adolescents, particularly in obese adolescents.[6] Childhood obesity is well recognized as leading to adult obesity, which, in turn, increases the prevalence and accelerates the course of several forms of cancer.

Nevertheless, there appear to be nutritional factors that might be specifically involved in the development of cancer during childhood and adolescence. Immune deficits could be important in cancer proliferation, and specific dietary factors, such as zinc,[7] clearly regulate immune competence. Hormonal secretion, particularly of insulin-like growth factor[8] and insulin,[9] is influenced by dietary factors, which, in turn, influence immune function. The colonization of the gut has been proposed as another factor specifically involved in the development of immune response in childhood[10] that could influence risk of cancer later in life. Nutritional and metabolic factors influence the child under treatment for cancer and the risk of second malignancy.[11]

A body of knowledge thus suggests that diet and nutrition in childhood set the stage for adult cancer as well as influence the prevalence of cancer in childhood itself. The pathogenesis of cancer is complex, but it might be useful to assess the current status of the scientific basis for making cancer prevention recommendations for children, as well as identifying the gaps in knowledge that need to be addressed by future research.

Let us begin by examining some of the specific nutritional factors that might relate to cancer etiology in children.

BREAST-FEEDING

There has been interest for many years in the possible association between breast-feeding and reduction in risk of subsequent maternal breast cancer. For example, Chinese women who breast-fed their children for 9 or more years had less than 40% of the risk for breast cancer than did mothers of infants breast-fed for 3 or fewer years.[12] Although long-term breast-feeding is common in China, it is hardly practiced at all in Western societies, but other findings show that breast-feeding for 6 or more months is associated with significant risk reduction of breast cancer compared with no breast-feeding.

More recently, there are suggestions that maternal breast-feeding might also have a protective effect on development of cancer in children. In one report, those women who reported having had any degree of breast-feeding as infants had 0.7 risk of developing breast cancer as adults. The reduction in risk was similar in premenopausal and postmenopausal women.[13] In a case-control study undertaken in the United States by Davis and colleagues, a negative correlation was observed between the duration of breast-feeding and the incidence of a variety of malignancies in the children.[14] For those who had been bottle-fed exclusively or breast-fed for periods shorter than 6 months, there was nearly a doubling of overall cancer risk compared with the rate in children who had been breast-fed for longer than 6 months. The protective effect of breast-feeding was strongest for lymphoma: children who were not breast-fed at all or breast-fed for less than 6 months had more than five times the risk of lymphoma than those who had been breast-fed for 6 or more months. These results are dramatic but, in our opinion, still preliminary because of the small number of cases involved.

Similarly, in a case-control study of children aged 2 to 14 years from the United Arab Emirates, breast-feeding for 6 months or less was associated with significantly increased risk for acute lymphocytic leukemia (OR = 2.5), Hodgkin's lymphoma (OR = 3.8), and non-Hodgkin's lym-

phoma (OR = 4.1) compared with that of children breast-fed longer than 6 months.[15]

A comprehensive study intended to identify risk factors for acute childhood leukemia found that breast-feeding for any period reduced the risk of childhood leukemia by about one-fifth.[16] The reduction in risk was comparable for acute lymphoblastic leukemia and acute myeloid leukemia and appeared to be greater for both types with more prolonged breast-feeding.

Parker, in summarizing the results of recent reports, concluded that the evidence in its entirety is in support of a significant protective effect of breast-feeding on childhood leukemia and lymphoma.[17] Based on the effects described so far, Parker estimated that as many as one-fourth of the cases of childhood leukemia and lymphoma could be prevented if all infants were breast-fed. This benefit is in addition to other well-established effects of breast-feeding, including improving immunologic function, resisting infection, and reducing obesity and the prevalence of subsequent chronic diseases as adults.

SEXUAL ACTIVITY

One of the health risks of early adolescent sexual activity that has not received adequate attention is an increase in the prevalence of cervical cancer. Although health professionals tend to think of this cancer as being restricted to adult women, in fact, it is being found increasingly in adolescents.[18] The age at which invasive cervical cancer is first diagnosed has been decreasing in Western countries[19] and has been correlated with the age of first sexual intercourse.[20] Certain methods of contraception, such as condoms and diaphragms, which form barriers, tend to reduce the risk of cervical cancer somewhat. The infrequent use of these methods by adolescents further compounds the risk of unprotected sexual activity. Adolescence is a critical time because the cervical epithelium is undergoing rapid evolution and is particularly sensitive to carcinogens.[19,21]

The worrisome rise in cervical cancer offers the opportunity for nutritional intervention at a time when it could potentially be highly effective. The most appropriate nutritional regimen for the prevention of early cervical cancer, however, is not clearly established at present. It is likely to include cessation of smoking and alcohol use, as well as folate and zinc supplementation. Further research is needed on the natural history of cervical cancer in young women because it is not known with certainty what percentage of cases will remain localized and what percentage will become invasive, and whether nutritional factors regulate invasiveness.

PESTICIDES AND OTHER ENVIRONMENTAL CARCINOGENS

The role of pesticides as possible causes of cancer in childhood has attracted recent interest. Children can be exposed to pesticides not only in foods that they consume but also in the environment of household gardens and farms. A recent report found an association between neuroblastoma in young children above the age of 1 year and an environment with high concentrations of pesticides in the garden.[22] It is conceivable that pesticides compromise immune function and limit immune surveillance.[23] Other pesticides have estrogen-like activity and could possibly disrupt normal development by inducing higher than normal concentrations of hormonal stimuli that regulate neural cell development.[24]

In any event, the entire subject of potential risks of pesticides serves as a lightning rod for controversy. At present, these findings are intriguing but can be viewed only as preliminary, requiring further extension and confirmation before they can serve as guidelines for public health recommendations. Obviously, unnecessary exposure of children to pesticides should be avoided, but their significance as a major cause of childhood malignancy is still unclear.

There is no doubt that there are a large number of toxic substances in the environment that potentially could be causes of childhood cancer. These substances can be grouped into several categories:

- products of nitrosation, including betel nut and nitrites
- natural carcinogens, such as mycotoxins, pyrrolizidines, and safrole
- products of pyrolysis and smoking of food to yield carcinogenic hydrocarbons
- certain specific food additives, including flavors, azo dyes, pollutants, and contaminants[25]

These agents generally have a long latent period so that exposure during early infancy and childhood conceivably could be carcinogenic during the period of late childhood or in adult life.[25] More information is urgently needed on the factors that govern bioavailability, absorption, excretion, and metabolism of these potential carcinogens and on possible nutritional means of prevention.

Recent reports have proposed that some cases of childhood leukemia and neuroblastoma could be attributable at least in part to the role of external pollution. Infante-Rivard and colleagues have alerted the scientific community to the possible association of contaminated drinking water, with its contents of trihalomethanes, metals, and nitrates, with increased prevalence of acute lymphoblastic leukemia.[26] This is an intriguing suggestion that needs further extension and confirmation. One critic of the study felt that it could explain at most only a small fraction of the total number of cases.[25] Daniels and colleagues reported an association between exposure to pesticides and incidence of neuroblastoma.[22] This preliminary finding is also provocative but needs further support.

The results of studies of pesticides are disquieting because they raise the prospect that these environmental agents could lead, over the long run, to cancer development. Herbicide and pesticide use is widely practiced in the United States, and it is likely that for any given dose of these agents, children might be more vulnerable than are adults.[27,28]

A disturbing report indicated that baby bottle nipples and children's pacifiers contain appreciable concentrations

of nitrosamines and their precursors.[29] Under conditions of normal use, as much as one-third of the nitrosamines in the nipples were taken up by the formula within a few hours. This study, if confirmed and extended, urges intense scrutiny of such baby products on an international basis because they could cause serious hazards that are avoidable.

CHILDREN'S DIETS

As noted above, children are becoming more and more obese; this is generally attributable to a combination of reduced physical activity and larger portion sizes of readily available high-calorie food. Efforts to link childhood cancers with weight gain or with specific dietary items, however, have generally proven elusive. It is of interest, therefore, that more than 20 years ago, an association between rhabdomyosarcoma in childhood and consumption of organ meats was described with a relative risk (RR) of 3.7.[30] A small number of cases were involved, but the association was quite strong. It would have been helpful if the duration of adherence to this diet had been specified. To our knowledge, this intriguing relationship still requires confirmation with respect to rhabdomyosarcoma. If verified, it would be one of the first examples of a cancer in childhood that is influenced by some of the same factors linked to cancer in adults.

Several studies have examined the possible association between brain tumors and cured or organ meat consumption by mothers during pregnancy. It seems fair to conclude that increased maternal consumption of cured meats has been observed in some studies of infant brain tumors, but the associations are by no means definitive, and they have not been observed in every report.[31] There seems to be no clear relationship between consumption of cured or organ meats by children and the development of any cancer, except as noted above.

MALNUTRITION AND CANCER IMMUNITY

Causal relationships among malnutrition, immune deficiency, and susceptibility to cancer development have been suspected for more than three decades. Malnutrition is increasingly recognized as a frequent cause of immune deficiency (see also Chapter 20, "Malnutrition and Host Defense").[32–34] Although the relationship between malnutrition and impaired host defense against infections is supported by many studies and observations, establishing analogous relationships for immune response against cancer has proven complex.

Tumors compete for the same nutrient supply as the host, and dietary composition affects tumor growth.[35,36] Spontaneous tumors are immunologically "self," and classic antibody responses are rarely detectable and perhaps might be only weakly recognizable by the host immune system. Furthermore, evidence that caloric restriction reduces cancer risk in the cancer-prone animal might be interpreted to mean that nutrient intake generally supports cancer growth.[37,38] The discussion presented here will show that nutrients have differential effects on tumor growth and host immune response. Caloric restriction in animal models does not translate easily to human tumor risk, although these investigations could reveal key interactions relevant to obesity. Furthermore, new data reveal the potential effectiveness of human immune response to tumors.[39–42] On balance, emerging data suggest that nutrients are regulators of immune response and as such are also critical host modifiers for risk of cancer development.

Malnutrition and Host Response to Cancer

Malnutrition is frequently an important complication of malignancy despite normal nutrient provision, and poor nutrient status appears to confer risk of reduced response to cancer treatment.[43,44] This can present as progressive wasting in many types of cancer and is currently recognized as a critical factor in morbidity and mortality.[45,46] Loss of skeletal muscle protein and depletion of body lipid stores are notable in the cachectic patient. Furthermore, adipose tissue is depleted as well, in association with nitrogen loss. Metabolic change is associated with alterations in circulating hormone concentrations, including insulin, glucagon, and glucocorticoids.[47] Effects on metabolism are examined in Chapter 41.2, "Cancer Treatment."

Cancer-associated anorexia and cachexia are characterized by a persistent inflammatory immune response and a catabolic hormonal environment marked by increased circulating levels of tumor necrosis factor α (TNF-α), also known as cachexin.[48,49] Other cytokines, including interleukin(IL)-1, IL-6, interferon-γ, and factors such as leukemia inhibitory factor and ciliary neurotrophic factor, are also mediators of the cachectic process.[50–52] Some investigators have proposed that anorexia could involve persistent stimulation of anorexigenic neuropeptides, such as corticotropin-releasing factor, acting to inhibit the neuropeptide Y orexigenic network.[51] Other studies have focused on the possible role of leptin, the proinflammatory and cytokine-like hormone that acts as a negative feedback signal in the control of food intake and body weight but also affects immune response. However, current studies indicate that increased levels of proinflammatory cytokines, including IL-1, IL-6, TNF-α, and interferon-γ, do not correlate with increased levels of leptin. Although some individual patients show significantly increased levels, no direct correlations have emerged.[53,54] Thus, the basic causes of anorexia in cancer patients remain unclear.[55]

Cachexia, which is often independent of anorexia, is closely associated with an increased and deregulated inflammatory response and appears to reflect the stress of host defense and evolving immune deregulation in response to the presence of the tumor.[43,46–48] Nutritional support and appetite stimulation are largely ineffective in restoring lean body mass in the cancer patient, although weight gain and quality of life can be improved.[48,56] In contrast, reducing the proinflammatory response, specifically with fish oil supplying eicosapentanoic acid through dietary means, appears promising in reversing the catabolic environment.[38,57] Perhaps equally importantly, directed nutrient support could be capable of enhancing immune response toward the tumor and therefore could potentially exert a protective effect against metastasis.

Deficient Immune Response and Cancer Risk

Deficient immune response is often observed in studies of cancer patients when thymus-derived, T-lymphocyte proliferation to mitogens is assessed in vitro.[58–60] However, spontaneous T-cell activation and increased circulating levels of cytokines such as interferon-γ are also observed,[58] suggesting a link between increased inflammatory cytokine production and reduced response to another stimulus. Heimdal and colleagues recently showed that decreased response to nonspecific mitogen and increased spontaneous T-cell activation are associated with poor prognosis in head and neck cancer.[59] Current studies also report that an increased inflammatory response characterized by high circulating levels of IL-2 receptors is linked to poorer response to immunotherapeutic use of IL-2 in the cancer patient.[60]

These studies suggest causal links among deregulation of the cytokine network, effects on the neuroendocrine response, and host response to cancer. As discussed below, the pattern of cytokine response the host produces in response to tumor could be prognostic. Thus, re-establishment of nutrient balance might be used to modify host response and decrease risk of inadequate treatment response.

The concept that tumor antigens could ever be significantly immunogenic in the cancer-bearing host, despite being of self-origin, is gaining credence as investigations reveal existence of tumor-reactive cells using novel recombinant protein strategies.[40] Related studies have shown that type and strength of host response to tumor vaccine are specifically related to cancer survival and are also independent of response to other, unrelated antigens or to nonspecific activators.[39] Furthermore, emerging studies are showing that the type of immune response that patients develop toward autologous tumor is related to outcome.

For example, in the case of experimental murine lymphoma, host immune response that is predominated by production of T helper type 2 (Th2) cytokines has been shown to be fatal.[61] Extensive investigation into why response to tumor antigens is frequently ineffective has shown that tumors induce immune dysfunction in the host through a variety of mechanisms, including blockade of monocyte antitumor defense. For example, tumors produce cytokines, growth factors, and other molecules, including IL-4, IL-6, IL-10, tumor growth factor β1 (TGF β1), prostaglandin E_2 (PGE_2), and monocyte colony-stimulating factor (M-CSF), that have differential effects on immune cells in different blood compartments, leading to suppression of monocyte-mediated host defense.[62] These tumor mechanisms operate through impact on the cytokine response, and this response is critically modulated by nutrients (see Chapter 20, "Malnutrition and Host Defense").

Until comparatively recently, evidence that immune deficiency alone is a risk factor for cancer was sketchy because primary immune deficiency was underdiagnosed and few follow-up studies were completed or reported. With continued study, the relationship between impaired immune response and cancer has been clearly shown. Immune deficiency arising from primary genetic causes or in the context of immune system infection is a significant and direct cause of increased susceptibility to cancer. Malignancies, particularly B cell lymphoma, often develop in patients with common varied immunodeficiency or hypogammaglobulinemia.[63,64] Human immunodeficiency virus (HIV) infection, which produces profound immune deficiency, is frequently associated with cancer even in the context of effective antiretroviral therapy. Increased incidence of Kaposi's sarcoma and non-Hodgkin's lymphoma has been consistently observed in epidemiologic studies of HIV-infected adults, in whom appearance of these tumors is diagnostic for acquired immune deficiency syndrome (AIDS). Now that children congenitally infected with HIV are living longer with better treatment, they are developing these malignancies with a frequency that is similar to that reported for adults.[65,66]

Nutrients as Modifiers of Host Response

Worldwide variation in diet is thought to account for perhaps one-third of the environmental differences in cancer incidence.[67] However, the exact causal relationships have been difficult to establish. Intake of fruits and vegetables and increased fiber consumption are clearly protective against certain cancers,[68–71] and some current supplementation studies indicate benefit.[72,73] Variable and conflicting results have also been reported,[74,75] suggesting difficulties in obtaining clear results with single interventions when underlying variables among participants, such as smoking—currently on the rise in adolescents—can confound the observations.

Nutrients can have different effects in pediatric cancer patients because presentation is often acute and occurs over a wide range of ages and developmental stages that need to be considered in terms of both effects on growth and possible interactions with the immune system. Severe weight loss is a notable cause of morbidity in children with cancer.[76] As discussed in Chapter 41.2, "Cancer Treatment," the basis of weight loss in children with cancer is incompletely understood but includes increased protein turnover and loss of the normal compensatory mechanisms that occur in starvation.[77,78]

Whereas children with failure to thrive often have decreased immune response, especially reduced reactivity on skin testing, there is no clear association with spontaneous tumor development. Children with Bloom syndrome have genetic susceptibility to almost all cancers and also have marked growth deficiency. In a recent study, Keller and colleagues reported that all children with Bloom syndrome are stunted throughout life. In addition, more than half of children with Bloom syndrome are significantly wasted until 8 years of age. Yet this difference was unrelated either to early death or to malignancy when wasted children with Bloom syndrome were compared with children with Bloom syndrome who were not wasted.[79]

Among children, the predominant malignancies are hematopoietic, and some studies of untreated children have reported no anthropometric changes even when high-risk disease was considered.[80] However, more subtle changes could prove important in stratifying children who would benefit from early intervention.[81] For example, recent studies show that chronic zinc and magnesium

deficiency are differentially prevalent among children with lymphoblastic leukemia and lymphoma.[82] Both zinc and magnesium deficiencies have profound effects on immune response. Thus, the importance of evaluating children with cancer for potential nutritional support is increasingly recognized and could reduce risk of inadequate response to therapy by increasing immune response, as well as by supporting tolerance of therapy and improving quality of life.[77,81,83]

Risk that chemotherapy will lead to febrile neutropenia, precipitating an inflammatory syndrome and weight loss, is well recognized as a major concern in pediatrics.[84,85] Importantly, bone marrow recovery is often uneven, and reconstitution of immune response can lag behind, leaving the weakened host vulnerable to infection. Cytokines are involved in the etiology of sepsis and are more predictive than acute-phase proteins, such as C-reactive protein,[86] because these are markers of a process in which loss of immune function is central. Future studies might include the impact of dietary elements such as glucans, which appear to exert growth factor effects in supporting hematopoiesis and immune response in the cancer patient.[87]

Tumor phenotype is affected by environmental nutrients.[35,36] Growing tumors require more nutrients, and nutrient modulation can strongly affect metastatic activity.[88] In general, antioxidant nutrient supplementation and protein depletion appear to reduce tumor growth.[89,90] Furthermore, a large body of data over many decades strongly supports the protective effect of caloric restriction in reducing tumor growth in animal models of solid tumors.[37] Caloric restriction could also have a benefit in obese persons with risk of colon cancer, as measured by effects on rectal cell proliferation.[91] One epidemiologic study on adult height and risk of breast cancer found that adolescent caloric restriction during World War II leading to reduced final height was associated with reduced risk of breast cancer.[92] Relationships to specific foods eaten or not eaten, however, was outside the scope of the study.

In contrast, the Netherlands Cohort Study, which performed a similar examination, found no correlation between energy restriction owing to food deprivation during the adolescent growth spurt and decreased incidence of breast cancer.[93] Whereas anorexia nervosa can be associated with reduced risk of cancer in women, another relevant study also noted the suggestion of a possible increase in men.[94] Studies using the cancer-prone p53-deficient mouse convincingly show that caloric restriction reduces insulin-like growth factor I and leptin levels, reduces cell proliferation, including thymocytes, and increases latency of spontaneous tumor appearance while decreasing tumor progression.[38,95]

On the other hand, deficiencies of micronutrients, such as zinc, can increase cell proliferation and enhance tumor incidence experimentally.[96] The value of caloric restriction, which is based on increasing the caloric expenditure-to-intake ratio possibly through adrenal hypertrophy,[97] might be less relevant in growing children and even potentially dangerous, especially when compared with more moderate approaches that include increasing exercise as a safe means of reducing risk.[98] In light of new data suggesting fundamental gender-related differences in immune response and other studies linking neuroendocrine and immune response in a range of stress-producing circumstances, such as trauma and severe nutrient deprivation, the effects of caloric restriction on the immune system need to be studied in greater detail.[99–101]

Taken as a whole, these studies have introduced a note of caution regarding the possible risk of indiscriminate nutrient supplementation in cancer. However, as epidemiologic and experimental studies have suggested the benefit of such dietary constituents as fiber in cancer prevention, alternative dietary approaches have emerged for the cancer patient. Although most are nutritionally adequate for adults, no anticancer diet has been shown to cure cancer, and there is concern that such diets might not be adequate for children.[102] As discussed below, the balance of studies to date suggest that support of the mucosal immune system in the cancer patient is beneficial and often critical. Therefore, despite theoretic concerns that nutrients provided to stimulate host immunity might in fact feed the tumor, evaluation and treatment of malnutrition in the pediatric cancer patient are recommended as a means of reducing risk of poor outcome.[76,77,83]

NUTRIENT SUPPORT OF MUCOSAL IMMUNE RESPONSE

Products of digestion have been linked with cancer risk. For example, increased calcium from milk consumption in adolescence, which can lower levels of 1,25-dihydroxyvitamin D, has been linked to susceptibility to testicular cancer in men but has shown a protective effect for breast cancer among women.[103,104] The mechanisms of these effects likely involve changes at several levels and precede tumor development by months or years. Furthermore, levels of nutrients known for chemoprotective effects, such as betacarotene, zinc, and selenium, studied in children at the time of cancer presentation do not appear to correlate with outcome.[105] Understanding the interaction among nutrients, the gastrointestinal immune system, and the emerging role of the normal or commensal microflora could illuminate some of the critical relationships.

Immunonutrition

Concerns that total parenteral nutrition (TPN) can enhance tumor growth in the cancer patient have been allayed by growing experience, such as a recent report that TPN was beneficial in treatment of malnourished patients undergoing high-dose IL-2 therapy for metastatic cancer.[106] TPN has also proven useful in support of catch-up growth in the child with cancer[107] and could support restoration of innate immune function.[108] However, nutrient metabolism provides an essential stimulus for the induction, differentiation, and maintenance of the mucosal immune system.[109,110] Prolonged illness, reduced dietary intake, and lack of enteral feeding directly affect this. Lack of enteral dietary intake impairs mucosal IgA and secretory component production, the number of IgA-containing cells, and the level of IgG, as shown in recent studies.[111,112]

The enteral route of nutritional intake promotes mucosal growth.[113] Loss of this stimulation is associated with immune suppression, as shown by the negative effects of parenteral nutrition. Glutamine, arginine, certain combinations of omega-3 polyunsaturated fatty acids, and dietary nucleotides are necessary for recovery of mucosal immune function.[114] Experimental and human studies have shown that glutamine supplementation of the tumor-bearing host attenuated loss of protein caused by glutamine depletion of host tissues and had a protective effect on immune and gut-barrier function.[115] The benefit of other nutrient combinations is not as clear.

A recent meta-analysis evaluated response to key nutrient enteral supplementation in gastrointestinal surgery and found reduction in infections.[116] However, this benefit was not as clear for cancer patients given early enteral feeding after surgery for upper gastrointestinal malignancy.[117] Supply of normally nonessential amino acids, specifically arginine and glutamine, promotes cellular proliferation in the gut, T-cell production, and the development of host defense against infection.[118] The central impact of glutamine administration on immune function appears to be mediated through initiation of a Th2-type cytokine response with increased IL-4 production and mucosal IgA level,[119] which has been shown to improve both gut-associated lymphoid tissue (GALT) and respiratory tract immunity.

Commensal Microbes and Probiotics

As discussed above, nutrients stimulate and act as substrates for the development of mucosal immunity. In addition, emerging studies have shown that lactic acid bacteria traditionally used in the production of food can play a key role in support of a healthy gastrointestinal tract. Mucosal immune response is largely developed after birth in response to microbial interactions. Microflora mold the architecture and physiology of the mucosa through activation of immune response, and this interaction continues to influence immune response throughout life.[120,121] Emerging studies suggest that the specific composition of microflora is highly varied in different cultures.[122] Normal flora do not directly harm the normal host and also contain certain commensals that produce nutrients, absorbable peptides, and vitamins that benefit the host.[123,124]

The potential significance of this lifelong interaction could be studied only comparatively recently, with the advent of genetic typing. These studies show that the well-characterized beneficent commensals, such as lactobacilli, form a small and rather fragile part of the overall flora.[122] Commensal bacteria are mainly obligate anaerobes, whereas key pathogenic bacteria are facultative anaerobes and replicate faster in the presence of oxygen. Thus, lactobacilli and bifidobacteria, which are normal gut commensals, survive and replicate in the presence of oxygen but not as effectively as *Escherichia coli* does.

Metchnikoff was the first to propose that lactic acid bacteria could have a favorable effect on health,[125] but the concept of probiotic bacteria as living microbes introduced to improve intestinal microbial balance is recent.[126] Probiotic bacteria can be administered to stabilize the gut mucosal barrier[127] and have been found effective against bacterial and viral diarrhea in infants,[128] perhaps against antibiotic-associated diarrhea[129] and even against the effects of *Clostridium difficile*.

Experimental studies have shown that probiotic lactobacilli can replace microflora that produce carcinogens and tumor promoters, neutralize carcinogens, and produce antitumor factors through direct actions in the gastrointestinal tract.[130,131] Furthermore, related studies indicate that consumption of certain fructans, such as oligofructose and insulin, which have been observed to selectively increase the growth of intestinal probiotic bacteria such as bifidobacteria, exerts a beneficial prebiotic effect, leading to reduced colon cancer risk.[132] Essential characteristics for probiotic efficacy include resistance to acid and bile and ability to colonize and adhere to the colonic mucosa.[133] Moreover, current studies suggest that probiotic lactobacilli can promote immune response and serve as immunoadjuvants and that lactobacilli can be used to increase weak systemic immune response, even in the HIV-positive host.[10,120,134]

Recent studies show that lactic acid bacteria synergize with the immunomodulatory effects of alkylglycerols.[135] Mechanisms of action could include competition for specific ecologic niches, immunologic stimulation of the mucosal barrier, and induction of specific cytokine patterns.[128,136,137] Indirect evidence suggests that some probiotic bacteria could protect against risk of cancer.[138] In the colon, probiotics or prebiotics could have detoxifying effects on genotoxins.[139] Ingestion of prebiotics affects the spectrum of fermentation products, leading to high concentrations of short-chain fatty acids. Gut flora have been shown to induce chemopreventive glutathione transferase activity.[139] These changes could provide a balance to the potentially pathologic consequences of normal persistent microbial colonization of the gut.[140]

Although studies in humans are preliminary, there are suggestions that lactic acid bacteria could have a balancing effect on immune function in addition to antimicrobial effects. For example, probiotic bacteria appear to improve conditions related to food allergies and to down-regulate a proinflammatory response to milk in hypersensitive subjects while up-regulating the same response in healthy, unaffected persons.[141,142] Consumption of lactobacillus-fermented dairy products could elicit antitumor effects. These effects are possibly attributed to the inhibition of mutagenic activity and a decrease in activities of several enzymes implicated in the generation of carcinogens, mutagens, or tumor-promoting agents.[143] Future studies are needed to show how these interactions will affect lifetime risk of cancer and whether the child with cancer can benefit from probiotics.

Future Directions

The challenge of understanding the nutritional factors that might be involved in the pathogenesis of cancers in adults is difficult enough, but in childhood it is even more difficult. The prevalence patterns of cancer are different, the time periods of exposure to carcinogens or to relevant dietary fac-

tors are shorter, and there is a significant lack of appropriate biomarkers. Furthermore, fewer studies have been carried out among children, and those cancers most extensively explored with respect to diet in adults, namely lung, colon, breast, and prostate, very rarely occur in childhood.

Thus, it is apparent that very little information is currently available on the dietary and nutritional factors that promote cancer in infancy and childhood. In particular, the possible effects of maternal dietary and metabolic influences during pregnancy and lactation require clarification. To elucidate these possible relationships and to describe the underlying mechanisms involved precisely, our research must become more interdisciplinary. It is vital to link basic science with clinical investigation. We should be investigating gene–nutrient interactions using the latest techniques in molecular biology and molecular nutrition, such as DNA microarray, in order to provide recommendations for cancer prevention in childhood. It is essential that we gain an understanding of the relationships among dietary constituents, risks of carcinogens, and genetic polymorphisms.

CHAPTER 41.2

CANCER TREATMENT

Sarah Jane Schwarzenberg, MD, Sally Weisdorf-Schindele, MD

The need for nutrition support in children with cancer is dictated by how the combined impact of the tumor, the chosen therapy, and their complications affect host metabolism. The prevalence of weight loss and malnutrition at the time of cancer diagnosis is low in children compared with that in adult cancer patients.[1,2] This may be partly attributable to the higher incidence of leukemia in children, in which energy expenditure is not affected and tumor metabolic burden is small, and to the lower incidence of solid tumors in children compared with adults. Few pediatric malignancies affect the digestive system directly, and tumors that secrete metabolically active peptides are rare in children. Loss of appetite is more likely to be owing to therapy and the psychological effects of cancer diagnosis and treatment. However, reduced food intake can be related to cancer cachexia in children, and children are more susceptible to cancer-related undernutrition.[3,4]

Increased energy requirements have been reported in some, but not all, studies of adult patients with cancer. This has not been found to be the case in the single pediatric study to date.[5] The authors of this study reported that leukemia patients were not different in energy expenditure at diagnosis or during the first 2 weeks of therapy from age- and sex-matched controls. Energy needs of individual children who are undergoing therapy would be affected by decreased energy intake, infection, surgical stress, and cancer cachexia.[6]

TUMOR CACHEXIA: IMPACT OF CANCER ON TISSUE METABOLISM

In the first edition of this text, Dr. Kien described cancer cachexia as "a malnourished state characterized by weakness, anorexia, and altered body composition."[7] In this state, the body's response to starvation is altered, with loss of the ability to conserve nitrogen during food deprivation. Normal adaptation to starvation results in decreased protein synthesis, protein catabolism, and protein turnover, but in cancer cachexia, the rate of each of these processes is increased. Hepatic gluconeogenesis and protein synthesis increase at the expense of somatic protein, yet serum albumin may be low owing to increases in body water. Lipid stores are depleted and serum lipid is elevated, suggesting a loss of feedback control over peripheral triglyceride breakdown.[8] Glucose requirements appear to be increased, hepatic gluconeogenesis increases, and insulin resistance has also been documented.[9] Characteristically, cachexia is irreversible with the simple provision of adequate energy and protein. Cachexia, then, is similar to the hypermetabolism of sepsis, which is described below.

Of the various theories that have been proposed to explain cachexia, most evidence suggests that circulating cytokines cause these metabolic alterations.[10] Septic hypermetabolism, which is the systemic response to severe illness, and cancer cachexia are associated with a similar group of cytokine mediators. Lymphocyte-derived proteins (ie, cytokine, lymphokine, or interleukin [IL]) are released as a nonspecific response to tissue injury or immune insult, with resulting local and systemic effects. Lymphokine release can lead to a cascade of further lymphocyte response with release of other active peptides. Various cytokines are being studied, both as potential mediators of cancer cachexia and to provide potential therapeutic approaches to reversal of the cachectic metabolic derangement.[11] Several of these are discussed here briefly.

Tumor necrosis factor (TNF; cachectin) was identified as a peptide produced by macrophages in response to bacterial lipopolysaccharide and as a serum factor responsible for antitumor activity.[12] In animal studies, injection of TNF reproduced symptoms of cancer cachexia,[13] whereas anti-TNF antibodies reversed these effects.[14] Measurable quantities of TNF have been found in some, but not all, sera of cachectic cancer patients.[15] TNF is thought to act primarily locally rather than systemically.[16] Parenterally administered TNF probably causes cachexia by direct action on the brain.[17] The action of TNF is mediated in concert with the action of other cytokines (see below). Studies are in progress investigating the use of anti-TNF antibody as an adjunct to nutrition support in cachectic patients.[18]

IL-1 is also produced by macrophages in response to endotoxin. Its actions are similar to those of TNF, and the effects of the two cytokines are synergistic.[19] IL-1 has not been detected in the serum of either animals or humans with cancer[20]; however, systemic administration of IL-1 induces changes in hepatic protein synthesis that are similar to the changes observed in cachexia.[21] When IL-1 and TNF are administered to animals, they become hyperglycemic as gluconeogenesis and glucose turnover are increased.[22] IL-1-mediated inhibition of lipoprotein lipase results in hypertriglyceridemia,[23] similar to TNF. IL-1 induces production of TNF that, along with other cytokines, mediates some of IL-1's actions.[24] Antibodies to IL-1 are also being studied as adjunctive therapy for cancer cachexia.[14]

IL-6 and interferon-γ (IFN-γ) are cytokines that are part of a pathway induced by TNF or IL-1.[25] IL-6 is secreted by fibroblasts and macrophages stimulated with TNF, IL-1, and endotoxin.[14] As a mediator of the acute-phase response, circulating levels of IL-6 are associated with poor prognosis in sepsis.[26] Serum IL-6 concentrations have been shown to increase with increasing tumor burden in animals and with TNF treatment in cancer patients.[27] IFN-γ is produced by activated T lymphocytes, stimulates macrophages, and has antiviral properties. Anti–IFN-γ antibody was given to tumor-bearing animals, with resultant improved appetite and reduction in weight loss.[28] IFN-γ, like TNF, inhibits lipoprotein lipase activity.[29]

Because all of these active peptides have antitumor as well as antihost effects (ie, cachexia), the research goal is to discover how antitumor activity can be preserved at the same time that metabolism can be modulated by manipulating these effectors.[14,28] At this point in time, cachectic, like hypermetabolic, patients can be supported, but without the expectation that nutrition support can reverse the metabolic derangement (see below).

TUMOR THERAPY: IMPACT OF TREATMENT ON NORMAL METABOLISM

Surgery causes additional metabolic and nutritional stress in patients with malignancy. Meta-analyses of studies evaluating the efficacy of perioperative nutrition support have concluded that in normally nourished patients, nutritional support has no impact on surgical recovery and subsequent tolerance for intensive chemotherapy or radiation therapy.[30] Patients who are expected to have prolonged postoperative recovery of intestinal function benefit from parenteral support.[31] Also, for patients who are malnourished before surgery, perioperative nutrition support improves surgical outcome. A more recent study has shown that enteral therapy modulates cytokine responses after surgery. These responses were actually more exaggerated when parenteral nutrition (PN) was used.[32]

Chemotherapy often disrupts oral intake but can also result in dysfunction of the gastrointestinal tract, liver, or pancreas. Antimetabolites, alkylating agents, and inhibitors of nucleotide synthesis can cause oral or esophageal ulceration, anorexia, nausea, vomiting, and enteritis with malabsorption and consequent diarrhea. Asparaginase and streptozocin can disrupt pancreatic islet cell function and result in diabetes. Excess weight gain can result from increases in energy intake secondary to glucocorticoid treatment.[33] Antimetabolites can result in liver dysfunction. The latter is more likely to occur during infectious episodes. Although the physical effects of chemotherapy are generally short term and self-limited, there may be persistent changes in taste sensation and food preferences or the development of a psychological aversion to feeding. Conversely, preexisting malnutrition may alter the effectiveness of chemotherapeutic agents as well.[34]

Radiation therapy can have both acute and chronic effects. Acutely, radiation to the head and neck can cause mucositis, anorexia, nausea, vomiting, dysphagia, dysgeusia, and diminished salivation.[35] Irradiation of the chest can damage the esophagus. Stomach and or bowel irradiation will cause nausea, vomiting, and diarrhea. Chronically, stricture formation can occur in the small or large intestine. Other pathologic consequences that have been reported include villous atrophy, lymphangiectasia, ulceration and inflammation, perforation, fistulization, and vasculitis.

Hematopoietic cell transplantation (HCT) has previously represented the extreme end of the spectrum of chemotherapy and radiation effects. However, developments in HCT in the last several years have resulted in a much wider range of the intensity of supportive care that is needed by HCT recipients. Much of this widening of the spectrum of supportive care is attributable to developments in the use of hematopoietic growth factors. Cytokine therapy has had a major impact in autologous transplantation and is being used to reduce complications of allogeneic transplantation as well.[36,37] Colony-stimulating factors are used to stimulate hematopoietic stem cell graft function, decreasing the period of time in which HCT recipients are neutropenic and susceptible to infection.[38] The debilitation of infection is often a limitation to a recipient's ability to maintain or resume adequate oral nourishment. Autologous transplantation has been impacted by the use of cytokines such that both autologous marrow and peripheral blood stem cell transplantation can now be done in the outpatient setting, particularly for nonhematologic malignancies.[39,40] Recipients are admitted to the hospital for any complications, which can include nutritional depletion. Recipients who are hospitalized for autologous transplantation are also not routinely started on PN. Criteria at the University of Minnesota for initiating PN in adult patients include the following: (1) the patient is taking in < 50% caloric requirements orally for at least 5 days and has weight losses of 5% of baseline weight, (2) the patient is at < 95% of ideal body weight, and (3) the patient's clinical condition has deteriorated. These criteria are used for both autologous and allogeneic recipients, and PN is not generally initiated until cytoreduction has been completed.

Conventional HCT still involves lethal chemotherapy and/or radiation therapy to achieve adequate cytoreduction for the patient to be able to engraft the donor stem cells (allogeneic HCT) or to reduce the tumor burden and rescue the patient with his own stem cells (autologous HCT).[41,42] This may follow closely an intensive induction course of chemotherapy or months of maintenance chemotherapy to ensure that the patient's disease is in remission at the time of preparation for HCT. Cytoreductive therapy causes painful mucositis in the oral pharynx and esophagus. Taste sensation is altered; both hypogeusia and dysgeusia are reported.[43] Normal growth and repair of intestinal mucosa are disrupted. Histologic changes attributable to cytoreductive conditioning therapy have been reported to persist as long as 21 days after transplantation.[44]

The loss of functioning intestinal epithelium results in malabsorption and reversal of salt and water absorption. The result is typically an interval of watery diarrhea in the first week following chemotherapy and/or radio-

therapy.[45] Stool sodium transiently increases to 50 to 80 mEq/L. There is usually enough mucosal disruption to cause a transient rise in exudative protein loss into the feces,[46,47] with concomitant loss of zinc, and failure to absorb minerals and vitamins.[48] In addition, the debilitated condition of the gastrointestinal tract at this time predisposes these patients to viral, bacterial, and fungal infestation of the bowel, leading to further mucosal damage and malabsorption and providing a portal of entry for systemic infection.

The benefits of maintaining nutritional intake during bone marrow transplantation (BMT) were established over 15 years ago.[49] In the randomized, controlled study done at the University of Minnesota, there was a clear long-term survival advantage for BMT recipients who received prophylactic nutrition support in the form of PN compared with control recipients who were fed ad libitum with intravenous supplementation of minerals and vitamins until nutritional depletion was documented. This effect was even stronger when the 104 allogeneic patients were compared separately from the 32 autologous patients (Figure 41.2-1). Improved survival may have been attributable to a nutritional effect on graft function, as was suggested by murine studies.[50] In this study, the control group was fed orally until four of six standard nutritional assessment measures fell below the 10th percentile values. Sixty-one percent of control patients met these criteria for nutritional depletion at a median of day 21 post-transplantation. These patients had significantly longer hospitalizations than the PN patients, whereas the other 39% of control patients who were able to maintain adequate oral nutrition had significantly shorter hospitalizations than PN patients. In another study published in the same year, intensive dietary counseling with use of both nasogastric feedings and intravenous protein supplementation, nutritional support was maintained without a prolonged course of PN in a majority (~ 75%) of patients without adverse effects on graft function.[51] In both of these studies, patients generally met the criteria for initiation of PN after several weeks of profound neutropenia, often with infection. Therefore, reducing the period of time following cytoreduction during which recipients are neutropenic with the use of colony-stimulating factor has reduced the requirement to use PN for all patients throughout the course of HCT. The resolution of mucositis and the ability of HCT recipients to resume oral intake frequently coincides with the appearance of circulating neutrophils. Although nutrition support remains an essential aspect of supportive care, the range of nutrition support options is now as varied as the settings for HCT. Nutrition support recommendations are now based on the nutrition status of the individual patient, and PN is no longer indicated for all HCT recipients.[52]

In addition to nitrogen losses occurring as a result of enteritis, patients can excrete tremendous amounts of nitrogen in urine during and immediately after cytoreductive therapy. Nitrogen losses have been documented in a number of studies.[53,54] This occurs whether or not patients are receiving nutrition support and is reflected in decreased visceral protein status by the second week post-transplantation.[55] It is often necessary to increase protein intake up to 3 to 3.5 g/kg in some children to achieve zero nitrogen balance in the face of nitrogen losses by the third week post-transplantation. It appears that, in therapy this intense, there is a certain obligate nitrogen loss owing to tissue damage and altered metabolism directly attributable to the catabolic effect of chemotherapy and radiation and compounded by relative immobilization and infection. The massive increased waste nitrogen must be processed by the liver via the urea cycle, which increases the energy demands of the liver and consequently of the whole patient.

Hypermetabolism and multiorgan failure syndrome are parts of a clinical spectrum initiated by a severe defect in tissue perfusion or oxygenation.[56] Hypermetabolism may result from sepsis, multiple trauma,[57,58] acute pancreatitis,[56]

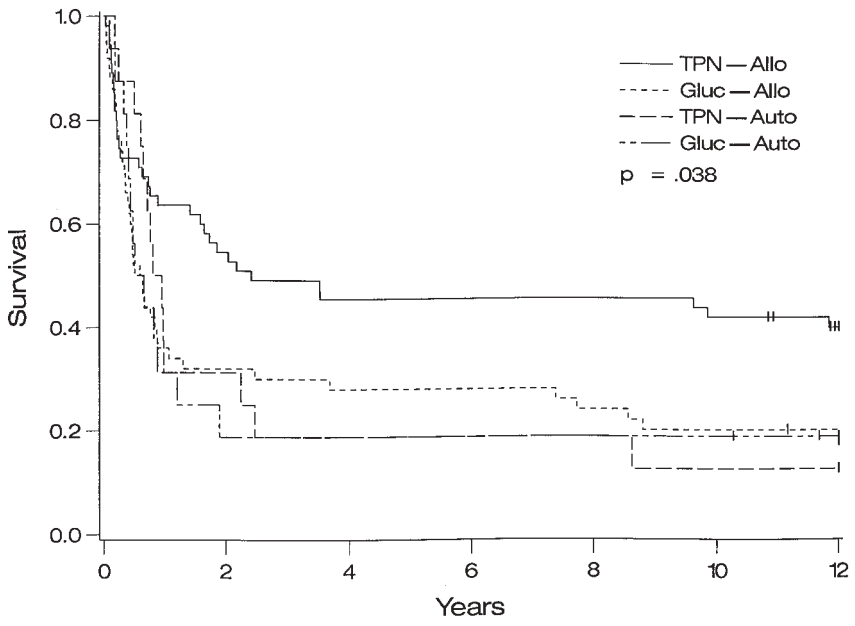

FIGURE 41.2-1 Results of the randomized, controlled study done at the University of Minnesota comparing survival in bone marrow transplantation recipients who received prophylactic nutrition support in the form of parenteral nutrition compared with control recipients who were fed ad libitum with intravenous supplementation of minerals and vitamins until nutritional depletion was documented. or other catabolic events (such as severe graft-versus-host disease [GVHD] in HCT patients). Sepsis is the most common stress associated with hypermetabolism in cancer patients, and the risk is increased by the use of PN.[59] The mediators of hypermetabolism are thought to be the same or similar active cytokine peptides as the mediators of cachexia.[60] The hypermetabolic state may resolve over 7 to 10 days or may persist, with progressive kidney and liver dysfunction. These final stages constitute multiorgan failure syndrome, which has a mortality rate in excess of 50%.[56]

Similar to cachexia, hypermetabolism is characterized by the loss of body protein, in distinction to simple starvation, in which lean body mass is preserved. Protein catabolism is accounted for, in part, by use of amino acids from skeletal muscle in areas of wound healing or in acute-phase response protein synthesis. However, in the hypermetabolic state, amino acids are also used for gluconeogenesis, and branched-chain amino acids may be oxidized outside the liver for energy. The net result is a dramatic shift to negative nitrogen balance and azotemia, with hyperglycemia.[56,61,62]

POSTSURVIVAL ISSUES: IMPACT OF LATE EFFECTS OF CHILDHOOD CANCER AND ITS TREATMENT ON NUTRITION

There has been significant progress in the treatment of childhood cancer, with an estimated survival for these patients now of 80%. This means a yearly increase in the survival population of approximately 6,000 children. As this number has grown and aged, many long-term complications of the therapy they received have become apparent. Complications of radiotherapy or chemotherapy may be recognized years after treatment. Persistent toxicity may be appreciated only when it manifests as failure to thrive, poor growth, or failure of normal sexual development.[63] Table 41.2-1 lists some specific consequences of childhood cancer therapy that may lead to problems with growth or nutrition. In addition, we cover more fully two of the more common problems, excess fat mass and obesity associated with treatment of leukemia and impairment of normal bone formation, which occurs after many forms of cancer therapy.

Acute lymphoblastic leukemia (ALL) is the most common malignancy of childhood. Its treatment, although largely successful, is commonly associated with reduction in growth, reduction in lean body mass, and increased fat mass.[3] About 40% of children treated for ALL exhibit obesity in the late recovery period.[64,65] This childhood and adolescent adiposity frequently results in obesity in the adult, with the attendant risks of cardiovascular disease and type 2 diabetes.

Studies of preobese ALL patients have shown reduced total energy expenditure, related to reduced physical activity.[66] Cranial irradiation is a major risk factor for obesity,[65,67] although nonirradiated patients also have an increased risk of obesity of about 20%. Although cranial irradiated patients do not eat more than nonirradiated patients, their activity is less. In part, this may be the result of complications involving the musculoskeletal system, which lead to pain and fractures. The resting metabolic rate was significantly reduced in the irradiated group compared with the nonirradiated group. They are also at increased risk of hypothalamic abnormalities.[65]

No study has systematically attempted to intervene in this condition. It would be expected that a thorough endocrinologic evaluation would be a necessary first step in the management of this problem. Increased activity,

TABLE 41.2-1 Effects of Childhood Cancer Treatment on Growth and Nutrition

Late Effect	*Likely Causes*	*Useful Adjunctive Studies*	*Other Information*
Short stature	Cranial radiation (dose dependent), high-dose prednisone and methotrexate, spinal radiation	Growth hormone testing, thyroid function studies, tests of gonadal dysfunction	In some studies, only pulsatile growth hormone was affected
Obesity	Etiology unclear; may be related to adrenocorticosteroid therapy	Thyroid function studies, imaging of hypothalamus	
Weight loss	Multifactorial		
Dental abnormalities (delayed or arrested tooth development, malocclusion, or caries)	Cranial radiation	Evaluation by dentist or oral surgeon	May manifest as reduced intake
Chronic enteritis or intestinal fibrosis or stricture	Radiation of gastrointestinal tract	Barium studies of small bowel and/or colon, evaluation for malabsorption, quantitative assessment of macro- and micronutrients	Stomach and small intestine are more radiosensitive than colon and rectum
Hepatic fibrosis/cirrhosis	High-dose hepatic radiation, methotrexate	Liver enzymes; coagulation studies; vitamin A, E, and D levels; liver biopsy	
Second malignancy	Multifactorial	Oncologic evaluation	May manifest as weight loss
Psychosocial problems	Multifactorial	Psychological assessment	Anxiety or depression may manifest as weight loss

Adapted from information in Dreyer ZE et al. [63]

which will need to be carefully supervised by a physical therapist, will likely be a cornerstone of therapy.

Similar obesity has not been seen after HCT, even when irradiation is involved. The European Bone Marrow Transplantation Late-Effects Working Party has shown that irradiation, whether total-body irradiation, thoracoabdominal irradiation, or cranial irradiation, is associated with diminished height. Nutritional status in general, however, is good 5 years after an HCT.[68]

Reduced bone mineral density (BMD) in survivors seems to be a short-term problem if properly managed. If longitudinally monitored, BMD is often diminished at the start of cancer therapy and may further decline during the treatment period.[69] There are several factors involved in this decline, among them poor vitamin D status and poor calcium intake during chemotherapy,[70] hypomagnesemia associated with hypermagnesuria resulting from steroids and/or aminoglycosides,[71] and reduced activity.[65]

However, long-term studies of these patients largely suggest that BMD improves after the completion of chemotherapy. Henderson and colleagues found that, 1 year after the end of chemotherapy, BMD z-score was –0.37 ± 0.27 in the lumbar spine, with a similar finding in the proximal femur.[69] The large study of Kadan-Lottick and colleagues of survivors of ALL demonstrated normal whole-body areal BMD z-scores. This was true despite the fact that 28% of this population had at least one fracture after the diagnosis of ALL. It should be noted that, despite the overall good results, 11% of individuals had osteopenia. BMD improved after completion of chemotherapy.[72] In a study of Danish survivors of childhood cancer, the median length of follow-up was 10.7 years from diagnosis, yet the median BMD z-score was low, –0.5 (areal density, whole-body scan).[67] Thus, although great recovery is possible, we must be alert to identify the survivor with remaining osteopenia.

Therapeutic intervention must focus on the osteopenic long-term survivor. It will be important to identify risk factors that lead to osteopenia and determine if mineral supplementation and/or weight-bearing exercise can reduce this late complication of cancer therapy in children.

PRACTICAL INFORMATION FOR NOURISHING PATIENTS DURING THERAPY

Indications and Treatment Choices

Although controversies still exist concerning the role of nutritional support in cancer therapy, malnutrition remains a strong indication for intensive nutritional support therapy.[73] Support is indicated for all malnourished children whether at diagnosis, during induction and/or maintenance therapy, or in terminal care. Nutrition support therapy is also indicated when there will be a period of time lasting over 5 days when patients are unable to eat owing to recovery from surgery or in the case of a previously documented inability to eat during chemotherapy. A 2- to 3-week period of severe mucositis is well documented to occur in a majority of patients following HCT.

General goals of nutrition support are to reduce morbidity and minimize complications. Four of the ways in which optimal nutrition support may potentially serve these goals are (1) to provide bowel rest during intensive therapy with severe gastrointestinal side effects, (2) to decrease transfusion dependence by decreasing the amount of time in which patients are cytopenic,[74] (3) to decrease incidence of infection by improving return of immune competence, and (4) to increase the patient's sense of well-being. To achieve these ends, therapy needs to be individualized because in individual patients, optimal support will differ: some patients will require PN, others will require supplementary PN or supplementary peripheral PN, and still others will be able to achieve optimal intake and absorption with chemically defined enteral diets or supplements.[75]

Enteral Feedings

Increasingly, it is clear that enteral feedings provide the most physiologic method of nourishing the patient with cancer, with, in general, fewer and less severe complications and the least cost.[76] The gut should be the "default" method of feeding, with PN used in patients unable to be nourished enterally.

In the surgical patient, oral feeding should be attempted as soon as bowel function returns. Although gastric motility may be abnormal for a prolonged interval, small bowel motility may improve rapidly, allowing the use of nasojejunal feedings until a patient is ready to resume oral intake. In patients receiving intensive chemotherapy and radiation or BMT, oral intake can resume when mucositis subsides and narcotic therapy is reduced. Continuing parenteral amino acid is often necessary, even in a patient consuming adequate calories, because protein-containing foods are often refused. A dietitian trained in cancer management is essential to counsel patients regarding appropriate food choices and encourage patients to keep retrying foods.[77]

Contraindications to enteral feeding include bowel obstruction, severe enteritis, and severe malnutrition at diagnosis.[76,78] Impediments (but not necessarily contraindications) to enteral feedings include nausea and vomiting, severe mucositis, oral aversion, and intestinal motility disorder. New information regarding the treatment of nausea and mucositis may improve oral intake in children with cancer, and more centers are using nasogastric feedings when the intestine is the appropriate route, but the child cannot ingest enough. Some patients leave the hospital on PN or nasogastric feedings, and children are often resistant to oral intake until in familiar surroundings. If there is no organic cause of prolonged refusal of enteral intake, food aversion is suspected, and behavioral modification therapy can be sought.

The choice of enteral feeding is wide. Oral feedings should be tailored to fit the child's tastes, which may not be the same as before therapy began. For example, taste sensation is altered after HCT, with a decreased threshold for sweet and salt that may last for more than a year.[43] A variety of tumor types lead to dysgeusia, with a heightened sense of taste for bitter and reduced capacity to sense sweet.[79] Although these studies were performed in adult

cancers, clinical experience suggests similar alterations of taste sensation in children with cancer. Feedings delivered through a tube can be either elemental or nonelemental. Elemental formulas are more expensive and should be used when there is severe enteritis or evidence of malabsorption.

It has been the practice at many institutions for neutropenic patients to be fed restricted diets to limit their exposure to microorganisms.[80] It is clear that certain foods pose an increased risk for the neutropenic patient (as well as, in some cases, for the normal patient). Poorly cooked meat is a risk for these patients, as may be aged or fermented products, such as aged cheeses. Raw fruits and vegetables may also have large numbers of microorganisms present. Unfortunately, it is unclear to what degree these restrictions are effective in reducing infections in neutropenic patients. Most infections are hospital acquired, rather than food borne.[81] The severity of the restrictions further limits choices for patients. Although many centers continue to use some restrictions for neutropenic patients, some are allowing raw fruits and vegetables if they are well washed.

Nutritional support guidelines generally cover strategies for patients undergoing chemotherapy or HCT. It is important to realize that patients who complete therapy undergo a recovery period when catch-up growth and rehabilitation occur. During this phase, patients continue to need guidance with regard to food choices and graduated exercise programs. Patients who have advanced cancer can also benefit from nutrition support counseling to allow them to be as active as possible prior to death.[82] There is virtually no information on nutrition support management in children who are survivors of cancer in these situations.

Managing Mucositis, Vomiting, and Anorexia

Mucositis, vomiting, and/or anorexia associated with cancer and cancer therapy can limit oral intake in many patients. A full discussion of these complications is beyond the scope of this text, but some general comments and appropriate references are provided. The information provided, with few exceptions, derives from the adult cancer literature. Few studies directly address these complications in children, although it might be expected that children might have different degrees of complications and require different treatments, given the difference in therapy and underlying tumors.

Mucositis is a common, debilitating complication in which mucosa in the gastrointestinal tract, lost as a result of cancer therapy, are replaced very slowly because of injury to the basal tissue layers. Ulceration and superinfection may occur. Mucositis limits oral intake. Therapy for mucositis is limited, but some options are effective.[83,84] The basic principles are to relieve pain, provide nutrition and hydration, and treat any superinfection. All patients should have routine mouth cleansing with a saline solution. Pain management often requires narcotic therapy, which may reduce gastrointestinal motility and further impair oral intake. Oral glutamine is controversial; one study demonstrated a reduction in oropharyngeal mucositis in HCT with glutamine,[85] whereas another study in patients with gastrointestinal cancer showed no effect.[86] Granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor stimulate increased growth of mucosal cells in the oropharynx, reducing the length and severity of mucositis. Other, novel therapies are being investigated and may further improve the prospects for oral intake in children with cancer.[83,84]

Nausea and vomiting are also common during cancer therapy. The severity of this side effect depends on the agent used, the dose administered, and the route of administration. Host factors may also be important.[87] Treatment of the child with nausea begins with identification of any infectious or metabolic causes of nausea and vomiting (eg, uremia, oral thrush, or electrolyte disturbances). Radiation therapy to the abdomen and GVHD may lead to partial bowel obstruction, exacerbated by narcotic agents. However, chemotherapy itself is at the root of most nausea and vomiting in children with cancer.[88]

In chemotherapy-induced emesis, cytotoxic agents stimulate the release of serotonin in the gastrointestinal tract. The serotonin binds to 5-hydroxytryptamine$_3$ receptors in the intestine, stimulating the vagus nerve to transmit signals to the chemoreceptor trigger zone in the brain. Cells in this zone then stimulate the vomiting center, which responds with gastroparesis and retching.[87] Although there are many agents that are useful in different stages of chemotherapy-induced nausea and vomiting, metoclopramide and the serotonin receptor antagonists (ondansatron, granisetron, and dolasetron) are most effective as they directly impact the underlying physiology of the problem. In children especially, diphenhydramine may be required to reduce side effects of metoclopramide.[87,89]

In adults, anabolic agents are recommended in some situations for patients with cancer cachexia (for a recent review, see Langer and colleagues[90]). Similar studies in children are limited, and it is not recommended that these agents be used in children except in very specific circumstances. Megestrol acetate, an orexigenic agent (appetite stimulant), has been studied in children and is also the agent most commonly used in adults. In children with human immunodeficiency virus, megestrol acetate promotes weight gain. Adrenal function may also be suppressed, at times requiring corticosteroids to relieve symptoms.[91] Weight gain is generally composed of fat and water, with little change in lean body mass[90]; however, it may improve quality of life in children with advanced, untreatable cancer and severe failure to thrive. Other agents, including anti-TNF-α medications (melatonin and thalidomide) and anabolic agents (growth hormone, oxandrolone), are under investigation in adults.[90]

Nasogastric Feedings and Gastrostomies

Concerns have long been expressed about the safety and efficacy of nasogastric feedings in children undergoing chemotherapy. Among the concerns are bleeding, vomiting with the necessary tube replacement, sinusitis from sinus os occlusion, and poor parental and patient acceptance of nasogastric tubes. In the last decade, as the benefits of enteral feeding have become apparent, nasogastric feedings have been attempted in both HCT and cancer patients.

Pietsch and colleagues fed 17 children with high-risk cancer or HCT by nasogastric tube for a total period of 216 days.[92] The children were not randomly assigned to tube feedings. Although 6 children vomited out their tubes, they were replaced without incident. No child experienced tube-related sinusitis or bleeding. The conclusion is that nasogastric feedings should be further explored in children with cancer, including those at high risk.

In children with solid tumors, administration of nasogastric feedings in those patients with clear evidence of malnutrition at the onset of or during chemotherapy reduced the incidence of nonleukopenic infections.[93] This study also emphasized the need for aggressive management of vomiting to promote enteral nutrition and weight gain. Formulas with higher energy density are more effective in promoting weight gain and improving body composition than are standard formulas, probably because smaller volumes are required for adequate calorie intake.[93]

Both aggressive enteral feeding programs and nasogastric feedings have been used in children undergoing HCT, with generally positive results.[51, 94,95] Although more children fail to complete nasogastric protocols in HCT than in cancer chemotherapy, it is not clear if this is owing to the more severe complications of HCT or the result of differences in the practices of the institutions performing the studies. There is a need for studies to assess whether polymeric or monomeric formulas are most appropriate in HCT patients.

In summary, enteral feeding via a nasogastric feeding tube is appropriate for many children undergoing HCT or chemotherapy. The paucity of controlled trials of specific feeding protocols limits the recommendations, but a prudent course can be suggested with the current information. The criteria proposed by den Broeder and colleagues for initiating nasogastric feedings may serve as guidelines until more specific criteria are established through clinical research. Specifically, consider nasogastric tube feedings when the child has malnutrition at diagnosis, when weight decreases more than 5% compared with weight at diagnosis, or when the child's oral intake is < 80% of the child's total estimated energy requirement.[93] High-energy, polymeric formulas are more likely to achieve the desired weight gain.

The studies thus far suggest that most children with cancer or HCT will tolerate nasogastric feeding tubes for the time necessary to improve and maintain a reasonable level of nutrition. Patients unable to tolerate nasogastric feedings or who will require supplemental feedings for a prolonged time (generally > 3 months) may be candidates for a feeding gastrostomy. Several studies have shown that gastrostomies are safe and effective in children with cancer.[96–98] They can generally be placed under general anesthesia percutaneously during endoscopy. Children with significant mucositis may require radiographic placement to avoid pulling the gastrostomy tube through the eroded esophagus.[99]

Complications included incisional pain, leakage of gastric juices, and local infection, usually during periods of neutropenia, and may occur in about 40% of patients.[96,99] Serious complications, including peritonitis, occur in < 10% of patients.[99] Complications can be reduced with good wound care, avoiding attempts at traction removal until chemotherapy is complete or engraftment has occurred after HCT and, in the HCT patient, scheduling placement of the tube 3 weeks before cytoreduction begins.[96,100] In some centers, neutrophil counts less than 500 and platelet counts less than 50,000 are considered relative contraindications to gastrostomy tube placement.[99]

Parenteral Therapy

When patients are unable to ingest adequate nutrients owing to surgery, radiation, chemotherapy, or combinations of these, such as HCT, PN is indicated. For adequately nourished patients, a graded approach is recommended; such a regimen is used in HCT patients. PN is initiated for HCT patients when the oral intake is less than 50% of the basal energy expenditure (BEE) calculated using the Harris-Benedict equations plus 10% for growth. Initially, 120 to 130% BEE is prescribed, and approximately 33% of total calories are given as lipid daily. Lipid-based PN has been shown to be associated with a lower incidence of lethal acute GVHD when compared with carbohydrate-based PN.[101] Protein is given at the Recommended Daily Allowance (RDA), 2 g/kg in children. Because this is the period during which tissue damage is occurring, resulting in an increased endogenous nitrogen burden, exogenous nitrogen is prescribed only for maintenance of lean body mass. This maintenance formula is similar to that prescribed for patients receiving chemotherapy or for post-surgical patients who are unlikely to eat for at least 5 days. Electrolytes, minerals, vitamins, and trace elements are added to the PN according to the RDA and individual needs. Multivitamin mix and standard trace element solutions containing chromium, zinc, copper, manganese, and selenium are added.[102]

At the time of engraftment, or about 21 days post-transplantation, the energy intake is decreased to 100 to 110% BEE, and protein intake is increased to compensate for negative nitrogen balance, hypoproteinemia, and tissue repair as the marrow graft begins to function and mucositis resolves. This recommendation anticipates the additional protein required for tissue repair and regrowth but decreases the amount of energy the patient uses to dispose of a high-caloric intake.

Managing Hypermetabolism

The metabolic changes of hypermetabolism cannot be corrected with either glucose infusions or insulin. The goals of nutrition support in the hypermetabolic patient are to avoid starvation and to maintain acceptable levels of electrolytes, glucose, and blood urea nitrogen (BUN). Protein is administered at increased levels, up to 1.5 to 2.0 g/kg/day in adults and up to 2.0 to 2.5 g/kg/day in children, to compensate for urinary nitrogen loss, unless uremia supervenes. Glucose administration should not exceed 5.0 g/kg/day, and fat intake should not exceed 30% of calories. This therapy will not achieve positive caloric balance in hypermetabolism, nor will it prevent loss of lean body mass. It will, however, support the ongoing inflammation-associated protein synthesis and may improve nitrogen balance, which has been associated with increased survival.[56,61,62]

Complications requiring adjustments of nutritional management include azotemia, which requires decreasing protein intake or dialysis to permit increased protein support. Patients with respiratory difficulty may benefit from decreasing their carbon dioxide production by reducing the glucose infusion rate. Indirect calorimetry can indicate if caloric intake is too high. Excess energy intake does not preserve lean body mass or restore the patient to health more quickly but promotes hyperglycemia, lipogenesis, hypertriglyceridemia, and hepatic steatosis. Fluid overload in the stressed patient is an indication to concentrate PN, decreasing free water and correcting hyponatremia. Electrolyte supplementation can be given separately from the PN, avoiding the need for frequent PN reformulation. Recommended allowances of trace elements and vitamins may not be adequate in the severely stressed patient, particularly for zinc, copper, and vitamin K. Patients with renal or hepatic dysfunction may require further modification of the PN, and serum trace element monitoring can anticipate chromium toxicity or excessive manganese and copper supplementation.[57,61]

Monitoring Nutrition Support

To individualize therapy, certain nutritional/metabolic parameters need to be monitored. It is somewhat arbitrary to distinguish between a monitoring schema to follow nutrition therapy and one to follow the overall medical status of the patient. Certain laboratory studies are indicated to anticipate and correct potential metabolic problems that can be caused by PN or metabolic problems of other causes that can be treated with the PN solution. From a collection of studies, a consensus can be derived (Table 41.2-2).

Weight is followed primarily to judge hydration status, which is also reflected by electrolytes, BUN, creatinine, and albumin. Changes in glucose tolerance can signal infectious as well as metabolic complications. The association between hyperglycemia and *Candida* sepsis was initially described some years ago.[103] Liver function abnormalities may result from PN, or liver dysfunction from other causes may require modification of the PN formula (see below).

Parenteral and enteral protein and caloric intake are recorded daily to allow for reduction of parenteral intake as enteral intake increases. Measurement of electrolytes, major minerals, and zinc is needed to adjust a patient's PN formula. Ascribing abnormalities in serum albumin to protein nutrition does not seem to be reliable in this setting.[101] Serum albumin is helpful in assessment of fluid status and as a guide to albumin replacement therapy for maintenance of intravascular volume. Transferrin seems more reflective of amino acid intake for visceral protein synthesis.[49] We have found that prealbumin levels reflect caloric, rather than protein, intake and should not be used to adjust protein intake. Although nitrogen balance is helpful, attempting to maintain positive balance is unrealistic and could result in an increased demand on the liver to process ammonia. Measurement of resting energy expenditure and respiratory quotient can assist in individualizing therapy and anticipating complications.[104] The quantity and appropriate mix of energy-producing substrate can be optimized with these data.[53]

Complications of Nutrition Support

There are risks for complications in both parenteral and enteral nutrition support, and these are covered in detail in other chapters in this text. Some of the more common problems encountered in cancer patients are reviewed briefly.

Catheter-Related Complications Central venous access catheters remain a major source of complications in cancer patients, especially those with neutropenia. The incidence of central line sepsis is high, despite the use of strict aseptic technique for blood draws, infusions, and tubing changes, as well as daily site cleaning and dressing changes. Christensen and colleagues have reported the infection risk associated with PN in 310 pediatric patients with cancer.[59] These patients had central venous access devices (CVADs) in place for the delivery of chemotherapy and supportive care. Overall, the infection rate was 0.06 infections/100 days. During the period of PN administration, the rate increased to 0.5 infections/100 days. After adjustment for diagnosis and CVAD type, the risk of infection was 2.4-fold greater in patients given PN (95% confidence interval 1.5 to 3.9; $p < .001$). In a prospective study of 143 Hickman catheter placements in 111 BMT recipients, 44% of the patients had positive blood cultures during the lifetime of the catheter.[105] Of these infections, 40 of 63 were coagulase-negative *Staphylococcus*, suggestive of primary line sepsis rather than catheter contamination from a blood-borne enteric source. The majority of these infections are treated with antibiotics and not catheter removal.[106] In the prospective study, mechanical obstruction occurred in 38% of the catheters; half of these episodes required no intervention, whereas the others responded to heparin or urokinase or required catheter replacement.

Hepatic Enzyme Elevations PN is associated with hepatic dysfunction, although, in general, patients with cancer or BMT are rarely treated with PN long enough to develop cirrhosis or clinically significant hepatic failure. The causes are still being elucidated and appear to be complex.[107,108] In many cases, cholestasis associated with PN may cause confusion when the clinician is considering the differential diagnosis of cholestasis in the patient with cancer. Stopping the PN is not appropriate unless enteral alimentation can be used as malnutrition also has adverse consequences for the liver.

Initially, there is an elevation of transaminases occurring approximately 1 to 2 weeks after the start of PN infusion. Elevated serum bilirubin and canalicular enzymes (alkaline

TABLE 41.2-2 Nutrition Support Monitoring Studies

Daily: weight, urine glucose, calorie/protein intake, and, for first 3 days, electrolytes, blood urea nitrogen (BUN), glucose, and creatinine
Biweekly: glucose, BUN, creatinine, electrolytes, calcium, magnesium, phosphorus, hepatic transaminases, 5′-nucleotidase, bilirubin, and alkaline phosphatase
Weekly: triglyceride, albumin, transferrin, nitrogen balance, BUN, and zinc

phosphatase, 5′-nucleotidase) may occur 2 to 3 weeks into therapy. Histopathologic changes in the liver include steatosis, glycogenosis, intrahepatic cholestasis, and sometimes a nonspecific portal infiltrate. Most abnormalities resolve on discontinuation of PN, cycling, or adjustment of the nonprotein calone–to-nitrogen ratio (NPC:N), and there is little or no functional disability of the liver.

With long-term PN therapy, functional abnormalities may develop. Steatonecrosis and fibrosis can occur and may progress to cirrhosis with complications of hepatic dysfunction and portal hypertension. The time course for development of this lesion is variable; some studies have shown fibrosis with as few as 6 months of PN. Finally, acalculous cholecystitis or gallstone formation can occur during the administration of PN.[109]

Steps may be taken to reduce the likelihood of PN-associated hepatic dysfunction. Some suggested therapies that may modify liver enzyme or bilirubin increases include the following:

1. Appropriate therapy for any other causes of liver dysfunction such as sepsis, hepatitis, hepatotoxic medications, veno-occlusive disease, or GVHD
2. Administration of PN over 12 to 18 hours rather than 24 hours[110,111]
3. Initiation of small enteral feeds[112]
4. Empiric reduction of the total calorie intake by 10 to 15% to reduce the NPC:N[112]
5. Treatment with ursodeoxycholic acid, 15 to 20 mg/kg/day orally divided into three or four doses to decrease cholestasis
6. In older children and adults, a trial of metronidazole to decrease intestinal bacteria and thus decrease endotoxin formation

Treatment modalities being examined include modified enteral feedings with medium-chain triglycerides and/or marine oils rich in omega-3 fatty acids, administration of antioxidants (vitamin C, vitamin E, or *N*-acetylcysteine), reduction in intravenous lipid calories, and administration of cholecystokinin.[108] Carefully controlled clinical trials will be necessary to demonstrate that any of these novel therapies improves PN-associated liver disease.

Complications Associated with Enteral Feedings The most common problem associated with enteral feedings in the child with cancer is determining when the feedings are being tolerated. Commonly, abdominal pain, diarrhea, or nausea will lead to the feedings being stopped or temporarily held. To prevent failure of an enteral feeding regimen, it is essential that a well-thought-out protocol be established with clear guidelines for when feeds may be held. Such a protocol can be found in a recent article by Spain and colleagues.[113]

NOVEL THERAPIES

The trend in nutrition support research is toward specific nutrient modifications during critical illness to promote immune function or healing or to reduce infectious complications ("immunonutrition").[114,115] It is prudent to view early studies with a degree of skepticism; many therapies show promise in small trials but ultimately prove to be of no benefit to the patient in large-scale studies. In particular, in cancer, the modification of the immune system may improve the well-being of the host but may or may not be detrimental to the eradication of the cancer itself.

Most immune-modifying nutritional therapies include some combination of arginine, glutamine, nucleotides, and polyunsaturated fatty acids. Although some of these products are being tested parenterally, it is more common to see enteral products with some of these substrates.[115] In principle, each of these components affects some aspect of the immune defense syndrome: improving the intestinal mucosal barrier, improving the cellular defense function, or modifying the systemic inflammatory response.[115] Meta-analysis of randomized, controlled clinical trials of enteral supplementation with some of these nutrients in adults with gastrointestinal cancer suggests that this therapy may reduce infectious complications and hospital stay.[116] Further clinical research will determine whether this modality is of use in the treatment of children with cancer. Two of these components, glutamine and marine oils, have been specifically studied in patients with cancer or HCT and are reviewed here.

Glutamine plays a crucial role in nitrogen transport, is an important scavenger of ammonia, and is required for nucleotide synthesis. Intestinal mucosa, because of its high turnover rate, uses large amounts of glutamine. In the enterocyte, metabolism of glutamine produces α-ketoglutarate, which enters the tricarboxylic acid cycle, and ammonia, citrulline, alanine, and proline. Alanine is used by the liver for gluconeogenesis, whereas citrulline is used in the kidneys to synthesize arginine and in the liver as a component of the urea cycle. Critical illness is associated with depletion of plasma glutamine levels, with impaired maintenance of intestinal structural integrity. In these situations, glutamine is an essential amino acid. Glutamine depletion has been shown to lead to loss of the intestinal mucosal integrity, resulting in increased bacterial translocation and increased episodes of sepsis owing to enteric organisms. It is likely that glutamine is conditionally essential in catabolic states.[117,118]

Glutamine supplementation of PN was studied in allogeneic HCT patients in a double-blind, randomized trial. The PN was identical in calorie and nitrogen content; one group received standard amino acids and the other group received glutamine, 0.57 g/kg/day, with standard amino acid solution to the same total nitrogen content as the control group. The group receiving glutamine demonstrated improved nitrogen balance and decreased morbidity compared with the control group. The number of bacterial infections and the length of hospital stay were less in the glutamine group.[119] Subsequent studies of adults with cancer and/or HCT have suggested that this amino acid may improve nitrogen balance and reduce infections and length of hospital stay.[119] The use of glutamine as a nutritional supplement in children with cancer is limited to case reports.[120]

Omega-3 polyunsaturated fatty acids are enriched in marine oils. They include eicosapentaenoic and docosa-

hexaenoic acids. Administration of omega-3 polyunsaturated fatty acids appears to modify inflammation by altering the fatty acid composition of the cell membrane. They displace omega-6 polyunsaturated fatty acids. This alteration in membrane fatty acid composition alters membrane fluidity and the production of lipid-derived mediators of inflammation. In particular, displacement of omega-6 polyunsaturated fatty acids reduces production of arachidonic acid series of derivatives.[115]

Supplementation of enteral nutrition with marine oils has been suggested to prevent and treat cancer cachexia in adults with cancer. Small controlled clinical trials have demonstrated improvement in nutritional status and reduced evidence of inflammation with use of fish oil–enriched nutritional supplements.[121,122] Further research is necessary to determine if the potential benefits of marine oils will be achieved in children with cancer.[115]

COMPLEMENTARY AND ALTERNATIVE NUTRITIONAL THERAPIES

Complementary therapies are those not supported by evidence-based clinical studies used in conjunction with standard medical care. Alternative therapies are those not supported by evidence-based clinical studies used in place of standard medical care. Both classes of therapies are used frequently by patients with cancer. In one study, half of all pediatric cancer patients had used complementary/alternative therapies at some point during their illness.[123]

Nutritional therapies are very attractive to many patients. First, studies support a relationship between diet and cancer development. Second, food and, by extension, dietary supplements, vitamins, and micronutrients are viewed as "natural" and, thus, safe. Finally, the industry that produces complementary/alternative nutritional regimens and supplements is a multibillion dollar industry without regulation but with a clear incentive to promote their products regardless of the degree of evidence for effectiveness. Compared with chemotherapy and radiation therapy, food appears much less harmful. However, many of the complementary/alternative nutritional regimens and supplements are directly harmful or, by displacing standard medical therapy, indirectly harmful.

Classes of therapies commonly encountered include complete dietary modification, for example, macrobiotic diets, raw vegetable diets, or juice diets. Currently available evidence does not support the claims made for the extreme dietary modifications in the cure of cancer, and rigid adherence may result in poor weight maintenance and reduced growth in children.[82,124] Other therapies include megavitamin therapy and antioxidant or trace element supplementation. Concerns with regard to these therapies include the potential toxicities of some treatments and the question of whether the tumor or the normal tissue is more affected by these treatments. Again, no therapy has been shown to be effective in cancer treatment using evidence-based criteria.[82,124] There are a plethora of therapies using various herbs and botanicals, some in conjunction with other nutritional regimens.

Considerable study of nutritional therapies is ongoing; however, most of the research investigates the impact of these treatments on adult-type cancers. Few studies are addressing pediatric-type, nonepithelial cancers. Generalizing from studies of adult cancer to those of children is fraught with problems.[124]

It is essential that physicians managing children with cancer become knowledgeable about complementary/alternative therapies. Patients and parents should be questioned regarding the use of these therapies. Patients and their families are frequently looking for some aspect of care to control; diet seems a harmless choice. Particularly because diet during and after cancer therapy is often ignored by conventional medical therapy, there is little to dissuade them, unless their physician becomes involved in these decisions. Establishing a nonjudgmental but candidly informative discussion of complementary/alternative therapies offers the physician a chance to educate parents about their choices. Physicians and families can access information about complementary/alternative nutritional therapies at the Web site of the Office of Complementary and Alternative Medicine of the National Institutes of Health (<http://www.cancer.gov/occam>), where there are several links to reliable information.

CHAPTER 42

DIABETES MELLITUS

Joseph I. Wolfsdorf, MB, BCh, Maryanne Quinn, MD, Roberta D. Laredo, RD, LD, CDE

Recommendations for medical nutrition therapy of diabetes mellitus have repeatedly changed since the advent of insulin therapy in 1922. Nevertheless, meal planning remains a cornerstone of the management of all types of diabetes mellitus, and nutrition education is an essential component of a comprehensive program of diabetes education for patients and their families.[1] This chapter briefly reviews the history of medical nutrition therapy, the scientific basis on which the general principles are founded, and recent investigations that implicate dietary factors in the etiology of immune-mediated or type 1a diabetes mellitus. This is followed by a discussion of the goals of treatment, the principles of meal planning, and formulation of an individualized meal plan in light of current evidence and recommendations promulgated by the Food and Nutrition Committee of the American Diabetes Association (ADA) in 2002.[2]

PREVALENCE, DEFINITION, AND CLINICAL DESCRIPTION OF DIABETES MELLITUS

Diabetes mellitus is not a single entity but a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both.[3] Most cases of diabetes fall into two broad etiologic categories. Type 1 diabetes is the most common form in children and adolescents and is caused by an absolute deficiency of insulin secretion. Type 2 diabetes is the most common form of diabetes worldwide, comprising 80 to 90% of the overall diabetic population, and is caused by a combination of resistance to insulin action and an inadequate compensatory insulin secretory response.[4–7] Type 2 usually has its onset in middle life, often in association with obesity and hypertension. Until recently, immune-mediated or type 1a diabetes was the only type of diabetes prevalent among children in the United States, and 1 to 2% of children had type 2 or other rare forms of diabetes. However, the prevalence of type 2 diabetes in youth has increased at an alarming rate,[8–12] and recent reports indicate that 8 to 45% of children with newly diagnosed diabetes have nonimmune-mediated diabetes.[13] The variation in the percentages reported appears to depend on race/ethnicity and sampling strategy. Most of these children have type 2 diabetes, but other types are being increasingly identified. For example, maturity-onset diabetes of youth (MODY) is occasionally seen in adolescents.[14,15]

The prevalence of diabetes in the United States is about 1.7 cases per 1,000 people less than 20 years of age and the annual incidence of new cases of type 1 diabetes in people younger than 20 years is approximately 18 per 100,000. The peak incidence is at 10 to 12 years in girls and 12 to 14 years of age in boys. The empirical risk of developing diabetes before 20 years of age is about 0.5%.[16] It is estimated that about 150,000 children and teenagers in the United States have type 1 diabetes.

Type 1a diabetes occurs in genetically predisposed individuals as a consequence of immune-mediated destruction of the insulin-secreting beta cells of the pancreatic islet.[17,18] The onset of clinically overt diabetes represents a late stage in the process of chronic progressive beta cell destruction and occurs when the majority of beta cells have been destroyed. The disease typically presents with rapid onset of polyuria, polydipsia, and weight loss. The cardinal features are attributable to an absolute deficiency of insulin, which leads to hyperglycemia (the result of decreased uptake and use of glucose by liver, muscle, and adipose tissue and uncontrolled hepatic gluconeogenesis), unregulated release of free fatty acids from adipose tissue, and increased ketogenesis.

Patients with type 1 or insulin-dependent diabetes mellitus (IDDM), as the name implies, depend on exogenous insulin to survive. Normally, insulin is secreted in an oscillatory fashion at a low basal rate on which are superimposed periodic increases in insulin secretion in response to ingestion of food. In contrast, when insulin is injected subcutaneously, it is absorbed from the injection site in a more or less predictable fashion that depends on the type and combination of insulins used. Each type of insulin has a characteristic time of onset, time and duration of peak effect, and total duration of action. Consequently, meals and snacks have to be timed to match the pharmacokinetics of insulin. Short-acting insulin delivered via continuous subcutaneous insulin infusion (insulin pump therapy) significantly reduces the variation in absorption.[19]

Children with idiopathic or nonimmune-mediated type 1 diabetes may be difficult to distinguish from those with immune-mediated diabetes. Most patients with idiopathic type 1 diabetes are African American and have atypical diabetes mellitus ("type 1.5" or "Flatbush" diabetes). They, typically, have a positive family history of early-onset diabetes in several relatives in multiple generations. Although insulin may not be required for survival after the acute

metabolic deterioration has resolved, blood glucose control usually is poor without insulin therapy, and ketoacidosis may recur.

MODY is a form of diabetes that includes several disorders caused by monogenic defects in beta cell function inherited in an autosomal dominant pattern.[15] The clinical spectrum of MODY is broad, ranging from asymptomatic hyperglycemia to a severe acute presentation. MODY occurs in all racial and ethnic groups. The genetic abnormalities are thought to be rare, and molecular diagnostic testing, currently available only in research laboratories, is required for specific classification. Until such testing is widely available, children with MODY should be classified as having the type of diabetes that best fits their clinical picture.

Individuals with nonimmune-mediated diabetes may have clinical presentations indistinguishable from those of patients with immune-mediated type 1 diabetes. This is relevant because as the number of children with type 2 diabetes increases, it becomes increasingly important to classify their diabetes correctly to institute appropriate therapy.

Acute, life-threatening consequences of diabetes are hyperglycemia with ketoacidosis or the hyperosmolar nonketotic syndrome. Long-term complications of chronic hyperglycemia include retinopathy with potential loss of vision, nephropathy leading to renal failure, and peripheral and autonomic neuropathy with associated risk of foot ulcers and limb amputation and gastrointestinal, genitourinary, and cardiovascular symptoms. Glycation of tissue proteins and other macromolecules and excess production of polyol compounds from glucose are among the mechanisms thought to produce tissue damage from chronic hyperglycemia.

The initial classification is usually based on the clinical picture at presentation. Children with immune-mediated type 1 diabetes are typically not overweight, have a short duration of symptoms, and frequently have ketosis, and 30 to 40% present with ketoacidosis. As the childhood population in the United States becomes increasingly overweight, the percentage of children with immune-mediated type 1 diabetes who are coincidentally overweight, if not obese, is increasing. After metabolic stabilization, they may have an initial period of diminished insulin requirement (the honeymoon period), after which they require daily insulin replacement for survival and are always at risk for ketoacidosis. In contrast, approximately 95% of children with type 2 diabetes are either overweight or obese at the time of diagnosis and typically present with glucosuria, absent or mild polyuria and polydipsia, and little or no weight loss. Up to 33% have ketonuria at diagnosis, and 5 to 25% of patients classified as having type 2 diabetes present with ketoacidosis. Children with type 2 diabetes are usually older than 10 years of age and are in middle to late puberty; 45 to 80% of patients have at least one parent with diabetes, and 74 to 100% have a first- or second-degree relative with type 2 diabetes. Children and adolescents of African American, Hispanic, Asian, and American Indian descent are disproportionately represented.

HISTORY OF MEDICAL NUTRITION THERAPY FOR TYPE 1 DIABETES MELLITUS

Until the advent of insulin therapy in 1922, the only available treatment was diet and exercise. Meal plans severely restricted the total intake of energy and were low in carbohydrate and high in fat.[20] Nutrition recommendations were often based on dogma and a limited understanding of the metabolic derangements. Today, medical nutrition therapy, largely based on scientific evidence, continues to be a major component of the management of diabetes. After the introduction of insulin, nutrition recommendations changed but generally involved restriction of carbohydrate to a maximum of 40% of total energy because this was thought to reduce the severity of hyperglycemia.[21,22] By early in the twentieth century, several studies had already shown that a high-carbohydrate meal plan, provided that it was restricted in total energy, had beneficial metabolic effects.[23–25] Change was slow, and despite evidence to the contrary, patients continued to be indoctrinated in the use of a low-carbohydrate, high-fat meal plan until 1971, when the Committee on Food and Nutrition of the ADA formally recommended liberalizing the consumption of carbohydrate.[26] Sucrose had, traditionally, not been permitted in the meal plans of people with diabetes mellitus. However, considerable scientific evidence, accumulated over the past two decades, has shown that sucrose as part of the meal plan does not impair blood glucose control in people with either type 1 or type 2 diabetes (vide infra).

Increasingly widespread use of intensive insulin therapy (either multiple daily injections, so-called basal-bolus therapy, or continuous subcutaneous insulin infusion via an insulin pump), in combination with carbohydrate counting, allows patients with type 1 diabetes to live more normal lifestyles and have more dietary flexibility while maintaining near-normal blood glucose levels.

DIETARY FACTORS IN THE PATHOGENESIS OF TYPE 1A DIABETES MELLITUS

The role of diet, particularly cow's milk protein, in the pathogenesis of human type 1a diabetes is controversial.[27] Changes in food, particularly its protein content, influence the onset of diabetes in rodent models of autoimmune diabetes. These observations have been invoked as evidence that complex natural ingredients in standard human and rodent diets may be involved in the autoimmune-mediated destruction of beta cells.

Antibodies reactive against a peptide sequence contained within bovine serum albumin (BSA) occur in humans, biobreeding (BB) rats, and nonobese diabetic (NOD) mice, which cross-react with an islet antigen designated p69. Together with suggestive epidemiologic data, these observations have given rise to the controversial theory that dietary cow's milk may contribute to the pathogenesis of type 1a diabetes in susceptible individuals.[28] Removal of bovine proteins from the diet prevents diabetes in NOD mice.[29] Some investigators have shown that diets

containing cow's milk are diabetogenic in the BB rat; others have not confirmed the finding.[30] Diet clearly has a major diabetogenic effect in BB rats[31,32] and NOD mice[32]; however, the exact chemical identity of the food diabetogen(s) is still not clear.

The nature of the interaction among genetic, environmental, and immunologic factors in the etiology of type 1a diabetes remains poorly understood. The genetic predisposition to diabetes is associated with specific DQ and DR alleles in the human leukocyte antigen (HLA) region of chromosome 6, but the observation of less than 50% concordance for type 1 diabetes in identical twins indicates that environmental factors are also involved. The earliest report of an association between breast-feeding and protection from IDDM appeared in 1984.[33] A meta-analysis concluded that children with diabetes are 60% more likely to have had an early exposure to cow's milk than nondiabetic children.[34] When exposure to whole cow's milk was examined in children at high and low risk for IDDM, as defined by genetic markers in the HLA region, a gene–environment interaction was demonstrated. Exposure to cow's milk before 3 months of age and having the high-risk genotype was associated with an 11-fold increased risk of IDDM compared with subjects who possess no risk factors.[35] In Finland, 100% of newly diagnosed diabetic children have elevated serum levels of antibodies to BSA compared with less than 4% of control children.[36] These findings have not, however, been replicated.

The locus transcribing ICA69, a beta cell surface protein of the human pancreas, shows two short regions with nucleotide sequences similar to that of BSA but not human albumin.[37] These two antigenic determinants (ICA69 and BSA) could play a role in the induction of cow's milk–induced beta cell autoimmunity based on a theory of pathogenesis that involves molecular mimicry.[36] Alternatively, the similarity of these two antigens may simply be a case of cross-reactivity between anti-ICA69 antibodies and anti-BSA antibodies and have no role in the etiology of type 1 diabetes.

Increased levels of antibodies to cow's milk protein and β-lactoglobulin have been observed in newly diagnosed diabetic children.[38–40] The significance of the elevated levels of β-lactoglobulin antibodies is unclear. If molecular mimicry between ICA69 and BSA is involved in the etiology of type 1 diabetes, one would expect BSA antibodies to be elevated rather than the other antibodies to cow's milk proteins. Other exposures in the infant diet have not been as extensively evaluated as cow's milk–based formulas. Exposure to solid foods by 3 months of age was associated with a 2.5-fold increased risk of type 1 diabetes.[35] In Sweden, children with diabetes consumed larger quantities of protein and nitrosamines before diagnosis than did age-matched control children.[41]

Although equivocal and inconclusive, considerable epidemiologic evidence and experimental data from studies in genetically susceptible animals suggest that dietary exposures in infancy may be associated with an increased risk of type 1 diabetes. Early introduction of cow's milk in infants may contribute to the development of childhood diabetes.[42,43] A large-scale trial of dietary cow's milk protein restriction in infants at risk of type 1 diabetes is currently under way in Finland.[44]

GOALS OF MEDICAL NUTRITION THERAPY

The goals of medical nutrition therapy of children and adolescents are as follows:

1. To provide adequate energy to ensure normal growth and physical development
2. To integrate insulin regimens into usual eating and physical activity habits
3. For youth with type 2 diabetes, to facilitate changes in eating and physical activity habits that reduce insulin resistance and improve metabolic status and gradually achieve a more desirable weight for height
4. For individuals being treated with insulin or insulin secretagogues (type 2 diabetes), to provide self-management education for treatment and prevention of hypoglycemia, acute illness, and exercise-related blood glucose perturbations
5. To attain and maintain optimal metabolic outcomes, including near-normal blood glucose levels without excessive hypoglycemia, a lipid and lipoprotein profile that reduces the risk for macrovascular disease, and blood pressure levels that reduce the risk for micro- and macrovascular disease
6. To prevent and treat the chronic complications of diabetes and modify nutrient intake and lifestyle as appropriate for prevention and treatment of obesity, dyslipidemia, cardiovascular disease, hypertension, and nephropathy
7. To improve general health through healthful food choices and physical activity
8. To address individual nutritional needs taking into consideration personal and cultural preferences and lifestyle while respecting the individual's wishes and willingness to change

The Diabetes Control and Complications Trial (DCCT) confirmed that long-term maintenance of blood glucose levels near to normal delays or prevents the microvascular complications of type 1 diabetes.[45] This study also demonstrated that intensive management of type 1 diabetes is associated with a threefold increase in severe hypoglycemia and a tendency to gain weight. Obesity (greater than 120% of ideal body weight or body mass index [BMI] > 95th percentile) was more common in intensively treated patients.[46] Weight gain in intensively treated patients with type 1 diabetes has been primarily attributed to the elimination of glucosuria (70% of the weight gain) and a 5% reduction in daily energy expenditure (30% of the weight gain).[47] Recurrent symptomatic hypoglycemia requiring oral sources of carbohydrate to restore euglycemia also contributes to the tendency to gain weight in some intensively treated patients.

Our ability to help patients achieve these objectives is still limited by the imperfection of insulin replacement,

which does not precisely mimic normal physiology, the lack of methods to continuously monitor blood glucose concentrations, and the risk of severe hypoglycemia when glucose levels are near to normal but insulin delivery is not regulated by a closed-loop feedback system.[48]

The child with diabetes and his or her family have to assume primary responsibility for routine daily management, and the role of the health care professional is that of educator, advisor, and motivator. Even modest objectives are not achievable in all patients because psychosocial and economic factors make it impossible for some children and their families to perform daily all of the tasks that comprise a comprehensive treatment program.[49,50] The goals of therapy can, however, be accomplished in most patients most of the time by individualized meal planning, flexible insulin regimens and algorithms, self-blood glucose monitoring, and education of older children and adolescents that promotes independent decision-making.

GENERAL PRINCIPLES

There is little or no research on the nutrient requirements of children and adolescents with diabetes. Therefore, nutrient recommendations are based on the requirements of healthy children and adolescents.[51] The nutritional needs of children with diabetes do not differ from those of healthy children. They do not require special foods, nor do they need different amounts of vitamins or minerals.[52] The total intake of energy must be sufficient to balance the daily expenditure of energy and to satisfy the requirement for normal growth. This allowance has to be adjusted periodically to achieve an ideal body weight and to maintain a normal rate of physical growth and maturation. For patients with type 2 diabetes, most of whom are obese, the objective of medical nutrition therapy is to lose weight and then maintain a desirable weight without compromising linear growth and to achieve target blood glucose and hemoglobin A_{1c} (HbA_{1c}) goals.[13]

In contrast to healthy children, in whom insulin secretion is precisely regulated by the ingestion of food, children with type 1 diabetes must match their food consumption to the anticipated time of action of the specific insulin that is being used. For example, because intermediate-acting insulin is continuously released from the subcutaneous injection site into the circulation, hypoglycemia may occur between meals. Consequently, most patients whose insulin regimens include twice-daily intermediate-acting insulin have a snack between meals and at bedtime to prevent hypoglycemia.

It is essential that the patient and his or her family understand the importance of consistency with respect to both timing of meals and snacks and their content of carbohydrate, fat, and protein. How to adjust the meal plan for periods of either planned or spontaneous physical activity and unexpected illness must be addressed as part of a comprehensive program of nutrition education and counseling.

FORMULATION OF THE MEAL PLAN

Newly diagnosed children usually present with weight loss. Therefore, formulating the meal plan begins with estimating energy requirements to restore and then maintain an appropriate body weight and allow for normal growth and development. Energy requirements vary with age, height, weight, and sex, as well as with physical activity, season of the year, and stage of puberty. A child's actual food intake, estimated from a 24-hour or 3-day diet history, should be used as the primary indicator of daily energy needs. If the child's actual food intake cannot be satisfactorily determined, the nutrition prescription can be based on a formula for estimating energy and protein allowances. One method commonly used to estimate energy requirements is based on age and can be used as a crude approximation for children up to 12 years of age: basal daily needs for all children = 1,000 kcal; add to the basal needs 125 kcal × age in years for boys and 100 kcal × age in years for girls. Add up to 20% more kilocalories for very active children. Appendix 2 contains a guide to Recommended Daily Allowances (RDAs) for protein and energy for children and adolescents.[51] Because the energy needs of children continuously change, food intake should be re-evaluated at 3- to 6-month intervals, depending on the age of the child.[53,54]

Medical nutrition therapy begins with an assessment by a registered dietitian, which takes heed of the ethnic, religious, and economic factors that pertain to the individual patient and his or her family. The meal plan must take into account the child's school schedule, early or late lunches, gym classes, and after-school physical activity. Children's activities often differ on weekdays compared with weekends and holidays, and appropriate allowance must be made for these differences.

Children's daily eating patterns generally include three meals and two or three snacks, depending on the length of time between meals, age of the child, and level of physical activity. Although their daily energy intake is relatively constant over time, young children adjust their energy intake at successive meals.[55,56] The highly variable food consumption from meal to meal typical of young children is especially challenging when the child has type 1 diabetes. This normal pattern must be taken into consideration when meal planning advice is given to the parents of young children with type 1 diabetes. Administration of rapid-acting (lispro) insulin after the meal, which has been shown to achieve postprandial blood glucose targets, has provided a solution to this problem.[57,58] The purpose of snacks is to prevent hypoglycemia and hunger between meals. Patients who use intensified insulin regimens (multiple daily doses of rapid-acting insulin or an insulin pump) use pre- and postprandial blood glucose monitoring and individualized insulin-to-carbohydrate ratios (eg, 1 U per 15 g carbohydrate) to choose insulin doses to match carbohydrate intake.

The dietitian has the important task of evaluating the patient's and family's understanding of basic principles of nutrition and teaching them to apply this knowledge to the formulation of an individualized meal plan. The aim is to lay a foundation for lifelong healthful eating habits for the child and family. Even the most intensive regimens of insulin administration are not successful without careful attention to meal planning.[59] Nutrition education, like all

aspects of diabetes education, has to be an ongoing process with periodic review and revision of the meal plan and assessment of the child's and parents' levels of comprehension, ability to solve problems, and adherence to the nutrition goals. Teaching should be followed by systematic assessment of the patients' ability to perform in an environment that approximates as closely as possible the behaviors expected in the natural environment.[60]

Energy

The nutrition prescription must be sufficient to ensure normal growth and physical development. For overweight and obese children and adolescents with type 2 diabetes, energy is reduced to arrest weight gain while supporting normal linear growth and physical development. Even modest weight reduction increases sensitivity of tissues to insulin and improves fasting and postprandial plasma glucose levels.[61,62]

The child's appetite must be considered when determining energy requirements and the nutrition prescription. Because energy requirements change with age, physical activity, and growth rate, an evaluation of height, weight, and energy intake is recommended every 3 to 6 months.[63] Good metabolic control is essential for normal growth and development.[64] At each visit, the clinician should meticulously plot the child's growth data and screen for symptoms and signs of inadequate insulin delivery, hypo- or hyperthyroidism, celiac disease, and adrenal insufficiency when the child is not tracking along his/her height, weight, and BMI percentiles.

Once the nutrition prescription has been determined, the proportion of macronutrients can be modified, as necessary, according to blood glucose and plasma lipid goals and requirements for growth and development. Older children and teens can be taught to adjust the dose of insulin to match their carbohydrate intake, and most do well with this approach as it enhances their independence, helps them fit in with their peers, and develops a trusting and caring relationship with the health care team. Withholding food from a child because the blood glucose level is high, as an alternative to adjusting the dose of insulin, is strongly discouraged.

Carbohydrate

The ADA recommends that 60 to 70% of total energy be distributed between carbohydrate and monounsaturated fat.[65] Dietary dogma in diabetes has been to avoid simple sugars and replace them with complex carbohydrates. This belief was based on the assumption that simple sugars are more rapidly digested and absorbed than starches and would, therefore, aggravate hyperglycemia to a greater degree. During the past two decades, however, the blood glucose responses to various carbohydrate-containing foods have been extensively investigated, and there is little scientific evidence to support this assumption. Numerous factors influence the glycemic response to food, including the amount of carbohydrate,[66] the type of sugar (glucose, fructose, sucrose, lactose),[67] the nature of the starch (amylose, amylopectin, resistant starch),[68] cooking and food processing (degree of starch gelatinization, particle size, cellular form),[69] and food structure,[70] as well as other food components (fat and natural substances that slow digestion: lectins, phytates, tannins, fiber, and starch-protein and starch-lipid combinations).[71,72] The glycemic response to a particular carbohydrate food depends on whether it is eaten alone or as part of a mixed meal.[73] Fasting and preprandial blood glucose concentrations,[74–77] the severity of glucose intolerance,[78] and the second meal effect[79] are other factors that can affect the glycemic response to foods.

The glycemic index (GI), proposed in 1981 as an alternative system for classifying carbohydrate-containing food, measures the glycemic response (an indicator of the rate at which the blood glucose level rises and how it is sustained over time) after ingestion of carbohydrate. GI is defined as the incremental area under the plasma glucose response curve after consumption of a standard amount of carbohydrate from a test food relative to that of a control food, either white bread or glucose.[80] The glycemic and hormonal responses to a large number of ingested carbohydrates have been systematically examined and their GIs defined.[80–86] As a result of these studies, the validity of the dogma that ingestion of simple sugars causes a rapid and pronounced rise in blood glucose, whereas complex carbohydrates produce only modest increments in blood glucose concentration, began to be disputed,[87] and it is now clear that there is a wide spectrum of biologic responses to different complex and simple carbohydrates, with so much overlap that they cannot be simply classified into two distinct groups. Even a single food produces a substantially different glycemic response when it is prepared in different ways. For example, a pureed apple causes a greater increment in blood glucose than does an apple eaten whole.[88] Similarly, ground rice or rice flour causes a greater glycemic and insulinemic response than does whole cooked rice,[84] and cooking increases the glycemic response to starch.[89] Blood glucose levels after ingesting wheat flour in the form of pasta are lower than after an equal amount of wheat flour in bread.[90] Thus, the form of a carbohydrate-containing food, in addition to its chemical composition, influences its glycemic effect. The effect of food form alters the rate of digestion and absorption and, therefore, affects postprandial glycemia. Fruits and milk cause a lower glycemic response than most starches, and sucrose causes a glycemic response similar to that of bread, rice, and potatoes. In general, most refined starchy foods eaten in the United States have a high GI, whereas nonstarchy vegetables, fruits, and legumes tend to have a low GI.

The usefulness of low GI diets in individuals with type 1 diabetes continues to be controversial.[91] Three short-duration (3 to 6 weeks) studies of the effect of low GI foods on glycosylated proteins in patients with type 1 diabetes showed a 12 to 27% decrement in fructosamine in those who decreased their dietary GI by 12 to 26%.[92–94] Insulin requirements have been reported to be lower on a low GI diet, [93] but other studies have not observed this effect.[94–96] In a cross-sectional study of 2,810 people with type 1 diabetes, the GI calculated from 3-day food records was examined for its relation to HbA_{1c} and serum lipid concentrations.[97] HbA_{1c} levels were lower in the lowest GI quartile

compared with the highest quartile. Of the serum lipids, only high-density lipoprotein (HDL) cholesterol was independently related to the GI. The effects on lipids after low - compared with high-GI diets appeared to be minimal.

There is a strong relationship between the premeal insulin dosage and the postprandial response to the carbohydrate content of the meal.[98–101] In individuals using intensive insulin therapy, the total amount of carbohydrate in the meal does not influence the glycemic response if the premeal insulin is adjusted for the carbohydrate content of the meal. The premeal insulin dosage required is not affected by the GI, fiber, fat, or caloric content of the meal, nor do wide variations in the carbohydrate content of meals modify the basal (long-acting) insulin requirement. The concept of total carbohydrate intake determining the premeal insulin dosage is further supported by data from the DCCT. Individuals who adjusted their premeal insulin dosages based on the carbohydrate content of their meals had 0.5% lower HbA_{1c} levels than those who do not adjust premeal insulin doses.[59] Day-to-day consistency in the amount and source of carbohydrate has been associated with lower HbA_{1c} levels in individuals who receive fixed doses of short-acting (or rapid-acting) and intermediate-acting insulin.[102]

Low GI diets significantly improve metabolic control in adults with type 2 diabetes but have not been studied in children and adolescents with type 2 diabetes.[103–106] Although it is clear that carbohydrates cause differing glycemic responses, the literature demonstrates only modest long-term beneficial effects of low GI diets on glycemia and lipid concentrations. The recently published recommendations of the ADA, citing methodologic issues with some of the studies, concluded that there is insufficient evidence of substantial long-term benefit to recommend use of GI in the management of diabetes.[2] The total amount of carbohydrate consumed should be emphasized rather than its source.[2]

Fiber

Fiber refers to the portion of a plant that is not digestible in the human small intestine. It was thought to have no nutritive value, and in the past century, the quantity of fiber in the American diet has declined. During the last two decades, however, considerable attention has been focused on the various plant fibers because of their influence on gastrointestinal physiology. It is now known that fiber markedly influences the digestion, absorption, and metabolism of many nutrients.[107–110] Cellulose, lignins, and certain hemicelluloses, the fibers present in vegetables and grains, are usually insoluble in water. Many fruits and certain legumes are rich in water-soluble fibers such as pectins, guar, and storage polysaccharides. When carbohydrate is ingested together with soluble fiber, the resulting increase in blood glucose concentration is less than when carbohydrate is ingested alone.[111] Normally, a large test meal containing carbohydrate, protein, and fat causes significantly less postprandial glycemia when the meal is supplemented with guar.[112] The attenuated increment in blood glucose concentration that occurs when guar is added to ingested carbohydrate is attributable to delayed rather than incomplete absorption of carbohydrate.[113]

Short-term studies using large amounts of fiber (> 30 g/day) in small numbers of suboptimally controlled type 1 diabetic subjects suggested a positive effect of fiber on glycemia.[114–117] However, in subjects using intensive insulin therapy, 56 g of fiber had no beneficial effect on glycemic control.[95] Subjects receiving two or more injections per day and with baseline HbA_{1c} levels of 7 to 10% were randomized to either a high-fiber (50 g/day) low-GI diet or a low-fiber (15 g/day) high-GI diet for 24 weeks. The high-fiber diet significantly decreased mean daily blood glucose concentrations, number of hypoglycemic events, and, in the subgroup of patients compliant with diet, HbA_{1c} levels but had no beneficial effect on cholesterol, HDL cholesterol, or triglyceride concentrations.[118] Conversely, a cross-sectional analysis of dietary fiber in type 1 diabetes patients enrolled in EURODIAB IDDM showed that a higher intake of fiber was independently associated with higher levels of HDL cholesterol in both men and women and lower low-density lipoprotein cholesterol levels in men but not in women.[119] No substantial differences were observed between soluble and insoluble fiber intakes.

These observations suggest that inclusion of plant fiber in the diet may benefit patients with diabetes by diminishing postprandial hyperglycemia. Furthermore, certain soluble plant fibers significantly reduce serum cholesterol concentrations and decrease fasting serum triglyceride levels in diabetics with hypertriglyceridemia.[109] The mechanism responsible for the effects on cholesterol and triglycerides is not known.

Fiber intake for people with diabetes should be the same as for the general population. For adults, daily consumption of a diet containing 20 to 35 g dietary fiber from a wide variety of food sources is recommended. This goal can be readily achieved by increasing the consumption of minimally processed foods, such as grains, legumes, fruits, and vegetables.[120] Dietary fiber guidelines for children with diabetes are the same as for nondiabetic children. Updated Adequate Intakes (AI) for children and adolescents are as follows[121]:

AI for Children	
1–3 years	19g/day of Total Fiber
4–8 years	25 g/day of Total Fiber
AI for Boys	
9–13 years	31 g/day of Total Fiber
14–18 years	38/day of Total Fiber
AI for Girls	
9–13 yers	26g/day of Total Fiber
14–18 years	26 g/day of Total Fiber

In summary, it appears that the glycemic load of meals and snacks is more important than the source or type of carbohydrate. The glycemic load is defined as the weighted average of the GI of individual foods multiplied by the percentage of the dietary energy as carbohydrate and has been

proposed as a method to characterize the impact of foods and dietary patterns with different macronutrient composition on glycemic response. For example, a carrot has a high GI but a low glycemic load, whereas a potato has both a high GI and a high glycemic load. Individuals using intensive insulin therapy should adjust their premeal insulin dosages based on the carbohydrate content of their meals. Individuals receiving fixed daily insulin dosages should try to be consistent in their day-to-day carbohydrate intake. The use of low-GI foods may reduce postprandial hyperglycemia and may have long-term benefit on HbA_{1c} levels.

Protein

The optimal protein intake for individuals with diabetes has not been determined. Protein requirements are not increased when diabetes is well controlled with insulin; therefore, children with diabetes should follow the RDA guidelines suggested for children without diabetes. The physiologic requirement is determined by the amount of protein necessary to sustain normal growth. This requirement is based on ideal weight for height and varies with age, being highest in infancy and early childhood. The protein requirement (per kilogram body weight) of infants, children, and adolescents is higher than that of adults. Protein intakes range from 12 to 20% (0.9 to 2.2 g/kg body weight/day) of total daily caloric intake. Any ingested protein that exceeds the body's requirement for new protein synthesis enters the carbon pool and is converted into either glucose or fat. It is recommended that protein should constitute 15 to 20% of the total daily intake of energy, the same as for nondiabetic children and adolescents.

Dietary protein should be derived from both animal and vegetable sources; however, the source of protein is not especially important as long as all of the essential amino acids are provided in adequate amounts. To lower the consumption of saturated fat, less protein should be derived from red meat, whole milk, and high-fat dairy foods than is customary in the United States. With the onset of nephropathy, lower intakes of protein should be considered. A protein intake similar to the adult RDA (0.8 g/kg body weight/day), ~ 10% of daily calories, is sufficiently restrictive and is recommended for individuals with evidence of nephropathy. With protein intake of 0.6 g/kg/day, evidence of protein undernutrition has been reported.[122]

Fat

The prevalence of macrovascular disease is markedly increased in persons with diabetes mellitus.[123] Its major clinical consequences are atherosclerosis of the coronary, cerebral, and lower-extremity large arteries. In Westernized populations, atherosclerotic vascular disease is the major cause of mortality and morbidity in patients with diabetes. About 75% of patients with diabetes in Europe and North America die of coronary heart disease. This terrible toll is not inevitable. In other parts of the world, diabetic patients who escape atherosclerosis have low serum cholesterol levels and live on diets that are usually high in starch and have a low content of saturated fat. Cognizance of these facts compels us to focus attention on the amount and type of fat consumed by persons with diabetes in North America. A survey of Joslin Clinic patients with type 1 diabetes for 15 to 20 years, conducted between 1986 and 1988, showed that fat accounted for 36 to 40% of total calorie consumption.[124]

There is a clear relationship between hyperlipidemia and increased cardiovascular morbidity in type 2 diabetes, whereas in type 1 diabetes, microvascular disease is the more urgent problem. Although microvascular disease does not appear to be related to abnormalities of lipid metabolism, patients with type 1 diabetes eventually also develop atherosclerosis and its sequelae.

Excessive saturated fat, cholesterol, and total energy lead to increased blood levels of cholesterol and triglycerides. Because hyperlipidemia is a major determinant of atherosclerosis,[125] the meal plan should be modified to mitigate this risk factor. The recommended percentage of energy from fat depends on goals for body weight and plasma glucose and lipid concentrations. Children and adolescents with well-controlled type 1 diabetes are not at high risk for developing lipid abnormalities but should be screened and monitored according to guidelines issued by the National Cholesterol Education Program (NCEP) and by the American Academy of Pediatrics.[126,127] For children and adolescents who are growing and developing normally and have normal plasma lipid levels, recommendations are that less than 10% of energy comes from saturated fat, the daily intake of cholesterol should be less than 300 mg, and consumption of transunsaturated fatty acids should be minimized. Total fat should be reduced in the obese child in an effort to reduce total energy consumption. The consumption of saturated fat can be reduced by eating less red meat, whole milk, and high-fat dairy foods; eating more poultry, fish, and vegetable proteins; and drinking more low-fat milk.

The NCEP Step II diet guidelines should be implemented in the patient with elevated LDL cholesterol (> 100 mg/dL).[128] The guidelines recommend that total fat represent no more than 30% of total calories, less than 7% of calories is from saturated fat, and dietary cholesterol is 200 mg/day.

Sodium

The average consumption of salt in populations correlates well with the prevalence of hypertension,[129] and a high intake of sodium causes high blood pressure in susceptible individuals. Most processed foods contain considerably more sodium than similar foods prepared from raw ingredients. Sodium is present in the form of sodium chloride; it may also be present as sodium glutamate, added to enhance flavor, or as sodium nitrite included as a preservative. The leaders in sodium content are take-out or "fast foods," which account for an ever-increasing proportion of the US diet. It has been estimated that 70% of the sodium in the US diet is derived from prepared foods.

Sodium consumption in persons with diabetes should be the same as for the general population, between 2,400 mg[130] and 3,000 mg daily.[131] A reduction in salt

intake lowers blood pressure in both normotensive and hypertensive individuals. In nondiabetic adults, a reduction in salt consumption lowers systolic blood pressure by 4 to 5 mm Hg[132,133]; therefore, for diabetic patients with hypertension (in children and adolescents defined as the average of three separate systolic and/or diastolic blood pressures > 95th percentile for age, sex, and height), a reduction in salt intake to 2,400 mg daily is recommended. Note, however, that sodium restriction has not been tested in the diabetic population in controlled clinical trials.[134] To achieve these goals, patients should be taught to reduce their use of table salt and decrease their consumption of convenience foods.

Sweeteners

Sweetness is an established property of the Western diet.[135] The average per capita consumption of sugars in the United States is estimated to be 94 g per day, accounting for 22% of energy intake.[136] If the intake of sucrose has to be restricted as part of treatment, most patients demand an alternative source of sweetness if they are to adhere to their meal plans. Two varieties of sweeteners are available: nutritive and non-nutritive.[137]

Nutritive Sweeteners These include sucrose, fructose, sorbitol, xylitol, and corn sweeteners such as corn syrup, fruit juice or fruit juice concentrate, honey, molasses, dextrose, and maltose.

Sucrose Several studies have shown that sucrose as part of the meal plan does not adversely affect blood glucose control in individuals with type 1 or type 2 diabetes.[86,138–145] Therefore, sucrose and sucrose-containing foods may be substituted for other carbohydrates but may not simply be added to the meal plan. When making such substitutions, consideration must be given to the nutrient content of sucrose-containing foods, as well as the presence of other nutrients frequently ingested with sucrose, such as fat. Data are conflicting, and additional research will be necessary to determine whether dietary sucrose adversely affects serum lipids in people with diabetes.

The most recent ADA recommendations emphasize that priority should be given to the total amount of carbohydrate consumed rather than the source of the carbohydrate.[2] In clinical practice, therefore, the guiding principle should be "a carbohydrate is a carbohydrate." For example, a six-cookie serving of Nilla Wafers by Nabisco that contains 15 g of carbohydrate and 5 g of fat is approximately equivalent to one Eggo waffle. A serving of jelly beans containing 15 g of carbohydrate is equivalent to 4 oz of orange juice and may be used interchangeably. Each meal must be evaluated as a whole because the fiber, fat, and protein content, as well as the method of food preparation (as noted above), influences the glycemic response to the carbohydrate content of the meal.

Fructose Fructose is a constituent of sucrose and is present as the free monosaccharide in many fruits, vegetables, and honey. It accounts for ~ 9% of the average energy intake in the United States. About one-third of dietary fructose comes from fruits, vegetables, and other natural sources in the diet and about two-thirds come from food and beverages to which fructose has been added.[146] Fructose is similar in taste to sucrose but is 1.2 to 1.8 times sweeter. It is absorbed more slowly from the intestinal tract than glucose, sucrose, or maltose and is converted to glucose and glycogen in the liver.[147,148] Several studies have shown reduced postprandial plasma glucose levels when isocaloric amounts of fructose replaced sucrose or starch in the diets of people with diabetes.[86,139,149,150] Fructose has also been used in children in amounts up to 0.5 g/kg/day.[151] The potential benefit is tempered by the concern that fructose may have adverse effects on serum lipids, especially LDL cholesterol.[150] Consumption of large amounts of fructose (15 to 20% of daily energy intake [90th percentile of usual intake]) has been shown to increase fasting total and LDL cholesterol in subjects with diabetes[150] and fasting total and LDL cholesterol and triglycerides in nondiabetic subjects.[152] Therefore, people with dyslipidemia should not consume large amounts of fructose. There is no reason to avoid fruits, vegetables, and honey, in which fructose occurs naturally. Because of concern about the potential adverse effect of large amounts of fructose on serum lipids, fructose as a sweetening agent in the diet of people with diabetes may have no overall advantage over other nutritive sweeteners.

***Sugar Alcohols* (*Polyols*)** Sugar alcohols are classified as hydrogenated monosaccharides. These include sorbitol, mannitol, xylitol, hydrogenated disaccharides (eg, isomalt, maltitol, lactitol) and mixtures of hydrogenated mono-, di-, and oligosaccharides (eg, hydrogenated starch hydrolysates).[153]

Sorbitol is about half as sweet as sucrose. It is slowly and only partially absorbed from the gut and then metabolized in the liver by sorbitol dehydrogenase to fructose. Sorbitol has been assigned an energy value of 2.6 kcal/g; however, its precise caloric value is uncertain.[2] Its slow absorption causes blood glucose levels to rise less rapidly than after sucrose and other carbohydrates. When the daily intake exceeds 30 to 50 g, sorbitol can cause flatulence, intestinal cramps, and osmotic diarrhea.[154] The available evidence suggests that isocaloric substitution of sorbitol in the diet does not alter metabolic control.

Xylitol, a pentahydric alcohol, is as sweet as sucrose and is widely distributed in fruits and vegetables. The ingestion of xylitol in a single dose of 30 to 40 g causes diarrhea,[155] thus limiting its usefulness as an isocaloric carbohydrate substitute. It is metabolized to glucose, pyruvate, and lactate, mainly by the liver and, to a lesser extent, by the kidneys. Xylitol is slowly converted to glucose. There is scant information available on the effect of long-term oral administration on blood glucose control of diabetes. Many so-called dietetic foods marketed for people with diabetes contain sorbitol or xylitol instead of sucrose. In general, the sugar alcohols offer no nutritional advantage over other nutritive sweeteners and are usually more expensive.

Resistant starch (nondigestible oligosaccharides and the starch amylose) is not digested and, therefore, is not absorbed as glucose in the small intestine. It is, however,

almost completely fermented in the colon and produces about 2 kcal/g of energy. It is estimated that resistant starch and unabsorbed starch represents ~ 2 to 5% of the total starch ingested in the average Western diet.[156] Legumes are the major source of resistant starch (2 to 3 g per 100 g cooked legumes). Uncooked cornstarch contains about 6 g resistant starch per 100 g dry weight.[157] Single meal studies have found that meals high in resistant starch caused some reduction in postprandial glucose and insulin responses compared with meals with equivalent amounts of digestible starch. Uncooked cornstarch as part of the bedtime snack has resulted in less hypoglycemia at 2 am in children and at 3 am in intensively treated type 1 diabetic adults.[158–160]

Other Nutritive Sweeteners These include corn sweeteners such as corn syrup, fruit juice or fruit juice concentrate, honey, molasses, dextrose, and maltose. These sweeteners have the same calorie value as sucrose, and there is no evidence that they have any advantage over sucrose in terms of causing a less pronounced increase in blood glucose concentrations. All nutritive sweeteners contribute calories and, like sucrose and fructose, must be accounted for in meal planning.

Non-nutritive Sweeteners (High-Intensity Sugar Alternatives, Low-Calorie or Alternative Sweeteners) Saccharin, aspartame, acesulfame potassium (K), and sucralose are approved for use by the Food and Drug Administration (FDA) in the United States.

Saccharin was discovered in 1897 and, until the advent of aspartame, was the most commonly used artificial sweetener. It leaves a slightly bitter, metallic aftertaste. Administration of large amounts of saccharin to rats is associated with an increased occurrence of bladder tumors, which raised concerns about its carcinogenic potential and safety for use in human beings, but it is no longer on the FDA list of cancer-causing chemicals.[161]

Aspartame has been available since the early 1980s. It is a dipeptide consisting of phenylalanine and aspartic acid and is 200 times sweeter than sugar.[162] At one-tenth of a calorie, it has the sweetness of a teaspoon of sugar. It rapidly gained widespread popularity as an alternative to saccharin. The FDA determines an acceptable daily intake (ADI) for all food additives, including non-nutritive sweeteners. The ADI is defined as the amount of a food that can be safely consumed on a daily basis over a person's lifetime without any adverse effects. Actual intake is much less than the ADI. The ADI for aspartame is 50 mg/kg/day. The range of actual consumption at the 90th percentile is 2 to 3 mg/kg body weight, well below the ADI.

Acesulfame K is a white, colorless, crystalline sweetener approximately 200 times sweeter than sucrose. It is a derivative of acetoacetic acid and has a structure similar to that of saccharin.[163] It was approved for use by the FDA in 1988 and is marketed in the United States under the brand name Sunette when used as an ingredient of foods and as Sweet One when sold as a tabletop sweetener. It is stable both in liquids and during baking and cooking.

Sucralose is the newest product approved by the FDA. It was approved for use in 1998 under the brand name Splenda. It is made from sucrose through a process in which three hydrogen-oxygen groups are replaced with chlorine atoms. Sucralose is 600 times sweeter than sucrose. It is very stable and can be used for baking and cooking and has no effect on glucose homeostasis in diabetic subjects.[164,165]

TYPE 2 OR NON–INSULIN-DEPENDENT DIABETES MELLITUS IN CHILDREN AND ADOLESCENTS

Type 2 diabetes used to be virtually exclusively seen in adults. Changes in energy intake and expenditure have resulted in an epidemic of obesity in children and adolescents in the United States,[166] which has been temporally associated with an alarming increase in the prevalence of type 2 diabetes in children and adolescents, especially in minority populations, in the past decade. Almost 95% of patients are either overweight or frankly obese.[13,167]

Even in the absence of glucose intolerance, simple obesity is associated with impaired insulin action and with a reduced number of insulin receptors on target tissues.[61,62,168] In children, body composition is also a major determinant of insulin sensitivity. Adiposity accounts for 55% of the variance in insulin sensitivity in white children.[169] An inverse relationship between increasing adiposity and insulin sensitivity has also been demonstrated in black children. As BMI and percent adiposity increase, insulin sensitivity decreases and serum insulin levels increase.[170]

In adults, weight reduction alone causes increased sensitivity to insulin and improves fasting and postprandial hyperglycemia.[61,62] Similarly, plasma glucose levels decrease in type 2 diabetes following moderate calorie reduction.[171,172] Accordingly, lifestyle changes that lead to weight loss should be the cornerstone of therapy in all patients with type 2 diabetes.

Medical nutrition therapy for these patients emphasizes healthful eating to support optimal growth and weight management. Simple recommendations such as the elimination of sugar-containing sodas and juices and decreasing consumption of calorie-dense "fast foods" can improve blood glucose levels.

Children with type 2 diabetes should receive comprehensive self-management education similar to that for patients with type 1 diabetes. The entire family should be referred to a dietitian with knowledge and experience in nutritional management of children with diabetes. Nutrition recommendations should be culturally appropriate and sensitive to family resources and involve the entire family. Family members should be encouraged to adopt healthful eating habits and receive guidance on behavior modification strategies to change their lifestyles and decrease consumption of high-energy high-fat foods and incorporate daily aerobic physical activity into their lives.[173] To increase children's physical activity, the amount of time devoted to sedentary activities such as viewing television, playing video games, and sitting in front of a computer must be strictly limited.[174,175]

Treatment aims to normalize fasting and postprandial blood glucose and HbA_{1c} values and to identify and control any associated comorbidities such as hypertension and hyperlipidemia.[176] The ultimate goal of treatment is to reduce the risk of the acute and chronic complications associated with diabetes. The early age of onset of type 2 diabetes in children can reasonably be expected to increase the risk of microvascular complications, which are directly related to the duration of diabetes and hyperglycemia.

EDUCATION OF THE PATIENT AND FAMILY

It is hardly possible to overstate the importance of educating patients and their families in the basic principles of nutrition and in their application to the formulation of an individualized meal plan. The aim is to lay the foundation for lifelong healthful eating habits. A registered dietitian, experienced in the nutritional needs of the growing child and the behavioral issues that impact on adolescent diets, should be an integral member of the diabetes treatment team and is primarily responsible for teaching children and their families the principles of medical nutrition therapy and their application in the development of an individualized meal plan. Nutrition education must be an ongoing process, with periodic review of the meal plan and assessment of the child's and parents' level of comprehension. A single instructional session is inadequate. The patient with newly diagnosed diabetes and his or her parents should meet with a dietitian several times during the first few days after diagnosis. Within a few weeks of the child resuming his or her usual schedule, the patient and family should review the meal plan with a dietitian, who should also be available to patients and their families for telephone consultation. Because children's energy needs change with growth and variations in physical activity, food intake should be reassessed every 3 to 6 months in young children.[54] In older individuals, continuing education reinforces the principles of nutrition, and consultation with a dietitian is recommended at least annually. If the patient's glycemic control is poor, if growth is failing, if weight gain is excessive, or if other problems arise, the dietitian should be reconsulted to review the meal plan and to make appropriate dietary recommendations. The use of imaginative teaching methods and materials, applied on an individual basis, will engage the attention and cooperation of children and parents more effectively than abstract concepts of nutritional principles and detailed diet sheets that list the composition of individual foodstuffs.

THE MEAL PLAN

The meal plan must be simple, practical, and easy to modify and must offer foods that are interesting, tasty, and inexpensive. In the diabetes program at Children's Hospital Boston, meal planning is based on a combination of carbohydrate counting and the traditional exchange system, individualized to meet the ethnic, religious, and economic circumstances of each family. The exchange list system for meal planning is the most widely used substitution system. It was originally developed in 1950 by a joint committee of the ADA, the American Dietetic Association, and the Diabetes-Arthritis Program of the US Public Health Service and most recently was updated in 2003.[177] The system is based on six exchange lists: milk, fruit, vegetable, starch, meat, and fat. Each list indicates the appropriate size or volume of each food exchange. Thus, by prescribing the meal plan in terms of numbers of exchanges for each meal, consistency of total calories and of the proportions of nutrients can be maintained while allowing the patient a wide choice of foods. Accurate measurement of portion sizes has to be learned, and weighing and measuring foods help to achieve familiarity with the sizes of food portions specified in the exchange list. Weighing food is an educational exercise to train the eye and need not be continued indefinitely. However, if blood glucose control appears inexplicably to deteriorate, it is useful to resume weighing and measuring food portions to ensure that amounts are not excessive. Even the exchange system is not intended to be used in isolation; rather, it is intended to be one component of a nutritional program directed by a trained dietitian.

An example of how this system is applied to an individual patient is illustrated below. An 11-year-old girl's height is 144 cm (50th percentile on the Centers for Disease Control and Prevention's growth chart) and weight is 37.4 kg (50th percentile). Her daily energy requirement based on the RDA to support growth in the 50th percentile is 1,756 kcal. An appropriate distribution of macronutrients could be 50% of the total calories from carbohydrate, 20% as protein, and 30% as fat:

	Kcal	*G*
50% carbohydrate	884	221
20% protein	368	92
30% fat	531	59
Total kcal	1,783	

Table 42-1 shows how this patient's daily food allowance is distributed among the six food groups.

CARBOHYDRATE COUNTING

Carbohydrate counting is a meal planning method in which the grams of carbohydrate or number of carbohydrate servings eaten at each meal and snack are counted. Carbohydrate is the main nutrient in starches, fruits, milk, and sugar-containing foods and has the greatest effect on the blood glucose level. Therefore, it is the most important macronutrient to control to maintain optimal glycemic control. Using the exchange lists, one starch choice is considered to be equivalent to either one fruit choice or to one milk choice, and each contains approximately 15 g of carbohydrate and is equal to one "carbohydrate choice." A typical breakfast of two starch exchanges, one fruit exchange, and one milk exchange is equal to 60 g of carbohydrate or four carbohydrate choices. The "Nutrition Facts" on food labels list the portion size and the total amount of carbohydrate measured in grams per serving. Foods not included in

TABLE 42-1 Distribution of Daily Food Allowance among Six Food Groups

Group	*Exchanges*	*Carbohydrate*	*Protein*	*Fat*
Starch	8	120	24	
Fruit	4	60		
Milk	3 low fat (1%)	36	24	9
Vegetables	1	5	2	
Meat	6 medium fat		42	30
Fat	4			20
Grams		221	92	59
Calories (%)		884 (49.6)	368 (20.6)	531 (29.8)

the exchange lists may be incorporated into a meal plan. The serving size of sucrose-sweetened foods is typically smaller and less nutrient dense than foods with a lower sugar content. Moderation is important for optimal nutrition and satiety. For example, 3/4 cup of Frosted Flakes or 1 1/2 cups of regular Cheerios have approximately 30 g of carbohydrate. Accordingly, 3/4 cup of Frosted Flakes or 1 1/2 cups of Cheerios with 1 small banana and 1 cup of milk are both examples of a 60 g carbohydrate breakfast.

Carbohydrate counting allows flexibility in food choices and minimizes "cheating" as all foods can be included in the meal plan. See Table 42-2 for a sample menu incorporating both the exchange servings and grams of carbohydrate for the child described in the text.

Adherence

Adherence to a meal plan is one of the behaviors patients must maintain for optimal management of type 1 diabetes and strongly correlates with blood glucose control in children less than 16 years old.[178] For many patients, this is the most difficult aspect of diabetes management.[179–182] Patients frequently do not adhere to their prescribed meal plan,[49,50,183,184] and parents often have difficulty helping their young child to follow a meal plan.[182] Schmidt and colleagues, for example, found that subjects added or deleted approximately one of four prescribed food exchanges daily.[184] Furthermore, many children (and their parents) do not possess the knowledge and skill required for good dietary adherence regardless of motivation.[60,185] Approximately 60% of Finnish adolescents reported at least a satisfactory level of adherence to their meal plans.[186] In the United States, a self-report survey of 144 adolescents who attended a tertiary care diabetes program showed that 15% took extra insulin to cover inappropriate food intake, 73% ate inappropriate foods, and 50% missed meals and snacks.[187]

Management of diabetes is difficult for children and adolescents, and as children progress through adolescence and into young adulthood, satisfactory adherence to therapy and optimal glycemic control become increasingly difficult to achieve and maintain.[188] To achieve better diabetes outcomes, families must remain actively involved in their youngster's diabetes management, regardless of the child's age, even as the primary responsibility for diabetes care shifts from parent to adolescent.[189–191]

Health care professionals involved in the care of children with diabetes should not be discouraged from helping their patients to overcome the barriers to adherence so that they will be able to enjoy the benefits of good diabetes control.[45,192] Empirical research shows that adherence to the meal plan can be improved by psychosocial factors such as promoting a positive attitude toward the illness and its treatment as well as supportive relationships with their family, peers, and health care team.[186] Frequent follow-up and ongoing education to individualize the meal plan and set attainable goals are necessary to teach the patient and his/her family how to match insulin to exercise and food.[193,194] Self-monitoring of blood glucose and carbohydrate counting provide patients with a greater degree of dietary flexibility and enable adolescents to take a more active and informed role in their diabetes nutritional management.[191,195,196]

SUMMARY

Nutrition recommendations for treatment of diabetes have repeatedly changed since the preinsulin era, in which a starvation diet with negligible carbohydrate and 70% of calories from fat was the recommended treatment. Today, there is no one "diabetic diet." The recommended diet can be defined only as a meal plan based on a nutrition assessment and mutually accepted treatment goals and desired outcomes. Nutrition therapy should be

TABLE 42-2 Sample Menu Based on the Daily Food Allowance*

Foods	*Exchanges*	*Carbohydrate (g)*
Breakfast		
3/4 cup cornflakes	2 starches	30
+ 1 slice toast		
1 small banana	1 fruit	15
1/2 cup 1% fat milk	1/2 low-fat milk	6
1 tsp margarine	1 fat	
Snack		
1 granola bar	1 starch	15
Lunch		
2 slices bread	2 starches	30
1 slice turkey, 1 slice cheese	2 meat	
Lettuce + tomato	"free vegetable"	
1 tsp mayonnaise	1 fat	
1 cup 1% fat milk	1 low-fat milk	12
1 small apple	1 fruit	15
Snack		
17 grapes	1 fruit	15
3 cups low-fat popcorn	1 starch	15
Supper		
1/2 cup mashed potatoes	1 starch	15
3 oz chicken	3 meat	
1/2 cup broccoli	1 vegetable	5
1 small orange	1 fruit	15
2 tsp margarine	2 fat	
1 cup 1% low-fat milk	1 low-fat milk	12
Snack		
3 graham cracker squares	1 starch	15
1 ounce string cheese	1 meat	0
1/2 cup 1% fat milk	1/2 low-fat milk	6

*For child described in the text.

individualized and consideration given to usual eating habits and other lifestyle factors. Monitoring clinical and metabolic parameters including blood glucose, glycosylated hemoglobin, lipids, blood pressure, and body weight, as well as quality of life, is crucial to ensure successful outcomes. Modern diabetes management, combining frequent self-monitoring of blood glucose with multiple-dose insulin regimens, or insulin pump therapy, and mastery of carbohydrate counting, has made it possible for children and adolescents with diabetes to have considerable dietary flexibility while maintaining near-normal glycemic control.[197]

CHAPTER 43

ACUTE DIARRHEA

Caleb K. King, MD, PhD, Christopher Duggan, MD, MPH

Diarrheal diseases are a major cause of pediatric morbidity and mortality worldwide, with 1.5 billion episodes and 1.5 million deaths of children under age 5 years estimated to occur annually.[1,2] If these statistics appear daunting, they should be compared with data from 1992, when 3 million annual deaths were estimated,[3] and 1982, when 5 million deaths were estimated.[4] The story underlying these statistics is the remarkable success of worldwide campaigns to treat acute diarrhea with oral rehydration therapy (ORT). The development of ORT is among the most successful collaborations ever between basic and applied biomedical research and one of the most significant applications of nutritional therapy to the management of acute disease. Interestingly, it is also a case of reverse technology transfer,[5] in which work originally carried out for benefit of those in countries with less developed economies has changed the standard of practice, even in the most developed setting.

It is, however, clear that the full benefits of the nutritional therapy of acute diarrhea have not been realized. Shortcomings in treatment are significant because, even in countries with established market economies, diarrheal diseases account for a substantial portion of pediatric hospital admissions and remain a significant cause of morbidity.[6] It may be argued that the full implementation of ORT for treatment of acute diarrhea in countries with developed market economies has lagged behind its use in less developed countries, perhaps because of ingrained use of intravenous therapy or the reduced appeal of a technologically simple solution.[7] In addition, it has been difficult to establish continued feeding during diarrheal episodes as normative therapy, in spite of a wealth of in vitro and in vivo data supporting the role of continued nutrition in improving measurements of gastrointestinal function, as well as anthropometric, biochemical, and clinical outcomes.[8,9]

This chapter reviews the historical background and scientific basis of ORT and provides a framework for assessing and treating the dehydrated patient or the patient at risk for dehydration. The discussion focuses on common clinical scenarios and traditional practices, especially with regard to feeding. The limitations of ORT are discussed, as well as areas of ongoing research.

HISTORICAL BACKGROUND

Early attempts at treating dehydration resulting from diarrhea were first described in the medical literature in the 1830s during epidemics of *Vibrio cholerae* infections.[10,11] It was not until 100 years later that the use of intravenous fluids became widespread. Accurate chemical analysis of diarrheal stools eventually permitted the formulation of physiologically appropriate replacement solutions, leading to the successful treatment of cholera with intravenous fluids by the 1940s.[12] Further research into intestinal electrolyte transport led to the development of oral solutions for rehydration.[13,14] In 1971, these were put to the test in the field with the large-scale treatment of refugees from the Bangladesh war of independence.[15] The remarkable success of oral solutions hastened the development of the World Health Organization (WHO) guidelines for ORT and production of standard packets of oral rehydration salts. It may be argued that the initial application of ORT to cholera epidemics in the developing world hindered the acceptance of this therapy as a mainstay in the United States and Europe. With time, however, ORT has become accepted as the standard of care for clinically efficacious and cost-effective management of acute diarrhea,[16,17] although it remains underused in settings in which parenteral rehydration has been the established practice.[18–21]

PHYSIOLOGIC BASIS FOR THE USE OF ORAL REHYDRATION SOLUTIONS

Fluid must be absorbed and reabsorbed for survival. Under the best of circumstances, the adult intestinal epithelium must handle 6,500 mL fluid per day, the combination of oral intake, salivary, gastric, pancreatic, biliary, and upper intestinal secretions. This is typically reduced to 1,500 mL by the distal ileum and is further reduced in the colon to stool output less than 250 mL/day.[22] Were it not for this ability for net absorption, there would be no balance of fluid to replace insensible losses and that necessary for renal filtration. During disease, the volume of intestinal fluid output is remarkably increased, overwhelming reabsorptive capacity, leading to diarrhea.

Applied clinical research, first carried out among cholera patients, showed that diarrhea in cholera is not the result of a failure of intestinal reabsorption but a state of extreme output in which reabsorptive mechanisms remain intact.[23] Not only *V. cholerae* but many strains of *Escherichia coli*, *Shigella, Salmonella*, and other pathogenic bacteria have been shown to produce toxins that bind to

enterocyte receptors, causing chloride-mediated secretion stimulated by second messengers, such as cyclic adenosine monophosphate, cyclic guanosine monophosphate, and calcium.[24,25] Even those infectious agents typically classified as causing osmotic diarrhea may, in some cases, also increase enterocyte secretion. *Rotavirus*, for instance, damages the villous brush border, causing osmotic diarrhea, but also produces an enterotoxin that causes a Ca^{++}-mediated secretory diarrhea.[26,27]

Basic scientific studies of intestinal solute transport mechanisms were also crucial in outlining the processes by which solute absorption is maintained. Water passively follows the osmotic gradient generated by the transcellular transport of electrolytes and nutrients. Although three principal mechanisms of sodium absorption have been described,[22] that essential to the efficacy of oral rehydration solutions (ORSs) was shown to result from the stoichiometric cotransport of sodium and glucose molecules at the intestinal brush border.[28] Figure 43-1 provides a schematic of the cotransport process. Cotransport across the luminal membrane is facilitated by the protein SGLT1. Once in the enterocyte, the transport of glucose into the blood is facilitated by GLUT 2 in the basolateral membrane. The Na^+-K^+ adenosine triphosphatase provides the gradient that drives the process. Clinical studies have demonstrated that this mechanism remains intact even in patients with severe diarrhea.[23]

In 1975, the WHO and the United Nations Children's Fund (UNICEF) agreed to promote a single solution (WHO-ORS) containing (in mmol/L) sodium 90, potassium 20, chloride 80, base 30, and glucose 111 (2%). This composition was selected to allow a single solution to be used among diverse populations in different countries. Although this solution performed well over 25 years, subsequent clinical research, documented in numerous controlled trials and summarized in a recent meta-analysis,[29] has favored the adoption of a lower-osmolarity standard solution. Based on these findings, UNICEF and WHO organized an expert consultation on oral rehydration that recommended a reduced-osmolarity solution.[30] In May 2002, WHO announced a new ORS formulation consistent with these recommendations, with sodium concentration 75 mEq/L, glucose 75 mmol/L, and total osmolarity 245 mosm/L.[31] See Table 43-1 for a comparison of the two solutions.

HOME MANAGEMENT OF ACUTE DIARRHEA

The simplicity of treatment based on ORSs makes possible the management of uncomplicated cases of diarrhea at home. As long as caretakers are properly instructed with regard to the need for clinical assessment when children appear significantly ill or appear to be failing treatment, then it is appropriate to begin therapy at home. Early intervention may reduce complications such as dehydration and poor nutrition. In developed, as in developing, settings, early administration of ORS may lead to fewer office or emergency room visits,[32] hospitalizations, or deaths.

In fact, it has always been the case that mothers and other caretakers begin treatment of diarrhea at home.[33] The advent of ORT allows a therapy that is more effective and less harmful than many traditional home therapies. All families should be encouraged to have a supply of ORS in the home at all times, much in the same way that acetaminophen and adhesive bandages are viewed as staples of the medicine chest. As soon as diarrhea begins, one of the commercially available products can be started at home. Although it is possible to produce a homemade solution with appropriate concentrations of glucose and sodium, possibilities for serious error abound, so that standard commercial oral rehydration preparations should be recommended where they are readily available and not prohibitively expensive. Regardless of the fluid used, an age-appropriate diet should be given as well.[9] The most crucial aspect underlying home management of diarrhea is the need to give increased volumes of fluid as well as to maintain adequate caloric intake. Infants should be offered more frequent feeds at the breast or bottle, and children should also be given more fluids.

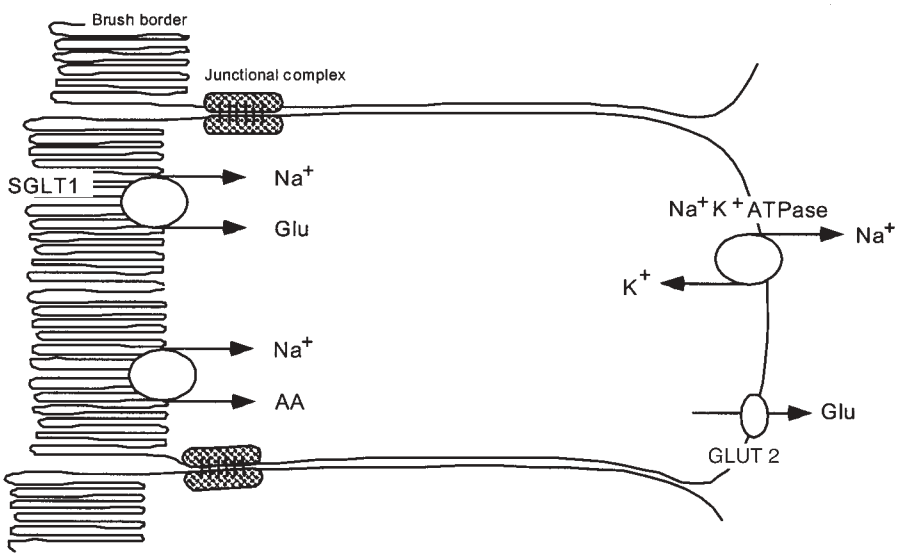

FIGURE 43-1 Solute-coupled sodium absorption. ATPase = adenosine triphosphatase.

TABLE 43-1 Comparison of 1975 and 2002 WHO-ORS

	Glucose (mmol/L)	*Na (mmol/L)*	*K (mmol/L)*	*Cl (mmol/L)*	*Citrate (mmol/L)*	*Osmolarity (mOsm/L)*
WHO-ORS (2002)	75	75	20	65	10	245
WHO-ORS (1975)	111	90	20	80	10	311

ORS = oral rehydration solution; WHO = World Health Organization.

Caretakers should be educated to recognize signs of illness or treatment failure that necessitate medical intervention. Infants with acute diarrhea are more prone to become dehydrated than are older children because they have a higher body surface-to-volume ratio, a higher metabolic rate, and relatively smaller fluid reserves and depend on others for fluid. For this reason, parents should seek medical care promptly for infants with diarrhea even before the first signs of dehydration are evident. Indications for prompt medical evaluation are summarized in Table 43-2. No guidelines have established a specific age under which evaluation is mandated, but, in general, infants should be evaluated by a health professional when there is risk of dehydration; in general, the smaller the child, the lower the threshold for hands-on evaluation. When fever is present, infants and children should be evaluated according to current guidelines. Naturally, underlying conditions, including history of prematurity, metabolic disorders, immune compromise, and recent recovery from surgical interventions, may prompt early evaluation, as may concurrent illness, even a concurrent respiratory infection. Children with dysentery (visible blood or mucus in stool) should be brought in for medical evaluation.

In developed settings, the decision as to whether to bring a child to an office or emergency room setting for evaluation is generally made after consultation with a physician or other health care provider over the telephone. Questions should focus on those factors putting a child at risk for dehydration. Whenever possible, quantification is helpful. The clinician should request a thermometer reading of temperature rather than an impression of fever and should determine how many hours or days the child has been ill, the number of episodes of diarrhea or vomiting, and the apparent volume of output. It should be noted that parents and other caretakers may fail, during a telephone call, to mention underlying conditions without prompting, so some questions regarding past medical history are essential.

Naturally, parents or other caretakers cannot be assumed to have skills of assessment comparable to a clinician, but their report of any of the easily recognized signs of dehydration may indicate the need for immediate evaluation. Reports of changing mental status are particularly concerning. When the child's condition is in doubt, there should be a low threshold for recommending office or acute care evaluation. The hands-on visit provides an opportunity for physical assessment, including vital signs, more detailed history, and better family instruction.

CLINICAL ASSESSMENT

Diarrhea may be characterized by the passage of three or more loose, watery stools per day. The volume of fluid lost through the stools can vary from 5 mL/kg/day (near normal) to 200 mL/kg or more.[34] Dehydration (loss of body water) and electrolyte losses follow untreated diarrhea and cause the primary morbidity of acute gastroenteritis. Loose stools may be among the presenting signs of nongastrointestinal illnesses, including meningitis, bacterial sepsis, pneumonia, otitis media, and urinary tract infection. Vomiting alone can be the first symptom of metabolic disorders, congestive heart failure, toxic ingestions, or trauma. To rule out other serious illnesses, a detailed history and physical examination should not be neglected in the diagnosis of acute gastroenteritis.

History taking should include questions about the onset, frequency, quantity, and character (including the presence of bile, blood, mucous) of vomiting and diarrhea. Recent oral intake, including food, fluids, and breastfeeding, as well as urine output, should be carefully noted and previous weight recorded, if known. Associated symptoms, including fever or changes in mental status, should be noted. Past medical history should include questions regarding underlying significant medical problems, history of other recent infections, and human immunodeficiency virus (HIV) status, if known. Relevant social history may include the number and nature of caretakers, which may affect instructions regarding follow-up care.

As part of the complete physical examination, an accurate body weight must be obtained, along with temperature, heart rate, respiratory rate, and blood pressure. When premorbid weight is not known but a previous growth curve is available, an estimate of fluid loss may be obtained by subtracting current weight from expected weight based on previous weight-for-age percentile.[35] The quality of this estimate will vary, depending on the number and variability of prior data points. The general condition of the patient

TABLE 43-2 Indications for Medical Evaluation

Young age, with low threshold for evaluating all children under 10 kg and lowest threshold for those under 6 mo
History of prematurity, underlying chronic medical conditions, or concurrent illness
Fever ≥ 38°C for infants under 3 mo, ≥ 39°C ages 3 to 36 mo
Visible blood in the stools
High output, including large-volume diarrhea and persistent vomiting
Caretaker's report of signs consistent with dehydration, including sunken eyes, decreased tears, dry mucous membranes
Changes in mental status including irritability, apathy, and lethargy
Poor apparent response to ORT already given or inability to administer ORT

ORT = oral rehydration therapy.

should be assessed, with special concern given to infants and children who appear listless, apathetic, or less reactive. The appearance of the eyes should be noted, including the degree to which they are sunken and the presence or absence of tears. The condition of the lips, mouth, and tongue will yield important clues as to the degree of dehydration, even if the patient has recently taken fluid. Deep respirations may be suggestive of metabolic acidosis. Faint or absent bowel sounds may suggest ileus. Extremities should not be neglected as general perfusion and capillary refill help the assessment of dehydration, as does examination of skin turgor. Visual examination of the stool can confirm abnormal consistency and determine the presence of blood or mucus.

The clinical signs and symptoms of dehydration are outlined in Table 43-3. Although it may be helpful in some instances, assessment of the anterior fontanel is absent from Table 43-3 because numerous studies have shown that it may be an unreliable or misleading sign. In infants and children, a fall in blood pressure is a late sign that heralds shock and may correspond to fluid deficits greater than 10%. Increases in heart rate and slowed peripheral perfusion may be more sensitive indicators of moderate dehydration, although both may be difficult to interpret as both may vary with the degree of fever. Decreased urine output is a sensitive but nonspecific sign.[35] Urine output may be difficult to measure in infants with diarrhea, although increased urine specific gravity may indicate dehydration when urinalysis is indicated.

Some guidelines, including 1992 Centers for Disease Control and Prevention (CDC)[36] and 1996 American Academy of Pediatrics (AAP) guidelines,[16] divide patients into subgroups for mild (3 to 5% fluid deficit), moderate (6 to 9% fluid deficit), or severe dehydration (> 10% shock or near shock). Other classification schemes, including 1995 WHO and 2001 European Society of Paediatric Gastroenterology, Hepatology and Nutrition (ESPGHAN) guidelines,[37] divide patients into those showing no signs of dehydration (< 5%), some signs of dehydration (5 to 10%), and severe dehydration (> 10%). Studies that have looked carefully at the correlation of clinical signs of dehydration with post-treatment weight gain suggest that the first signs of dehydration may not be evident until 3 to 4% dehydration, with more numerous clinical signs evident at 5% dehydration and those signs indicating severe dehydration not evident until fluid loss of 9 to 10%.[35,38] Because of this threshold effect, it may be difficult to distinguish between mild and moderate dehydration based on clinical signs alone. For this reason, Table 43-3 groups together patients with mild to moderate dehydration and notes that these signs may be seen over a relatively wide range of fluid loss, from 3 to 9%. The magnitude of ongoing losses and the patient's oral intake will determine the success of ORT as much as current status. The goal of assessment is not to determine the patient's hydration status once and for all but to provide a starting point for treatment and conservatively determine which patients may be safely sent home for therapy, which should remain for observation during therapy, and which should receive more intensive therapy immediately.

Supplementary laboratory studies in the assessment of the patient with acute diarrhea are usually unnecessary, including serum electrolytes.[34,39] Stool cultures are indicated in the case of dysentery but are generally not indicated in acute, watery diarrhea in the immunocompetent patient. Laboratory studies should not, however, be neglected where they may give important clues as to underlying or alternative causes of illness. For instance, urine cultures should not be neglected where there is reason to be concerned for urinary tract infection, and blood cultures and white blood cell count with differential are indicated where the clinical presentation suggests possible sepsis.

THERAPY OF ACUTE GASTROENTERITIS BASED ON DEGREE OF DEHYDRATION

Table 43-4 outlines the "Seven Pillars of Good Treatment of Acute Gastroenteritis," adapted from ESPGHAN guidelines,[37] and Table 43-5 provides a summary of specific

TABLE 43-3 Signs of Dehydration

	Minimal or No Dehydration	*Mild to Moderate Dehydration*	*Severe Dehydration*
Mental status	Well, alert	Normal, fatigued or restless, irritable	Apathetic, lethargic, unconscious, floppy
Thirst	Drinks normally, may refuse	Thirsty, eager to drink	Drinks poorly, unable to drink
Heart rate	Normal	Normal to increased	Tachycardia, with bradycardia in most severe cases
Quality of pulses	Normal	Normal to decreased	Weak, thready, or impalpable
Breathing	Normal	Normal, fast	Deep
Eyes	Normal	Slightly sunken	Deeply sunken
Tears	Present	Decreased	Absent
Mouth and tongue	Moist	Dry	Parched
Skin fold	Instant recoil	< 2 s	> 2 s
Capillary refill	Normal	Prolonged	Prolonged, minimal
Extremities	Warm	Cool	Cold, mottled, cyanotic
Urine output	Normal to decreased	Decreased	Minimal
Loss body weight	< 3%	3–9%	> 9%

Adapted from Duggan C et al[36] and World Health Organization.[34]

treatment recommendations synthesized from CDC, WHO, AAP, and ESPGHAN guidelines.[16,34,36,37] Although the first pillar, the use of ORS, should seem self-evident, one recent national survey of physicians in emergency care facilities in the United States showed that many would treat mild dehydration with intravenous therapy and half would always or almost always use intravenous therapy for a moderately (5 to 10%) dehydrated child under age 2.[21] Treatment should include two phases: rehydration and maintenance. In the rehydration phase, the fluid deficit is replaced quickly, over 3 to 4 hours, and clinical hydration is attained. In the maintenance phase, maintenance calories and fluids are given. Rapid realimentation should follow rapid rehydration, with a goal of rapid return to an age-appropriate unrestricted diet, including solids. Gut rest is not indicated. If anything, diet should be increased as soon as tolerated to make up for lost caloric intake during the acute illness. Lactose restriction is generally not necessary, nor are changes in formula usually indicated. Full-strength formula is generally tolerated and allows more rapid return to full caloric intake. Breast-feeding should be continued at all times, even during the initial rehydration phases. In both phases, fluid losses from vomiting and diarrhea are replaced in an ongoing manner. No unnecessary medications should be used, and laboratory studies should be limited to those necessary to guide management.

TABLE 43-4 Treatment of Acute Gastroenteritis

The "Seven Pillars of Good Treatment"	
I.	Use of ORS for rehydration
II.	Fast oral rehydration, over 3–4 h
III.	Rapid realimentation with age-appropriate unrestricted diet
IV.	Formula continuity: use of diluted formula is unjustified; special formula is usually not necessary
V.	Continuation of breast-feeding at all times
VI.	Additional ORS for ongoing losses
VII.	No unnecessary laboratory tests or medications

Adapted from Sandhu BK.[37]
ORS = oral rehydration solution.

MINIMAL DEHYDRATION

For those patients with minimal or no dehydration, treatment is aimed at replacing ongoing losses. Children with diarrhea must have increased fluid intake to make up for losses and to cover maintenance needs. In principle, 1 mL of fluid should be given for each gram output. In hospital settings, soiled diapers can be weighed (without urine) and the estimated dry weight of the diaper can be subtracted. When losses are not easily measured, a reasonable rule of thumb is that one may give 10 mL/kg additional fluid allotted for each watery stool or 2 mL/kg for each episode of emesis. Nutrition should not be restricted. Instructions regarding dietary therapy are given below.

MILD TO MODERATE DEHYDRATION

Children who are found on assessment to have mild to moderate dehydration should have their estimated fluid deficit rapidly replaced, with additional fluid given for ongoing losses. Current guidelines recommend giving 50 to 100 mL ORS per kilogram over 2 to 4 hours to replace estimated fluid deficit, with additional ORS given to replace ongoing losses. WHO guidelines recommend a maximum rate of 20 mL/kg/hour,[34] but the rate may be individualized. Using a teaspoon, syringe, or medicine dropper, small volumes of fluid (eg, one teaspoon) should be offered at first, with the amount gradually increased as tolerated. If a child appears to want more than the estimated amount of ORS solution, more can be offered. Although it is safe to give ORS very rapidly, vomiting may be increased with larger boluses. Frequent small-bolus feedings will generally be tolerated. Nasogastric (NG) feeding allows continuous administration of ORS at a slow, steady rate. Clinical experience supports the use of NG feedings even in vomiting patients. Rehydration via NG tube may be particularly useful in an emergency department setting where rapid correction of hydration may prevent unnecessary hospitalization. Although rapid intra-

TABLE 43-5 Summary of Treatment Plans

Degree of Dehydration	*Rehydration Therapy*	*Replacement of Losses*	*Nutrition*
Minimal or no dehydration	N/A	1 mL ORS for each g lost to vomiting or diarrhea or 10 mL/kg for each diarrheal stool, 2 mL/kg for each episode emesis	Continue breast-feeding; resume age-appropriate normal diet after initial hydration, including adequate caloric intake for maintenance*
Mild to moderate dehydration	ORS 50–100 mL/kg over 3 to 4 h	Same as above	Same as above
Severe dehydration	LR or NS in 20 mL/kg IV boluses until perfusion and mental status improve. Then give 100 mL/kg ORS over 4 h or 100 mL/kg D5 1/2 NS IV over 8 h	Same as above; if unable to drink, give via nasogastric tube or give IV D5 1/4 NS with 20 mmol/L KCl/L	Begin oral or enteral feedings after initial hydration as soon as acidosis corrected

Adapted from current guidelines (see text).[16,34,36,37]
*Overly restricted diets should be avoided during acute diarrhea. Breast-fed infants should continue to nurse ad libitum even during acute rehydration. Infants too weak to eat may be given breast milk or formula via nasogastric tube. Full-lactose formulas are generally well tolerated. If lactose malabsorption appears clinically significant, lactose-free formulas may be used. Complex carbohydrates, fresh fruits, lean meats, yogurt, and vegetables are all recommended.
IV = intravenous; LR = lactated Ringer's; N/A = not available; NS = normal saline; ORS = oral rehydration solution.

venous hydration may also prevent unnecessary hospital admissions, one recent study showed that rapid NG rehydration was well tolerated, more cost-effective, and associated with fewer complications.[39]

OUTPATIENT OBSERVATION

Because a certain percentage of children with mild to moderate dehydration will fail to improve with ORT, it is prudent to observe dehydrated children until signs of dehydration subside. Similarly, children who do not show clinical signs of dehydration but who demonstrate unusually high output may be held for observation. Hydration status should be reassessed on a regular basis, with more frequent monitoring given to those patients whose status is more tenuous. This may be carried out in an emergency room, office, or other outpatient setting. Once dehydration is corrected, if ORT appears to be going well and if the child's caretakers demonstrate comprehension of home rehydration techniques, understand indications for returning for further evaluation, and have the means to do so, then further management may be carried out at home. Even among those whose illness appears uncomplicated on initial assessment, a small percentage may fail ORT, so that some plan for reassessment must be in place. Caretakers should be encouraged to return to medical attention should they have any concerns, if they are not sure that rehydration is proceeding well, or, naturally, should new or worsening symptoms develop.

MANAGEMENT IN THE HOSPITAL

Indications for management of the child in the hospital include (1) inability of caretakers to manage ORT at home; (2) significant difficulties administering ORT, including vomiting, ORS refusal, or inadequate intake; (3) concern for possible comorbidity, complicating course; (4) failure of treatment, including worsening diarrhea or dehydration in spite of ORT; (5) severe (> 9%) dehydration; (6) social or logistical issues that may prevent return evaluation if necessary; (7) or any factors, for example, very young age, unusual irritability or drowsiness, progressive course of symptoms, or uncertainty of diagnosis, that may indicate close observation.

SEVERE DEHYDRATION

Severe dehydration constitutes a medical emergency. Intravenous rehydration should begin immediately. Twenty milliliters per kilogram boluses of lactated Ringer's (LR) solution, normal saline, or a similar solution should be given until pulse, perfusion, and mental status return to normal. This may require two intravenous lines or even alternative access sites (eg, intraosseous infusion, venous cutdown). The patient should be closely observed during this period and vital signs monitored on a regular basis. Where available, serum electrolytes, bicarbonate, blood urea nitrogen, creatinine, and serum glucose should be obtained, although it is safe to commence rehydration therapy without these results as normal saline or LR infusion is the appropriate first step in either hyponatremic or hypernatremic dehydration. Hypotonic solutions should not be used for acute parenteral rehydration.[40]

The severely dehydrated patient may require several boluses, which may be carried out in short succession. Practically speaking, overly rapid rehydration is unlikely to occur as long as weight-based boluses are given with close observation. Errors occur most commonly in settings in which adult dosing is given to infants (eg, "500 cc normal saline intravenous bolus × ii" would provide 200 mL/kg for the average 2 to 3 month old). Edema of the eyelids and extremities may indicate overhydration. Diuretics should not be given. Once the edema has subsided, the patient may be reassessed for continued therapy. With very frail or malnourished infants, it may be prudent to proceed with 10 mL/kg boluses because of their poorer ability to increase cardiac output and because it may be especially difficult to distinguish dehydration from sepsis in these patients. The smaller boluses will also facilitate closer evaluation. Please see Chapter 53, "Protein-Energy Malnutrition." In general, frequent reassessment of hydration status should be performed to follow the adequacy of replacement therapy. Failure to respond to fluid bolus should raise the suspicion of alternative or concurrent diagnoses, including, as mentioned, septic shock, as well as metabolic, cardiac, or neurologic disorders.

As soon as the patient's level of consciousness returns to normal, therapy can often be changed to the oral route, with the patient taking by mouth the remaining estimated deficit. An NG tube may be helpful for patients too weak to drink adequately but with normal mental status. Although no studies have specifically documented increased aspiration risk with NG tube use in obtunded patients, intravenous therapy is ordinarily favored in these patients. If further intravenous therapy is necessary after initial resuscitation, ESPGHAN guidelines call for the use of 5% dextrose, 0.45% saline over 8 hours to replace calculated deficit, followed by 5% dextrose, 0.18% saline solution (with 20 mmol/L potassium once urine output is documented) for ongoing losses and maintenance.[37] Although it is reasonable to leave intravenous access in place in these patients should it be needed, early reintroduction of ORS is safer. The use of intravenous catheters is associated with frequent minor complications, including extravasation of intravenous fluid, and rare significant complications, including the inadvertent administration of inappropriate fluid, such as those containing excessive potassium. In addition, early ORS will likely encourage earlier resumption of feeding, and some recent data suggest that resolution of acidosis may be more rapid with ORS compared with intravenous fluid.[39]

DIETARY THERAPY

Recommendations for maintenance dietary therapy depend on the age and diet history of the patient. Breastfed infants should continue nursing on demand. Those on formula should continue their usual formula immediately

on rehydration in amounts sufficient to satisfy energy and nutrient requirements. Lactose-free or lactose-reduced formulas are usually not necessary. A meta-analysis of clinical trials shows no advantage of lactose-free formulas over lactose-containing formulas for most infants, although some infants with malnutrition or severe dehydration recover more quickly when given lactose-free formula.[41] Patients with true lactose intolerance will have exacerbation of diarrhea when a lactose-containing formula is introduced. The presence of low pH (< 6.0) or reducing substances (> 0.5%) in the stool in the absence of clinical symptoms is not diagnostic of lactose intolerance. Although medical practice has often favored beginning feeds with diluted (eg, half- or quarter-strength) formula, there is insufficient evidence to justify this practice; in general, full caloric intake should be restored as soon as possible.

Soy formulas containing soy fiber have been widely marketed to physicians, as well as directly to consumers, in the United States as Isomil DF. Brown and colleagues showed that added soy fiber reduced liquid stools without changing overall stool output.[42] This "cosmetic" effect might have some benefits with regard to diminishing diaper rash and encouraging early resumption of normal diet but is probably not sufficient to merit its use as a standard of care. A more recent trial by Burks and colleagues showed a reduction in the duration of antibiotic-associated diarrhea in older infants and toddlers fed soy formula with added soy fiber.[43]

Children receiving semisolid or solid foods should continue to receive their usual diet during diarrhea. Foods high in simple sugars should be avoided as the osmotic load may worsen diarrhea. For this reason, large amounts of juice, gelatin desserts, and other highly sugared liquids should be avoided. Some guidelines have recommended avoiding fatty foods, but it is difficult to maintain adequate calories without some fat, and fat may, in fact, reduce intestinal motility. The practice of withholding food for 24 hours is inappropriate. Early feeding may decrease changes in intestinal permeability brought about by infection,[44] reduces illness duration, and improves nutritional outcomes.[8,9] Highly specific diets, such as the BRAT (bananas, rice, applesauce, and toast) diet, have been commonly recommended. Although, interestingly, one recent study has shown some benefit from green bananas and pectin in persistent diarrhea,[45] the BRAT diet is unnecessarily restrictive and, like juice-centered diets, may provide suboptimal nutrition for the patient's nourishment and recovering gut.

Many children have multiple episodes of diarrhea in a single season, so that diarrhea may contribute to poor nutrition, which may, in turn, worsen the course of subsequent episodes.[46] For this reason, ESPGHAN guidelines call for increased nutrition in the 2 weeks following an episode of diarrhea.[37] WHO guidelines recommend caloric supplements following episodes of diarrhea, such as added cereal in milk, oil in cereal, and foods with high nutrient density.[34] In general, current guidelines call for age-appropriate unrestricted diets, including complex carbohydrates, meats, yogurt, fruits, and vegetables. Children should maintain caloric intake during acute episodes as best possible and should subsequently receive additional nutrition to make up for any shortfalls arising during the illness.

LIMITATIONS OF ORT

Although ORT is recommended for all age groups and for diarrhea of any etiology, some restrictions to its use do exist. In children presenting in shock, the administration of oral solutions may be contraindicated as airway protective reflexes may be impaired. Likewise, patients with abdominal ileus should not be given oral fluids until bowel sounds are audible. It should be remembered that intestinal intussusception may present with diarrhea, including bloody diarrhea. Radiographic and surgical evaluations are warranted when the diagnosis is in question.

Stool output in excess of 10 mL/kg/hour has been associated with a lower rate of success of oral rehydration[47]; however, no patient should be denied ORT simply because of a high purging rate because most patients will respond well if given adequate replacement fluid.

A small proportion of infants with acute diarrhea experience carbohydrate malabsorption, with a dramatic increase in stool output following the administration of ORS. The presence of stool-reducing substances alone is not sufficient to make the diagnosis because this is a common finding in patients with diarrhea and does not in itself predict failure of oral therapy. Patients with true glucose malabsorption will also show an immediate reduction in stool output when ORS is replaced with intravenous therapy. The incidence of clinically significant glucose malabsorption during acute diarrhea is probably less than 1%, although rates as high as 8% have been reported in selected populations.[48]

Many patients with acute diarrhea have concomitant vomiting. Most, however, can be successfully rehydrated with oral fluids if small volumes of ORS (5 mL) are given every 5 minutes, with a gradual increase in the amount consumed. Administration via a spoon or syringe with close supervision helps guarantee a gradual progression in the amount taken. Often, correction of acidosis and dehydration lessens the frequency of vomiting. Continuous slow NG infusion of ORS via a feeding tube may be helpful. Even if some emesis occurs after NG administration of fluid, treatment may not be adversely affected.[39] The physician may characteristically meet some resistance in implementing NG rehydration in the vomiting child. Education of the hospital staff may be helpful as the NG tube may not only help the initial rehydration but may also speed tolerance of refeeding, leading to improved patient disposition and quicker discharge.

HYPERNATREMIC DEHYDRATION

Patients with hypernatremic dehydration respond well to ORT. Those with severe dehydration should first receive intravenous hydration, as outlined above. Subsequent hydration may be achieved with ORS.[49] As with normonatremic dehydration, ORS should be given both to replace the calculated deficit and for ongoing losses. ORS is safer

than intravenous therapy because it is less likely to lead to a precipitous decline in serum sodium, which may increase intracranial pressure.[37] ESPGHAN guidelines recommend (slow) intravenous rehydration only should ORT fail, replacing the calculated deficit with 5% dextrose/0.45% saline over 8 hours, followed by repeat plasma sodium. If the patient is still hypernatremic, this may be repeated, followed by maintenance with 5% dextrose/0.18% saline.

PHARMACOLOGIC THERAPY

Antibiotics

Because viral agents are the predominant cause of acute diarrhea, the routine use of antimicrobial agents for the treatment of diarrhea wastes resources and may lead to increased microbial resistance. Especially in the hospital setting, bacterial causes of diarrhea are unusual. A survey of several years of stool cultures submitted to the microbiology laboratory at Children's Hospital in Boston, Massachusetts, revealed such infrequent occurrence of bacterial infections that the practice of sending stool cultures in patients who develop diarrhea while hospitalized has been abandoned. Hospitalized patients and patients with a history of recent antibiotic use are, however, at risk for infections with *Clostridium difficile*. Infections with *C. difficile* documented by toxin assay should be treated with metronidazole 30 mg/kg divided three times daily given orally. Oral vancomycin is also effective but should be reserved as a second-line agent, given its expense and concerns over the possible emergence of vancomycin-resistant *Enterococcus*.

Even when a bacterial cause is suspected, antibiotic therapy is generally not indicated in most children because most cases of acute diarrhea are self-limited and not shortened by antibiotics. In addition, antibiotics may cause harm. There is evidence that antibiotic use may increase the risk of hemolytic uremic syndrome from *E. coli* infections.[50] There remains some concern that treatment of *Salmonella enteritis* may increase the risk of the carrier state, although patients under 3 months old or with bacteremia should be treated.[51] Exceptions to these rules involve the special needs of individual patients, for instance, immune-compromised hosts, or patients with underlying disorders, such as those with sickle cell disease, who should be treated for *Yersinia enterocolitica*.[52]

Nonantibiotic Drug Therapies

The use of nonspecific antidiarrheal agents such as adsorbents (eg, kaolin-pectin), antimotility agents (eg, loperamide), antisecretory drugs, or toxin binders (eg, cholestyramine) is a common practice. Few data are available to support their efficacy. The side effects of these drugs are well known, in particular among the antimotility agents, including opiate-induced ileus, drowsiness, and nausea owing to atropine effects and binding of nutrients and other drugs. One report from Pakistan detailed 18 cases of severe abdominal distention in association with use of loperamide, including at least 6 deaths.[53] Bismuth subsalicylate has shown some efficacy in traveler's diarrhea and other causes of acute gastroenteritis in children,[54] and although the side effects are less than antimotility agents, some theoretic concerns over the potential toxicity of salicylate remain. In any event, reliance on antidiarrheal agents shifts the therapeutic focus away from appropriate fluid, electrolyte, and nutritional therapy and adds unnecessarily to the economic cost of the illness.

It should be noted that none of the drugs mentioned above specifically address the underlying causes of diarrhea, specifically increased secretion by intestinal crypt cells. Racecadotril, an enkephalinase inhibitor, preserves the antisecretory activity of enkephalins, first discovered in 1975. It does not slow intestinal transit or promote bacterial overgrowth.[55] Its use has shown promise in two controlled clinical trials in children, significantly reducing acute watery diarrhea compared to placebo.[56,57] As long as it use does not distract from ORT and education regarding home management of diarrhea and cost is reasonable, racecadotril may prove to be a useful adjunct to the treatment of watery diarrhea.

Similarly, the use of antiemetics may be warranted in some cases. Although the use of phenothiazines may interfere with oral rehydration by causing sleepiness, two recent randomized, double-blind, placebo-controlled pediatric trials have shown ondansetron, either by oral[58] or intravenous[59] route, to be effective in decreasing vomiting and limiting hospital admission. The cost is not trivial, and nausea is frequently self-limited, but where admission or even the need for outpatient intravenous therapy is avoided, this intervention may be cost-effective.

FUNCTIONAL FOODS

Functional foods may be defined as those that have an effect on physiologic processes separate from their established nutritional function.[60] Probiotics, live microorganisms found in fermented foods, intended to promote intestinal health, are the classic functional food. The modern interest in probiotics may date from Metchnikoff's hypothesis that fermented milk products were responsible for the longevity of Bulgarian peasants.[61] Although a number of recent reviews[62] and journal supplements[63] have more broadly evaluated their use, numerous recent studies have looked specifically at their use in reducing the severity or duration of diarrheal illnesses in children, especially those caused by *Rotavirus*[64] or associated with antibiotic use.[65] Generally, these have included various species of lactobacilli or bifidobacteria, or the nonpathogenic yeast *Saccharomyces boulardii*. The mechanism of action may include competition with pathogenic bacteria, either for receptor sites or intraluminal nutrients, production of antibiotic substances, and enhancement of host immune defenses.[66,67] One recently published meta-analysis concludes that *Lactobacillus* spp are both safe and effective as treatment for children with infectious diarrhea.[68] One recent comprehensive review concluded that there is evidence for the efficacy of a wide variety of probiotics in acute gastroenteritis, especially *Rotavirus*.[69] A recommendation also emerges from a recent meta-analysis of probi-

otic use in antibiotic-associated diarrhea.[70] Because these products are generally not regulated, there is potential for great variability among products, so that it may be difficult for the prescribing physician to make an informed recommendation. But the relatively low cost and safety of probiotics may make recommendation of specific products worthwhile, especially where doing so may improve compliance with ORT.

Prebiotics differ from probiotics in that they are nutrients, rather than organisms, used to preferentially stimulate the growth of health-promoting intestinal flora.[71] Presumably, their use could be synergistic with probiotics. The oligosaccharides found in breast milk have been called the prototypic prebiotic in that they foster the growth of lactobacilli and bifidobacteria in the colon of breast-fed neonates.[72] The prebiotic effects of inulin and fructose oligosaccharides have been studied primarily in vitro and in animal model studies.[73] Specific recommendations should await well-controlled human trials, but in the meantime, it should be noted that dietary fiber may serve as a prebiotic as well as a modifier of intestinal motility agent. Current guidelines recommend fiber-containing fruits and vegetables as part of the diet of children recovering from acute gastroenteritis.

SUPPLEMENTAL ZINC ADMINISTRATION

Many reports have linked diarrhea and abnormal zinc status,[74] including increased stool zinc loss,[75] negative zinc balance,[76] and reduced tissue levels of zinc.[77] It has long been observed that diarrhea may occur with severe zinc deficiency, as in acrodermatitis enteropathica, but the broader clinical question is whether more incremental deficiencies of zinc may play a role in childhood diarrhea and whether supplementation may be of benefit, either for improved outcomes in acute or chronic diarrhea or as prophylaxis against diarrheal disease.

A large number of studies have addressed these questions. One early study showed reduced duration of acute diarrhea in patients with low rectal zinc levels.[77] In Bangladesh, zinc supplements also improved markers of intestinal permeability in children with diarrhea.[78] In India, zinc supplementation was associated with a decrease in both the mean number of watery stools per day and the number of days with watery diarrhea.[79] More recently, prophylactic zinc supplementation in India was associated with substantially reduced incidence of severe and prolonged diarrhea, two of the most important determinants of malnutrition and diarrhea-related mortality.[80] In Nepal, this effect was shown to be independent of concomitant vitamin A administration, with very few side effects noted in a substantial number of patients, apart from a slight increase in emesis.[81] In Peru, zinc administration was also associated with a reduction in duration of persistent diarrhea.[82] In two different pooled analyses of randomized, controlled trials in developing countries, the Zinc Investigators' Collaborative Group reviewed evidence that zinc supplementation is beneficial for treatment of acute and persistent diarrhea[83] and as a prophylactic supplement for decreasing incidence of diarrheal disease and pneumonia. Among infants and young children who received supplemental zinc for 5 or 7 days per week for 12 to 54 weeks, the pooled odds ratio for diarrhea incidence was 0.82 (95% confidence interval [CI] 0.72 to 0.93) and that for pneumonia incidence was 0.59 (95% CI 0.41 to 0.83).[84] Further research is needed to identify the mechanism of action and to determine optimal schemes for delivery of zinc to the neediest populations. It remains to be seen whether zinc supplements are useful in more developed settings.

OTHER CLINICAL SCENARIOS

Acute Bloody Diarrhea (Dysentery)

Dysentery is defined as acute bloody diarrhea caused by invasive microbial infection. This does not include occult blood (detected by guaiac card only), streaks of blood on the surface of formed stool, or melena. The reader is referred to WHO guidelines, which discuss the evaluation and management of dysentery at length.[34,85,86] AAP, CDC, and ESPGHAN guidelines[16,36,37] do not specifically address dysentery. The treatment of dehydration in dysentery follows the same principles as the treatment of acute watery diarrhea. The child with bloody diarrhea is at higher risk for complications, including sepsis and other systemic disease, so that the threshold for admission to the hospital for close observation is lower. Stool cultures are indicated in the setting of acute bloody diarrhea and are helpful for guiding therapy. Food should not be withheld in dysentery any more than in other cases of diarrhea. Because patients with dysentery may have significant anorexia, they should be coaxed to eat.[86] More frequent, smaller meals may be better tolerated. Children convalescing from dysentery should be given extra food to help them regain nutrition lost during the acute illness.

Cholera

Cholera differs from other causes of acute diarrhea in that (1) it may occur in large epidemics involving adults and children; (2) it produces voluminous diarrhea, which may lead to shock and death by dehydration in a very short period; and (3) certain antibiotics may shorten the course.[34] Management of cholera may be carried out using the methods for assessment of dehydration and treatment plans outlined above and summarized in Tables 43-3, 43-4, and 43-5. The health worker must be prepared to deliver prodigious quantities of fluid, either by ORS or intravenously, to overcome ongoing losses. These losses should be quantified so that treatment may be updated and modified under continuous close observation. Unlike diarrhea from other causes, where cereal-based ORSs are equivalent to standard ORSs, there may be some advantages in using rice-based ORS in treating cholera.[87] Traditional wisdom held that sodium concentrations of ORS used in treating cholera should be higher than those for other causes of diarrhea (based on measured stool sodium losses), but a CHOICE study group trial showed no clinical difference between those treated with the lower-osmolarity solution compared with a stan-

dard solution, apart from some increased incidence of asymptomatic hyponatremia.[88]

Persistent Diarrhea

Persistent diarrhea may be defined as diarrhea of acute onset that lasts more than 14 days. The approach to the patient with persistent diarrhea should include assessing and treating diarrhea, as in the acute presentations. In the developing world, bacterial infections are risk factors for persistent diarrhea and therefore warrant aggressive therapy. Education regarding sanitation and hygiene may reduce rates of reinfection. Attention to nutrition is crucial, with restoration of nutritious diet, including adequate calories, a key element of therapy. WHO guidelines recommend at least two Recommended Dietary Allowances (RDAs) of folate, vitamin A, iron, zinc, magnesium, and copper,[34] although, as discussed above, zinc supplementation may be the most important of those mentioned and should be continued for prophylaxis against additional episodes after appropriate therapy is complete.[84]

In the developed world, persistent diarrhea is often the result of restricted diets, either low in fat, which modulates intestinal motility, low in fiber, which may promote balanced intestinal flora, and/or high in high-osmolarity carbohydrate drinks. Dietary modification should be attempted before undertaking an extensive diagnostic evaluation.

Diarrhea with Severe Malnutrition

Assessment of the malnourished child is difficult because many of the signs outlined in Table 43-1 may be unreliable. Skin turgor may appear poor owing to the absence of subcutaneous fat. Eyes may be sunken from loss of periorbital fat. Irritability or apathy from malnutrition may complicate the assessment of mental status. When possible, malnourished children with diarrhea should be referred to a hospital. A severely malnourished child with signs of dehydration without a history of increased stool output should be treated for septic shock.[34] Because of the increased risk of bacteremia in severely malnourished children, and, in fact, in a broad range of children with diarrhea in a less developed setting,[89] the use of empiric antibiotics is not unreasonable where blood cultures cannot be obtained, although the literature regarding choice of antibiotics, doses, and duration is sparse.

Because intravenous therapy may cause overhydration and heart failure in the severely malnourished child, except for treatment of shock, slow oral rehydration is the treatment of choice. An NG tube may be used for children who drink poorly. Rehydration should begin with 10 mL/kg over 2 hours. This rate may be adjusted based on the child's thirst or ongoing stool losses. Increasing edema may be evidence of overhydration.

Full-strength WHO-ORS contains too much sodium and inadequate potassium for the severely malnourished child. WHO guidelines recommend modified solutions, as outlined in Table 43-6. Feeding should begin as soon as possible once hydration has been achieved and should continue every 2 to 3 hours day and night. Malnourished children often exhibit anorexia and require coaxing to eat.

CHOICE OF ORS

Table 43-7 outlines the composition of several commonly available ORSs, as well as other beverages frequently used for inappropriate rehydration. In July 2002, WHO and UNICEF recommended a significant change in ORS composition, including a reduction in sodium and glucose to maintain a 1:1 molar ratio but to decrease total osmolarity to 245 mOsm/L. The change was prompted by clinical trials showing that this solution resulted in less use of supplemental intravenous fluid therapy as well as lower stool output and less vomiting compared with the previous WHO standard ORS.[29,90] Although the differences in measured stool output resulting from different ORS formulations may be modest, reduction in intravenous fluid use is a substantial economic and health benefit of the new solution. The composition of the new solution is also more in line with solutions more commonly used in industrialized countries. Studies are still needed to confirm the safety of this new solution in areas of the world where cholera is an important cause of diarrhea.

NEW SOLUTIONS

Numerous improved ORSs have been attempted. These have generally included additional substrates for sodium cotransport (such as the amino acids glycine, alanine, and, glutamine)[91,92] or, as reviewed by Fontaine and col-

TABLE 43-6 ORS for the Severely Malnourished Child

Simple ORS for the Severely Malnourished Child	*More Effective ORS for the Severely Malnourished Child*
Dilute 1 L WHO-ORS to make 2 L	Dilute 1 L WHO-ORS to make 2 L
Add 45 mL KCl solution from stock solution containing 100 g KCl/L	Add the following salts:
Add and dissolve 50 g sucrose	3.6 g KCl
	1.3 g K citrate
Children given this solution should also receive	1.2 g MgCl
	130 mg Zn acetate
2 mL 50% MgSO4 solution (4 mEq Mg/mL) IM once and zinc chloride solution (10 g/L) 1 mL/kg/d until diarrhea stops	22 mg CuSO4
	0.44 mg NaSeO4
	0.20 mg KI
	Add and dissolve 50 g sucrose

leagues,[87] substituting complex carbohydrates for the glucose (rice- and other cereal-based ORSs) to reduce osmolarity while preserving glucose-sodium cotransport. Given trials to date, the amino acid preparations do not appear to be more effective than traditional ORSs and are more costly. Rice-based ORS may be recommended where training is adequate and home preparation is preferable and appears to be particularly effective in treating diarrhea from cholera.[87,93] Nevertheless, given the simplicity and safety of ORS packets in developing countries and commercially available ORSs in developed countries, these remain the first choice for most clinicians.

Other potential additives to ORS include substances capable of liberating short-chain fatty acids. These include amylase-resistant starch derived from corn[94] and partially hydrolyzed guar gum.[95] The presumed mechanism of action is the enlistment of increased colonic sodium uptake coupled to short-chain fatty acid transport. Other possible future ORS composition changes include the addition of probiotics, prebiotics, and zinc.

BARRIERS TO ORT

Barriers to the use of ORS and continued nutrition during diarrheal disease include, among patients, cultural practices[33] and lack of information[96] and, among physicians, preference for intravenous hydration, even where evidence suggests improved results from oral rehydration.[19,21,97] At the other extreme from the development of the ultimate ORS, it remains distressingly common for patients, even at times under physician supervision, to attempt rehydration with solutions bearing no resemblance to physiologically based ORS. Table 43-7 includes a number of fluids commonly used in treating diarrhea, which do not contain physiologically sound concentrations of carbohydrates and electrolytes. An informal survey of numerous hospital Web sites reveals outdated recommendations for the treatment of diarrhea that include nonstandard fluids. A recent case report of one child whose care was compromised by following advice obtained from a prominent hospital's Internet site highlights the continued gap between knowledge and practice and the ongoing need to disseminate accurate information regarding oral rehydration.[98]

CONCLUSION

The treatment of acute diarrhea has for many years been shown to rely on the simple but overwhelmingly effective therapy of oral rehydration. More recently, the important coprinciple in case management of early refeeding of children immediately on rehydration has also gained wider acceptance. The combination of oral rehydration and early nutritional support promises to safely and effectively guide a patient through a bout of diarrhea. If the principles of therapy outlined above are accepted by all levels of the medical community, and if education of parents includes beginning ORT at home, numerous deaths and unnecessary hospitalizations can be avoided. Meanwhile, we await further technological breakthroughs (eg, improved vaccines, superior rehydration solutions) to better combat one of the most important public health problems today.

CHAPTER 44

CHRONIC DIARRHEA AND INTESTINAL TRANSPLANTATION

Olivier Goulet, MD, PhD

Chronic diarrhea with prolonged mucosal injury, by inducing an imbalance between the infant's energy requirements and the dietary protein and caloric supply, is a source of protein-energy malnutrition (PEM). In addition, in children suffering from sepsis, malnutrition may occur quite rapidly, setting up a vicious cycle, with worsening of the PEM. In underdeveloped countries, it is calculated that 40 to 60% of infant diarrheal deaths are attributable to persistent diarrhea in combination with malnutrition.[1,2] Treatment of digestive disease and nutritional rehabilitation have to be achieved together. Each time the gastrointestinal (GI) tract can be used for refeeding, it should be used. However, in some situations, in which the GI tract is insufficient to cover the protein and energy requirements, parenteral nutrition (PN) is required to correct PEM. This nutritional support is efficient but at risk of metabolic complications directly related to the homeostatic changes secondary to severe malnutrition and known as the "refeeding syndrome."[3] This chapter examines the main consequences of PEM and the means whereby appropriate nutrition may be provided according to its advantages and risks for malnourished pediatric patients suffering from severe protracted diarrhea treated in hospital. According to the course of both digestive disease and nutritional rehabilitation, long-term nutritional support may be required.

CHANGES INDUCED BY MALNUTRITION

Interrelated factors are involved in children suffering from severe malnutrition: abnormal body fluid, electrolytes, and mineral balance; energy and protein deficiency; abnormal GI function; and depression of the immune system. An understanding of these factors should help to prevent or limit the consequences of PEM, as well as refeeding syndrome–related complications.

Abnormalities of Body Fluids, Electrolytes, and Minerals

Severe PEM, whatever its cause and whichever edema is present, is associated with water and sodium overload. Total-body water, whether measured by isotope dilution or tissue analysis, is generally greater in malnourished subjects, particularly in the presence of edema. Increases of some 20 to 25% have been reported,[4] with total-body water levels reaching 89% of body weight in some cases, whereas water accounts for only 60 to 67% of body weight in normal children. Some of the excess water is found in the intracellular space, but most is found extracellularly.[5] Sodium and water accumulation is probably owing to dysfunction of the enzyme Na^+-K^+-adenosine triphosphatase (ATPase).[6] Extracellular water accumulates, for the most part, in the interstitial spaces as the result of hypoalbuminemia and a fall in plasma osmotic pressure; intravascular volumes may be reduced by nearly 50% because of decreased plasma and red cell volumes. The ensuing reduction in renal plasma flow, hyperaldosteronism, and increased levels of antidiuretic hormone prolong and aggravate fluid retention.[5] The hemodynamic consequences of this abnormal distribution of extracellular fluid are an elevation of pulmonary and systemic vascular resistance, a fall in ventricular pressure, and a prolongation of circulation time, which explains the hypotension and bradycardia with risk of hypovolemic shock. Providing too much sodium and water to malnourished children is unsafe, leading to a risk of heart failure.[7] Oral rehydration solution with a high sodium content must be used very carefully in severely malnourished children.[8] Such children also have a low total-body potassium content, as evidenced by whole-body counting of ^{40}K radioactivity.[5] Total-body potassium is reduced, in certain cases by as much as 50%, attaining levels of 25 to 30 mmol/kg (normal 45 to 50) mmol/kg).[4] The depletion is both intra- and extracellular and is related to a reduction in total-body protein as well as to a true potassium deficiency. Both factors should be taken into account during recovery, particularly the cellular inflow of potassium during glucose infusion and the incorporation of potassium during protein synthesis. Low potassium stores increase mortality, especially from cardiac arrest,[9] cause sodium retention, and contribute to the persistence of edema.[10]

Severe malnutrition is associated with multiple deficiencies, of which magnesium and zinc have a special link to diarrhea. Phosphorus is always decreased in children with PEM. A fall in its urinary excretion with hypercalciuria and hypophosphatemia signals phosphorus depletion, which may become apparent only when anabolic metabolism begins.[11] Magnesium is reduced by 20 to 30% in mus-

cle[5]; plasma magnesium levels, however, are variable. Magnesium deficiency is associated with low potassium retention because children fail to retain potassium as long as their magnesium deficiency remains uncorrected. This may be related to a dysfunction of the enzyme Na^+-K^+-ATPase, which may aggravate the potassium deficiency.[6] Simultaneous correction of both deficiencies is required in the management of severely malnourished children. Zinc deficiency is often associated, especially in children suffering from protracted diarrhea.[12] Zinc supplementation decreases the risk of persistent diarrhea and seems warranted during rehydration of severely malnourished infants.[8,13] Iron deficiency frequently occurs and is partly responsible for alterations in immune defense mechanisms. It also has an anti-infection role by inhibiting bacterial growth. Deficiencies of copper, chromium, and selenium are usual, especially when there are abundant GI losses. Because of their importance in protein synthesis, glucose use, hematopoiesis, and polyunsaturated fatty acid metabolism, it is essential that deficits be corrected. The levels of most vitamins are usually lower, as indicated by reduced plasma and leukocyte levels and by their urinary excretion. Because of the many metabolic processes that vitamins govern, it is important to correct deficiency not only of fat-soluble vitamins but also of ascorbic acid and most of the B vitamins, especially at the onset of anabolism. Requirements should be adjusted to protein intake and, particularly, to energy needs.

The kwashiorkor syndrome, one of the most important forms of PEM, is very rare in developed countries. It is characterized by gross edema, skin and hair changes, neurologic abnormalities, and fatty liver. The kwashiorkor syndrome classically has been equated with pure protein deficiency in the face of adequate intakes of energy and other nutrients. Although conceptually useful, this view is probably simplistic. More recent data suggest that oxidative stress contributes to the cell damage occurring in various organs of children with kwashiorkor.[14,15] Their antioxidant status is more severely impaired than in any other form of PEM, and levels of highly unsaturated polyunsaturated fatty acids in plasma phospholipids and erythrocyte phosphatidylcholine are significantly reduced.[16] Plasma concentrations of the lipid peroxidation products as well as the urinary excretion of leukotriene E_4 have been found to be enhanced.[17] This may contribute to the formation of edema via increased capillary permeability. Provision of early antioxidants seems to be the logical approach in the therapy of this rare syndrome.[18,19]

Energy and Protein Deficiency

Glycogen stores are reduced by 50%, whereas blood glucose levels are maintained by increased hepatic glucose-6-phosphatase activity and particularly by increased gluconeogenesis, which depends on cortisol and growth hormone secretion and uses glycerol, glucogenic amino acids, lactate, pyruvate, and alanine. Reduction of glucose oxidation also contributes to the adaptation.

In case of additional stress, the abnormalities in response to a carbohydrate load reflect the metabolic disturbance. This may be owing to a reduction in insulin synthesis and secretion, but, in many cases, blood levels of insulin are high, indicating "peripheral insulin resistance."[20] This resistance is the result of several factors, such as chromium and potassium depletion and increased secretions of growth hormone, cortisol, catecholamines, and free fatty acids.

A marked decrease in adipose tissue—indeed, its almost complete disappearance—is usually observed.[20] Plasma triglyceride, cholesterol, phospholipid, and linoleic acid concentrations fall; very-low-density lipoproteins (VLDLs) are undetectable; and low-density lipoprotein (LDL) levels are reduced. In contrast, most of these values increase under the stress of an acute infection.[21] On the other hand, an increase in liver triglycerides may account for 40% of the hepatic volume,[20] and several factors may be responsible for this overload, namely deficiencies of VLDL, more specifically a decrease in VLDL apoprotein synthesis, and a lack of lysine, carnitine, choline, and essential fatty acids (EFAs).[20] As a result, liver function and the clearance and synthesis of triglycerides are critically impaired. Moreover, peripheral triglyceride use is reduced, owing, in particular, to decreased lipoprotein lipase activity; the use of intravenous fat emulsions at the early phase of renutrition is thus inappropriate.

As already noted, impaired function of the enzyme Na^+-K^+-ATPase partly accounts for sodium and water retention, as well as potassium, phosphorus, and magnesium depletion, which may be corrected by administering glucose. Adaptation to energy deficiency is characterized by a relative reduction in oxygen consumption and energy expenditure; the changes in basal metabolic rate are difficult to interpret but may fall.[5] Rates of cellular division and protein synthesis also may account for this decreased energy expenditure. Growth hormone plasma levels are elevated, whereas insulin-like growth factor I is low.[22] If the energy intake does not supply these minimum requirements, then the endogenous stores—free fatty acids, amino acids, and ketone bodies—are used immediately. Any infections, surgical stress, or GI losses accelerate the process. With a lack of energy stores, thermoregulation is impaired, and hypothermia is a constant threat that can be fatal.

In pediatric patients suffering severe malnutrition, total-body protein decreases by 20 to 30% and muscle protein by 50%. The rates of albumin synthesis and breakdown fall by 50%, and total reserve is reduced by 50%, especially in the extravascular pool, because the albumin is shifted into the plasma.[5] Despite this adaptive process, hypoalbuminemia is one of the most reliable indices of malnutrition. Transferrin, ceruloplasmin, and retinol binding protein are lowered to varying degrees, as are fibrinogen and other coagulation proteins, such as factors II, VII, X, and V. Because of the short half-lives of these proteins, the rapid variations in their plasma levels serve as indicators of nutritional status.[23]

The plasma concentration of essential amino acids decreases by 50%, which explains the fall in the essential-to-nonessential amino acid ratio. The decrease in plasma concentration is greatest for the branched-chain amino acids; valine levels may be decreased eightfold.[5] High cor-

tisol and growth hormone levels and a fall in insulin have been cited as possible causes of this phenomenon, as well as an increase in their muscle catabolism. Adaptation to low nitrogen intake includes reuse of 90 to 95% of amino acids (normal 75%) and decreased urea production, with a fall in its excretion in the urine, so conserving nitrogen. Ammonia excretion, however, increases because of potassium depletion and the acidosis that is induced by protein and fatty acid catabolism.[5] Muscle protein reserves are used to maintain the plasma and liver amino acid pool and to ensure the production of alanine as a glycogenic liver substrate by transamination of branched-chain amino acids and the use of liver amino acids for protein synthesis rather than urea production. Liver protein synthesis is thus spared in comparison with that of muscle protein. In case of aggression such as trauma, burns, or, especially, severe sepsis, muscle catabolism is particularly increased, worsening the negative nitrogen balance.

Gastrointestinal Dysfunction

Dysfunction of the GI tract during childhood PEM, especially from severe protracted diarrhea, includes varying degrees of morphologic and functional intestinal disturbances, together with abnormal bacterial proliferation. These aggravate the malnutrition and explain the difficulties of restarting GI feeding. Abnormal intestinal bacterial flora, in either qualitative or quantitative terms, suggest changes in the gastric and intestinal defense systems. The gastric bactericidal barrier is modified because of mucosal atrophy and a decrease in hydrogen ion secretion. In the intestine, apart from oral gastric contamination, other factors combine to explain the abnormal bacterial proliferation, for example, reduced intestinal motility, reduction in biliary and pancreatic secretions, excess of residual intraluminal unabsorbed nutrients, reduction in immunoglobulin (Ig)A secretion, and adherence to the mucosa of bacteria such as *Escherichia coli*. Changes in the mucosal barrier and intestinal permeability also allow endotoxin absorption and transfer of bacterial and alimentary antigens conducive to gram-negative sepsis and perhaps to an immunoallergic process.[24] Morphologic changes are variable and may be characterized by mucosal atrophy with the disappearance of the villous structure, a reduction in the mitotic index, and cellular infiltration of the lamina propria.[25] On the other hand, there may only be structural changes in the enterocytes, which are visible only with electron microscopy at the brush border and in the endoplasmic reticulum.[26] Most of the enzyme activities are invariably reduced.[25] Specific disturbances of vitamin B_{12} and conjugated bile acid absorption in the ileum and of sodium-potassium exchange and water absorption in the colon are also frequent.[27] Conditions for impaired digestion and increased malabsorption of nutrients, water, and electrolytes are therefore present.

Depression of the Immune System

A high incidence of severe infections is observed in malnourished infants owing to specific, nonspecific, and nutritional immunity depression.[28] More specifically, it may be a result of protein, energy, vitamin, and mineral deficiencies, acting separately or in association, directly or indirectly, on each of the immune response systems. Cellular immunity is impaired during malnutrition as shown by delayed hypersensitivity reactions to various antigens and impairment of the lymphoblastic transformation test.[28] Lymphocyte distribution is changed with a relative and absolute reduction in the number of T lymphocytes, mainly CD4+. The ratio CD4+-to-CD8+ seems to be a good marker of PEM. The number of B lymphocytes remains constant. The mechanism and the significance of these various abnormal responses are complex, probably multifactorial, and related to thymic atrophy, lymphoid depletion, and involution of the thymus-dependent peripheral areas accompanied by reduction of cell proliferation and protein synthesis. All of these features are reversible when the malnutrition is treated. They are attributable primarily to protein-energy deficiency but vitamin or trace element deficiencies including iron, folate, pyridoxine, and zinc.[28]

Plasma levels of the various classes of immunoglobulins are generally normal, which compares with the normal number of B lymphocytes but does not exclude the possibility of a defective humoral response; additional infection may lead to an increase in immunoglobin level. Isohemagglutinin titers are normal, but antibody responses to viral, bacterial, or parasitic infections may be abnormally low in malnourished children. The production of secretory IgA 11S in nasopharyngeal secretions, tears, and saliva may be normal but is usually reduced, and this may account for the entry of organisms responsible for infections of the respiratory and GI tracts.[28] There may be a correlation between this disorder and the reduced synthesis of IgA by the fewer IgA plasma cells in the submucosa and/or decreased synthesis of the secretory component secondary to villous atrophy.

NUTRITIONAL SUPPORT

Initial Management and Prevention of Refeeding Syndrome

If PN is required because of severe malnutrition and inability of the GI tract to cover the protein-energy requirements, it has to be provided very carefully. Indeed, refeeding syndrome may be observed in severely malnourished patients receiving concentrated calories via PN.[29] Refeeding syndrome was also described in patients receiving enteral nutrition.[30] This syndrome includes the metabolic and physiologic consequences of the depletion, repletion, compartmental shifts, and interrelationships of the following: phosphorus, potassium, magnesium, glucose metabolism, vitamin deficiency, and fluid resuscitation.[11,29–31] Indeed, the net effect of the hormonal and metabolic changes of starvation is to facilitate survival by a reduction in basal metabolic rate, conservation of protein, and prolongation of organ function, despite the preferential catabolism of skeletal muscle tissue. Infants and children who have suffered from malnutrition for weeks or months will also experience a significant loss of visceral cell mass. Refeeding the malnourished child disrupts the adaptive state of semistarvation.

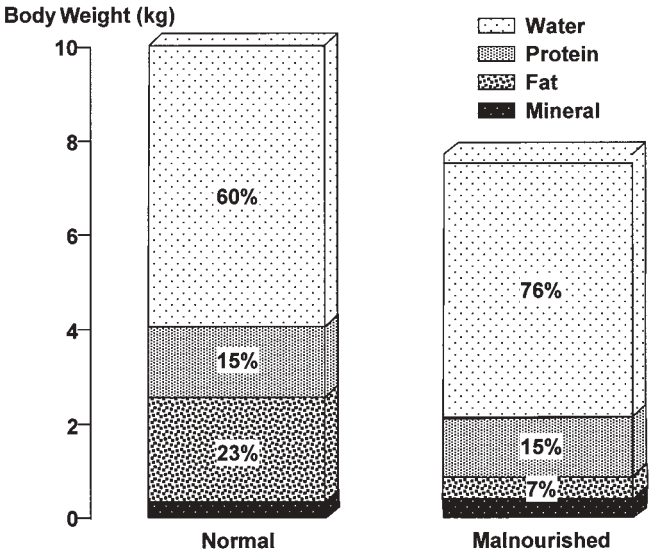

FIGURE 44-1 Changes in body composition during protein-energy malnutrition.

As refeeding is initiated, there is a rapid reversal in insulin, thyroid, and adrenergic endocrine systems. Basal metabolic rate increases, and glucose becomes the predominant cellular fuel. The body immediately begins the process of rebuilding lost tissue. Anabolism is accompanied by positive balance of intracellular minerals. As minerals shift to intracellular spaces, serum levels may plummet. Body fluid compartments redistribute as intracellular fluid increases; extracellular fluid may increase or decrease depending on the previous intake, the persistent digestive losses, and the refeeding regimen. These rapid changes in metabolic status can create life-threatening complications, so the nutritional regimen must be chosen wisely and monitored closely. Several potential metabolic complications of the refeeding syndrome are listed in Table 44-1.

To reduce the risk of refeeding complications, several conditions are required at the initial phase of renutrition of severely malnourished infants and children:

- *Prevention of water and sodium overload.* It is necessary to reduce the patient's water and sodium intake, depending on the hydration state, to prevent water and sodium overload resulting from their excessive retention, accentuated by increased secretions of vasopressin and aldosterone. Early weight gain may be the consequence of fluid retention. Monitoring of water and electrolyte intake must include uncontrolled losses as well as those from the Gl tract. One of the difficulties in such situations is the need to take into account a third sector, such as intraperitoneal or intestinal fluid retention. Monitoring of body weight changes, urine collection, assessment of blood, and urinary electrolytes are essential.
- *Oncotic pressure restoration.* The infusion of macromolecules aims to restore oncotic pressure and to minimize hemodynamic problems, worsened by a water-electrolyte imbalance. Albumin is the best infusate, but fresh frozen plasma or blood may be required in cases of anemia and/or coagulation disorders. Artificial ventilation may be required in those, generally few, cases with a poor cardiorespiratory status.
- *Carbohydrate intake.* Constant administration of carbohydrate is required to maintain blood glucose homeostasis as the reserves are very low; parenteral administration of glucose requires care because of the risk of hyperglycemia with osmotic diuresis and hyperosmolar coma.
- *Potassium repletion.* Correction of potassium depletion is of great importance but should be achieved progressively with monitoring of renal and cardiac functions. It can be dangerous to try to correct the deficiency too rapidly at a stage at which the capacity for fixing potassium remains low because of reduced protein mass; excessive intake leads to the cardiac risk of hyperkalemia.
- *Body temperature monitoring.* It must be monitored because PEM can lead to hypothermia, often associated with hypoglycemia and bradycardia. On the other hand, hyperthermia or excessive reheating increases water loss as well as energy expenditure. Maintenance of a stable body temperature between 36°C and 37°C by appropriate warming techniques is essential. Careful daily nursing to prevent cutaneous lesions and musculotendinous retractions is also very important.
- *Prevention of infection.* The infective, metabolic, and GI problems must be constantly borne in mind during treatment of pediatric patients with severe PEM. The

TABLE 44-1 Metabolic Disorders Associated with Refeeding Syndrome

Hypophosphatemia
Cardiac: altered myocardial function, arrhythmia, congestive heart failure, sudden death
Hematologic: altered red blood cell morphology, hemolytic anernia, white blood cell dysfunction, thrombocytopenia, depressed platelet function, bleeding
Hepatic: liver dysfunction
Neuromuscular: acute areflexic paralysis, confusion, coma, cranial nerve palsies, diffuse sensory loss, Guillain-Barré–like syndrome, lethargy, paresthesias, rhabdomyolysis, seizures, weakness
Respiratory: acute ventilatory failure
Hypokalemia
Cardiac: arrhythmias, cardiac arrest, increased digitalis sensitivity, orthostatic hypotension, electrocardiographic changes (T-wave flattening or inversion, U waves, ST-segment depression)
Gastrointestinal: constipation, ileus, exacerbation of hepatic encephalopathy
Metabolic: glucose intolerance, hyporeflexia, paralysis, paresthesias, respiratory depression, rhabdomyolysis, weakness
Renal: decreased urinary concentrating ability, polyuria and polydipsia, nephropathy with decreased glomerular filtration rate, myoglobinuria (secondary to rhabdomyolysis)
Hypomagnesemia
Cardiac: arrhythmias, tachycardia, torsade de pointes
Gastrointestinal: abdominal pain, anorexia, diarrhea, constipation
Neuromuscular: ataxia, confusion, fasciculations, hyporeflexia, irritability, muscle tremors, painful paresthesias, personality changes, positive Trousseau's sign, seizures, tetany, vertigo, weakness

risk of infection, an expression of both specific and nonspecific immunity depression, may jeopardize the prognosis and aggravate nutritional problems at any time. Clinical and paraclinical investigations must be performed repeatedly to look for widening foci of infection (respiratory, GI, skeletal, and urinary) and for their systemic spread. When a localized or systemic infection is identified, specific treatment is urgently required. The routine use of antibiotics in the absence of bacteriologic evidence in a malnourished child is inadvisable; antibiotics should be given only if sufficient indirect evidence points to the likelihood of infection. Active intestinal parasitosis should, of course, be vigorously treated. Evidence or suspicion of an infection is an essential factor in modifying water, electrolyte, and nutrient intake and also in the choice of the feeding technique.

- *Protein and energy intake.* It is difficult to suppress protein catabolism under these conditions of stress and low energy intake. Excessive nitrogen intake may lead to hyperammonemia and/or acidosis by exceeding the renal clearance capacity for H+ and phosphate ions. An intake of 0.5 to 1 g/kg of parenteral amino acids or oral peptide is sufficient to maintain the plasma amino acid pool. The protein-energy deficiency and other related disorders must be corrected during the days following the initial period of stress. This type of correction should be made carefully and gradually because the deficits are profound and of long standing. It is essential to provide both nitrogen and calories simultaneously and in the correct ratio. The increase in energy intake, if progressive, avoids acute episodes of sodium and water retention accompanied by oliguria and a fall in urinary sodium and potassium output. It is likely that these changes are carbohydrate dependent because their occurrence and equally rapid reversal develop with changes in glucose rate of infusion. This antinatriuretic effect of glucose appears to be similar to the antinatriuresis observed during feeding after a phase of experimental fasting. The insulin secreted induces sodium tubular reabsorption, and the alkalosis that develops might be attributable to increased tubular absorption of bicarbonate.
- *Micronutrients.* The provision of appropriate nutrient solutions requires an understanding of the nutritional relationships between nutrients, electrolytes, vitamins, and trace elements. It is during this initial phase that any deficit owing to incorrect intake will become apparent through either clinical or laboratory signs. These deficits can usually be prevented by giving them in the following proportions: 200 to 250 kcal, nitrogen 1 g, calcium 1.8 mmol, phosphorus 2.9 mmol, magnesium 1.0 mmol, potassium 10 mmol, sodium and chloride 7 mmol, and zinc 1.2 mg. Similarly, it is essential to adapt the intake of copper, manganese, chromium, iron, iodine, cobalt, and fluoride and the group B vitamins especially, as well as the intakes of EFAs, tocopherol, and selenium.
- *Adaptation of intake.* After the initial phase of renutrition, most complications can be prevented by careful supervision and the provision of appropriate intakes. It is essential that the infusion rate, body temperature, cardiac and respiratory function, urinary volume, twice-daily weight, and digestive output are continuously monitored. During the first 5 days, and also when the osmotic load is increased, urine should be checked for osmolality, pH, glucose, and protein. The plasma and urinary ion data, plus the calcium, phosphorus, magnesium, glucose, and hematocrits, should be obtained twice during the first week and then once weekly; plasma proteins, albumin, bilirubin, alkaline phosphatase, and transaminase values should be assessed routinely. These data, as well as knowledge of the patient's state and age, should make it possible to progressively regulate and control the intake and avoid problems of overload or depletion.

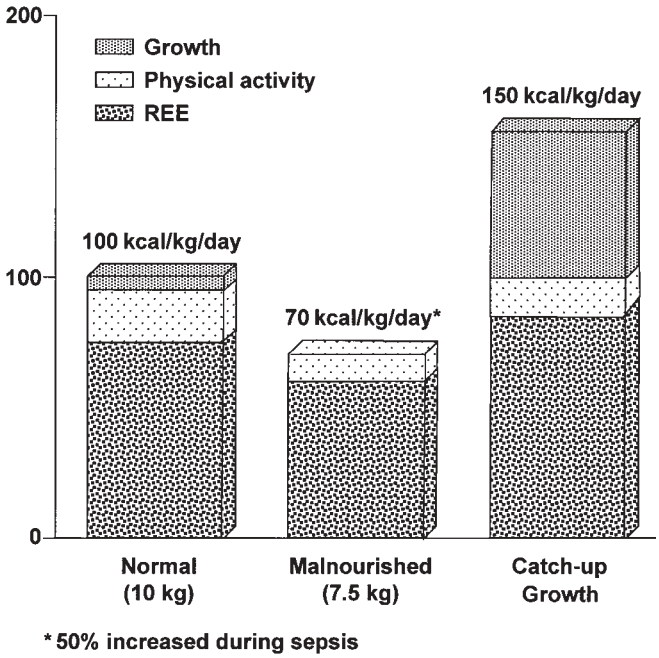

FIGURE 44-2 Changes in energy expenditure during severe protein-energy malnutrition and catch-up growth. REE = resting energy expenditure.

Route of Refeeding

Chronic diarrhea with malabsorption can be the result of a large number of causes (Table 44-2). It is obvious that dietetic and nutritional interventions are important in each of these conditions. However, in circumstances in which the disease is well identified, it is clear that the selection of the proper feeding management is also well defined (eg, celiac disease, saccharase-isomaltase deficiency, congenital chloridorrhea). As the full discussion of each condition is beyond the scope of this chapter, we instead limit our attention to severe protracted and intractable diarrhea of infancy (PDI and IDI).[32]

Enteral Feeding Enteral feeding (EF) makes it possible to use the functioning GI tract to nourish compromised pediatric patients. Digestive disease leading to an anatomic

TABLE 44-2 Main Causes of Chronic Diarrhea

Disorders of enterocyte digestive/absorptive functions
Sucrase-isomaltase deficiency
Glucose-galactose malabsorption
Congenital chloridorrhea
Congenital sodium-losing diarrhea

Lymphangiectasia

or functional reduction of the absorption capacity of the small bowel represents the main indication for EF, including short-bowel syndrome,[33] severe diarrhea with villous atrophy,[34–38] and inflammatory bowel disease.[39] The physiologic basis of continuous EF is of great interest in patients with GI disorders and PEM. However, some patients with severe PDI and those with IDI fail to respond to continuous EF and require PN. We studied 60 infants who required at least 1 month of total PN.

The main data of this survey are provided in Tables 44-3 and 44-4. Two-thirds of patients had severe PDI from various origins, including multiple food allergy or persistent postenteritis diarrhea. In this setting, PDI has an evident effect on nutrition, leading to the well-known vicious circle of diarrhea-malnutrition-diarrhea. The pathogenesis of this condition is complex and variable (Figure 44-3). This translates into a wide range of small intestinal, mucosal, morphologic, and biochemical changes. Intestinal mucosa may appear from normal to villous atrophic mucosa with continuous or patchy appearance, brush border, and/or intraluminal digestive enzyme deficiencies and variable degrees of increased permeability, to the presence of intraluminal bacterial overgrowth.

As such, it is clear that optimal nutritional management becomes fundamental. Feeding choices that would allow both the resolution of the PDI episode and nutritional repletion are not simple. The digestion of lactose is most frequently impaired, but the absorption of monosaccharides can also be impaired as a result of a reduced surface area. On the other hand, increased concentration of deconjugated bile acids is known to inhibit active glucose transport.[35]

The practical nutritional approach for infants and children with PDI in developed countries is to remove cow's milk proteins and lactose from the diet. A formula whose nitrogen component is based exclusively on a nutritional complete and a balanced solution of free amino acids may be used. Such formulas are, by definition, unable to trigger any allergic reaction. It may be indicated in children with persistent symptoms of formula protein intolerance after treatment with protein hydrolysates, as already reported.[36]

In wasted children with a poor appetite or with digestive intolerance and insufficient weight gain, continuous enteral (nasogastric tube) feeding (CEF) is required.[37]

Physiologic Changes during CEF Continuous gastric emptying related to continuous infusion rate can be achieved if the infusion rate, caloric load, and osmolarity of the mixture are not excessive. Below 3 kcal/minute, the gastric emptying rate increases with increasing caloric load up to the same level as the enteral feeding infusion rate. Excessive infusion rate, caloric load (> 1 kcal/mL), and/or osmolarity (> 350 mosm/L) of the nutritive solution increase the risk of nausea and vomiting.[40] The type of triglyceride, for example, long-chain (LCT) versus medium-chain triglyceride (MCT), may change gastric emptying.[41]

Motor migrating complex, as during fasting, is observed during CEF. The nature of triglycerides and/or the molecular weight of peptides and proteins modify the jejunal motility. Gallblader motility is maintained during enteral infusion, as assessed by ultrasonography. The type of infused lipids, MCT versus LCT, may influence gallblader motility.[42] However, biliary complications, such as sludge or cholelithiasis, are rare, even during long-term CEF.

The gastric secretion depends mostly on protein intake and, in the case of an elemental diet, on the composition of amino acids.[43] It is not demonstrated that the type of diet, elemental, semielemental, or polymeric, modifies gastric acid secretion. Cholecystokinin secretion and pancreatic secretion remain under CEF. There is a correlation between the secretion of chymotrypsin and lipase and the amount of nitrogen infused within the jejunum.[44] Secretory responses do not differ between elemental or polymeric nitrogen intakes.[45]

Experimental CEF in animals has shown that the absorption capacity of the distal small bowel and colon, despite a normal architecture of enterocytes' enzymatic and functional capacity, is decreased; in addition, DNA and quantity of protein are reduced.[46] This could be the consequence of the almost complete absorption of nutrients within the proximal part of the small bowel, leading to a lack of stimulation of the distal segment. On the other hand, it has been suggested that the beneficial effect of CEF, such as in the treatment of severe protracted diarrhea, might be mediated by the suppression of protein dietary antigens. However, recent studies in rats demonstrated that CEF does not modify growth and mucosal morphology but decreases the number of intraepithelial lymphocytes and epithelial expression of major histocompatibility complex

TABLE 44-3 Main Characteristics of Infants with Protracted (PDI) and Intractable (IDI) Diarrhea of Infancy (Personal Data)

(MHC) II antigens regardless of the molecular form of nitrogen supply.[47]

The thermogenic effect of alimentation is related to the increase of energy expenditure following ingestion of food. The increase of energy expenditure induced by CEF in normal subjects is lower than that for the same nutrient load as bolus.[48] Thus, the constant administration of energy substrates could reduce the energy storage and maintain homeostasis at a lower energy expenditure.[49]

Finally, CEF, by the slow and continuous administration of nutrients into the GI tract, allows it to achieve its optimal use, despite its pathology. By changing the conditions of flow and contact of the nutritive solution, CEF may increase the capacity of intraluminal digestion and intestinal absorption. This feeding technique seems logical and efficient when the absorptive surface is reduced, such as in some forms of severe PDI with villous atrophy.

Nutritive Solution Composition and Regulation of Intake

Techniques for delivering EF and related complications are presented in Chapter 10, "Protein-Energy Malnutrition: Pathophysiology, Clinical Consequences, and Treatment."

The nutritive solutions should have an osmolarity below 320 mosmol/kg and contain substrates, which are rapidly transferred across the intestine and leave no intraluminal residue. In the case of severe protracted diarrhea, all substrates requiring intraluminal hydrolysis (proteins, starches, LCTs) should be excluded, as should potentially highly antigenic substrates (cow's milk proteins, gluten, and soya). All solutions must be sterile because of the high risk of bacterial proliferation and translocation. Initial EF can require a diet in which each of the constituents is modified independently and thus introduced sequentially.

Nitrogen The absorption of amino acid is more rapid and efficient when given in the form of short peptides than free amino acids.[50,51] In addition, the quality, in terms of

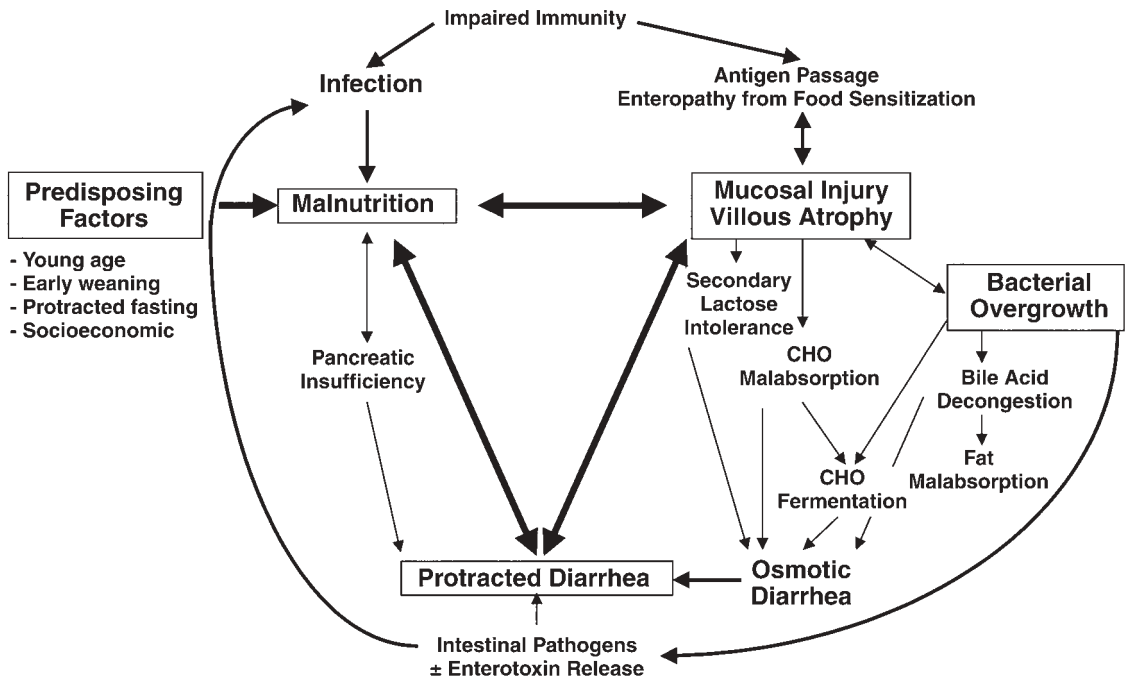

FIGURE 44-3 Pathogenic scheme in protracted diarrhea of infancy. CHO = carbohydrate.

digestion and intestinal absorption of protein hydrolysates, depends on the type of hydrolysate; for example, lactalbumin is better than casein.[52] Thus, the initial use of a solution of polypeptides with a lower osmolality than that of a mixture of amino acids is recommended. However, a free amino acid–based diet has been successfully used in cases of severe PDI.[36,53] More data are required for establishing recommendations for the use of such an amino acid–based diet. Nitrogen needs vary depending on tolerance and range from 350 to 500 mg/kg/day or even more in some highly catabolic situations. The nitrogen-to-calorie ratio must be considered, with protein intakes accounting for 10% of the energy intake.

Carbohydrates Disaccharidase enzymatic activity is depressed in severe malnutrition states and digestive disease. Lactase appears to be the most sensitive to injury and the last of the disaccharidases to recover. In addition, certain drugs, such as neomycin or colchicine, depress the intestinal disaccharidases. Thus, it is important to avoid dietary sources of lactose. Other disaccharides should be given in limited amounts at initial feeding as their corresponding brush border enzymatic activities are reduced. Nevertheless, if the carbohydrate intake during the initial days of EF is exclusively glucose, its high osmolality (5.5 mosmol/g) limits the rate at which it can be infused and thus the total amount given. The subsequent introduction of low-osmolality oligosaccharides may allow the intake to reach 20 or even 24 g/kg/day, especially in infants, without overpassing a solution osmolality of 350 mosm/L.

Lipids The behavior of MCTs within the intestinal lumen and its absorption characteristics are primarily owing to their greater water solubility. They are hydrolyzed faster than LCTs in the small intestine by pancreatic lipase; they are converted almost exclusively into free fatty acids and glycerol and reach directly the portal circulation and liver. Nevertheless, in the case of pancreatic insufficiency, MCTs may be absorbed intact. The excessive use of a diet rich in MCTs can lead to osmotic diarrhea as a result of the rapid hydrolysis of MCTs. Dicarboxylic aciduria has been described in infants supplemented with MCT-rich formulas without any proof of a deleterious effect.[54] The provision of EFAs must be considered because MCTs contain no EFAs. In addition, the administration of MCTs decreases the absorption of LCTs; supplementation with linoleic acid to an MCT formula may be insufficient to prevent EFA deficiency, leading to providing EFA parenterally. However, most of the formulas containing MCT also include up to 50% of lipids as LCTs. By stimulating biliary and pancreatic secretions, LCTs promote increased intestinal motility; an excess of LCTs in the intestinal lumen, especially if they are hydroxylated by bacteria, reverses the rate of water and electrolyte absorption and worsens malabsorption. In these conditions, the addition of cholestyramine may be appropriate associated with an EFA supplementation. Finally, an intake of 3 to 4 g/kg/day of lipids may be achieved, depending on absorption capacity and digestive tolerance.

Other Constituents Recommendations for vitamins and trace elements intakes are provided in Chapter 6, "Trace Elements," and Chapter 7, "Vitamins."

Commercially available semielemental diet formulas containing protein hydrolysate and MCTs can be used safely in children by slowly increasing the volume and the concentration of the solution. The low osmotic load of these products allows increasing concentration if necessary up to 1 kcal/mL. Thus, nutritional solutions in which each of the constituents is modified independently are mostly used in special situations of severe or selective malabsorption.

EF can be used after a prolonged period of PN or simply after a brief phase of peripheral venous infusion. EF is progressively introduced depending on the child's clinical state and the digestive disease. The first step includes the progressive reduction of the PN intake and stepwise EF increase according to digestive tolerance. The water and sodium intake should be increased to compensate for the intestinal losses generally induced by the start of EF; the tolerance is estimated from the weight of the child, the volume and osmolality of urine samples taken at 6-hour intervals, and the plasma osmolality. The tolerance and needs are estimated from 24-hour urine analyses, while attempting to maintain a natriuresis of 2 to 3 mmol/kg/day. At the same time, potassium intakes are adjusted as a function of the nitrogen and energy intake. Glucose is used initially, and the amount is increased progressively and controlled according to the stool volume, pH, and absence of reductory bodies. In the first days of feeding, at least a molar ratio of glucose and sodium is maintained. Protein hydrolysates are gradually introduced according to digestive tolerance.

The weaning period varies from a few days to several weeks or months. Anorexia can be avoided by the maintenance of sucking and swallowing functions during the period of CEF. In addition, it has been demonstrated that non-nutritive sucking during EF enhances growth and intestinal maturation in premature babies.[55] Weaning includes a period of continuous nighttime feeding supplemented by five or six meals in the daytime until the latter account for 50% of the total intake. Oral feeding must be carefully increased because of the relatively low intestinal activity owing to long-term CEF.

Parenteral Nutrition

Infants with IDI require long-term PN. Those who have congenital disease of intestinal mucosa and permanent intestinal failure require indefinite PN and intestinal transplantation. Thus, long-term PN is based on very rigorous methods aiming to avoid PN-related complications (see Chapter 57, "Parenteral Nutrition," for details of management).

Vascular Access Peripheral venous administration is the easiest and least hazardous method, requiring rigorous asepsis, especially in malnourished children, from severe PDI. However, only iso-osmolar solutes, providing insufficient protein-energy intake, can be used because of the risk of superficial phlebitis. In some cases, a further limiting factor can be that access to superficial veins is restricted or

impossible. Infusion into the superior vena cava with a central venous catheter (CVC) is accompanied by specific complications, such as thrombosis or sepsis. Only silicone CVC should be used, the size of which is selected according to the child's weight and age. The CVC can be inserted percutaneously, either via an epicranial vein or via an upper limb superficial vein or in a jugular or subclavian vein in older children.[56] Surgical insertion of the CVC requires adapted techniques to avoid vascular injury, bleeding, or infection. CVC with a Dacron cuff, ensuring efficient anchoring, may be inserted either percutaneously or surgically. In each case, the cutaneous and venous entry sites should be separated by a 5 to 10 cm subcutaneous tunnel; one must be careful because subcutaneous tissue is particularly thin in severely malnourrished children. The cutaneous exit site should be given meticulous daily care using iodinized disinfectants and be protected by an occlusive dressing, which is changed every day. The use of a 0.22 mm antibacterial membrane filter between the catheter and the administration tubing during perfusion remains a controversial issue. The choice of pump is important, satisfying three criteria: reliability at low flow rates, easy to use, and fitted with a safety alarm capable of signaling a change in flow rate, an air bubble, or a blockage leading to increased pressure. Solutions for PN must be prepared under strict asepsis by using antibacterial filters under a laminar flow hood.

Parenteral Nutrition Intakes The composition of the intravenous feeding solution should be adjusted at least daily according to the clinical and biologic criteria and as a function of the recovery from malnutrition and/or the transition from parenteral feeding to EF. Parenteral intakes are progressively introduced, according to tolerance, to cover the requirements of protein, energy, and trace elements.

Nitrogen Intake. PEM secondary to chronic disease as well as acute illness such as injury or infection is associated with the loss of body fat and skeletal-muscle mass. When the disease is prolonged and the child is severely malnourished, a variety of clinical events may occur in association with catabolic state. These alterations include immunosuppression, delayed wound healing and tissue repair, and loss of muscle strength. The accelerated breakdown of body protein can be slowed by the administration of adequate quantities of energy, protein (amino acids), and other essential nutrients. However, measurements of body composition and substrate-flux studies indicate that it is extremely difficult to maintain or replenish body protein during catabolism.[57] Thus, reducing the debility associated with catabolic process could potentially enhance recovery and decrease the consequences of illness on protein retention and height growth velocity.

Nitrogen intake depends on the age and degree of malnutrition.[58] In infants, it varies from 400 to 800 mg/kg/day when GI losses are great.[59] In older children, 300 mg/kg/day is usually sufficient.[60] Such intakes, which are higher than the growth requirement, cover excessive nitrogen losses induced by catabolism. Greater amounts are unsuitable because with a constant caloric intake, there is a negative correlation between nitrogen intake and the amount retained with a danger of hyperaminoacidemia, metabolic acidosis, or iso-osmolar coma. Such intakes may also be responsible for some of the reported anomalies in phosphorus and calcium metabolism.[61] Nitrogen source available for PN comes from various mixtures of crystalline L-amino acids shown to be effective in clinical use, providing appropriate nitrogen use and retention. Amino acid solutions for use in PN are selected according to the following criteria[62,63]: (1) whether the solution contains all or only some of the naturally occurring amino acids, (2) the total amino acid nitrogen content, (3) the osmolality and electrolyte content, and (4) the amount of essential amino acids per gram of total nitrogen (E:T).

Pediatric solutions appear to be better suited for use in newborns, premature babies, or malnourished infants (Primene, Baxter, Maurepas, France; Vaminolac, Fresenius, Kabi, Germany). Both products have an E:T ratio greater than 3 and differ from standard solutions with a higher percentage of branched-chain amino acids, modified aromatic amino acid contents (one-third reduction in phenylalanine), and modified sulphur-amino acid content, with methionine reduced by 50% and an increase in cysteine. Both solutions also contain taurine, which is absent from standard solutions and increased lysine contents.

Because the efficacy of PN cannot be easily improved by quantitative modifications, the addition of specific amino acids or other sources of nitrogen to the feeding formulas might be logical in critically ill children. Glutamine (Gln), being the most abundant amino acid in the body, is absent from the currently available amino acid solutions. Gln is considered unstable in aqueous solutions and during heat sterilization with the formation of pyroglutamic acid and ammonia. Although Gln is a nonessential amino acid, the nutritional requirement for this amino acid during catabolic illness may differ greatly from those during health. During starvation or stress, the concentration of free Gln in the intracellular amino acid pool of skeletal muscle rapidly decreases. Gln exported from the muscle is used primarily by visceral organs; in the kidney, it serves as an ammonia donor; in the GI tract, it serves as a primary oxidizable fuel source for enterocytes and colonocytes.[64] Gln also supports other rapidly proliferating tissue, such as fibroblasts or lymphocytes. Gln-supplemented total parenteral nutrition (TPN) has been shown to preserve gut structure and to improve gut immune function in animal models.[65] Recent studies have shown the clinical benefits of Gln-supplemented TPN in adult patients undergoing bone marrow transplantation.[66,67] The use of Gln-containing dipeptides is proposed regarding the instability of free Gln. Improved nitrogen balance has been shown in patients receiving alanyl-glutamine–supplemented TPN.[68] In addition, Gln dipeptide–supplemented PN prevents intestinal atrophy and increased permeability in critically ill adult patients.[69]

Ornithine α-ketoglutarate (OKG) is a salt formed with two molecules of ornithine and one molecule of α-ketoglutarate. OKG has been sucessfully used by the enteral and parenteral route in burn, traumatized, and sur-

gical patients and in chronically malnourished patients. The mechanism of action of OKG is not fully understood, but it was clearly demonstrated that it is a precursor of Gln.[70] In addition, the secretion of anabolic hormones (insulin, human growth hormone) and the synthesis of metabolites (polyamines, arginine, keto acids) may be involved.[71,72]

In the near future, more specific therapeutic approaches of protein metabolism might be achieved. This perspective is of great importance for children regarding the consequences of inadequate protein metabolism on growth velocity during recovery from malnutrition.

Energy Intake. The infusion rate of glucose must be kept constant without exceeding a rate of 1 g or 1.5 g/kg/hour. Under these conditions, the appearance of a glucosuria indicates a technical problem with the infusion or some stress, particularly an infection. Energy intake is closely correlated with that of nitrogen. In infants, intake varies from 100 kcal/kg/day to 120 kcal/kg/day, but the intake is reduced to 60 to 80 kcal/kg/day in older children.[73]

TPN for infants and children used to provide most of the energy as glucose, although it is not precisely known how much of the intravenously administered glucose is oxidized.[74] Glucose-based TPN has been shown to cause an adverse effect related to glucose storage, particularly as fat. This might account for the extensive lipid deposition reported both in liver and adipose tissue.[75] In these conditions, fat infusion further increases fat deposition and may result in fat overloading. Thus, substitution of part of the glucose calories avoids the undesirable effects reported with glucose-based TPN. In addition, it has been shown that the use of intravenous fat emulsion (IVFE) improves nitrogen retention.[76,77] IVFE provides a highly concentrated source: 2.2 kcal/mL for the 20% emulsion compared with 0.68 kcal/mL for a 20% dextrose solution. The concentrated calories and low osmolality of IVFE make it ideal for peripheral PN. In addition, TPN without lipids creates a metabolic situation likely to produce an EFA deficiency.[78] Glucose infusion stimulates secretion of insulin, which reduces lipolytic activity and prevents release of tissue linoleic acid reserves. The onset of EFA deficiency is even more rapid when there is a preexisting nutritional lack, such as in very young or malnourished infants. Seventy percent of infants less than 1 year old on TPN without lipids develop an EFA deficiency within 1 to 2 weeks.[79] The restart of anabolism can, because of adequate energy and nitrogen intakes, lead to the onset of EFA deficiency. A linoleic acid supply of about 2 to 3% of the total energy input is recommended.[80] A daily supply of 4% or 450 mg of linoleic acid per 100 kcal is often necessary to correct a preexisting deficiency. The lipid supply should also include α-linolenic acid ($C_{18:3}$ n-3). Although its function and requirements are still poorly defined, an intake of about 40 to 50 mg/kg/24 hours, equal to about 0.5% of the total energy intake, is normally provided.

Carnitine is necessary for optimal oxidation of fatty acids. Carnitine, in the form of acyl carnitine, transfers free fatty acids into mitochondria, where they are recombined with coenyzme A (CoA) to form acyl CoA. Plasma levels of carnitine decrease rapidly in premature newborns and small-for-gestational-age neonates during the first days of life if no exogenous carnitine is provided,[81] raising the question of carnitine supplementation for children on TPN.[82] In the absence of specific recommendations, a supplement of 1 to 2 mg/kg/day may be advisable. A supplementation with α-tocopherol as an antioxidant, at a dose of 0.6 mg/g of unsaturated fatty acids, is recommended.[83]

Despite the advantages of IVFE and the need to correct any EFA deficiency, there are restrictions to the administration of lipids to malnourished infants. Malnutrition reduces lipoprotein lipase (LPL) activity, but this reappears with the onset of anabolism.[84] The substrate itself also stimulated LPL synthesis. It is therefore recommended that IVFE should not be administered until a few days after the start of PN. There may also be several classic contraindications to the use of IVFE during the initial phase, such as sepsis, thrombocytopenia, disseminated intravascular coagulation, respiratory distress syndrome, or metabolic acidosis.

Traditionally, IVFE has been prepared with soybean oil; other emulsions are now available. IVFEs containing MCTs are rapidly oxidized when used as a calorie source. Fatty acids from the hydrolysis of MCTs are the primary substrate for ketogenesis. Carnitine is needed to transport long-chain fatty acids into the mitochondria, but malnourished and seriously ill patients may be carnitine depleted. An energy source able to bypass this route into the mitochondria would, in theory, be useful for such patients. Medium-chain fatty acids can enter the mitochondria by simple diffusion, independent of the carnitine enzyme, and produce an elevation of plasma ketones.[85] MCTs have been shown to improve nitrogen balance in postoperative patients, but this positive effect remains controversial according to several other studies.[86,87] The use of MCTs in malnourished infants with severe protracted diarrhea indicates, after 15 days on TPN, that it is well tolerated and can provide advantages in terms of nitrogen metabolism by supplying the equivalent of 25% non–protein-energy intake.[88] MCT emulsion is also well tolerated on long-term TPN.[89]

A new 20% IVFE containing 17% olive oil and only 3% soybean oil is currently available and will probably be available for pediatric patients.[90]

Optimal Glucose-to-Fat Ratio. Studies performed in infants or neonates have assessed glucose and fat use and have determined the optimal lipid intake.[91,92] Fat infusion aiming at a significant contribution to the coverage of energy expenditure requires that glucose oxidation be equal to or lower than maximal oxidative glucose disposal. Hence, glucose infusion rates should be lower than 18 g/kg/day.[91] A study in malnourished infants and young children has shown a maximal lipid use rate of about 3.3 to 3.6. g/kg/day.[93] Above these values, there is an increased risk of fat deposition secondary to the incomplete metabolic use of infused lipid. Pierro and colleagues showed similar results in a short-term study performed in surgical neonates on TPN.[92]

Thus, administration of 2 to 3 g/kg/day of lipid is required as soon as the clinical situation permits, representing up to 30% of non–protein-energy intakes. A slow infusion rate, such as 0.1 to 0.2 g/kg/hour, allows the best

metabolic use and may avoid fat overload and reticuloendothelial system involvement.[94] IVFE may be infused either as a piggyback or as a ternary mixture. Use of an all-in-one mixture is not currently widespread in pediatric patients compared with adult patients.

Adaptation of Intake. Following the initial phase of refeeding (see above), water and electrolyte intake must be varied according to the age, degree of malnutrition, and water-electrolyte status, needing adjustment, for example, if there are intestinal losses. Infants require 120 to 140 mL/kg and older children 80 to 100 mL/kg/day. All normal infants and children need 3 to 5 mmol of chloride, sodium, and potassium per kilogram per day. When there are losses owing to vomiting or gastric aspiration, 8 mmol of sodium, 1 mmol of potassium, 6 mmol of H+ ions, and 12 mmol of chloride should be added to each 100 mL of water. In the case of enterostomy, 15 mmol of sodium, 1 mmol of potassium, 10 mmol of chloride, and 5 mmol of bicarbonate should be added to each 100 mL of water.

With a nitrogen intake of 400 mg/kg/day and a calcium intake of 1.7 mmol/kg/day, the daily requirement of phosphorus is 2.3 mmol/kg for bone growth and nitrogen anabolism. If the phosphorus intake is lower or the intake of nitrogen and/or calcium is higher, severe phosphorus depletion results. Magnesium requirements are usually satisfied by 1 mmol/kg/day.

Vitamin and trace element intakes are provided as a function of the intake of the respective nutrients and their anabolism. For infants and older children, adherence to the recommendations in Chapters 6 and 7 helps to prevent depletion or excess. These intakes should be adjusted in cases of catabolic stress, such as an infection or intestinal losses. Complications of PN are listed in Chapter 57, "Parenteral Nutrition."

When PN has to be continued after the initial phase of renutrition, if the metabolic and nutritional status permits, cyclic PN should be started. The advantages of cyclic infusion are metabolic, physical, and psychological.[95] In addition, cyclic PN allows the patient to be discharged home if long-term PN is required.[96]

PERMANENT INTESTINAL FAILURE

The term "intestinal failure" is now often used to describe GI function insufficient to satisfy body nutrient and fluid requirements. The first recognized condition of intestinal failure was short-bowel syndrome. Severe motility disorders such as chronic intestinal pseudo-obstruction syndrome in children and congenital intractable intestinal mucosa disorders are also responsible for intestinal failure because no curative treatment for these diseases is yet available. PN and home PN remain the mainstay of therapy for intestinal failure, whether it is partial or total, provisional or permanent.[96,97] However, some patients develop complications while receiving standard therapy for intestinal failure and are considered for intestinal transplantation. The main long-term PN-related complications include catheter-related sepsis (CRS) and thrombosis, liver disease both being potentially life threatening.

Complications of Long-Term PN

Catheter-Related Sepsis and Thrombosis CRS is one of the most serious complications that can arise during PN, and the use of a CVC undoubtedly increases the risk of infection. The care of the child should be undertaken by physicians and nurses who have been specifically trained in this technique. Fever or clinical signs suggestive of CRS should lead to a thorough search for a source of sepsis, together with a white blood cell count, C-reactive protein, and coagulation tests. Samples for blood culture should be taken via the catheter and from a peripheral vein. If the body temperature remains elevated, antibiotic therapy should be started, using antibiotics against *Staphylococcus*. Removal of the catheter is not considered unless the PN program is close to completion, and in other cases, it can be considered only if the patient continues to deteriorate even when appropriate antibiotic therapy had been started. With good technique, displacement or obstruction of the catheter and thrombosis of the superior vena cava are rare.

PN-Associated Liver Disease Liver disease can occur rapidly because many factors are involved in hepatobiliary complications in patients with permanent intestinal failure.[98–104] The main factors related to liver disease are as follows: (1) severe necrotizing enterocolitis in premature or small-for-gestational-age babies, (2) bowel rest suppresses or reduces biliopancreatic and digestive secretions, (3) disruption of the enterohepatic cycle (ileal disease or resection), (4) bacterial overgrowth and translocation (endotoxinemia), and (5) recurrent CRS. Other factors are directly related to PN such as inadequate amino acid content of PN solutions, aluminum overload, excessive glucose intake, or excessive lipid intake (lipid peroxidation, reticuloendothelial system overload).

The first and most sensitive laboratory indications are increases in alkaline phosphatase and γ-glutamyltransferase activities. An increase in transaminase activity is also an early and specific sign, but it is less sensitive. Steatosis is the first histologic manifestation, followed by cholestasis and portal and periportal cell infiltration. Hepatic fibrosis indicates severe liver disease but is fortunately rare if PN is performed correctly and/or for a short period of time.

Some measures have been found to limit liver disease effectively: (1) stimulation of the enterobiliary axis by the ingestion of LCTs or breast milk or by the injection of cholecystokinin analogs; (2) suppression of intraluminal bacterial overgrowth caused by intestinal stasis by giving metronidazole; (3) by using ursodeoxycholic acid (10 to 20 mg/kg/day); (4) by decreasing the aluminum content of the PN solution; (5) by limiting glucose intakes to reduce hepatic fat accumulation; (6) by using an appropriate type and amount of lipid emulsion, which provides EFAs and reduces glucose load; (7) by using the new pediatric adapted amino acid solutions, which provide appropriate amino acids as well as taurine; and (8) cyclical PN, which contributes to decreasing hyperinsulinism and reducing liver steatosis.

PN-Related Bone Disease The so-called PN-related bone disease may occur in cases of protracted PN. It resembles rickets, with fractures of the limbs, which are sometimes asymptomatic and are discovered only after routine radiographic examination.[104] The most constant laboratory features are an elevated alkaline phosphatase activity and hypercalciuria, with normal or subnormal levels of vitamin D metabolites and parathyroid hormone. Bone histology shows osteomalacia-like changes with reduced mineralization and an excess of osteoid tissue. The etiology of these bone lesions is probably multifactorial: excess vitamin D or disorders of its metabolism mean that it must be given very carefully on long-term PN. It is also possible to reduce the hypercalciuria by ensuring that the supplies of phosphorus, nitrogen, and energy are properly balanced, while reducing the supply of amino acids, especially the sulfur-containing amino acids. Finally, it is necessary to ensure that the solutions used for children are not contaminated with aluminum.[105] Prevention of this "'bone disease" depends primarily on regular measurements of urinary calcium, which should not exceed 5 mg/kg/24 hours, and serum alkaline phosphatase activity.

INTESTINAL TRANSPLANTATION

Recent advances in immunosuppressive treatment and the better monitoring and control of acute rejection have brought intestinal transplantation into the realm of standard treatment for intestinal failure. In the early 1990s, two advances made intestinal transplantion a promising option for the treatment of end-stage intestinal failure: the combination with liver transplantation and the development of tacrolimus.[106,107] The results from the Intestinal Transplant International Registry indicate that intestinal transplantation is currently an acceptable clinical modality for selected patients with permanent intestinal failure.[108,109] Although it has been used in humans for the past two decades, this procedure had a slow learning curve. According to the current results, this challenging procedure may be performed in children only under certain conditions.

Indications for Intestinal Transplantation

Indications for intestinal transplantation involve mostly pediatric patients and may be divided into three main groups: short-bowel syndrome, intestinal motility disorders, and congenital disease of epithelial mucosa.

Shortly, in patients with short small bowels on long-term PN, intestinal transplantation can be envisaged only once it has been formally shown that the remnant bowel cannot adapt.[110,111] Surgical approaches such as lengthening of the small bowel, loop interposition, or assembly of a "reverse" intestinal loop should be attempted.[112–114] Trophic factors such as recombinant human growth hormone might be helpful in some patients and might contribute to decreasing the need for intestinal transplantation in the near future.[115–117] Therefore, only a small number of patients with short-bowel syndrome are candidates for intestinal transplantation in the absence of life-threatening complications, especially progressive liver disease, which raises another problem. The prevalence of complicated home PN-related liver disease increases with a longer duration of PN.[118]

Motility disorders in childhood include extensive Hirschsprung's disease and chronic intestinal pseudo-obstruction syndrome (CIPOS). The first causes the same problems as short-bowel syndrome, with two main differences. The nonfunctioning colon is excluded and the Hirschsprung's disease–free small bowel has motility disorders. Therefore, when normally innervated small bowel is shorter than 60 cm, the probability of long-term PN dependency is high. Logically, this situation requires a combined colon transplantation. CIPOS is a very heterogeneous condition with regard to clinical presentation, histopathologic features, severity of motility disorders, and outcome.[119–121] In our experience, 20 to 25% of patients will become definitively dependent on PN.[120] Recent data reported that intestinal transplantation or multivisceral transplantation has been performed in CIPOS patients, including some with associated urinary tract involvement.[122,123] Munchausen syndrome by proxy causing intestinal pseudo-obstruction must be recognized, even if difficult, and never justifies intestinal transplantation, as previously reported.[124]

Two congenital intractable epithelial mucosal diseases are responsible for permanent intestinal failure and are currently recognized as requiring intestinal transplantation: microvillous inclusion disease and epithelial dysplasia. Both are autosomal recessive inherited disorders with neonatal onset of severe watery diarrhea and total malabsorption. Microvillous inclusion disease involves the intracellular pathway of brush border development,[125] whereas epithelial dysplasia is associated with abnormal enterocytes and basement membrane.[126] The primary inherited defect is currently not known for either of these diseases. Children with one of these two mucosal diseases have undergone successful small bowel transplantation (SBTx) in isolation or in combination with the liver.[127–129]

Complications after Intestinal Transplantation

The intestine differs from other solid organs in its association with a large lymphoid system, the gut-associated lymphoid tissue. This complex lymphoid system includes Peyer's patches, mesenteric lymph nodes, plasma cells, and mature T lymphocytes disseminated within the intestinal mucosa. The sensitization of recipient lymphocytes to alloantigens in the Peyer's patches and mesenteric lymph nodes favors the homing of mature alloreactive T cells into the intestinal graft. On the other hand, the intestine is permanently exposed to potentially harmful pathogens, a major threat for recipients of intestinal grafts, amplified during rejection by the destruction of the epithelial barrier. These singularities of the gut may impede intestinal transplantation for several reasons: (1) the gut-associated lymphoid tissue can induce graft-versus-host disease (GVHD) and may enhance allograft rejection and the subsequent risk of gram-negative sepsis; (2) the secretion of lymphokines or the production of cytotoxic T cells in response to intraluminal pathogens may impede the induction of tolerance and

thereby favor allograft rejection; (3) the need for heavy immunosuppressive treatment increases the risk of developing opportunistic infection and post-transplantation lymphoproliferative disorders. GVHD has been extensively studied in animal models of intestinal transplantation. In humans, despite the presence of circulating donor-derived lymphocytes during the first few weeks after transplantation, clinical signs of GVHD have rarely been reported.[130] GVHD is therefore not a major complication after intestinal transplantation.

Intestinal allograft rejection remains the major complication after intestinal transplantation. As a result of increased immunosuppressive treatment, graft rejection may further precipitate opportunistic infections that become additive factors in patient and graft losses. As rejection can occur rapidly and can be life threatening, close monitoring is required. This has led to the development of numerous diagnostic methods, which have not been validated in human intestinal transplantation or have limited value.[131–133] Therefore, regular biopsies of the proximal and distal ends of the graft for histologic or immunohistochemical analysis are required.[134–136] Clinical signs of rejection occur later than histologic and immunohistochemical signs and correspond to a relatively advanced rejection process with marked histologic lesions. In addition, clinical manifestations are nonspecific markers of rejection. It is thus of importance to differentiate other sources of potential intestinal allograft disease that may clinically mimic rejection, such as post-transplantation lymphoproliferative disorders, Epstein-Barr virus, cytomegalovirus, adenovirus, or other bacterial/viral enteritis. Rejection and sepsis can be intimately related after SBTx, when rejection compromises normal intestinal barrier mechanisms and bacterial translocation results, with consequent multiorgan failure.

Intestinal Graft Function

Provided that the small intestine survives ischemia and reperfusion injury, long-term graft absorptive function depends on the effects of denervation, lymphatic disruption, immunosuppressive treatment, rejection, and infection.[137–140] These factors may explain impaired function of the intestinal graft and a delay in achieving intestinal autonomy. Studies performed in animals have shown that intestinal transplantation disturbs the absorption of carbohydrates, lipids, glutamine, water, and electrolytes.[141–145] The intrinsic motor activity of the small intestine is preserved, for the most part, although there is some discoordination between proximal and distal elements in the fed state.[146–156] Studies in dogs have shown extrinsic reinnervation of the intestinal graft wall along the arterial axis.[155] This process requires a prolonged period. In a syngeneic Lewis rat model, it was shown that nitric oxide and peptidergic neurons markedly decreased just after transplantation and that nitric oxide neurons recovered faster.[156]

Feeding must resume as early as possible after transplantation because this ensures optimal mucosal trophicity and reduces gastrointestinal stasis, which is a source of intraluminal bacterial overgrowth. Clinical experience has demonstrated that because of water-electrolyte malabsorption, abnormal motility, and impaired lymphatic drainage, it may take several weeks to achieve normal intestinal transit and stool volume. If the recipient has no colon, combined small-/large-bowel transplantation has physiologic advantages in terms of water and electrolyte reabsorption, slowing intestinal transit and trophic factors through colonic synthesis of short-chain fatty acids. Finally, it is currently considered that intestinal transplantation restores an enteral axis capable of ensuring digestion and absorption and that full function enables PN to be withdrawn completely.

Post-Transplantation Nutritional Management

Maximizing post-transplantion nutritional status is believed to increase the probability of a successful outcome. To achieve this objective, the following nutritional goals have to be met during the post-transplantation period: (1) continuation of PN during the early post-transplantation course, (2) initiation and adjustment of EFs, (3) oral stimulation and initiation of oral feeding, (4) maintenance of vitamin and mineral status, and (5) restoration of normal growth.

During the initial post-transplantation period, TPN is administered continuously, with modifications made to the electrolyte and macronutrient content of the solution based on serum and urine laboratory indices. Hyperglycemia may result from initial high steroid doses and steroid recycling during early rejection episodes and/or from tacrolimus. Post-transplantation pancreatitis may also affect glucose metabolism. Thus, insulin may be required in patients with severe hyperglycemia to maintain adequate caloric balance. Impaired renal function may require the limitation of nitrogen intake required for post-transplantation wound healing, and fluid restrictions may prohibit the ability to provide enough TPN volume to supply adequate calories. Use of intravenous lipid emulsion whenever possible, according to metabolic tolerance and infectious state, is recommended to achieve adequate calorie intake and the provision of EFAs. The type of emulsion has never been evaluated in such a situation and might be controversial. In our practice, we preferentially use MCT/LCT emulsion without overpassing 1.5 g/kg/day.

Continuous EFs through a gastrostomy or from proximal jejunostomy are started once intestinal motility occurs, generally within 1 week. EFs are initiated and advanced slowly unless contraindicated, as in the presence of severe diarrhea or vomiting and, of course, in the presence of an acute graft rejection. In our experience and elsewhere, the patients initially receive a low antigenic and low-fat formula and are subsequently transitioned over a period of weeks and months to a more complex product with intact macronutrients. The use of an amino acid–versus a peptide-based enteral product remains a controversial issue in the nontransplanted critically ill patient with impaired GI function. Nitrogen absorption from free amino acids and di- and tripeptide solutions without the presence of carbohydrate or fat are felt to be absorbed similarly, although by different active transport systems.[157] In the presence of carbohydrate and fat, however, nitrogen

absorption has been reported to be greater with a 100% elemental free amino acid protein source.[158] Moreover, the presence of free glutamine in powdered amino acid–based formulas bas been shown to be beneficial in protecting GI mucosa and reducing bacterial translocation.[159] Conversely, peptide-based elemental formulas are generally lower in osmolality, which may make them more suitable for use in the presence of increased stool output. A peptide-based isotonic formula used under such circumstances may also promote greater nitrogen uptake than an amino acid–based product, given that there would be less need to dilute the solution. It is impossible to identify significant differences in outcome as measured by the length of time until the patients are completely weaned from TPN, length of hospital stay, ileostomy output, or time until transition to oral intake alone by the type of enteral formula used. Most studies are limited by the small number of patients who received a peptide- or hydrolyzed casein–based enteral formula versus an amino acid preparation. Post-transplantation impaired lymphatic drainage with either chylous ascite or intestinal lymphangiectasia limits lipid intake. Low-fat and MCT-rich formulas are recommended at initiation of EF. Fat content can be adapted according to the occurrence of inadequate lymphatic drainage. In our experience, children with inferior vena cava thrombosis are at high risk of chylous ascite and must be fed very slowly, with adapted lipid intake (eg, MCT-rich formula). Commercially available formulas can limit the use of a combined low-fat/-amino acid preparation. More complex products with intact macronutrients are progressively introduced according to graft status, digestive tolerance, and capacity of eating. In children with eating disorders, EF can be progressively achieved by using a polymeric diet. PN weaning is a crucial objective, allowing intestinal transplantation to be considered successful.

Chronically ill infants and children are at risk for oral aversion caused by the loss of the sucking or swallowing reflex in those maintained on TPN or tube feeding for an extended period of time without oral intake. Further orally associated problems, including delayed speech and language development, may also result from this aversion. Pretransplantation management of eating disorders and early and adequate post-transplantation stimulation of oral feeding can reduce food aversion. It is essential to insert a digestive access (gastrostomy or proximal jejunostomy) at the time of transplantation surgery, especially in patients felt to have eating disorders. Psychological evaluation and assistance are, of course, required in each case. In our experience, all patients achieved oral feeding, sometimes up to 2 years after transplantation.

Finally, the course of post-transplantation nutritional therapy includes the period of initiation of EFs to achieve full digestive autonomy (discontinuation of PN) and complete oral feeding. It can take several weeks or months, depending on the pretransplantation nutritional status, rate of post-transplantation complications, and intestinal graft recovery and function. Data from the registry indicate that full nutritional autonomy with complete discontinuation of PN has been achieved in 77% of cases, and partial recovery was documented in another 14%, for a total rehabilitation rate of 91% in survivors.[110] In our experience, among 25 survivors after isolated (n = 5) or combined intestinal-liver transplantation (n = 20), all patients were weaned from PN, with delay ranging from 4 weeks to 3 years. In the absence of major complications, recipients of an isolated intestinal allograft can be weaned from PN relatively quickly within 4 to 6 weeks. The longer time to achieve full enteral nutrition after small bowel–liver transplantation (SBLTx) reflects a more prolonged recovery from the surgical procedure compared with isolated SBTx. Thus, the ultimate goal of independence from PN is achieved for the majority of patients. By using stool balance analysis in 12 PN-weaned transplanted children, we have shown that lipid absorption rate is decreased, ranging between 72 and 87%. With increased intakes according to Recommended Dietary Allowance, normal growth may be achieved in most children.

Nutritional Outcome

Beside the enteral or oral feeding approach, nutritional evaluation following intestinal transplantation is mandatory. However, only few nutritional data are available in children after intestinal transplantation.[160–164] We studied 13 children (8.8 ± 3.5 years) with at least 12 months follow-up (median 27 months).[165] PN was stopped 110 ± 84 days after grafting. They were on unrestricted oral feeding with enteral supplementation in 6 patients with varying degrees of eating disorders. At 12 months post-transplantation, body weight for age and height for age were decreased, at 89 ± 13% and 93 ± 5%, respectively. Body weight for height was increased (105 ± 9%), with fat body mass being 20.1 ± 4.3% of body weight. Growth velocity was decreased 6 months before and after grafting at 67 ± 38% and 57 ± 46% of normal for age, respectively, but was increased at 142 ± 64% of normal for age during the last 6 months of follow-up. Bone mineral density, measured by using dual-energy x-ray absorptiometry (DXA), was decreased in all children according to age. Nutritional parameters showed normal albumin and prealbumin plasma levels as well as plasma tocopherol. Conversely, both vitamin A and retinol binding protein plasma levels were decreased, as well as serum iron and ferritin.

Weight gain with excessive fat body mass and catch-up growth may be achieved after intestinal transplantation in most cases in our experience. However, in some cases, there is evidence of severe inhibition of linear growth at the time of transplantation, with no evidence of catch-up after transplantation.[163,164] Growth velocity is severely altered both before and just after transplantation owing to liver disease and high-dose steroids. Thus, catch-up growth is delayed. Thus, a follow-up period of 6 months is too short to observe positive trends in height/length. Despite normal growth, bone mineral density is low, and some nutritional biologic parameters are altered, such as vitamin A plasma levels. Monitoring should not be restricted to growth parameters but should include recording body composition and biologic parameters for achieving nutritional supplementation if required. In addition to these simple nutritional parame-

ters, future studies of post–intestinal transplantation nutrition therapy should evaluate bone mineral density on a longitudinal basis. DXA is undoubtedly required to assess bone mineral density. Indeed, insufficient bone mineral density may be attributable to previous long-term PN and might be worsened with high-dose steroids.

Candidates for Intestinal Transplantation

Intestinal transplantation is theoretically indicated for all patients permanently dependent on PN. Functional grafts lead to gastrointestinal autonomy (weaning off PN). However, as PN is generally well tolerated, even for long periods, each indication for transplantation must be carefully weighed in terms of survival rate, morbidity, and quality of life.[166–168] Intestinal transplantation is often accompanied by numerous life-threatening complications, such as those briefly reviewed above, leading to recurrent or long-term hospitalization and sometimes a poor outcome. An evaluation of the quality of life after intestinal transplantation among home PN has to be performed in transplanted patients using a validated quality of life instrument in the form of a self-administered questionnaire.[168] Intestinal transplantation recipients with functioning grafts reported a significant improvement in their quality of life. This information is encouraging and should be used toward future advancement in intestinal transplantation.

When long-term PN is effective and well tolerated, it can thus be used pending further progress in intestinal transplantation. In contrast, when PN has reached its limits, especially those associated with extensive thrombosis, recurrent sepsis, severe metabolic disorders, or advanced liver disease, intestinal transplantation must be undertaken. Patients with irreversible intestinal failure and end-stage liver disease are certainly candidates for a life-saving procedure such as combined SBLTx. Patients with irreversible intestinal failure and PN dependency without consistent liver disease must satisfy rigorous criteria to be considered candidates for isolated SBTx. They must fulfill at least one of the following criteria: extensive thrombosis impeding the ability to administer PN, recurrent life-threatening sepsis, severe metabolic disorders preventing nutritional requirements from being met with consequent failure to thrive in children, and underlying disease with high water-electrolyte losses with the risk of life-threatening dehydration in the case of PN disruption (eg, IDI from congenital intestinal mucosal disease). Some patients with severe chronic intestinal pseudo-obstruction may be disabled because of chronic, massive gastrointestinal dilation refractory to stomal decompression or partial enterectomy. They might be considered for intestinal transplantation, although the usual indications, including progressive liver disease, the threatened loss of vascular access, and recurring life-threatening sepsis, have not developed.

Finally, as pediatric patients represent almost two-thirds of the indications for SBTx, appropriate therapeutic strategies should be developed for all phases of intestinal failure. It is first required to recognize as early as possible the patient with irreversible intestinal failure such as extreme short-bowel syndrome or congenital disease of the intestinal mucosa or total aganglionosis. These patients should be referred at an early stage to multidisciplinary teams involved in SBTx in optimal nutritional status. For other patients, attempts at achieving intestinal autonomy (PN weaning) require appropriate management, as previously emphasized. Intestinal transplantation thus requires a strategy based on long-term medicosurgical management, aimed at demonstrating the irreversibility of intestinal failure, to avoid the complications of long-term PN and to refer early selected patients requiring this procedure.

CHAPTER 45

SHORT-BOWEL SYNDROME, INCLUDING ADAPTATION

Jon A. Vanderhoof, MD

Short-bowel syndrome provides the clinician with multiple challenges in nutritional therapy, perhaps more than any other single medical condition. It is a complex disorder that results in multiple disruptions of normal intestinal anatomy and physiology and produces a variety of nutritional, infectious, and metabolic complications. Short-bowel syndrome is usually defined functionally and is considered to exist when the patient has malabsorption in the presence of a shortened small intestine.[1] Malabsorption may involve nutrients, fluid, or electrolytes. Many of the clinical challenges lie in recognizing the many nutritional deficiency states that occur as a result of malabsorption secondary to the reduced absorptive surface area.

The prognosis of patients with short-bowel syndrome has been changing markedly over the past several years. The development of parenteral nutrition was a major step forward, permitting patients with shortened small intestine to live for extended periods beyond the development of the short-bowel state. Subsequent refinement in solutions, techniques, and catheters and new improved enteral feeding solutions had further impact on the prognosis in patients with short-bowel syndrome.[2,3] This disorder, which was formerly fatal, is now often compatible with long-term survival and potentially even a normal life span. The recent advent of intestinal transplantation is currently further altering the perspective of short-bowel syndrome. This chapter discusses the pathophysiology associated with short-bowel syndrome and the therapeutic steps that must be taken to permit patients with short-bowel syndrome to achieve their full potential.

ETIOLOGY

In most pediatric patients with short-bowel syndrome, the disorder begins at or near birth. However, a number of conditions later in life may result in the development of short-bowel syndrome in older children and adults. Neonates with short-bowel syndrome can be subdivided into those with and those without congenital anomalies.

Neonates who begin with normal intestinal anatomy constitute a large number of patients with short-bowel syndrome, which, in most of these cases, follows intestinal resection for necrotizing enterocolitis.[2–4] This occurs predominantly in the premature infant. The actual cause of this condition appears to be multifactorial, but ischemic injury to the small intestine may produce nonviable bowel, which subsequently must be resected. In this instance, ileal or proximal colonic resections are most common and extensive resection often results in compromised intestinal function. Later in life, anatomically normal patients may develop Crohn's disease, whereas patients with malrotation may develop a volvulus with intestinal ischemia. Tumors and radiation enteritis secondary to radiation therapy for neoplastic diseases are also common causes of short-bowel syndrome in older children and adults. Occasionally, Hirschsprung's disease may involve a portion of the small intestine in addition to the colon.

Short-bowel syndrome may also be the result of congenital anomalies. Atresia may occur anywhere in the small intestine, and these may be either isolated or multiple. Multiple atresias may result from anomalies of the superior mesenteric artery, known as "apple peel" or "Christmas tree" deformities of the small intestine. Congenital short-bowel syndrome, or shortened small intestine, may be present at birth. Patients with gastroschisis, an abdominal wall defect, may also have some degree of intestinal shortening, either congenitally or as a result of resection for ischemia or bowel injury.

There is little difference between these two groups from a functional perspective. However, certain anatomic considerations may have great impact on the patient's long-term prognosis and may alter the interventional steps required.

PHYSIOLOGIC ABNORMALITIES

Marked differences exist in the functioning of the proximal versus the distal small intestine, and these differences have a major impact on the management of patients with short-bowel syndrome. Typically, the jejunum has long villi, a large absorptive surface, and a high concentration of enzymes and transport carrier proteins. The epithelium is characterized by relatively large tight junctions between the epithelial cells. Because the tight junctions are the location of the paracellular pathway for transport and large quantities of fluid and smaller molecules pass through this pathway, the jejunal epithelium is relatively porous, allow-

ing free and rapid flux of water and electrolytes from the vascular to the intraluminal space. It is also the site of greatest nutrient absorption in the small intestine. On the other hand, the ileum is characterized by shorter villi, more lymphoid tissue, less absorptive capacity, and a tighter epithelium. Smaller tight junctions permit less flux of fluid from the vascular space to the lumen; therefore, the epithelium in the ileum is more effective in the conservation of fluid and electrolytes. Nutrients are absorbed less rapidly in the ileum than in the jejunum. The ileum also has certain capabilities that the jejunum does not have, mainly the absorption of vitamin B_{12} and bile salts through site-specific receptors. Normally, a large influx of fluid and electrolytes flows into the proximal small intestine to dilute highly concentrated nutrients delivered into the duodenum. Rapid mixing, digestion, and subsequent carrier-mediated transport of monosaccharides, amino acids, and dipeptides occur predominantly in the jejunum. Although some of these functions certainly occur in the ileum as well, the ileal epithelium is better suited to the reabsorption of water and electrolytes that were passively secreted owing to the osmotic gradient into the jejunum. The patient with a jejunostomy and a major ileal resection will therefore be susceptible to fluid losses from osmotic diarrhea, especially in association with carbohydrate feedings. However, patients with jejunal resection may tolerate such feedings better with less fluid loss.

Following ileal resection, patients may initially absorb more nutrients, although absorption will rapidly adapt as the ileum assumes jejunal function. Although the ileum can develop the absorptive capacity of the jejunum for various macro- and micronutrients, site-specific carrier-mediated transport of vitamin B_{12} and bile salts will never occur in the jejunum, and the patient will permanently malabsorb these substances following ileal resection. Many gastrointestinal hormones are also produced in the ileum, especially those that affect small intestinal motility, such as enteroglucagon and peptide YY. Ileal resection may impair regulation of gut motility by nutrients, especially fat. The antimotility effect of fat in the ileum is known as the ileal brake and is important in ensuring adequate fat absorption from the small intestine. Gastrin secretion is also increased in patients with short-bowel syndrome, probably because of the loss of the normal feedback mechanism owing to ileal resection. This abnormality partly explains the frequent occurrence of acid peptic disease and esophagitis in patients with short-bowel syndrome.

The ileocecal valve has two important functions. It serves as a barrier for reflux of colonic bacteria from the colon into the small intestine. It also appears to regulate the exit of fluid and nutrients from the small intestine. Consequently, its resection may have major negative effects on physiology following small-bowel resection.[2,3] A greater influx of bacteria from the colon into the small intestine results in bacterial overgrowth in the small intestine, resulting in a number of complications, to be discussed later. In addition, rapid transit of nutrients from the small intestine into the colon may exacerbate malabsorption and increase sensitivity to osmotic loads. More recent evidence suggests that the ileocecal valve may be less important than originally thought, and the adverse effects of ileocecal valve resection on the long-term outcome of short-bowel syndrome do not appear to be as great as originally thought.[5]

The major consequence of resection of the small intestine is malabsorption. This is primarily owing to reduction of the absorptive surface area with a concomitant loss of digestive enzymes and transport carrier proteins.[6] The consequences of nutrient malabsorption are easily demonstrated in patients with short-bowel syndrome. For example, malabsorption of rapidly digested carbohydrates produces tremendous osmotic diarrhea following resection of the ileum as reabsorption of water is impaired. Larger molecules such as proteins, which are usually ingested in smaller quantities, produce few symptoms when malabsorbed. Fats are also large molecules, and although they may be poorly absorbed, malabsorption of fat creates little additional fluid loss from the small intestine. However, fat absorption requires greater mucosal surface area; therefore, the coefficient of fat absorption may be less than for proteins and carbohydrates in patients with short-bowel syndrome. Fat-soluble vitamins may also be malabsorbed in large quantities in patients with short-bowel syndrome; therefore, vitamin deficiency states, especially fat-soluble vitamin deficiency states, are common. Following extensive ileal resection, reabsorption of bile salts may be impaired to such a degree that the patient will become bile salt depleted. Bile salt concentrations will fall below the critical micellar concentration, and fats cannot be solubilized. Fat-soluble vitamins and fats are therefore malabsorbed to a greater degree. Because it is thought that fat is not absorbed by a carrier-mediated saturable process, the total quantity absorbed may be increased by increasing dietary fat content, even though the coefficient of absorption may be reduced. Additional calories in the form of carbohydrate cannot be absorbed, however, once transport carriers are saturated. The possible exception is the fermentation of some malabsorbed carbohydrate to short-chain fatty acids in the colon or possibly in the distal small intestine if bacterial overgrowth is present. Colonic absorption of these substances may permit recovery of some additional calories. Consequently, preservation of the colon may be important not only for control of fluid and electrolyte losses but also for the potential provision of additional calories from short-chain fatty acids.[7]

Motility abnormalities are also found following intestinal resection. Transit time is greater in the jejunum following ileal resection. Gastric emptying is also more rapid following ileal resection but can be normalized if the colon is retained.[8] Additional functional abnormalities may result with time, often owing to compensatory changes that occur within the gastrointestinal tract. Intestinal transit time may increase as the intestine adapts in an attempt to increase nutrient contact time with the small-bowel mucosa. Mucosal surface area will likewise increase as the small intestine dilates. Unfortunately, both of these changes result in increased bacterial content in the small bowel, which results in a variety of complications that will be subsequently discussed.

Fortunately, the intestine is capable of significant adaptation resulting in enhanced absorption with time. These changes significantly alter physiology in short-bowel syndrome.

DESCRIPTION OF THE ADAPTATION PROCESS

Intestinal adaptation is characterized by hyperplasia of the mucosal epithelium.[9–13] An increase in crypt cell production rate precedes mucosal hyperplasia and results in increased crypt depth and subsequent lengthening of the intestinal villi. As a result, some dilatation of the small intestine occurs with increased folding of the mucosa and subsequent increase in mucosal surface area. As the process is hyperplasia and not hypertrophy, growth in cell number rather than cell size predominates. This observation is evidenced by parallel increases in mucosal DNA, protein, and weight. Increasing length of intestinal villi necessitates an increase in the rate of migration of cells from the crypt up the villus and also an increased rate of cell renewal. Cell number is the primary determinant of villus and microvillus surface area.[14] Increased absorption of almost all nutrients has been demonstrated following completion of the adaptation process, mostly in animal studies.[15–18] Disaccharidase digestion, monosaccharide absorption, and absorption of trace metals, vitamins, fluids, and electrolytes all increase significantly following resection. Within 8 weeks in the rat, enhanced glucose-dependent electrogenic sodium transport can be measured using Ussing chamber techniques.[19]

Electron microscopic studies demonstrate little change in enterocyte ultrastructure after 60% proximal small intestinal resection. The general structure of the single enterocyte is preserved, and all subcellular organelles appear morphologically intact. Resected animals demonstrate some dilatation of intracellular spaces on the tips of the villi. Microvillus surface also decreases as a function of time after proximal resection. No significant difference in the relative areas of mitochondria, rough endoplasmic reticulum, and nuclei are seen as a function of time following resection.[20]

Functional improvement of absorption does not immediately follow an increase in absorptive surface area. Digestive enzymes such as lactase, sucrase, and maltase are often decreased in hyperplastic epithelium, suggesting some functional immaturity. Replicative enzymes such as thymidine kinase are often increased. This functional immaturity appears to change gradually with time as absorptive function improves.[15–18] However, functional adaptation appears to be a diverse process. Improved absorption of some nutrients occurs much more rapidly than that of others.[21] Substantial confusion exists regarding the extent of improvement in intestinal function, primarily because of differences in expressing the data from the animal studies.[22,23] Tissue preparations—such as intestinal sacs or rings, isolated enterocytes, or membrane vesicles—commonly suggest impaired absorption because data are most often expressed based on a parameter of mucosal mass, such as DNA, protein, or weight. However, the marked increase in mucosal mass that occurs following resection actually results in an increase in intestinal function. Whenever possible, data should be expressed per centimeter of small intestine or related to small intestinal absorptive surface in some other way. When calculations are performed in this way, intestinal function improves in nearly all studies.

Analysis of transport kinetics defines the functional changes in hyperplastic mucosa. No changes in Km occur, suggesting no alterations in thickness of the unstirred layer. However, V_{max} for several substrates may be reduced by 50% when the data are expressed per unit of mucosal surface area. Individual enterocytes in the hyperplastic epithelium are likely to contain fewer carrier proteins than are found in the physiologic state. Nonetheless, reduced enterocyte function is overcome by the larger absorptive surface area.[24,25] Digestive enzyme function may vary significantly. In one study, specific activity of sucrase appeared to increase, but lactase decreased following resection. Analysis of messenger ribonucleic acid (mRNA) suggested that sucrase changes were pretranslationally regulated, but the decrease in lactase activity was a post-translational event.[26] Unfortunately, most studies have been performed 2 to 3 weeks postoperatively in an experimental model. It is not known for certain whether further maturation of the absorptive function occurs with time, but clinical experience strongly suggests that it does.

Functional adaptation may also occur independently of villus hyperplasia.[27] Increased glucose uptake has been observed even in the absence of increases in intestinal mass.[28] Differences in adaptive rates of glucose as well as amino acids have also been measured. Administration of higher nutrient concentrations can cause adaptive changes in the small bowel without changing morphology. Carbohydrate content, when increased, may result in marked enhancement of glucose transport without changing villus architecture or mucosal mass. Normally, the proximal small bowel contains greater mucosal mass than the distal small bowel, and villus length is increased over the distal small intestine. Consequently, there is a proximal to distal gradient in the transport of several nutrients, especially glucose. However, the gradient in the case of glucose is much more pronounced than the gradient for intestinal mass, suggesting that there is a functional adaptive response to the high concentrations of glucose, which occurs independently of the effect of nutrients on jejunal morphology. These morphologically independent adaptive changes in transport appear to be nutrient specific. For example, a high-carbohydrate, low-protein diet results in enhanced glucose transport but reduced amino acid transport. Likewise, a high-fructose diet induces fructose absorption, whereas glucose absorption is not altered. Conversely, high-glucose diets will stimulate glucose transport independently of fructose transport.

These morphology-independent changes may occur quite rapidly.[29,30] Glucose transport may be increased within 1 to 3 days of a change in dietary carbohydrate. Comparable changes in morphology may take 1 to 3 weeks. Synthesis of transporters and brush border diges-

tive enzymes appears to occur rapidly in response to large quantities of intraluminal nutrients.

Animal studies, mainly in dogs and rats, have been used to develop most of our understanding of intestinal adaptation. In the rat, mucosal adaptation occurs rapidly. Cell replication increases in the crypt as early as within 24 to 48 hours.[1] Likewise, in the rat, the villus hyperplasia process is often nearly complete by 2 to 3 weeks. Little corresponding information is available in humans, although clinical experience suggests that the adaptive process proceeds more slowly. The adult patient with short-bowel syndrome is likely to reach potential much more rapidly than a child. Data from rats have demonstrated that 3-week-old rats have less potential for total adaptation than 8-week-old animals, probably because the smaller animals were already under enough stimulation just to meet their growth needs alone and had little potential to adapt beyond their natural capacity.[31] In old animals, the adaptive response occurs much more slowly, although the capacity to adapt remains intact.[32] In children, a substantial potential exists for lengthening of the small intestine. Because little lengthening is possible in adults, growth in bowel length can greatly enhance the prognosis in infants with short-bowel syndrome. Children with very short bowels have a great capacity to increase bowel length when resection is performed in the neonatal period.[33] Extensive linear growth is observed in the normal small intestine during the first year of life and continues somewhat more slowly beyond that point. It is not clear whether there is much opportunity to enhance linear growth beyond that which normally occurs over a given segment of bowel, however. Clinical experience has taught us that pediatric patients may not reach their full adaptive potential following neonatal small-bowel resection until the fifth year of life.

Although most data have been derived from animal studies, some data are available regarding functional adaptation in humans. In children, a marked increase in glucose absorption was observed following an extensive resection using intestinal perfusion technique. Sucrose hydrolysis was increased in the same proportion as glucose absorption. Also, studies of human children have demonstrated intestinal hyperplasia, that is, an increased number of enterocytes per unit length of villus and a suggestion of increased villus length, although not statistically significant.[34]

IMPORTANCE OF ENTERAL NUTRITION

Enteral nutrition is extremely important in stimulating intestinal adaptation. Atrophy has been observed in the small intestine deprived of nutrient contact either by bypassing the small intestine surgically or by using parenteral nutrition.[35] Intravenous feeding following small-bowel resection results in slight mucosal atrophy, whereas enteral nutrition stimulates mucosal hyperplasia. The mechanism by which nutrients stimulate adaptation is complex.

Nutrient contact with the intestinal epithelium stimulates adaptation. Jejunal villi are normally longer than ileal villi, probably because they are exposed to high concentrations of nutrients. Therefore, when a segment of ileum is transposed into the jejunum, ileal mucosal mass increases rather markedly to the point where the length of the villi and the transposed ileum may actually exceed the length of villi in the adjacent jejunum.[36] Therefore, high nutrient concentration in the jejunum appears to stimulate villus length. Ileal villi appear to be as sensitive to nutrient concentrations as jejunal villi. However, the length of the small intestinal villi also appears to be genetically regulated as grafts of fetal duodenum develop longer villi than grafts of fetal ileum even in the absence of the influence of intraluminal factors.[37]

Enteral nutrition is also important for stimulating regeneration of the mucosa following injury. The combination of parenteral and enteral nutrition is superior to parenteral nutrition in stimulating intestinal regeneration of disaccharidases in a group of patients with protracted diarrhea of infancy.[38] A more rapid resolution of malabsorption and diarrhea following enteral nutrition alone versus parenteral nutrition in the same disorder has also been observed.[39] Enteral nutrition is also important in maintaining mucosal mass. Maintenance of mucosal mass and glucose absorption has been demonstrated to be improved following enteral versus parenteral nutrition, apparently as a result of direct nutrient contact. Direct nutrient contact is also important in the maintenance of normal glucose transport.

Stimulation of nutrient-sensitive epithelial cell proliferation appears to be a complex process. Originally, increased nutrient content was thought to produce hyperplasia by providing increased nutrition to enterocytes. It is more likely, however, that trophic factors, secreted locally and acting through a paracrine mechanism, work to stimulate epithelial cell proliferation and reduce apoptosis carbohydrates.[40] Nonmetabolized substances that require active transport are just as capable of stimulating adaptation as glucose.[41] Functional workload, therefore, appears to be the major stimulus for intestinal adaptation. Certain enteral nutrients may be more effective stimulants than others, probably because they require greater energy for digestion and absorption or because they result in enhanced release of trophic hormones. For example, hydrolyzable disaccharides induce greater mucosal adaptation than constituent monosaccharides.[41] Hydrolysis of the disaccharide in conjunction with subsequent absorption of the monosaccharide components appears to exert a greater functional workload on the intestinal mucosa. Inhibition of the sucrase enzyme with acarbose can abolish the stimulatory effect of sucrose on adaptation by eliminating the functional workload of sucrose hydrolysis. Likewise, lactulose, a nonabsorbable, nonmetabolized carbohydrate, requires no workload from the intestine and exerts no stimulatory effect on mucosal hyperplasia.[42]

Enteral nutrition also appears to promote adaptation through the stimulation of secretion of trophic gastrointestinal hormones. Thiry-Vella fistula models have been extensively used to demonstrate these effects. Thiry-Vella fistulae have an intact blood supply, but as they are isolated from the flow of enteric contents, they have no exposure to intraluminal nutrients (Figure 45-1). Enteral feedings are capable of stimulating intestinal adaptation not only in the

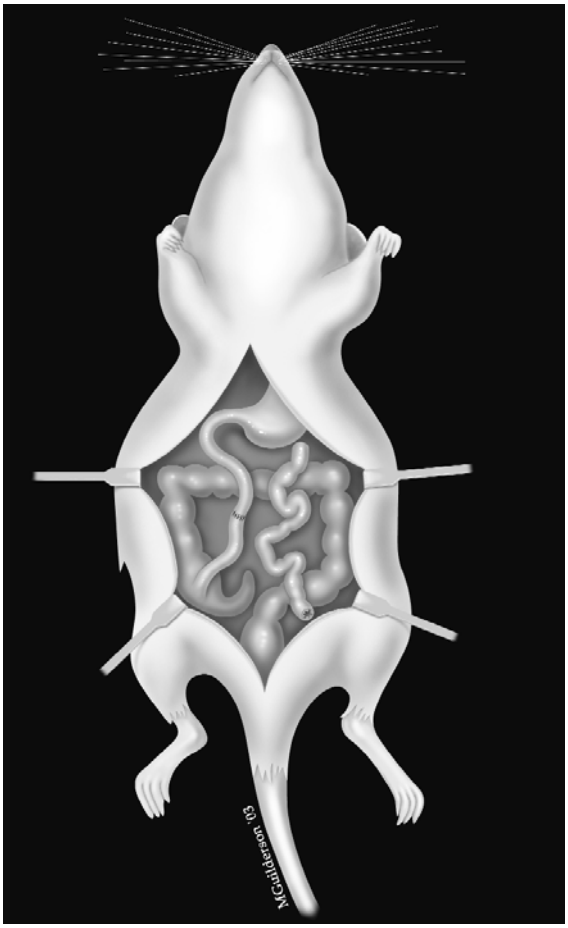

FIGURE 45-1 A Thiry-Vella fistula. A segment of distal jejunum and proximal ileum has been removed from continuity, its blood supply left intact, and ostomies created at both proximal and distal ends of the fistula.

small intestine but also in Thiry-Vella fistulae. Intravenous feeding, in contrast to enteric feeding, results in atrophy not only in the intact bowel but also in the Thiry-Vella fistula.[43] These findings are confirmed when mucosal mass in self-emptying blind loops is evaluated in animals receiving an 85% jejunoileal bypass in which mucosal mass markedly exceeds that in animals receiving only a 25% bypass. This observation suggests that the defunctionalized bowel responds to a greater adaptive stimulus produced from a reduction in the functioning small intestine.[44] Trophic gastrointestinal hormones circulating via the bloodstream appear to be an important means whereby intraluminal nutrients stimulate intestinal adaptation.

Additional evidence for this concept is derived from studies using parabiotic animals (Figure 45-2). In these experiments, one animal undergoes partial small-bowel resection. Blood is then cross-circulated between the two animals, and increased mucosal cell proliferation can be observed not only in the resected animal but also in its parabiotic partner.[45]

Intestinal adaptation can also be stimulated by increased production of gastrointestinal secretions. For example, transplantation of the ampulla of Vater into the distal small intestine may result in hyperplasia in the ileum in response to enteric feedings.[46,47] Pancreatic and biliary secretions entering the distal small bowel through the ampulla appear to stimulate villus hyperplasia. Diversion of pancreatic and biliary secretions into self-emptying ileal loops also induces villus hyperplasia.[48]

CANDIDATE TROPHIC HORMONES

At present, determination of hormones that regulate intestinal adaptation is an area of extensive research. Many hormonal mediators have been suggested (Table 45-1). Enteroglucagon, structurally similar to glucagon, has perhaps been studied most extensively. Patients with enteroglucagon-secreting tumors were initially found to develop massive mucosal hyperplasia, which resolved once the tumor was resected.[49] Therefore, the trophic effect of enteroglucagon in the small bowel became apparent. Enteroglucagon is known to be produced in highest concentration in the distal small intestine, which has the greatest potential for adaptation. Measurement of enteroglucagon levels and enteroglucagon mRNA levels reveals that they are increased following intestinal resection or jejunoileal bypass, situations in which mucosal hyperplasia is present.[50–52] Other studies have suggested that enteroglucagon may not play an important role in intestinal adaptation. Immunoneutralization of endogenous enteroglucagon by monoclonal antibodies does not obliterate the adaptive response.[53] Administration of enteroglucagon and glucagon to animals fails to stimulate mucosal hyperplasia.[54] In fact, the hormone appears to have antiproliferative properties when studied in an in vitro cell culture system.[53] Precursors to enteroglucagon have recently been demonstrated to be elevated following resection and may be the means through which enteroglucagon stimulates intestinal hyperplasia.[55] Ileal proglucagon mRNA levels rise rapidly following resection.[56]

Gastrin levels are also highly elevated following intestinal resection, and gastrin is a known trophic hormone to the stomach and proximal small intestine.[57,58] Hypergastrinemia appears to result in hyperplasia only in the very proximal small intestine, however, and is therefore not a likely candidate for regulation of the adaptation process. Neurotensin is found mainly in the central nervous system but is also present in the distal small intestine and appears to be an important regulator of intestinal motility. It has also been found to stimulate hyperplasia in the small intestine, although it may have a more important regulatory function in the growth of colonic mucosa.[59] Secretin and cholecystokinin have been shown to prevent mucosal hypoplasia when infused into parenterally fed dogs.[60,61] The effects of secretin, cholecystokinin, and neurotensin may all be explained by the stimulatory effect that these hormones have on pancreatic or biliary secretions.[62]

Epidermal growth factor (EGF), otherwise known as urogastrone, is a hormone that is present in breast milk and is known to stimulate proliferation of the intestinal epithelium. Its effects are most pronounced in the stomach, but it has been a recent candidate for involvement in the adaptation process.[63] It appears to stimulate ornithine decarboxylase,

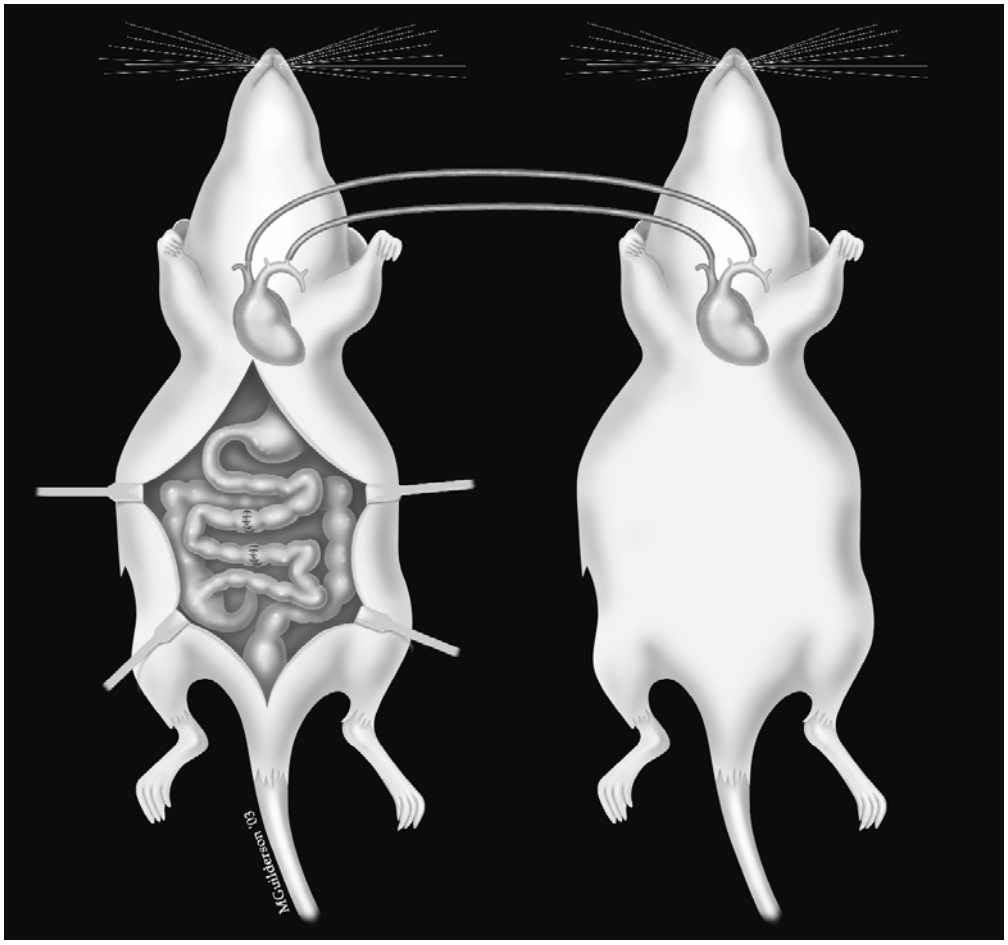

FIGURE 45-2 Parabiotic animals. Blood is cross-circulated between the two animals, one of which has undergone partial small intestinal resection.

important in polyamine synthesis, in the small intestine. Subsequent mucosal proliferation has been observed.[64] EGF receptors are present in the small intestine in high numbers, and this hormone is known to stimulate DNA synthesis.[65] High concentrations of EGF are found in the salivary and Brunner's glands, suggesting that EGF may exert its primary influence in the proximal small intestine. It may be important in maintaining normal mass in the physiologic state.

Insulin-like growth factor I (IGF-I) is a hormonal substance structurally similar to insulin. Also known as somatomedin C, this growth factor is responsible for many of the regulatory effects of growth hormone. Because plerocercoid growth factor, a growth hormone analog produced by a tapeworm, was shown to stimulate intestinal adaptation, the importance of growth hormone in regulating intestinal adaptation has received substantial interest.[66] Growth hormone itself has produced equivocal results, and studies showing a positive response in intestinal adaptation were hampered by the lack of control of nutrient intake.[67,68] Further studies using IGF-I and a truncated analog, des-IGF-I, in rats following small-bowel resection, however, demonstrated augmentation of the adaptation process.[69] Using a transgenic mouse model, further studies have demonstrated the importance of both IGF-I and growth hormone in regulating intestinal mass.[70] Studies in piglets demonstrated that colostrum, rich in IGF-I, had no benefits in inducing adaptation.[71] IGF-I appears to play a role in the adaptation process, perhaps independently of growth hormone.

Peptide YY may also be involved in intestinal adaptation. Elevation of peptide YY levels has been associated with enhanced adaptation produced by administration of menhaden oil. Concentrations of this hormone are markedly elevated in patients with short-bowel syndrome.[72] Because the hormone reduces gastrointestinal motility and also increases nutrient contact with the epithelium, peptide YY might potentially play a regulatory role in adaptation through its effect on motility. Additional factors of 4,500 and 1,500 daltons have also been identified that appear to

be associated with nutrient-induced gut adaptation.[73] Antitrophic hormones probably also exist. Transforming growth factor β-1 has been shown to induce stem cell quiescence in the intestinal mucosa of the rat.[74]

The most interesting trophic factor at the present time is glucagon-like peptide 2 (GLP-2). GLP-2 promotes nutrient absorption by expansion of the mucosal epithelium by stimulation of crypt proliferation and inhibition of apoptoses in the small intestine. GLP-2 also reduces epithelial permeability and decreases meal-stimulated gastric acid secretion in gastrointestinal motility. The specificity of GLP-2 in the intestine appears related to the highly localized expression of the GLP-2 receptor in the intestinal epithelium.[75] In rat models of intestinal adaptation, GLP-2 has been shown to induce morphologic adaptation.[76] In humans, GLP-2 has been shown to improve the intestinal absorption of energy and increased crypt depth and villus height.[77]

PROSTAGLANDINS

Prostaglandins may also play a role in regulating epithelial cell proliferation.[78] Prostaglandins have been shown to be trophic to numerous cell types, and inhibition of prostaglandin synthesis reduces the mitogenic effect of some gastrointestinal hormones.[79] In addition, 15,15-dimethylprostaglandin E_2 increases mucosal mass and intestinal length in rats. These effects are primarily present in the gastric antrum and very proximal small intestine. The 16,16-dimethylprostaglandin E_2 stimulates intestinal adaptation following resection.[80,81] Likewise, inhibition of prostaglandin synthesis using aspirin reduces the stimulatory effect of resection on intestinal mucosal mass, predominantly in the ileum.[81] Dietary arachidonic acid appears to facilitate the adaptation process by acting as a substrate for the synthesis of prostaglandins and not through derivatives of lipoxygenase, such as leukotrienes or thromboxanes.[82]

ROLE OF POLYAMINES

Polyamines are polycationic compounds present in all procaryotic and eucaryotic cells.[29,83] Putrescine is formed from the decarboxylation of ornithine by ornithine decarboxylase, the rate-limiting step in polyamine biosynthesis (Figure 45-3). Spermine and spermidine are subsequently synthesized. Ornithine carboxylase is present in low concentrations in resting and nondividing tissues. However, both the enzyme and polyamine concentrations are high in rapidly proliferating tissue such as the small intestinal epithelium.[84] Polyamines appear to be essential for normal cell growth and differentiation. Polyamine content increases during all proliferative states in the small intestine such as adaptive hyperplasia, recovery from mucosal injury, lactation, and poststarvation refeeding.[85–88] Ornithine carboxylase elevation is one of the earliest cellular events occurring following transition of epithelial cells from quiescence to active proliferation.[89]

Polyamines are known to stimulate mucosal hyperplasia. Blocking polyamine synthesis by ornithine decarboxylase reduces adaptation.[90] Likewise, blocking polyamine degradation using aminoguanidine increases intestinal adaptation.[91] In addition to the trophic effects, polyamines also appear capable of inducing maturation of sucrase isomaltase synthesis and sodium/glucose transport, probably mediated by both transcriptional and post-transcriptional events.[92] Unfortunately, using polyamines to stimulate adaptation may be difficult because of their short half-life. *Saccharomyces boulardii* has been shown to synthesize polyamines and, as such, might serve as a potential source of therapeutic polyamines. However, administration of *S. boulardii* to rats was not successful in inducing adaptation following small-bowel resection.[93]

POTENTIAL APPLICATIONS OF ADAPTATION

Dietary manipulation of the adaptation process has a major role in the treatment of short-bowel syndrome. Certain nutrients appear to be more capable of stimulating adaptation than others (Table 45-2). Most data evaluating the importance of various nutrients on stimulating adaptation have been obtained from experimental models, primarily in rats. Complex diets induce greater adaptation than elemental diets. This is likely because they demand a greater functional workload for assimilation.[94] When specific dietary components are evaluated, however, it appears that hydrolyzed protein appears to be more capable of stimulating adaptation than intact protein.[95] Two studies have demonstrated that long-chain fats are more trophic than medium-chain fats to the small bowel.[96,97] High-fat diets also appear to reduce starvation-induced mucosal injury more rapidly than diets high in carbohydrate or protein.[98] A higher percentage of long-chain triglycerides in the form of essential fatty acids may be of benefit when compared with formulas deficient in essential fatty acids as essential fatty acid deficiency appears to impair the adaptation process.[99] Menhaden oil, a highly unsaturated fish oil containing a high percentage of eicosapentaenoic acid, appears much more trophic to the small bowel than other fats, including safflower oil or beef tallow.[100] The beneficial effects of menhaden oil do not appear to be related to enteroglucagon but are associated with a small but signifi-

cant increase in peptide YY levels.[101] Other lipids may also be important in adaptation, including short-chain fatty acids. When added to parenteral nutrition solutions, atrophy is reduced. The addition of short-chain triglycerides to a chemically defined diet enhanced both jejunal and colonic adaptation compared with a control diet containing medium-chain triglycerides.[102] Mucosal atrophy associated with parenteral nutrition can likewise be reversed by administration of short-chain fatty acids.[103] Short-chain fatty acids may be useful to enhance intestinal adaptation following resection.[103]

Glutamine has received substantial interest in the treatment of a variety of gastrointestinal disorders primarily because of its apparent role in the nutrition of the small intestinal mucosa. Administration of glutamine reduces bacterial translocation in the small intestine and prevents mucosal atrophy in certain models. Intravenous glutamine also appears to have some trophic effect on the small intestine.[104] However, some studies have failed to demonstrate a trophic effect of glutamine even when used in pharmacologic concentrations.[105]

More recent evidence suggests that the use of glutamine and growth hormone may not be helpful in patients with short-bowel syndrome. The administration of glutamine and growth hormone in an experimental model appears to be effective in inducing adaptation but only when animals are maintained on parenteral nutrition and not given enteral feedings.[106] In another animal study, this time using supplemental enteral feedings, glutamine supplementation alone had no remarkable effects on bowel adaptation but appeared to enhance the supplemental beneficial effect of growth hormone.[107] However, in humans, growth hormone alone or in combination with glutamine with or without a low-fat diet demonstrated marginal, if any, benefit.[108] In a double-blind, placebo-controlled, crossover study in humans, no beneficial effects of oral glutamine and a high-carbohydrate, low-fat diet were observed.

Fiber may also enhance intestinal adaptation. Its effects are probably most important in the colon and are likely to be mediated through production of short-chain fatty acids. Pectin, when added to an elemental diet, improves adaptation in the jejunum, ileum, and colon following resection.[109–111]

COLONIC ADAPTATION

The colon also undergoes some adaptive changes following partial small-bowel or partial colon resection. If the right colon is removed, gradual improvement in sodium and water absorption occurs in the left colon.[112] In the rat, intestinal resection does not appear to alter absorption rates of sodium chloride and water in the cecum or colon, probably because of the large cecum present in the rat colon. Resection of the cecum in addition to massive small-bowel resection, however, results in a doubling of sodium and water absorption in the remaining colon. Growth of the cecum, therefore, appears to be an important compensatory mechanism in the rat following intestinal resection.[113]

The entire colon functionally adapts after small-bowel resection, but morphologic adaptation appears to occur only after massive resection of as much as 80%.[114] IGF-I appears to be important in colonic adaptation as well as small-bowel adaptation. IGF-I significantly enhances colonic mucosal growth and water absorption following resection and postresection up-regulation of colonic IGF-I mRNA. Alterations of the binding protein (BP) IGF-BP-3 and IGF-BP-4 mRNA expression have also been observed following small-bowel resection.[115] If a segment of colon is interposed into the small bowel, where it is exposed to higher concentration of undigested nutrients, some studies have even suggested that the colon is capable of assuming some small intestinal function. The exact extent of such adaptation, as well as whether it actually occurs, is controversial.[116] As in the small intestine, both glucose and glutamine can be used by colonic epithelial cells through the glycolysis pathway. However, the short-chain fatty acid butyrate can be used equally as well for fuel for colonocytes. Its oxidation does not appear to be adversely affected by either glucose or glutamine.[117] Fiber may therefore be an important fuel in short-bowel syndrome not only because of the trophic effect of short-chain fatty acids but also because of the importance of short-chain fatty acids for fuel for colonocytes.

CLINICAL MANAGEMENT

Parenteral Nutrition

Clinical management (Table 45-3) of patients with short-bowel syndrome is best considered in stages.[1,118–120] Initially, total parenteral nutrition is used for a short period of time to stabilize fluid and electrolyte status. The immediate postoperative period is characterized by a transient ileus, and all nutrients must be given parenterally. Patients then develop large-volume fluid and electrolyte secretions once the ileus resolves, and gastric fluid and ostomy losses may be high. Because these losses may vary significantly with time, placing the patient on a standard parenteral nutrition solution containing all appropriate macro- and micronutrients and normal concentrations of fluid and electrolytes for metabolic needs is often optimal. Excessive fluid losses from gastric tubes, gastrostomies, and diarrhea or ostomy fluid losses can then be replaced based on the electrolyte content of these secretions as determined in the laboratory. It is preferable to measure the volume of these secretions and replace them every 2 hours using a separate fluid and electrolyte solution. Losses tend to be high in sodium content, and solutions with at least 80 to 100 mEq/L of sodium are often required to maintain fluid

TABLE 45-3 Clinical Management of Short-Bowel Syndrome

Parenteral nutrition
Correct fluid and electrolyte losses
Replete nutritional deficiency states
Enteral nutrition
Slowly convert from parenteral to enteral nutrition
Use elemental diet containing adequate long-chain fats
Administer by continuous enteral infusion
Gradually increase enteral, decrease parenteral nutrition as tolerated
Dietary therapy
Reduce osmolality
High fat
High protein
Low carbohydrate
Provide macro- and micronutrients
Compensate for malabsorbed nutrients
Treat complications
Total parenteral nutrition liver disease
Push enteral feedings
Minimize infections and bacterial overgrowth
Bacterial overgrowth
Nutritional deficiency states
Monitor micronutrient, fat-soluble vitamin levels
Monitor success of therapy
Remember that not all supplements will be absorbed
In case of failure, consider transplantation or supplemental surgical procedures

and electrolyte homeostasis. As ostomy losses decrease, fluid replacement is reduced accordingly. The use of dual pumps, one for parenteral nutrition and the other for replacement solutions, may seem cumbersome, but a reduction in the wastage of parenteral nutrition solution and the reduced need for laboratory monitoring will compensate for the additional expense.

The first stage of therapy is also the time to replete any nutritional deficiency states that may have existed at the time of resection. In small infants, adequate nutritional therapy may have been delayed because of the transient ileus or poor gastrointestinal motility. Deficiencies in energy stores are not uncommon, and protein stores may be compromised as well. In older children, resection may have resulted from the preexistence of bowel disease, such as Crohn's disease, and unless preoperative management was optimal, a variety of macro- and micronutrients may well be deficient. Consequently, nutritional assessment and appropriate repletion of nutritional deficiencies remain an important early goal in the management of short-bowel syndrome.

Initiation of Enteral Nutrition

When fluid and electrolyte losses have decreased, a continuous enteral infusion is initiated. Most commonly, elemental diets are used in this setting.[121,122] Usually, these are started slowly, and the concentration is rapidly increased to 0.67 kcal/mL in infants or 1 kcal/mL in children and adults. Once this is done, the volume of enteral feedings can then be gradually increased as the volume of parenteral feedings is decreased. Initial advancement of concentration rather than rate of enteral feeding solution allows the transition from parenteral to enteral feeding to be conducted without overloading the patient with fluid.

Continuous enteral infusion is gradually advanced based on several parameters. A marked increase in stool loss by more than 50% is usually a contraindication to advancing enteral feedings. Likewise, stool losses greater than 40 to 50 mL/kg/day or ostomy output strongly positive for reducing substances suggests that enteral feedings should not be advanced. In patients with an intact colon, a decrease in stool pH below 5.5 is frequently indicative of carbohydrate malabsorption. Further advancement of enteral feedings is likely to result in a significant increase in osmotic diarrhea in such patients, and a delay in advancement is usually indicated.

The use of continuous enteral infusion in short-bowel syndrome is usually advantageous to the patient because feedings are frequently better tolerated in this fashion, permitting a greater percentage of total nutrition by the enteral route. Emesis is likewise reduced.[1] When continuous enteral infusion is used, carrier proteins are continuously saturated and intestinal function is optimized. The increased enteral calories also give one the opportunity to increase the functional workload of the small intestine, resulting in additional stimulation of intestinal adaptation. Administration of extra calories through the enteral route reduces the need for parenteral nutrition and thereby reduces the risk of parenteral nutrition liver disease, the major cause of morbidity and mortality in short-bowel syndrome.

Despite the inconvenience of enteral feeding, portable pumps and backpacks permit children with short-bowel syndrome to have reasonable mobility even if they are receiving their continuous enteral feedings 24 hours a day. Solids can also be initiated while patients are on continuous enteral feeding. If nasogastric tubes are in place, solids can be fed around the nasogastric tube without difficulty. Small bolus feedings are often tolerated well in these patients. Institution of solid feedings at the usual time and continued administration of small bolus feedings at least two or three times a day are important. They teach the infant how to suck and swallow and lessen the likelihood of feeding difficulties once tube feedings are discontinued.

The appropriate solids to give initially to patients with short-bowel syndrome are a matter of controversy. Tradition has suggested the use of high-carbohydrate diets. High-carbohydrate diets, however, are broken down rapidly to small molecules, creating an osmotic load in the small intestine and resulting in excessive fluid secretion. This is especially true in patients with ileal resections, in whom the jejunum is susceptible to fluid losses from osmotic overload. Feeding fats or proteins that are broken down to larger molecules and create less osmotic load results in less fluid loss. In addition, the role of fat as a trophic agent to the small intestine is another reason why the early introduction of fats is important. Recent data in experimental animals have demonstrated that (low-fat) diets actually result in reduced ability to transport lipids and that low-fat diets induce significantly lower final body weight in plasma lipids when compared with normal diets.[123] Consequently, patients may benefit from being given meat as their initial solid, and once some degree of tolerance has been achieved, the diet can

be expanded. Simple sugars, especially in high volumes or concentrations, should still be avoided because of the osmotic load.

Enteral Formulas

Patients with short-bowel syndrome are normally given elemental or chemically defined diets.[121,122,124] Truly elemental diets are not available for pediatric use. It is actually difficult to define what is meant by elemental diets. Normally, these are considered to be diets that contain amino acids rather than peptides. However, most protein is absorbed in the form of di- and tripeptides, so the concept of an elemental diet can probably be extended in pediatrics to the predigested partially elemental formulas known as extensive protein hydrolysates, available from several manufacturers. The most common protein source in North America is hydrolyzed casein. Carbohydrates are usually present from one or more sources, including partially hydrolyzed starch and disaccharides such as sucrose. A mixture of medium- and long-chain fats is included. Adult elemental formulas are usually inappropriate in pediatrics as they may be deficient in vitamins, minerals, and essential fatty acids. They also tend to be high in carbohydrate content and therefore are more likely to result in osmotic diarrhea. These formulas can be modified somewhat if a pure amino acid formula is desired or needed in infants because of protein allergy or intolerance. Addition of extra vitamins, minerals, and fats may permit their use in pediatrics with little difficulty.[122,124] In addition, increased fat content in pediatric formulations may be beneficial because of the stimulatory effect of fat on adaptation in the small intestine. Long-chain fats are more trophic to the small intestine than medium-chain fats (Figure 45-4). Furthermore, highly saturated fats derived from fish oil may prove to be even more effective in stimulating intestinal adaptation (Figure 45-5).

Commercially available protein hydrolysate formulas containing a mixture of medium- and long-chain fats are ideal for use in small infants with short-bowel syndrome. Examples include Alimentum (Ross, Columbus, OH) and Pregestimil (Mead Johnson, Evansville, IN). Both are relatively high in fat content, reducing the osmotic load in the small intestine. Both formulas contain substantial amounts of long-chain fats, important for their trophic effect. In older infants and toddlers, fiber-supplemented complex formulas may be instituted as they produce a firmer stool, and fiber, through its effect on short-chain fatty acid production, may also play a role in maximizing intestinal adaptation. (For enteral formulas, see the Appendix.) Newer formulas containing amino acids as a protein source and also a high percentage of fat are now available (Neocate, SHS; Elecare, Ross). Although they do not confer any absorption advantage, their added hypoallergenicity may be important, especially in small infants.

Advancing Enteral Nutrition

As parenteral nutrition is decreased and enteral nutrition is increased, intermittent parenteral nutrition can be used. The patient is given the parenteral portion of his nutrition over an 8- to 16-hour period each day. It is important to institute these changes in the hospital before the patient is discharged as intermittent parenteral nutrition improves the patient's freedom in the home and makes care much easier.[121,125–127] In small infants, parenteral nutrition may be required for the greater part of the 24-hour day, but soon the interval "off" parenteral nutrition can gradually be increased as the patient's tolerance of enteral calories increases with age. This is often a gradual change, taking several months to years. As tolerance improves, the rate of enteral administration is increased, and the duration of parenteral nutrition is decreased until the patient can be taken off parenteral nutrition for one or more nights per week. Changes should be

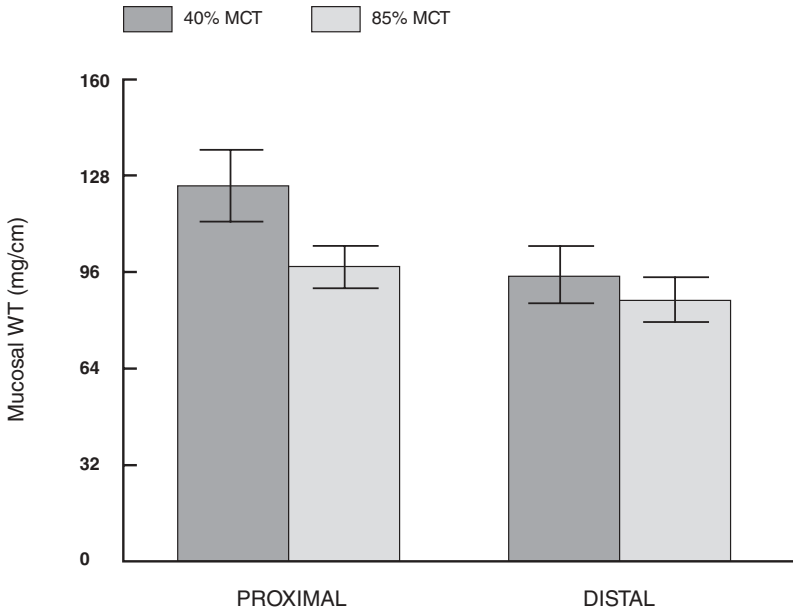

FIGURE 45-4 Mucosal weight in rats fed diets containing either 40% or 85% of their total lipid concentration as medium-chain triglycerides (MCT) for 3 weeks following 85% jejunoileal resection.

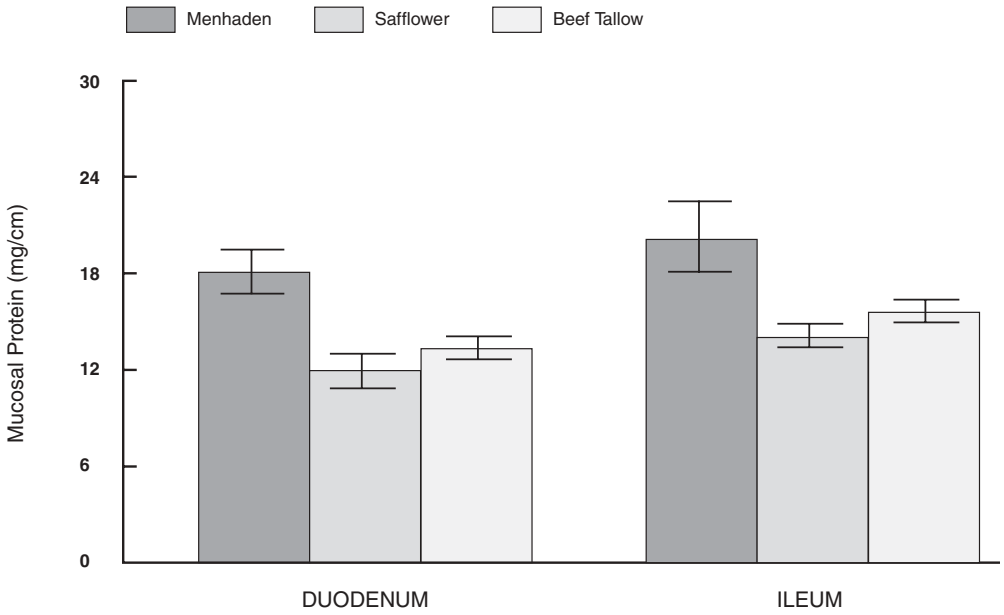

FIGURE 45-5 Mucosal protein concentration in rats fed menhaden oil, safflower oil, or beef tallow for 3 weeks following 85% jejunoileal resection.

isocaloric as the caloric density of the parenteral and enteral solutions may differ. Caloric changes are gradually increased, based on the child's growth needs, to ensure that the child parallels the 50th percentile for both height and weight. Excessive caloric administration is often a problem at this stage of management as the child is incapable of regulating his/her own nutrient intake. The physician must carefully monitor the child's growth to make certain that the patient's weight gain is appropriate for length.

Fluid losses are often substantial during early stages of short-bowel syndrome management. Ostomy output may have sodium concentrations of 80 to 100 mEq/L. The enteral diets may be diluted with oral electrolyte solution and the rate of administration increased accordingly to replace these losses and simplify patient management as well as improve absorption.[128] In the absence of small-bowel bacterial overgrowth, the antimotility agents, such as loperamide, may occasionally be useful in slowing intestinal transit and increasing fluid and nutrient retention. Long-acting release intramuscular octreotide has also been shown to be efficacious in this situation but is not commonly used.[129]

Early in the course of therapy, preparations for home parenteral nutrition should be made. Home parenteral nutrition reduces the cost of long-term management in patients with short-bowel syndrome and decreases family stresses and nosocomial infections. It has now become the standard of care in patients with short-bowel syndrome, and prolonged hospitalizations are rarely necessary, except for complications that may arise.

CHRONIC COMPLICATIONS

Managing the many chronic complications in short-bowel syndrome is difficult. Many of these complications result from parenteral nutrition, such as catheter-related problems, sepsis, and total parenteral nutrition liver disease. Others, such as bacterial overgrowth and micronutrient deficiency, may be more problematic after parenteral nutrition has been discontinued.

Bacterial Overgrowth

One of the least-recognized complications of short-bowel syndrome, but also one of the most treatable, is bacterial overgrowth. Bacterial overgrowth is considered to occur when bacterial content increases in the small intestine above normal levels.[130] Normal bacterial counts vary from 10^3 proximally to much higher concentrations in the distal small intestine. Gastric acid and bile normally limit the number of bacteria that can successfully colonize the small intestine. Bacteria are normally eliminated from the small intestine through a combination of antegrade peristalsis and mucosal immune factors. However, in short-bowel syndrome, many of these factors are disrupted. Anatomy may be abnormal, and motility is frequently impaired. Bacterial content of the proximal small intestine uncommonly exceeds 10^5. When motility is slowed, the bowel is dilated, and the ileocecal valve is absent, one can predict that bacterial overgrowth is present. Reduction in gut-associated lymphoid tissue following resection may also impair the immune response in short-bowel syndrome.[3]

Most commonly, the bacteria present are facultative organisms and a variety of anaerobic bacteria. These bacteria deconjugate bile salts, and this results in rapid reabsorption of bile acids, which depletes the bile salt pool. Micellar solubilization is therefore incomplete, and steatorrhea and malabsorption of fat-soluble vitamins result. Bacterial overgrowth also results in mucosal inflammation, which can impair adaptation and further exacerbate nutrient malabsorption. Additionally, bacterial over-

growth may compete with the host for vitamin B_{12} and perhaps other nutrients. Bacterial overgrowth symptoms include bloating, cramps, diarrhea, or gastrointestinal blood loss. When these symptoms are observed in patients with seemingly adequate gut length, bacterial overgrowth should be considered in the differential diagnosis. Bacterial overgrowth should also be considered when previously stable patients with short-bowel syndrome begin to deteriorate or lose weight.

Diagnosis of bacterial overgrowth, by definition, is based on the demonstration of increased bacterial content in the small intestine. This is usually assessed by aspiration of the small intestine and culture of the fluid. However, these techniques are often cumbersome, difficult to perform, and unreliable. Consequently, screening for bacterial overgrowth is helpful and, today, is most commonly performed through the use of breath hydrogen determination. Markedly elevated fasting breath hydrogen levels or a rapid rise in breath hydrogen following oral administration of glucose (2 g/kg up to a maximum of 50 g) suggests bacterial overgrowth. If the patient has rapid transit through the small intestine, rapid entry of the malabsorbed glucose into the colon may falsely elevate breath hydrogen content. Additional screening studies that are useful include urine indican and serum D-lactate. Small-bowel biopsies demonstrating inflammatory changes with no other apparent cause often suggest bacterial overgrowth. This occurs especially when the small intestine is dilated, motility is poor, or partial obstruction is present.

Additional complications of bacterial overgrowth include D-lactic acidosis and small-bowel colitis. D-Lactic acidosis results because bacteria are capable of producing both D- and L-lactate, but humans metabolize only D-lactate poorly. Lactic acid is produced in both forms from the malabsorbed carbohydrate, and D-lactate accumulates in the blood, resulting in neurologic symptoms varying from disorientation to frank coma.[131,132] Bacterial overgrowth also causes colitis or ileitis. Large ulcerations similar to Crohn's disease may be present. No granulomas are identified, however.[133] Arthritis or other rheumatologic symptoms occasionally occur in these patients, suggesting that the disorder may be immune complex related, possibly to absorbed bacterial antigens.[134,135] Occasionally, this complication responds to antimicrobial therapy, although sulfasalazine or more aggressive immunosuppression is often required. A short course of corticosteroids may produce marked improvement in patients with enterocolitis induced by small bowel bacterial overgrowth.

Treatment for bacterial overgrowth should be initiated with broad-spectrum antibiotics. These are initially given intermittently, usually the first 5 days of each month (Table 45-4). Oral metronidazole, 20 mg/kg/day, either alone or in combination with trimethoprim/sulfamethoxazole, is frequently effective. Oral gentamicin may also be used. It is minimally absorbed and well tolerated. Several other combinations are also helpful. Refractory patients may require continuous antibiotic therapy, and in this event, antibiotics may be rotated periodically to prevent overgrowth with resistant organisms. Need for rotation is variable but is often necessary every 2 to 3 months.

In some children, absence of an ileocecal valve results in severe overgrowth in the distal small intestine. This complication increases as children age, are capable of controlling their bowel movements, and attempt to defecate less frequently. Voluntary defecation several times a day can be encouraged in such patients, and clinical improvement may result. If not, daily saline enemas or, occasionally, enteral lavage with polyethylene glycol solutions are required to reduce bacterial content. Antimotility agents such as loperamide may exacerbate bacterial overgrowth and may be contraindicated for patients in whom gastrointestinal motility is already delayed. In the absence of bacterial overgrowth, such agents may be helpful in improving nutrient contact with the mucosa and may actually improve absorption.

Watery Diarrhea

Excessive fluid secretion frequently occurs in short-bowel syndrome. Often, it is simply a matter of excessive osmotic fluid load in the small intestine, usually as a result of excessive carbohydrate administration. This complication occurs more frequently with bolus than with continuous enteral feeding. Elevated serum gastrin levels, which are often present in patients with short-bowel syndrome, may occasionally result in secretory diarrhea and may respond to histamine$_2$ receptor antagonists. This form of therapy is usually disappointing, and, in our experience, this complication is rare. Somatostatin analogs have been used in a limited number of short-bowel patients with secretory diarrhea, with varying results.[135–137] Subjects often improve initially, but the favorable response is usually transient.[138] Cholestyramine is sometimes helpful in short-bowel syndrome with watery diarrhea. Cholestyramine binds bile acids, and as bile acid concentrations are increased in the colon following ileal resection owing to bile acid malabsorption, secretory diarrhea may occur. However, in the case of massive ileal resection, patients may have bile acid deficiency, which may be exacerbated by cholestyramine through binding of the few available bile salts left to facilitate fat absorption (Table 45-5).

Nutritional Deficiency States

Once patients are free of parenteral nutrition, they are subject to a wide variety of nutritional deficiency states.

The compromised intestinal function becomes a major problem in ensuring adequate nutrient stores. Usually, macronutrients such as carbohydrates, fats, and proteins can be absorbed in adequate quantities. Micronutrients, including trace minerals and vitamins, are often less well absorbed and are more likely to become deficient. Malabsorption of fat-soluble vitamins, especially A, D, and E, is common. Trace metal deficiencies are likely to occur, with iron and zinc being most common. A low serum zinc level, especially in association with a low serum alkaline phosphatase, suggests zinc deficiency. Zinc deficiency may result in poor growth as well as impaired intestinal adaptation. The typical clinical picture may include acrodermatitis enteropathica, with crusting rash around the eyes, nose, mouth, and anus and loss of hair. Both zinc and serum alkaline phosphatase levels are commonly low, and the syndrome usually responds to supplemental oral zinc.[139] Selenium absorption may also be impaired.[140] Low serum levels of calcium and magnesium are also frequently observed. Extra vitamin D and calcium may correct the calcium deficiency, but magnesium deficiency is more difficult to treat. Enterally administered magnesium salts often result in osmotic diarrhea, although some magnesium salts are better tolerated than others.[141]

Evidence of bony demineralization radiographically merits careful attention to vitamin D status as well as appropriate calcium and phosphorus administration, remembering that significant malabsorption of all vitamins and minerals is likely and that, occasionally, enteral repletion of all of these nutrients may be difficult, if not impossible. Occasionally, the supplemental parenteral vitamins, minerals, micronutrients, and even fluid may be required even if the patient is able to absorb enough calories and protein to meet growth needs.

The ileum is solely responsible for bile acid and vitamin B_{12} absorption, and following ileal resection, patients should be monitored carefully for vitamin B_{12} deficiency. Parenteral administration of vitamin B_{12} may be required every 1 to 3 months. Vitamin B_{12} deficiency may take years to develop, and periodic attention to this possibility is required.

Parenteral Nutrition Liver Disease

The major cause of death in children with short-bowel syndrome is parenteral nutrition liver disease. This disorder is common in children receiving long-term parenteral nutrition. The incidence increases in inverse proportion to age; therefore, it is more common in small infants.[2–4,6] There is much argument about how parenteral nutrition induces liver injury. Toxicity of amino acids, competition of amino acids with bile acids for transport across the canalicular membrane, production of toxins in the underused bowel, excess nutrient administration, toxic substances in parenteral nutrition solutions, and nonstimulation of gastrointestinal hormones that normally control biliary secretions have all been postulated. However, aggressive use of enteral feedings, in the hope of ensuring at least 20 to 30% of the total daily caloric intake through the enteral route, prevention of bacterial overgrowth in the small intestine, and reduction in catheter-related sepsis all appear to be helpful in reducing the risk of parenteral nutrition liver disease (Table 45-6). The newer parenteral nutrition solutions, especially designed for infants, are less likely to produce liver disease.

TABLE 45-5 Effects of Bile Salt Malabsorption

Mild
Secretory diarrhea
Severe
Fat malabsorption
Loss of calories
Loss of fat-soluble vitamins

Biliary disease may also occur in children on parenteral nutrition.[142] Twenty percent of infants receiving parenteral nutrition may develop cholelithiasis. This appears to be a multifactorial problem resulting from a combination of malabsorbed bile acids, altered bilirubin metabolism, and gallbladder stasis. In some centers, early cholecystectomy is advocated for patients on long-term parenteral nutrition.[142]

Catheter-Related Complications

Complications related to chronic indwelling central venous catheters occur frequently in patients with short-bowel syndrome.[143] In one series, central venous catheter replacement was needed a mean of every 200 days, with septic episodes typically occurring more frequently than once per year. Complications appear to be higher in infants less than 1 year of age. Catheter thrombosis is also a common problem. Central venous catheter infections appear to result from either poor catheter care or bacterial overgrowth, with subsequent seeding of the catheter from the blood with gut bacteria. Most catheter infections in children appear to be related to poor catheter care, even when the infections are caused by enteric organisms. A careful analysis of catheter techniques should always be the first step in evaluating patients with frequent central venous catheter infections.

SURGICAL ALTERNATIVES

Patients with short-bowel syndrome, especially those with bacterial overgrowth, may have anastomotic strictures. Further resection of an already shortened small intestine may be avoided by using a tapering enteroplasty, stricturoplasty, or serosal patching.[144] Bacterial overgrowth may be reduced through such procedures, and normal flow of luminal contents through the small intestine may resume. Occasionally, dramatic clinical improvement will occur following such procedures, especially if bacterial overgrowth has been clearly demonstrated.

Several procedures have been designed to slow intestinal transit.[145–150] These include reverse segments of small bowel or colon interposed to slow delivery of nutrients through the small intestine and creation of valves that produce a partial obstruction to disrupt the normal flow of contents through the small intestine. Unfortunately, these

Prevention of bacterial overgrowth

procedures produce an increase in bacterial overgrowth. They are usually contraindicated in patients with preexisting bacterial overgrowth, in which case, they will do more harm than good. It is unlikely that they will be of much benefit in children with short-bowel syndrome.

Increasing the length of the small intestine through the use of the intestinal lengthening or Bianchi procedure is helpful in a subgroup of patients with short-bowel syndrome.[151–157] In this procedure, the bowel is transected longitudinally, preserving the blood supply to both sides of the small intestine. A segment of bowel is thereby created that is twice the length and half the diameter of the original segment. The procedure should be performed only if the small intestine is dilated. It allows reduction of the diameter of the dilated bowel without loss of surface area and consequently reduces bacterial overgrowth. It should be considered primarily as a means of reducing bacterial overgrowth without loss of intestinal surface area. However, through progressive dilatation, an eventual increase in absorptive surface area results. In one series of 13 pediatric patients, marked improvement in absorptive capacity as measured by decreased parenteral nutrition and fluid requirements was achieved in most.[158] Although the procedure is successful only in the jejunum and the ileum, attachment of the antimesenteric side of the small intestine to the liver or abdominal wall may be performed. Vasculature will then grow into the bowel from the surface, and the small intestine can be divided laterally. This has been partially successful in at least one patient.[159]

Advances in parenteral nutrition and long-term management have made it possible for some children with under 15 cm of small intestine to survive and to eventually become independent of parenteral nutrition. Although the presence of an ileocecal valve markedly improves prognosis, some of these children have survived massive resection and adapted well, even in the absence of an ileocecal valve. As a general rule, patients with greater than 25 cm of small intestine at the time of neonatal resection who have an ileocecal valve or those with greater than 40 cm of small intestine at the time of neonatal resection who do not have an ileocecal valve have a reasonably good prognosis. In such instances, it is at least possible that the patient could eventually become independent of parenteral nutrition.[2–4,6,160] However, these numbers apply only to patients resected in the neonatal period, probably because substantial linear growth in the small intestine occurs during the first few months of life. Application of these numbers to older children results in excessive optimism. Ultimately, predicting the outcome in patients following a massive resection is difficult.[153–161] A recent multivaried analysis suggested that only residual small-bowel length was a significant predictor of the duration of parenteral nutrition in short-bowel syndrome. However, the study suggested that the use of breast milk or amino acid–based formulas might also play a role in accelerating adaptation.[162] The beneficial effects of amino acid formulas suggested the possibility that allergic inflammatory changes might play a role in prolonging the need for parenteral nutrition in some short-bowel patients.

Despite aggressive treatment of bacterial overgrowth, aggressive enteral feeding to stimulate adaptation, and the appropriate use of intestinal lengthening procedures and other forms of surgical therapy, many patients will never become independent of parenteral nutrition. If a resection is performed in a neonate, and that patient is still dependent on parenteral nutrition beyond 4 or 5 years of age, ultimate success without parenteral nutrition is unlikely. Parenteral nutrition is expensive, averaging about $100,000/year and frequently costing much more.

TRANSPLANTATION

To date, several hundred bowel transplantations have been performed, predominantly combined liver/bowel transplantations and isolated intestinal transplantations,[163–168] Presently, post-transplantation 1- to 2-year survival is better than 70%, with intestinal graft survival long term slightly better than 50%. Infection appears to be a greater problem in patients with small-bowel transplantation than in those with liver transplantation and is especially common in patients with combined liver/bowel transplantation. Apparently, the breakdown of the intestinal mucosal barrier during episodes of allograft dysfunction and rejection contributes to the recurring infection problem. Translocation of bacteria and fungi into the bloodstream is likely to remain a significant problem.

The key to success with intestinal transplantation appears to be aggressive immunosuppression. However, increased need for immunosuppression raises concern about the development of post-transplantation lymphoproliferative syndrome. This malignancy is related to the Epstein-Barr virus and is a significant problem following intestinal transplantation. It may respond to a reduction or cessation of immunosuppression, but loss of the graft is common following a reduction in immunosuppression.

The value of intestinal transplantation is now more defined. Intestinal transplantation is now considered appropriate for a subset of children with intestinal failure who remain dependent on parenteral nutrition and are likely to develop life-threatening complications arising from this therapy. Such life-threatening complications include parenteral nutrition–associated liver disease, recurrent sepsis, and threatened loss of central venous access.[169] Concern persists regarding post-transplantation lymphoproliferative syndrome, late-onset complications including rejection and other malignancies, and infectious complications. Greater experience should be sought before recommending this procedure for patients who are otherwise stable on parenteral nutrition (Table 45-7). The combined liver/bowel transplantation appears to be a potential option in patients with irreversible total parenteral nutri-

tion liver disease, and because of donor shortage, patients should be referred for transplantation once liver disease is considered irreversible. Preliminary experience suggests that isolated intestinal transplantation may have a more benign course and should probably be considered as a possibility at the early onset of liver disease to avoid a combined liver/bowel transplantation.

In children with intestinal failure associated with short-bowel syndrome and complicated by liver failure from parenteral nutrition, isolated orthotopic liver transplantation may occasionally be indicated.[170] This should be considered only in carefully selected children who have developed parenteral nutrition–induced liver disease who have not had an adequate trial of aggressive attempts to adapt to enteral feeding and who appear to have an adequate length of remaining small intestine without underlying bowel disease. Here, isolated orthotopic liver transplantation may be performed and followed by aggressive use of enteral nutrition to induce adaptation in the remaining gut. A recent report has suggested that a majority of such patients can be successfully weaned from parenteral nutrition without recurrence of the liver injury. This, therefore, avoids the much greater risk of complications associated with intestinal transplantation relative to isolated liver transplantation. In adults, a few cases of isolated ileal segment transplantation have been reported with what appears to be a reduced risk of rejection. However, ethical considerations have limited the usefulness of these patients and should probably not be attempted in children.[171]

With aggressive nutritional therapy, most patients with short-bowel syndrome do well. Careful attention to detail and monitoring for nutritional deficiency states and bacterial overgrowth are important factors in success. Surgical procedures, such as intestinal lengthening procedures, are helpful in a few patients, and in those for whom no other option exists, intestinal transplantation may offer a viable long-term alternative. Therefore, short-bowel syndrome should not be considered a fatal disorder as once was the case.

CHAPTER 46

THE CRITICALLY ILL CHILD

Patrick J. Javid, MD, Tom Jaksic, MD, PhD

Critical illness and surgical intervention in the pediatric patient are associated with a set of metabolic changes that are profound yet predictable. Over a half century ago, Sir David Cuthbertson described the fundamental aspects of this metabolic response to injury in the adult.[1] Research regarding the pediatric stress response has shown that although neonates and children share similar qualitative metabolic sequelae to illness with adults, significant quantitative differences exist.

An understanding of the metabolic events that accompany critical illness and surgery of the child is the first step in implementing adequate nutritional support. The goal of nutritional support therapy in this setting is to augment the short-term benefits of the pediatric stress response while minimizing the long-term harmful consequences. Ultimately, an individualized determination of nutrient requirements must be made to provide appropriate nutrients.

METABOLIC RESPONSE TO CRITICAL ILLNESS: AN OVERVIEW

Children, similar to adults, rely on the metabolic breakdown and transfer of protein, carbohydrates, and lipid to meet the catabolic demands of critical illness. Figure 46-1 illustrates the basic pathways involved in the pediatric metabolic response. In general, the metabolic stress response is characterized by an increase in net muscle protein degradation and enhanced movement of the free amino acid products through the circulation. These amino acids serve as the building blocks for rapid synthesis of proteins that act as inflammatory mediators for tissue repair and the inflammatory response. Remaining amino acids not used in this way are channeled through the liver, where their carbon skeletons are used to create glucose through gluconeogenesis. Although the catabolism of muscle protein is an effective short-term adaptation for the child, it is of limited duration and potentially damaging owing to reduced body stores.

Carbohydrate and lipid turnover is also increased several fold during the pediatric metabolic response. Although these metabolic alterations would be expected to increase overall energy requirements, recent data show that any increase is variable and far less than originally proposed. Overall, the energy needs of the critically ill child are governed by the severity and persistence of the underlying illness.

Finally, a unique hormonal and cytokine profile is found in the child with critical illness. Such patients demonstrate an elevation in serum levels of insulin, the catabolic hormones (glucagons, cortisol, catecholamines), and specific cytokines known to interact with the inflammatory process. Current research in this field is focused on ways to manipulate these hormonal and cytokine alterations to minimize the deleterious consequences induced by the stress response itself.

BODY COMPOSITION AND METABOLIC RESERVES

Table 46-1 outlines the macronutrient metabolic reserves of the neonate, child, and adult patient in terms of the percentage of total body weight.[2–4] The most striking difference in body composition between the adult and child is the quantity of protein in reserve and available at times of illness. As a percentage of body weight, the protein stores of adults are nearly twice those of the neonate. In contrast, carbohydrate stores remain constant and do not afford significant reserve at any age. Lipid concentrations are low at birth and increase gradually during development; premature infants have even lower proportions of stored lipid at birth.

In addition to the reduced macronutrient reserves in the child, both neonates and children have much higher baseline requirements. The resting energy expenditure for neonates is up to three times that for adults when standardized for weight.[5,6] This inverse relationship between energy expenditure and body weight is constant throughout mammalian species and is partially related to body surface area. The recommended protein and energy requirements of the healthy neonate, child, and adult can be found in Appendix 2. The protein requirements of the full-term neonate are nearly three times that of the adult. Moreover, premature neonates require a minimum of 2.8 g/kg/day of protein to maintain growth rates similar to those in utero, and this is 3.5 times the requirement for protein balance in the adult.[7] Thus, the critically ill child

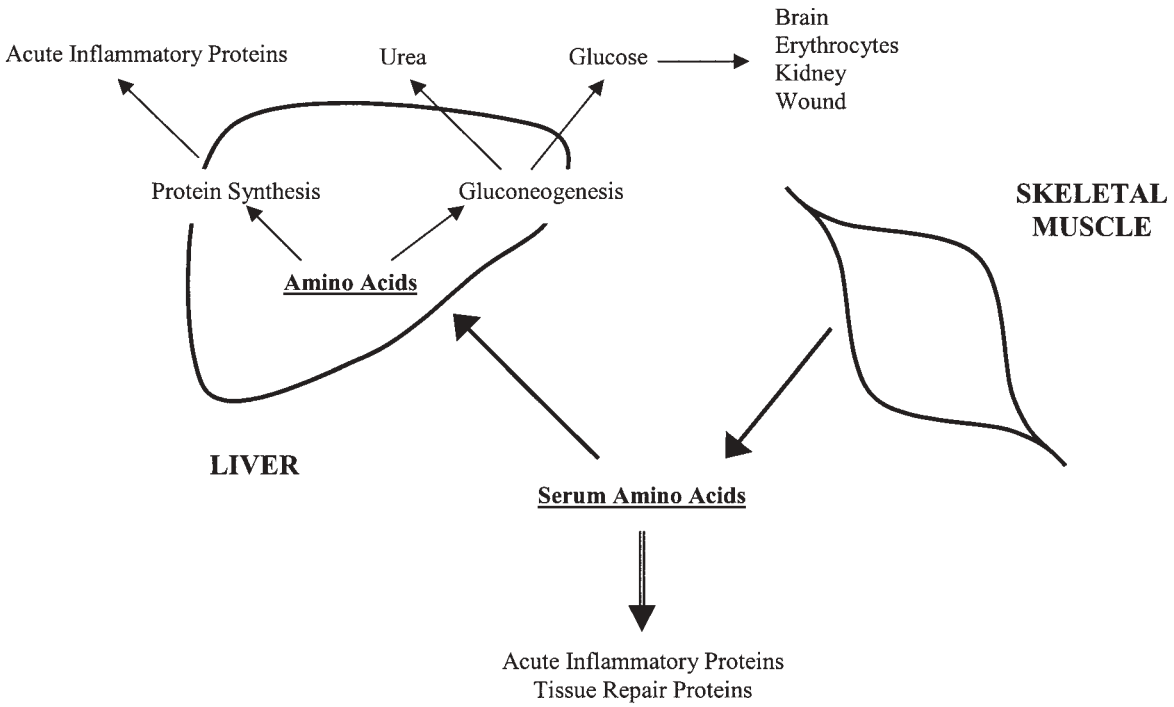

FIGURE 46-1 Illustration of the basic pathways in the metabolic response to critical illness.

has the potential to be much more susceptible to the harmful effects of protracted catabolic stress, and the prompt implementation of adequate nutritional support must be a priority in the patient's care.

NUTRIENT METABOLISM

Protein Metabolism

Amino acids are the key building blocks required for growth and tissue repair. The vast majority (98%) are found in existing proteins, with the remainder residing in the free amino acid pool. Proteins themselves are not static as they are continually degraded and synthesized in the process of protein turnover. The reuse of amino acids released by protein breakdown is extensive; protein turnover contributes more than two times the amino acids derived from protein intake. As a reference, healthy newborns have a protein turnover of approximately 6.7 g/kg/day, and adults have a protein turnover of approximately 3.5 g/kg/day.[8] An advantage of high protein turnover is that a continuous flow of amino acids is available for synthesis of new proteins. In this way, maximal physiologic adaptability is present at times of injury or illness.

TABLE 46-1 Body Composition of Neonates, Children, and Nonobese Adults as a Percentage of Total Body Weight

Age	*Percent Protein*	*Percent Fat*	*Percent Carbohydrate*
Neonates	11	14	0.4
Children (age 10 yr)	15	17	0.4
Adults	18	19	0.4

In the metabolically stressed patient, such as adults with severe burn injury or children with significant cardiorespiratory failure requiring extracorporeal membrane oxygenation (ECMO), protein turnover is double that of normal subjects.[9,10] Specifically, this process involves a redistribution of amino acids from skeletal muscle to the liver, wound, and other tissues taking part in the inflammatory response. The mediators of the inflammatory response—enzymes, serum proteins, and glucose (via gluconeogenesis)—are thus synthesized. Evidence for this process can be seen in the serum by the marked increase in hepatically derived acute-phase reactants (C-reactive protein, fibrinogen, α_1-antitrypsin, α_1-acid glycoprotein) and the reduction in transport proteins such as albumin and retinol binding protein.

Importantly, although children with critical illness have increases in both whole-body protein degradation and whole-body protein synthesis, it is the former that predominates during the stress response. Thus, these patients manifest net negative protein and nitrogen balance. Clinically significant negative protein balance is characterized by skeletal muscle wasting, weight loss, and immune dysfunction.[11]

Apart from the need for acute-phase protein production in the inflammatory response, another driving force for increased protein catabolism is the obligate production of glucose from amino acids through the process of gluconeogenesis. This process is essential as glucose is the preferred substrate for the brain, erythrocyte, and renal medulla and

is a versatile energy source for tissues involved in the inflammatory response. In this process, free alanine and glutamine are first produced by muscle protein degradation. These amino acids are then transported to the liver for glucose production. Alanine, through deamination to pyruvate, contributes a three-carbon unit toward gluconeogenesis, in the glucose-alanine cycle.[12] Glutamine is first converted to alanine in the intestinal mucosa and then transported through the portal vein to the liver, to be used in glucose production. Whereas in fasting subjects, alanine and glutamine account for over 60% of total amino acids released from muscle, this ratio is further accentuated in critical illness. From neonates to adults, increased gluconeogenesis is known to occur during illness and injury. On a per kilogram basis, this process is particularly prominent in patients with low body weight, presumably because of an elevated brain-to-body weight ratio and hence an increased requirement for glucose as an energy source.[13]

Because hepatic gluconeogenesis incorporates deamination of these amino acids to cleave the carbon skeleton, the ammonia moiety by-product is detoxified by the liver through the urea cycle. Urea is thus generated as a soluble and relatively nontoxic metabolite that can be safely excreted in the urine. In addition, glycolysis is often initiated for energy production given the anaerobic environment of injured tissue. Although this process is exceedingly inefficient compared to the aerobic oxidation of glucose, its end product, lactate, can eventually be reduced to pyruvate and shunted back into gluconeogenesis via the Cori cycle.

Although the catabolism of muscle protein to generate glucose and inflammatory response proteins is an excellent short-term adaptation, it is ultimately limited because of the reduced protein stores available in children and neonates. Interestingly, the provision of dietary glucose alone is ineffective in reducing the endogenous glucose production via gluconeogenesis in the metabolically stressed state.[14] Therefore, without elimination of the inciting stress for catabolism (ie, the critical illness or injury), the progressive breakdown of muscle leads to untoward consequences. Loss of diaphragmatic and intercostal muscle mass leads to respiratory compromise, and the subsequent loss of cardiac muscle predisposes to fatal arrhythmia. Fortunately, the provision of amino acid nutritional supplementation has been shown to improve overall protein balance in the premature neonate.[15,16] The mechanism for this change appears to be an increase in protein synthesis, whereas the rate of protein degradation remains constant.[17]

As expected, the amount of protein required to optimally enhance protein accretion is higher in critically ill than in healthy children. Infants demonstrate 25% higher protein degradation after surgery, a 100% increase in urinary nitrogen excretion with bacterial sepsis, and a 100% increase in net protein breakdown while on ECMO.[9,17] Children under treatment for cancer have also been shown to have increased net protein breakdown.[18]

The provision of dietary protein sufficient to optimize protein synthesis, facilitate wound healing and the inflammatory response, and preserve skeletal muscle protein mass is the single most important nutritional intervention in critically ill children. The quantities of protein recommended for critically ill neonates and children are outlined in Table 46-2.[9] Certain severely stressed states, such as significant burn injury or patients requiring ECMO, may require additional protein supplementation to meet metabolic demands. Hence, growth rates and other indices for protein accretion (ie, prealbumin levels) must be monitored closely in chronically ill patients. Excessive protein administration should be avoided as toxicity has been documented, particularly in children with marginal renal and hepatic function. Studies using protein allotments of 6 g/kg/day have found toxicity in neonates as demonstrated by azotemia, pyrexia, strabismus, and a lower IQ score.[19,20]

Although the precise amino acid composition to best increase whole-body protein balance has yet to be fully determined, stable isotope techniques now exist to study this issue.[21–23] Neonates, in particular, have immature biosynthetic pathways that may alter their ability to synthesize specific amino acids. For example, histidine is a conditionally essential amino acid until 6 months of age, and data suggest that biosynthetic pathways for cysteine, taurine, and proline may be of limited capacity in the premature neonate.[21–25] These immature amino acid pathways may have clinical relevance. Given that cysteine is essential for the production of the antioxidant glutathione, our laboratory has demonstrated that, in very low birth weight neonates, glutathione concentrations in erythrocytes are only 30 to 40% of that in normal infants (unpublished data). In addition, proline demand has been shown to increase significantly in patients with severe burns.[10] Therefore, it is likely that specific disease states may accentuate specific amino acid requirements, and further research is needed to determine optimal dietary protein supplementation for such conditions.

Energy Metabolism

During critical illness, increases in the metabolic turnover of protein, carbohydrate, and lipid provide an increased basal energy requirement for the pediatric patient. However, the question of whether total energy expenditure is actually increased in this cohort has drawn much interest. The question is important as the caloric provision for the critically ill child has significant consequences. For example, protein retention can be optimized by an adequate caloric allotment, and this is particularly true when protein intake is marginal.[26] Conversely, the dietary provision of excess calories from glucose results in an increased production of CO_2, with no change in loss of lean body mass.[27,28] Recent data have also shown a possible paradoxical increase in net protein degradation from excess carbo-

TABLE 46-2 Estimated Protein Requirements for Injured Children of Various Age Groups

Age (yr)	*Estimated Protein Requirement (g/kg/d)*
0–2	2.0–3.0
2–13	1.5–2.0
13–18	1.5

hydrate intake.[29] Therefore, a careful appraisal of energy requirements in the critically ill pediatric patient is required as both underestimates and overestimates can lead to injurious results.

Resting energy expenditure can be measured using direct or indirect methods. The direct method measures the heat released by a subject at rest and is based on the principle that all energy is eventually converted to heat. In practice, the patient is placed in a thermally isolated chamber, and the heat dissipated is measured for a given period of time.[30] Although precise, this method is not practical for most pediatric or critically ill patients. The indirect methods estimate energy production based on quantities of O_2 consumption or CO_2 production by the whole body during a specific time interval. The classic indirect method, indirect calorimetry, measures V_{O2} (the volume of oxygen consumed) and V_{CO2} (the volume of CO_2 produced) and uses a correlation factor based on urinary nitrogen excretion to calculate the overall rate of energy production.[31] This method uses the metabolic cart, a leak-free system with a computer-controlled gas exchange measurement device as well as 24-hour urine collection. Indirect calorimetry provides a measurement of the overall respiratory quotient (RQ), defined as the ratio of CO_2 produced to O_2 consumed, for a given patient. However, this method is not accurate in subjects with uncuffed endotracheal tubes or on an ECMO circuit. Newer techniques using stable isotopes to measure energy expenditure are now well validated and in use. Using ^{13}C-labeled bicarbonate and doubly labeled water ($^2H_2{}^{18}O$), studies in pediatric surgical patients have accurately measured total energy expenditure.[9,32] These techniques have been shown to correlate well with the gold standard of indirect calorimetry and have been used to measure energy expenditure of critically ill neonates in a variety of settings.[33]

Using these techniques to measure energy expenditure, it has become apparent that the severity and duration of the critical illness govern the energy needs of the ill child. In general, any increase in energy expenditure during illness or after operation is variable, and recent studies suggest that the increase is far less than originally hypothesized. In children with severe burns, the initial resting energy expenditure during the flow phase of injury is increased by 50% but then returns to normal during convalescence.[34] In neonates with bronchopulmonary dysplasia, in which the illness increases the patient's work of breathing, a 25% elevation in energy requirement is evident.[35] Newborns undergoing major surgery have only a transient 20% increase in energy expenditure that returns to baseline values within 12 hours postoperatively provided that no major complications develop.[36,37] Stable, extubated neonates 5 days after operation have been shown to have resting energy expenditures comparable to normal infants.[38] Effective anesthetic and analgesic management may play a significant role in muting the stress response of the neonate; studies have demonstrated no discernable increase in resting energy expenditure in neonates undergoing patent ductus arteriosus ligation who receive intraoperative fentanyl anesthesia and postoperative intravenous analgesic regimens.[37] Finally, by using stable isotopic methods, we have found that the mean energy expenditures of critically ill neonates on ECMO are nearly identical to age- and diet-matched nonstressed controls.[39] There was, however, a greater variability in energy expenditure among the critically ill cohort in this study. The one exception to this pattern may be children with head injury who have been shown to demonstrate a variable elevation in energy expenditure, presumably secondary to a marked rise in serum catecholamines.[40]

These studies suggest that critically ill neonates have only a small and perhaps negligible increase in energy expenditure. How can this be explained in the presence of a corresponding increase in illness-induced metabolic turnover of nutrients? Total energy requirement for all patients includes resting energy expenditure, energy allotted to physical activity, and diet-induced thermogenesis. By definition, resting energy expenditure also encompasses the energy requirement for growth. Although critically ill children have increased energy requirements from increased metabolic turnover, their growth is often halted or slowed during physiologic stress.[41] In addition, owing to the nature of the illness and administration of sedation and paralytic agents, levels of physical activity are low in the critically ill child.

Thus, for practical purposes, the recommended dietary caloric intake for healthy children represents a reasonable starting point for the upper limit of caloric allotment in the critically ill child.[42] Excessive caloric allotments can be harmful, leading to synthesis of excess fat and increased CO_2 production. Children fed through enteral administration require a further 10% increment in caloric regimen to account for obligate malabsorption. Owing to the high individual variability in energy expenditure, particularly in the most critically ill patients, the actual measurement of resting energy expenditure (ie, by indirect calorimetry) is recommended. It should be noted that predictive equations used with stress factors to account for the degrees of illness have proven inaccurate in determining individual energy expenditures; the preferred method to measure energy expenditure remains indirect calorimetry, when available.[43]

Once protein needs have been met, safe caloric provisions using carbohydrate and lipid energy sources have similar beneficial effects on net protein synthesis and overall protein balance in critically ill patients. The rational partitioning of these substrates requires knowledge of carbohydrate and lipid use in critical illness.

Carbohydrate Metabolism

Glucose production and availability are a priority of the metabolic response in critically ill children. Glucose is the primary energy used by the brain, erythrocyte, and renal medulla and is useful in the repair of injured tissue. Glycogen stores are limited and quickly depleted in illness or injury, resulting in the need for gluconeogenesis. In injured and septic adults, a threefold increase in glucose turnover and oxidation has been demonstrated as well as an elevation in gluconeogenesis.[44,45]

A significant feature of the metabolic stress response is that the provision of dietary glucose does not halt gluco-

neogenesis. Consequently, the catabolism of muscle protein to produce glucose continues unabated.[14] However, it is clear that a combination of dietary glucose and amino acids effectively improves net protein balance in critical illness. This occurs primarily through the augmentation of protein synthesis and has little, if any, effect on protein breakdown.[17,46]

In early nutritional support regimens for critically ill patients, excessive glucose allotments were used to attempt to overcome the need for gluconeogenesis and, in effect, protein degradation. As expected, the excess glucose was converted to fat, resulting in the net generation of CO_2. The synthesis of fat from glucose has an RQ of approximately 8.7. Clinically, this high RQ is not attained as glucose is never purely used for fatty acid synthesis. Nonetheless, the provision of excess glucose results in an elevated RQ and thus increases the ventilatory burden on the child. The mean RQ in postsurgical neonates fed a high-glucose diet is approximately 1.0, whereas comparable neonates fed with reduced quantities of glucose in combination with a standard concentration of lipid have an RQ of 0.83.[47] Using high-glucose total parenteral nutrition, hypermetabolic adult patients fed excess caloric allotments have a 30% increase in O_2 consumption, a 57% increase in CO_2 production, and a 71% elevation in minute ventilation.[27] In addition, aforementioned studies have found that excess glucose provisions may worsen negative protein balance in neonates requiring ECMO.[29]

Thus, avoidance of excess calories from glucose provisions and the use of a mixed-fuel system employing both carbohydrates and lipid are theoretically and practically useful in critically ill children, many of whom already have respiratory challenges from the nature of their illness. This approach also helps to alleviate difficulties with hyperglycemia in the relatively insulin-resistant stressed child.

Lipid Metabolism

Analogous to protein and carbohydrate metabolism, lipid turnover is generally accelerated by critical illness, surgery, and trauma.[46] Although lipid use is compromised in the initial, brief ebb phase following acute trauma or sepsis, overall lipid turnover increases dramatically during the predominant flow phase. Adult patients demonstrate two- to fourfold increases in lipid turnover compared with healthy controls, and this increase is proportional to the degree of illness.[48,49] This process involves the recycling of free fatty acids and glycerol into and from triglycerides. Approximately 30 to 40% of the free fatty acid moieties are oxidized for energy, and the RQ values postinjury are approximately 0.8. Infants and children subjected to uncomplicated abdominal surgery have also shown a reduction in RQ along with a decline in plasma triglyceride levels.[50] Recently, it has been shown that critically ill children do, indeed, have a higher rate of fat oxidation.[51] Thus, this suggests that fatty acids are, in fact, the prime source of energy in metabolically stressed children. Glycerol, released along with free fatty acids from the breakdown of triglycerides, may be converted to pyruvate and thereby shunted into the gluconeogenesis pathway. Again similar to protein catabolism, the provision of dietary glucose does not decrease glycerol clearance or overall lipid turnover.

Because of the increased demand for lipid use in critical illness coupled with the limited lipid stores in the pediatric patient, critically ill children are susceptible to the evolution of biochemical essential fatty acid deficiency if administered a fat-free diet.[52,53] In infants, linoleic and linolenic acid are considered essential, whereas arachidonic acid and docosahexaenoic acid are thought to be conditionally essential. If the body lacks dietary linoleic acid, the formation of arachidonic acid (a tetraene) by desaturation and chain elongation cannot take place. The same pathway then converts available oleic acid to 5,8,11-eicosatrienoic acid (a triene). Empirically, an elevated triene-to-tetraene ratio is characteristic of essential fatty acid deficiency.[54] Clinically, this syndrome presents as dermatitis, alopecia, thrombocytopenia, increased susceptibility to bacterial infection, and overall failure to thrive. To avoid essential fatty acid deficiency in critically ill or injured infants, the allotment of linoleic and linolenic acid is recommended at concentrations of 4.5% and 0.5% of total calories, respectively.[55]

The provision of commercially available lipid solutions to parenterally fed critically ill children reduces the risk of essential fatty acid deficiency, results in improved protein use, and does not significantly increase CO_2 production or metabolic rate.[56] There are disadvantages, however, with lipid administration including hypertriglyceridemia, increased rates of infection, and decreased alveolar oxygen diffusion capacity.[57–59] Most centers, therefore, start lipid supplementation in ill children at 1.0 g/kg/day and advance over a period of days to 2 to 4 g/kg/day, with monitoring of triglyceride levels. Lipid administration is generally restricted to a maximum of 30 to 40% of total calories, although this practice has not been validated by clinical trials.

Of note, normal ketone body metabolism is also markedly affected by critical illness. The product of incomplete fatty acid and pryruvate oxidation is acetyl coenzyme A, which forms the ketone bodies acetoacetate and β-hydroxybutyrate through a condensation reaction within the hepatocyte. In starved healthy subjects, a major adaptation to preserve skeletal muscle mass is the production of these ketone bodies, which can then be used as an energy source for the brain. However, in the 3-day period following trauma, there is a negligible elevation in serum ketone body levels.[60] This observation may be explained in part by the elevated serum insulin concentrations found during the metabolic stress response. Even low concentrations of insulin inhibit ketogenesis, a fact made evident by the absence of ketotic complications in type 2 diabetics. Hence, the elevated insulin concentrations seen in severe illness and injury serve to negate the ketotic adaptation found in starvation.

Electrolyte Metabolism

Requirements for the basic electrolytes—Na+, K+, Cl^-, HCO_3–, Ca2+—must be evaluated frequently in the critically ill patient. In addition to routine electrolyte monitoring, careful attention to phosphate and magnesium levels

is recommended. Hypophosphatemia may lead to hemolytic anemia and respiratory muscle dysfunction and may also be seen with refeeding syndrome in the ill child. Renal failure can result in the retention of phosphate, and nutritional allotments must be reduced accordingly. Deficiency of magnesium can cause fatal cardiac arrhythmia.

Abnormalities of acid-base physiology in the critically ill child can also influence the nutritional regimen. For example, head-injured patients often develop an iatrogenically induced respiratory alkalosis. If a metabolic alkalosis secondary to active diuresis or gastric suction is also present, Cl^- administration should be used to correct the alkalosis. Untreated alkalemia tends to inhibit the respiratory drive, shift potassium intracellularly, and decrease ionized calcium concentrations by increasing the affinity of albumin for calcium. Metabolic acidosis can also be seen in critically ill children, often from associated hypotension or ischemic etiologies. In this case, the provision of acetate instead of Cl^- in the parenteral nutrition regimen should be used so as not to worsen the existing acidemia. The provision of excess acetate at 1 mEq/kg/day is usually a safe adjunct to limit metabolic acidosis.

Vitamin and Trace Mineral Metabolism

Vitamin and trace mineral metabolism in critically ill and postoperative patients has not been extensively studied. For the neonate and the child, required vitamins include fat-soluble vitamins (A, D, E, and K) and water-soluble vitamins (ascorbic acid, thiamin, riboflavin, pyridoxine, niacin, pantothenate, biotin, folate, and vitamin B_{12}), and these are routinely administered. Because vitamins are not stoichiometrically consumed in biochemical reactions but rather act as catalysts, the administration of large supplements of vitamins in stressed states is not logical from a nutritional standpoint.

The trace minerals required for normal development are zinc, iron, copper, selenium, manganese, iodide, molybdenum, and chromium. Trace minerals are used in the synthesis of active sites of a ubiquitous and extraordinarily important class of enzymes termed metalloenzymes. As with vitamins, the role of metalloenzymes is to act as catalysts. Hence, unless there are excessive losses, such as increased zinc loss with severe diarrhea, large nutritional requirements in critical illness should not be anticipated. The Recommended Dietary Allowances of vitamin and trace mineral needs of healthy children and neonates are reviewed periodically and are well defined in the literature.[42] These recommended levels have been used in critically ill patients, and little evidence exists that they are nutritionally inadequate. In children with severe hepatic failure, copper and manganese accumulation can occur; thus, parenteral trace mineral supplementation should be reduced.

ROUTES OF NUTRITIONAL PROVISION

In the critically ill child with a functioning gastrointestinal tract, the enteral route of nutrient administration is preferable to parenteral nutrition. Enteral nutrition is physiologic and has been shown to be more cost-effective without the added risk of nosocomial infection inherent in parenteral nutrition.[61,62] The postpyloric feeding tube, placed at the bedside or with fluoroscopic guidance, helps to decrease the risk of aspiration and is a useful tool in the nutritional management of the critically ill child. Continuous feedings using standard formulas can adequately nourish the majority of injured patients. Diarrhea can often be avoided by carefully controlling the infusion rate until tolerance is established. At the time of extubation, tube feeds are held for 6 to 12 hours to lower the corresponding risk of aspiration. It is also recommended not to use enteral feeds with patients who are hypotensive or who have evidence of bowel ischemia so as to limit the risk of small-bowel necrosis associated with rapid enteral feeding.[63]

If the gastrointestinal tract is not functional and parenteral nutrition is necessary, central venous access is obtained to facilitate the administration of concentrated nutritional solutions. This obviates fluid overload from less concentrated solutions and avoids the risk of sclerosis of smaller peripheral veins. Percutaneously placed intravenous lines that are threaded centrally and standard central venous catheters are the preferred routes of administration. Intravenous lines in the groin are not preferred owing to their propensity for infection but may be necessary on a temporary basis in patients who have chronic access issues. In most pediatric intensive care unit patients, central access may be performed successfully at the bedside. Once gastrointestinal function has been re-established, the patient can usually be converted to an enteral nutrition regimen.

MECHANISMS OF THE METABOLIC RESPONSE

Although research continues to elucidate the metabolic changes associated with the pediatric stress response, future studies will aim to uncover the mechanisms behind these metabolic alterations. The goal of this research is ultimately to gain the knowledge necessary to control and modulate the response. In this way, many of the deleterious consequences associated with the metabolic stress response can potentially be circumvented. Two integrated and complex systems are involved: neuroendocrine pathways and inflammatory cytokines.

The neuroendocrine response to critical illness is relatively well defined, and its features are common to both children and adults. Beginning soon after the initial insult, a unique hormonal profile takes hold. Catecholamines are released from the adrenal medulla on stimulation by the sympathetic nervous system. The secretion of adrenocorticotropic hormone mediated by the anterior pituitary results in an increase in serum cortisol and aldosterone levels. Growth hormone and antidiuretic hormone are secreted by the anterior and posterior pituitary glands, respectively. In addition, glucagon levels rise with the surge in catecholamines. After a brief, initial decline, a rapid increase in serum insulin concentrations is found.[64–66] Overall, the hormonal changes in neonates and infants have been shown to

be of greater magnitude but shorter duration than those found in older children and adults.

The alterations in intermediary metabolism inherent in the metabolic response can be attributed, at least in part, to these hormonal changes. The mobilization of amino acids from muscle, the increased rate of gluconeogenesis in the liver, and the increased lipolysis from adipocyte stores can be explained by the elevations in glucagon, cortisol, and the catecholamines. The increase in net protein degradation, however, is not consistent with the persistent elevation of insulin, a known anabolic hormone. In this way, it has been postulated that injury-induced protein degradation is the result of a postreceptor defect in insulin action.[67] This hypothesis is further supported by the finding that burn patients do not demonstrate the same degree of inhibition of protein breakdown compared with normal controls when subjected to hyperinsulinemic euglycemic conditions.[68]

The presence of inflammatory cytokines can be found in the circulation within hours of elective surgery or trauma. These peptides are secreted by leukocytes in a variety of settings and help to mediate the inflammatory response. In general, the prototypical cytokine response in neonates does not markedly differ from that of older children or adults.

Interleukin (IL)-6 has been found in increased concentrations in the serum of children within hours after surgery, and this increase persists up to 24 to 48 hours postoperatively.[69] IL-6 levels have also been shown to be significantly elevated in critically ill children requiring ECMO.[39] IL-6 levels have been directly correlated with increased protein turnover and catabolism as well as a higher incidence of postoperative complications and mortality.[66,67] Tumor necrosis factor (TNF) has also been shown to increase in neonatal critical illness such as necrotizing enterocolitis and sepsis. It is hypothesized that TNF is involved in the release of prostaglandins, thereby mediating the hypotension associated with the septic state. The release of IL-2, IL-8, IL-11, interferon-γ, and other growth factors is also known to augment the immunologic and hormonal response to injury, although the precise effect of these cytokines on metabolism has not been fully defined.

CONCLUSION

The pediatric metabolic response to critical illness and injury is composed of a significant increase in the turnover of protein, carbohydrate, and lipid substrates. This process allows for the production of inflammatory response proteins that participate in the associated inflammation and wound healing. Extreme protein loss, consistent with the severity of the illness or injury, is a hallmark of this metabolic process. Interestingly, recent research has demonstrated that the overall energy expenditure of the child is not necessarily increased during this metabolic response. It is thought that the child shifts energy resources from normal growth and activity to provide fuel for the increased turnover of substrate.

Implementing an appropriate nutritional regimen to minimize the protein loss and to meet the energy requirements of the child is of paramount importance in the long-term management of children suffering from critical illness or major injury. Maintaining positive protein balance in the face of protein loss requires substantially increased protein allotments, especially in neonates. Excessive carbohydrate provisions do not blunt the metabolic response and, indeed, have been shown to have deleterious consequences. In addition, because the energy expenditure of these patients does not appear to increase significantly, the recommended caloric intake for healthy children in a similar age group represents a reasonable starting point for the upper limit of caloric allotment in critically ill children. Finally, exact measurement of energy expenditure using indirect calorimetry should be used in complicated patients and when patients do not respond over time to an appropriate nutritional regimen.

CHAPTER 47

HYPERLIPIDEMIA AND CARDIOVASCULAR DISEASE

Sarah de Ferranti, MD, MPH, Ellis Neufeld, MD, PhD

Atherosclerotic heart disease is a major cause of adult morbidity and mortality in the United States; coronary heart disease (CHD) affected 12.6 million Americans and caused nearly 530,000 deaths in 1999. Other atherosclerotic complications, including stroke and peripheral vascular disease, affect millions more.[1] The causes of atherosclerotic cardiovascular disease are multifactorial; however, nutrition is related to many traditional cardiovascular risk factors. Increased total cholesterol is an important risk factor for atherosclerosis and was found in half of the Framingham Heart Study adult cohort who sustained a myocardial infarction.[2] Reducing cholesterol by 8% reduces the risk of CHD by 19%.[3] Nutrition is an important determinant of lipid values. Other important cardiovascular risk factors include hypertension and obesity, and these factors are also modified by diet. Taking these facts into consideration, health care providers who deliver care to young persons can be assured that millions of today's youth, and a significant fraction of our practices, will sooner or later fall victim to atherosclerotic vascular disease.

Several lines of evidence suggest that atherosclerotic vascular changes begin by adolescence and that early intervention on a population basis and, for severe cases, on an individual basis is warranted. These lines of evidence, and the arguments for and against various screening and treatment strategies, are laid out in the comprehensive report of the National Cholesterol Education Program (NCEP) Expert Panel on Children and Adolescents.[4] These consensus guidelines were promulgated in 1991 by the American Academy of Pediatrics.[5] The NCEP pediatric guidelines have become somewhat dated in the dozen years since their initial presentation, but they still form the basis of updated recommendations for pediatric lipid practice from the American Academy of Pediatrics.[6]

In this chapter, we present evidence supporting the early onset of atherosclerosis in childhood, including new thinking in pathophysiology; briefly review lipid biochemistry; and describe different pediatric hyperlipidemias, nutritional and pharmacologic treatments, and practical clinical approaches to children with hyperlipidemia. We make specific note of examples in which our current practice or recommendations diverge from those of the NCEP.

PEDIATRIC ORIGINS OF ADULT ATHEROSCLEROSIS

Atherosclerosis usually takes decades to develop. Symptoms and sequelae from atherosclerotic vascular disease are extremely rare in children and adolescents and are limited to patients with profound genetic dyslipidemias. However, both the disease process itself and the nutritional habits that propagate the disease begin early. Autopsy studies of cohorts as early as the Korean War have shown atherosclerotic coronary artery disease in the second decade of life on gross examination[7] and by microscopy.[8,9] These pathology findings were correlated with hyperlipidemias in young persons in the United States in a landmark study termed Pathological Determinants of Atherosclerosis in Youth (PDAY),[10] among others.[11] In the PDAY study, fatty streak precursor lesions were present by age 15 years in the coronary arteries of children who died of noncardiac causes. Both the prevalence and extent of fatty streaks, and the degree of progression to raised vascular lesions (early atherosclerosis) by young adulthood, were directly related to increased non–high-density lipoprotein (HDL) cholesterol—that is, low-density lipoprotein (LDL) plus very-low-density lipoprotein (VLDL)—and decreased HDL cholesterol measured at the time of death.

Epidemiologic Evidence of a Connection between High Cholesterol in the Young and Heart Disease

Epidemiologic studies have shown that countries with higher rates of CHD have higher pediatric population mean total cholesterol.[12] Cholesterol levels in the pediatric age group are important because they predict adult cholesterol levels to a substantial degree. Cholesterol "tracks" quite well; children with very high cholesterol levels are highly

likely to be adults with high cholesterol. This has been demonstrated in a decades-long cohort project in Iowa, the Muscatine Study: nearly half of subjects with high cholesterol as children had high cholesterol levels as adults.[13]

There are data connecting cholesterol levels in young adults with CHD. Starting in the late 1940s, cholesterol levels were available for cohorts of Johns Hopkins University medical students. High total cholesterol values in the students predicted greater risk of CHD, mortality from CHD and overall mortality later in adult life.[14] This study provides the most compelling link between measured cholesterol levels in young persons and subsequent risk of heart disease 30 or 40 years later. Long-term intervention studies demonstrating a link between cholesterol levels in school-aged children and CHD in the fifth and sixth decades of life and showing that interventions in this age range prevent future disease have not been done; the length of follow-up is daunting. Therefore, the interventions we discuss below are based on inference, adult studies, and short-term intervention results in the young.

High-Risk Groups

Compared with the general population, specific identifiable groups of young people are at high risk of early atherosclerosis owing to hyperlipidemias. These include heart transplant recipients[15,16] and renal transplantation patients,[17,18] in whom the problem is related only in part to chronic transplant rejection. Children with diabetes mellitus are also at particular risk for cardiovascular disease in the long run. In assessing risk for individual children, solid organ transplantation and juvenile-onset diabetes can reasonably be considered to count as two risk factors in determining whether a child is a candidate for pharmacologic therapy.

EMERGING CONCEPTS IN ATHEROSCLEROSIS: APPLICATIONS IN CHILDREN AND ADOLESCENTS

The fact that half of adults in the Framingham Heart Study who had myocardial infarctions had normal cholesterol levels,[2] a finding supported by other studies,[19,20] has prompted researchers to search for other contributions to atherosclerosis. Although the prevailing theory of atherosclerotic disease since the 1960s has focused on cholesterol, recent thinking places emphasis on vascular and systemic inflammation as instrumental in the pathophysiology of atherosclerosis. A simple marker, serum C-reactive protein (CRP), is proving to be a valuable tool for assessing cardiovascular disease risk in adults. CRP is an acute-phase reactant. Transient inflammation, from minor infections for example, can readily raise the CRP level above a population upper limit of normal, 0.5 mg/dL. However, a highly sensitive CRP assay (hsCRP) detects variations in levels of less than 0.1 mg/dL. At these low levels, previously deemed normal, differences in CRP levels in the population predict cardiac risk. Studies examining adults having myocardial infarctions show abnormally elevated CRP; higher peak values predict worse outcomes[21] and larger infarcts.[22] Adults who have abnormal CRP levels even months or years after an acute coronary event have a significantly greater risk of recurrence.[23,24] Prospective evaluation in large cohort studies reveals that men and women without clinical atherosclerotic disease who have CRP values higher than the normal range are at risk for future cardiovascular disease.[25,26]

Relation of CRP Findings to Pediatric Lipid Disorders and Cardiac Risk

Inflammation probably has a role in the increased risk of future cardiovascular disease in pediatric patients. Only a fraction (between 23 and 43%) of the offspring of parents with early myocardial infarction have high LDL cholesterol.[27,28] This suggests that at least part of familial cardiac disease risk is not related to hypercholesterolemia and might be related to a hyperinflammatory state. In fact, one study found that children with first-degree relatives who had myocardial infarctions have abnormally elevated CRP levels.[29] Despite these intriguing results, no data available in late 2002 demonstrate a specific role for hsCRP as a screening tool in pediatric lipid practice. However, the test might be valuable in present practice in some individual patients at high risk as assessed by family history or by lipid levels and will likely have greater use in risk prediction in the future. The exact relationship between CRP and coronary risk is unclear. It is possible that ongoing, mild vascular inflammation contributes both to atherosclerosis and the increased CRP level.

The understanding of the role of inflammation in atherosclerosis has led to new thinking about therapies in adults, including acetylsalicylic acid, vitamins E and C, and betacarotene. However, a recent large study in adults found no difference in 5-year mortality, despite increases in serum levels of vitamins E and C and betacarotene; there is more to learn on this subject.[30] There have been no studies of these therapies in pediatric patients.

Homocysteinemia and Pediatric Evaluation for Cardiac Risk

Elevated level of the nonstructural amino acid homocysteine is another coronary artery disease risk factor that has lately become better understood. Three lines of evidence link homocysteine levels to atherosclerotic disease: (1) in large adult cohorts, including the Framingham Heart Study, mild hyperhomocysteinemia is predictive of coronary events[31]; (2) homocysteine itself causes vascular disease in animal models[32]; and (3) young patients with profound hyperhomocysteinemia owing to the rare genetic defect cystathionine-β-synthase deficiency (homocystinuria) have dramatic elevation in thrombosis risk. Dietary deficiencies of vitamin B_{12} (cobalamin), folate, or vitamin B_6 (pyridoxine) can all lead to hyperhomocysteinemia, as can genetic defects in absorption or metabolism of these vitamins.

The most common genetic association is with a heat-labile form of methylenetetrahydrofolate reductase, caused by a 677C-to-T polymorphism and present in more than one-quarter of Caucasians.[33] In the presence of this polymorphism, relative folate deficiency with resultant mild

elevation in homocysteine levels is fairly common in adults with poor folate intake. However, just as the significance of relative folate deficiency was becoming clear in the late 1990s, universal folate supplementation of cereals and enriched grain products to prevent neural tube defects was enacted, clouding the data on the relationship between folate supplementation and CHD. In a large cohort of pediatric patients studied for lipid nutritional intervention, the Dietary Intervention Study in Children (DISC), hyperhomocysteinemia was rare among several hundred subjects.[34]

LIPID BIOCHEMISTRY

Lipids, including cholesterol and other sterols, triglycerides, and free fatty acids, are essential for life. In humans, all but the essential fatty acids can be endogenously synthesized, but diet is a major contributor to total body lipid stores in typical diets in developed countries. Essential fatty acids include the basic precursors of the polyunsaturated fatty acids (eg, linoleic acid or linolenic acid).

Cholesterol is partially absorbed from the diet and partially synthesized by the liver. The only dietary source of absorbed cholesterol is animal products; 30 to 50% of dietary intake is absorbed. Strict vegans synthesize 100% of their cholesterol needs as vegetables contain no cholesterol. After absorption, cholesterol is esterified and carried in the serum on lipoprotein particles, as described below.

Fat, in the form of fatty acids and triglycerides (three fatty acids esterified to glycerol), is derived both from dietary sources and from endogenous synthesis, including excess carbohydrates and even proteins. Fatty acids can be "saturated," with hydrogen at each carbon; "monounsaturated," with one double carbon bond; or "polyunsaturated," with two to six double bonds. Naturally occurring dietary fatty acids are in the "*cis*" configuration at each double bond. Polyunsaturated fats are prone to spoilage by oxygen, light, and heat; therefore, food processing, especially catalytic hydrogenation processing, used to avoid rancidity, leading to non-natural fatty acid chemistry, including a "*trans*" bond configuration. Readers will be familiar with "partially hydrogenated" oils from the list of ingredients in many processed foods, especially snack foods. In general, the larger the proportion of partially hydrogenated fats, the larger the proportion of undesirable transconformation fatty acids. Dietary cholesterol (usually not much more than 300 mg/day) is re-esterified to fatty acids in plasma. Dietary triglycerides (typically dozens of grams daily) are degraded by lipase in the gut, absorbed, and re-esterified to re-form triglycerides. Dietary fat is distributed to body tissues, primarily the liver, in the form of chylomicrons.

Cholesterol esters and neutral fats such as triglycerides are negligibly soluble in water and therefore are carried in the bloodstream by lipoproteins. Free fatty acids in plasma are carried mainly on albumin and are rapidly taken up by tissues for re-esterification or for combustion as fuel. Lipoproteins are made up of hydrophobic lipids (triglycerides and cholesterol ester) on the inside and apoproteins, phospholipids, and unesterified cholesterol on the outside.

There are several types of lipoproteins, classified by density as determined using plasma ultracentrifugation: chylomicrons, which float as a creamy supernatant: HDLs, LDLs, and VLDLs.

Chylomicrons are synthesized in the intestine from dietary triglycerides, cholesterol, and apolipoproteins synthesized in the liver. Chylomicrons have the lipoproteins apo A, apo C, and apo C-II. The chylomicron delivers the triglyceride to muscle and adipose tissue, where it is modified by lipoprotein lipase, losing triglycerides, apo A, and apo C and gaining apo E. The chylomicron remnants are taken up by the liver via the apo E receptor and degraded.

HDL is the densest and smallest lipoprotein. The major proteins (apoproteins) in HDL are apo A-I, apo A-II, apo C, and apo E. HDL is the primary lipoprotein responsible for reverse cholesterol transport, returning cholesterol from other tissues back to the liver. HDL also transports cholesterol from other lipoproteins, such as LDL, and cell membranes to VLDL and chylomicrons.

LDL is the main reservoir of circulating cholesterol esters, supplying cell membranes and tissues. Each LDL particle carries an apolipoprotein B molecule, the protein responsible for LDL clearance by its cognate receptor. Cholesterol synthetic mechanisms are present in nearly all mammalian cell types, but exogenous sources are used prior to endogenous synthesis. Delivery to tissues is regulated by the number of LDL receptors, and a tight negative feedback system prevents cholesterol synthesis and downregulates LDL receptors in normal humans when extracellular LDL is abundant. Recent studies have noted an increased risk of atherosclerotic events in people with particularly dense LDL particles.

VLDL is manufactured in the liver, particularly during fasting, as the main source of triglycerides when chylomicrons are absent. VLDL is secreted into the bloodstream and triglycerides are removed in the periphery by lipoprotein lipase. The VLDL remnants are metabolized by the liver and serve as the precursor for LDL production.

HYPERLIPIDEMIA

Normal cholesterol levels are age dependent; children have lower levels than adults do. The NCEP guideline cutoffs for borderline and overt hypercholesterolemia, as well as for normal levels of HDL, triglycerides, and LDL, are shown in Table 47-1.

Establishing a Diagnosis

Hypercholesterolemia and hyperlipidemia are both multifactorial and polygenic traits. It is useful to distinguish primary (familial or sporadic) from secondary hyperlipidemia. In pediatrics, most cases of hyperlipidemia are primary; however, secondary causes of hyperlipidemia should be considered, evaluated, and ruled out because several of the secondary causes are treatable. Secondary causes of hyperlipidemia (Table 47-2) are often readily identified by a medical history and examination, with simple laboratory testing as indicated.

Among primary hyperlipidemias, dietary transgressions, lack of exercise, glucose intolerance, and obesity

Adapted from National Cholesterol Education Program (NCEP).[4]
Acceptable, borderline, and elevated cholesterol values according to the NCEP pediatric guidelines are shown for total cholesterol and low-density lipoprotein (LDL). For comparison, percentile values are shown for these measures and for high-density lipoprotein (HDL) and triglycerides. See National Cholesterol Education Program[4] for full percentile tables.
*Values are reported as serum; to convert to plasma values, divide by 1.03.
†LDL and HDL values for Caucasian subjects.

TABLE 47-2 Medical, Physiologic, and Pharmacologic Causes of Secondary Hyperlipidemia

Endocrine and metabolic states
- Diabetes mellitus
  - Type I: with concomitant primary hyperlipidemia, very high vascular risk
  - Type II: particularly related to high triglycerides
  - Insulin resistance states without overt diabetes (check for acanthosis nigricans)
- Pregnancy
- Hypothyroidism
- Hypopituitarism*
- Anorexia nervosa

Hepatic disease
- Hepatitis of any etiology
- Congenital biliary atresia†
- Acute intermittent porphyria
- Glycogen storage disease†
- Benign recurrent intrahepatic cholestasis

Renal disease
- Nephrotic syndrome†
- Any renal inflammatory state
- Hemolytic uremic syndrome
- Idiopathic hypercalcemia

Lysosomal storage disease
- Cholesterol ester storage disease
- Niemann-Pick disease
- Other conditions, such as Tay-Sachs disease, Gaucher's disease

Recognizable genetic syndromes
- Klinefelter's syndrome
- Progeria (Hutchinson-Gilford disease)

Systemic inflammatory states
- Trivial inflammation (eg, viral illnesses, simple urinary tract infection, sinusitis) can raise triglyceride levels; "healthy day" testing recommended
- Systemic lupus erythematosus: severe vascular risk if combined with primary hyperlipidemia
- Burns

Drugs and other agents
- Corticosteroids (systemic): primarily hypertriglyceridemia
- Thiazides
- Beta-blockers
- Oral contraceptives (third-generation oral contraceptive pills have beneficial effect on HDL, which can appear as benign elevation in total cholesterol)
- Antiepileptic medications
- Ethanol: low-dose, regular consumption increases salutary HDL; in excess, hypertriglyceridemia

*If hypopituitarism is suspected, thyroid-stimulating hormone alone, as advocated for primary screening, is not sufficient to rule out central hypothyroidism.
†Elevations can be severe with xanthomas.
HDL = high-density lipoprotein.

often accompany sporadic high cholesterol levels and complicate familial lipid disorders. Several of the familial lipid disorders are dominantly inherited with a gene dosage effect: heterozygous individuals have elevated lipids but are generally asymptomatic until the condition manifests as early stroke, angina, myocardial infarction, or sudden death in the fourth or fifth decade of life. However, homozygotes can manifest xanthomas, arcus cornea, and thickened tendons even before puberty and can have cardiovascular end points in early adulthood. Although multiple genes affect lipid levels, several monogenic conditions have been distinguished and can be readily recognized if family history and laboratory data are available. A simple guide for diagnosis based on lipid profile and family history is presented in Table 47-3.

Familial combined hyperlipidemia is the most common type of inherited hyperlipidemia. It is autosomal dominant and is found in 1 in 100 individuals. Of patients with early coronary heart disease, 10 to 15% carry this diagnosis. The

lipid abnormalities are moderate. About one-third of patients with familial combined hyperlipidemia have increased LDL primarily, one-third have increased triglycerides without altered LDL, and another third have increased triglycerides and increased LDL. The three types frequently coexist within a family.

Familial hypercholesterolemia, though rare, is the genetic lipid disorder best understood at a biochemical level. The cause is genetic defects in the LDL receptor gene. Heterozygotes have a decrease in the number of active receptors and homozygotes have absence or near absence of functional receptors. Heterozygous deficiency has a prevalence of 1 in 500 individuals in the United States (0.2%), but heterozygotes account for 5% of early myocardial infarction survivors. These individuals usually have total cholesterol levels in the range of 200 to 500 mg/dL (5.2 to 13 mmol/L). They have a family history of high cholesterol and early coronary disease and require pharmacologic treatment. Premature atherosclerosis is seen in 30% of adults heterozygous for familial hypercholesterolemia.[35]

Some populations with elevated familial hypercholesterolemia prevalence because of founder effects include French Canadians, Dutch Afrikaners in South Africa, and Lebanese Christians. Individuals with homozygous LDL receptor defects are rare, about one in a million individuals, and have very high total cholesterol levels of 500 to 1,000 mg/dL (13 to 25.9 mmol/L). These are children who could have myocardial infarctions and require not pharmacologic treatment, which is usually ineffective, but plasmapheresis or liver transplantation. In the complete absence of LDL receptors (familial hypercholesterolemia patients homozygous for null mutations), statins are utterly ineffective at standard doses. LDL apheresis with devices such as Liposorber columns is very effective, and carries lower risk than does liver transplantation. Gene therapy approaches have been attempted,[36] but long-term benefit remains to be demonstrated.[37]

TABLE 47-3 Phenotype and Family History Commonly Found among Pediatric Lipid Clinic Patients

Common Phenotypes	*Family History*	*Likely Diagnosis*
Elevated LDL* and total cholesterol only	Xanthomas/early heart disease†	Familial hypercholesterolemia (total cholesterol 500–1,000 mg/dL found in homozygotes)
Elevated triglycerides + low HDL, often with obesity	Type 2 diabetes or similar lipid patterns	High risk for metabolic syndrome
Moderately elevated triglycerides and LDL	Elevated triglycerides, LDL, or both	Familial combined hyperlipidemia
Low HDL only	Low HDL, early coronary heart disease	Familial hypoalphalipoproteinemia
High HDL (> 60 mg/dL), normal LDL	Often negative for early heart disease	Normal variant; in 20% of children with elevated total cholesterol, high HDL is the only abnormality; intervention not required

Cholesterol, HDL, and triglyceride values measured in a fasting state. Combination of phenotype with typical family history suggests diagnosis.
HDL = high-density lipoprotein; LDL = low-density lipoprotein.
*LDL is calculated from fasting values using the Friedewald formula, in which LDL = TC – (HDL + TG/5).
†Early heart disease is defined as myocardial infarction before age 55 in men and before in 60 in women.

Familial defective apoplipoprotein B is clinically similar to familial hypercholesterolemia, with similar prevalence for heterozygote and homozygote forms. Familial defective apolipoprotein B is attributable to decreased binding of LDL to its receptor because of a mutation in the apolipoprotein B protein itself rather than a receptor mutation. The condition is rare. The biochemical findings in untreated patients are indistinguishable from heterozygous familial hypercholesterolemia. However, response to pharmacologic therapy, including statins and other agents, tends to be poor, because the up-regulation of hepatic LDL receptors, a key step in the mechanism of action for statins and for bile-binding resins, will not increase clearance of the mutant particles from the blood.

Familial hypertriglyceridemia is characterized by high triglyceride levels, sometimes accompanied by low HDL. This is a very common profile, of polygenic origin, exacerbated by type 2 diabetes and obesity. Rare monogenic disorders cause chylomicronemia and profound hypertriglyceridemia. Homozygous deficiency of lipoprotein lipase or its cofactor, apolipoprotein C-II, causes isolated increase in chylomicrons, presents in children as recurrent pancreatitis, and is autosomal recessive. Affected individuals have xanthomas but do not have an increased risk of early myocardial infarction.

Familial hypoalphalipoproteinemia exists, but in the general population, low HDL is a common trait, and low HDL is especially prevalent among young survivors of myocardial infarction. With notable but rare exceptions, the exact genetic basis of low HDL is obscure. One allele of the apo A-I gene was found in 32% of adults with severe coronary artery disease and in 3 to 4% of those without CHD.[38]

A number of rare, inherited disorders of lipoprotein metabolism have been described. These are beyond the scope of this chapter.

Metabolic Syndrome

Lipoprotein (a) and Cardiovascular Risk Lipoprotein (a), or Lp(a), is a variant LDL particle with a covalently bound protein portion, termed apolipoprotein (a). This particle is not measured on standard lipid profiles. High levels are thought to be atherogenic because the particle not only participates in atheromatous plaques (as does LDL) but also impairs fibrinolysis because apolipoprotein (a) prevents normal plasminogen activation.[39] Lp(a) is genetically determined, and high levels are associated with increased risk of coronary artery disease. The levels within the population are not normally distributed. The majority of humans have normal levels of less than 30 mg/dL, but levels greater than 30 mg/dL are common in lipid clinic

settings. Very high levels (more than 100 mg/dL) deserve particular attention, but there is no pharmacologic treatment that specifically targets Lp(a). Lovastatin has produced some reduction in adults,[40] and others with severe CHD have been treated with plasmapheresis.

Metabolic syndrome, previously called syndrome X, is a collection of cardiovascular risk factors associated with a higher rate of atherosclerotic disease. In adults, metabolic syndrome involves hypertension, elevated fasting glucose levels, central obesity, low HDL, and high triglycerides.[41] This syndrome has not yet been well characterized in children, although it is likely that having a collection of risk factors such as these would put a child at increased risk for atherosclerotic disease in adulthood and therefore should alert the clinician to screen for dyslipidemias and other cardiovascular risk factors and to emphasize modification of lifestyle, including diet. Body mass index (BMI) above the 95th percentile for age in childhood is likely to be a risk factor for future metabolic syndrome.

Cholesterol Screening

Whom to Screen The NCEP and the American Academy of Pediatrics have recommended selective screening of children with risk factors for atherosclerosis, including family history of hypercholesterolemia or early coronary artery disease (Figure 47-1), after age 2 years. Universal screening of all children is not advocated, for these reasons:

- The cost of screening some 60 million young persons is not worth the marginal gain in identifying the small number of patients not identified by family history.
- Based on the NCEP screening algorithm presented in Figure 47-1, rescreening costs for the 15 million US children above the 75th percentile would be even higher.
- It would be rare to discover children by universal screening who would require medication before adulthood, and all children should follow a prudent (Step One) diet and exercise regularly.
- Labeling children unnecessarily as hypercholesterolemic could cause harm.

Nevertheless, several studies have shown that selective screening misses some children because of its dependence on family history—often the full family history is not available,[42] and very young children might have grandparents too young to have had early heart disease—and family history might be less predictive in black children than in white children.[43,44] Therefore, patients with unknown family histories can be screened at physician discretion, according to the NCEP guidelines. Health care providers might also check fasting lipid profiles or total cholesterol in children who have personal risk factors such as obesity, hypertension, or smoking.

What to Test The 1991 pediatric NCEP guidelines suggest initial screen by nonfasting total cholesterol only for children with a family history of hypercholesterolemia. False-negative and false-positive results are common,

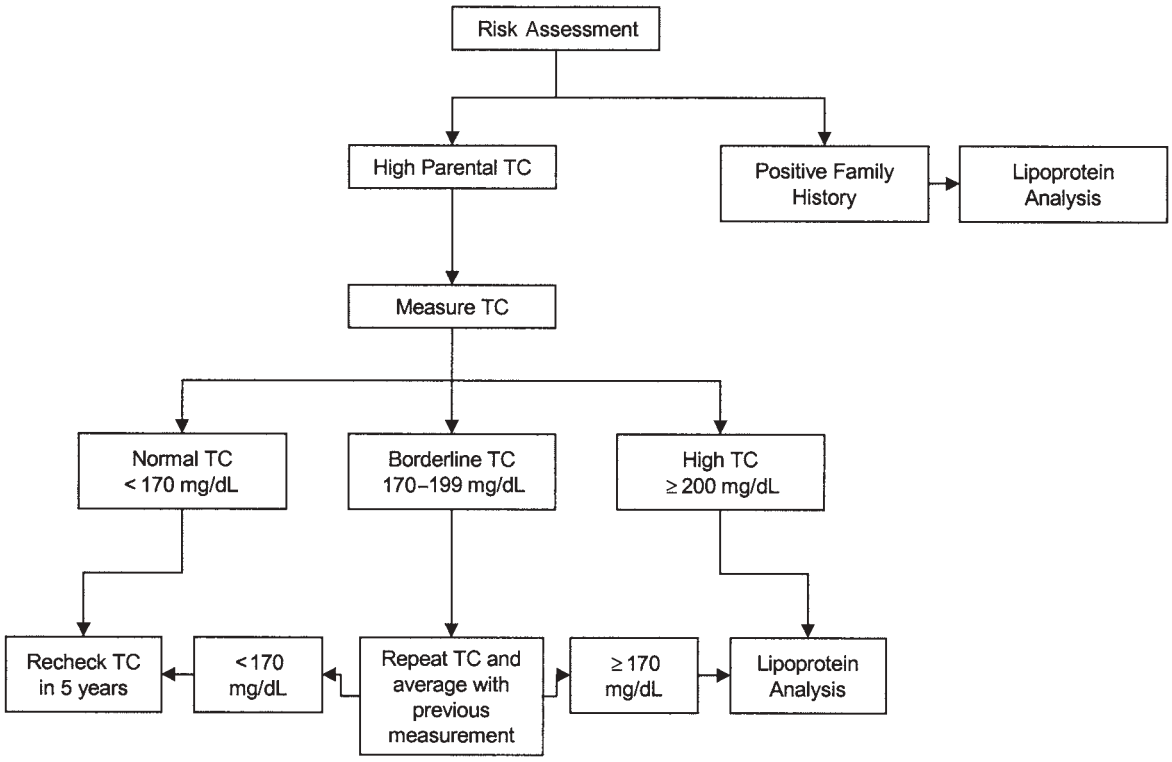

FIGURE 47-1 Selective screening approach recommended by the National Cholesterol Education Program Expert Panel on Children and Adolescents. Note that screening total cholesterol (TC), with a 75th percentile cutoff, requires a large volume of retesting because a single value between 170 and 200 mg/dL has limited positive predictive value.[75]

based in part on HDL cholesterol variance. By contrast, current NCEP guidelines for adults suggest screening with nonfasting total cholesterol *and* HDL cholesterol rather than total cholesterol alone.[45] Adding HDL to the screen adds to the initial cost but dramatically improves sensitivity and specificity of the screen; we believe it is well worthwhile. We recommend screening nonfasting total cholesterol and HDL cholesterol to primary care colleagues in our practice.

NUTRITION AND CHOLESTEROL IN CHILDREN

Dietary habits among American children have changed over the past several decades. Children, like all Americans, eat out more often, consuming 32% of their calories outside the home between 1994 and 1996 compared with 18% in 1977–78. Food eaten outside the home is usually higher in total and saturated fats and lower in calcium, iron, and fiber than food eaten at home.[46] Fruit juice has been recognized as a major source of calories; high intake has been associated both with poor growth and also with obesity, and some studies have shown higher total cholesterol to HDL ratios and lower absolute HDL with high intake of some types of juice.[47] There have been suggestions in recent years that dietary habits in infancy can have a significant impact on childhood cholesterol patterns and even on levels in adulthood. A recent meta-analysis of 1,532 British children and adults showed that breast-feeding was associated with higher total cholesterol and LDL in childhood and lower total cholesterol and LDL in adulthood.[48]

Management of obesity is covered elsewhere in this volume (see Chapter 54). From a lipid management point of view, in patients who are prone to hypertriglyceridemia on a genetic basis and for patients with obesity or at family history of type 2 diabetes, trends toward "super-sized" fast-food meals, juice, and sedentary lifestyle are highly detrimental.

TREATMENT FOR DYSLIPIDEMIAS

Dietary treatment is the first line of intervention in all childhood dyslipidemias, as it is in the adult population. Diet modification is emphasized even more in the pediatric age range than for adults because pharmacologic agents have been tested primarily in adults and safety data are somewhat limited in children. The NCEP has recommended a two-level nutritional approach, adopted with variations by the American Heart Association and the American Academy of Pediatrics. Step One reduces total fat intake to less than 30% of total calories, with a goal of saturated fat representing less than 10% of total calories and cholesterol intakes of less than 300 mg/day.[45] The Step Two diet restricts saturated fat intake to less than 7% of daily calories.

In practice, a Step One diet is readily achieved. Relatively few US children now eat too much cholesterol, in the form of eggs, for example. Some suggestions we provide to our patients for Step One diets are shown in Table 47-4. Professional nutritional counseling is very helpful for patients aiming for a Step Two diet. Dietary intervention trials in adults with fat reductions more stringent than the NCEP Step One diet show a total cholesterol reduction of between 10 and 15%.[49] Several studies demonstrate the efficacy of dietary interventions in children. One study showed that the Step One diet decreased total cholesterol and LDL cholesterol by 12%, although there was significant loss to follow-up of two-thirds of the enrollees.[50] Other studies have found decreases in total and LDL cholesterol of between 6 and 11%.[51,52]

Other dietary interventions have an impact on cholesterol levels in the pediatric ages. One small study of children with hypercholesterolemia showed that fiber supplementation decreases cholesterol while preserving HDL and is more effective than simply following the Step One diet alone.[53] Fiber seems to have an independent effect of reducing cholesterol in children.[54] Recently, counseling has focused not on eliminating fat from the diet so much as exchanging saturated fat for monounsaturated fat. Fat elimination can lead to substitution with refined sugars and carbohydrates that increase triglyceride levels, whereas increased intake of monounsaturated fats can raise HDL levels and improve the cardiovascular risk profile. The Mediterranean diet, one focusing on mono- and polyunsaturated fats, has been associated with a reduced risk of cardiac mortality and morbidity in adults after their first myocardial infarction.[55] It has not been systematically evaluated in children, although many practitioners recommend it to their patients and families. Weight loss in children has been shown to effectively decrease total cholesterol and triglycerides and to increase HDL.[56]

Some pediatric practitioners have raised concerns that these diets will hamper pediatric growth and development; however, the Dietary Intervention Study in Children (DISC) demonstrated that children on a Step One diet had the same growth and development, with somewhat lower cholesterol levels, than did children on a diet close to the usual American intake.[57] The Special Turku Coronary Risk Factor Intervention Project (STRIP) showed that dietary consumption of fat, saturated fat, and total cholesterol did not affect neurodevelopment, although higher protein intake was associated with better neurodevelopmental out-

TABLE 47-4 Simple Substitutions for the Step One Diet

For	*Substitute*
Fatty meats	Fish, skinless chicken, lean beef
Saturated fat (eg, butter)	Monounsaturated fat
Partially hydrogenated oils (*trans*-fatty acids) in regular margarines	Canola or olive oil, monounsaturated margarines (eg, Smart Balance)
Regular peanut butter (partially hydrogenated)	"Natural" peanut butter
Ice cream	Frozen yogurt
Whole milk	Skim or 1% milk
Regular cheese	Low-fat cheese
Lunch meats	Low-fat equivalents
Chocolate (saturated oils)	Cocoa flavoring
Less healthful lunch purchased at school	Lunch packed at home

come in boys, demonstrating that some degree of fat restriction is safe even in children less than 5 years old.[58]

Other interventions that have been explored, but not well exploited, are community-based programs. For example, school-based interventional strategies show some promise. In one study, after 5 years of group nutritional teaching, 2 hours per week, average total cholesterol was lower in children at the intervention schools than in the comparison groups.[59] Another similar study in Greece showed smaller increases in BMI and fat and saturated fat intake and larger decreases in total cholesterol in the intervention schools than in the control schools.[60] The DISC is the largest published experience with school-based interventions. The investigators found that even in the control schools, with modest education rather than formal interventions, cholesterol values improved. The American Heart Association Web site (<http://www.americanheart.org>) is an excellent resource for community-based interventions. The jumpSTART program offers a curriculum for third to fifth graders (<http://www.nhlbi.nih.gov/health/prof/heart/other/jumpstrt.htm>).

Special Nutritional Interventions: Stanol-Containing Margarines and Omega-3 Fatty Acids

Several specific nutritional tools modify lipid profiles. Certain sterols, similar in structure to cholesterol but not absorbed by the small intestines, lower cholesterol by inhibiting absorption of cholesterol, both dietary and in the form of bile acids. As part of a low-fat diet in adults, stanols decrease total cholesterol by 8 to 10%, in addition to the 7% reduction from the low-fat diet alone.[61] Few studies have been performed in children; one trial of stanol ester margarine in 24 children found a decrease from pretreatment levels in total and LDL cholesterol by 14 and 18%, respectively, after 12 weeks, although betacarotene and tocopherol levels also decreased.[62] In adults, n-3 polyunsaturated fatty acids (omega-3 fatty acids) have been shown to reduce the risk of cardiovascular mortality after a myocardial infarction,[63] but, of course, no such data are available for children. Fish are a rich source of omega-3 fatty acids and should be recommended. Flax oil and ground flaxseed are reasonable substitutes for fish for children who will not eat fish.

Pharmacologic Intervention

Adult studies demonstrate significant reduction in cardiovascular morbidity and mortality with cholesterol-lowering medications, not just in severely affected patients or those who have existing heart disease but also as primary prevention in patients with only moderate hypercholesterolemia.[64] As in adults, lipid-lowering drugs can be very effective in children. However, not enough data are available to weigh the potential long-term benefit against very low short-term risk of heart disease in young patients, together with the expense and potential risk of the medications.

In addressing this difficult choice, the NCEP recommendations take a compromise approach: after approximately a year of nutritional and lifestyle changes, children aged 10 years or older with severe hyperlipidemia, defined as LDL cholesterol of more than 190 mg/dL or greater than 160 mg/dL with two additional risk factors for cardiovascular disease, are eligible for consideration for pharmacologic treatment. In practice, we follow this guideline approximately, with the following modifications: we are less likely to consider medication in prepubertal patients if the beneficial HDL levels are high (consistent with the current adult guidelines, which take HDL cholesterol of more than 60 mg/dL as a negative risk factor). Conversely, we occasionally consider and treat children less than 10 years of age with medication for very abnormal profiles with severe family history. Usual dosages are shown in Table 47-5.

The few trials that have been done in children show efficacy rates for decreasing cholesterol levels that are similar to those of adults. Cholestyramine and colestipol are resins that bind to cholesterol in the gut and can lower cholesterol by 10 to 15%.[65,66] The bile acid binding medications are not absorbed, so there are no systemic effects; however, they have a gritty texture in powdered form and can cause constipation, so many children cannot tolerate them. Tablet forms of colestipol and cholestyramine are presently off the market. Colesevelam tablets are available and can be used in patients who do not tolerate the powdered forms but are old enough to swallow the large pills. Because they bind to lipophilic and acidic drugs, bile binding agents are challenging to use in patients on multiple crucial medications such as post-transplantation immunosuppressive agents. In these special patients, it would be reasonable to consider statin use earlier in a patient's course. Compliance with bile acid binding medications can be a problem that limits their usefulness, particularly in the younger child who might not understand the point of a preventive medication. Teenagers might have compliance issues as well, particularly with medications that require multiple doses per day.

Other lipid-lowering medications are systemically absorbed and are used with even more caution in children. Niacin can be an effective adjunct to lipid therapy in some adult settings, but flushing, abdominal discomfort and risk of hepatotoxicity limit its use in children.[67]

3-Hydroxy-3-methylglutaryl CoA reductase inhibitors, or statins, are the clear first-line agents for adults with elevated LDL cholesterol levels and have been used in selected, high-risk pediatric and adolescent patients for many years, but formal studies of safety and efficacy are few. Pravastatin was tested in 8- to 16-year-old boys and found to decrease total cholesterol by 25% and LDL cholesterol by 33%, without side effects, after 12 weeks of follow-up[68]; other short-term studies have supported these findings.[69,70] The longest trial of a statin medication reported to date is a 48-week follow-up trial in boys that showed significant efficacy, with a reduction of LDL cholesterol by 25% and no long-term endocrinologic or other sequelae.[71] Gemfibrozil and other fibric acid derivatives are indicated for hypertriglyceridemia in adults but are used only rarely, and only for very severe cases, in teenagers and almost never in younger patients.

TABLE 47-5 Dosages of Medications Commonly Used in Hyperlipidemia

Bile Binding Resins	*Dosage Forms*	*Typical Dosage Range*	*Comments*
Cholestyramine powder (eg, Questran, Lo-Cholest)	Generic powder is unflavored; Questran Light and Lo-Cholest are flavored	Weight < 40 kg: start with 2 g bid, increase to 4 g bid if well tolerated Weight > 40 kg: start as above, to 6 g bid; max. adult dose, 24 g/d	Not systemically absorbed; side effects of bloating, constipation fairly common
Colesevelam (Welchol)	625 mg tablets	Adult dose: 1,875 mg bid; pediatric dose: approx. 30 mg/kg bid, with liquids	Tablets are large; can be difficult for children to swallow
Statins†			
Lovastatin (eg, Mevacor)	10, 20, 40 mg tablets	Pediatric dose*: 10–20 mg qd or divided bid; adult dose: 20–80 mg qd or divided bid	Generic form available, inexpensive; works best with bid dosing; is the drug with longest experience and most pediatric safety data available
Pravastatin (eg, Pravachol)	10, 20, 40, 80 mg tablets	Adult dose: 10–40 mg qhs	
Simvastatin (eg, Zocor)	5, 10, 20, 40, 80 mg tablets	5–80 mg qhs	
Atorvastatin (eg, Lipitor)	10, 20, 40, 80 mg tablets		

Dosages are provided as a guide only and should be reviewed independently prior to prescribing.
*Children heavier than 40 kg are considered nearly adult sized and are dosed as adults.
†Statin therapy is contraindicated in pregnancy. Liver function tests (LFTs) should be monitored at baseline, after 6 weeks therapy, and then intermittently if normal. Caution patients about rare rhabdomyolysis; creatine phosphokinase should be checked if patient has myalgias. Sleep disturbances and abdominal discomfort are infrequent side effects.

Other Approaches for Severe Hypercholesterolemia

For patients with severe hypercholesterolemia unresponsive to diet or pharmacologic intervention, plasmapheresis or LDL apheresis with a Liposorber column has been successfully used in adults, lowering total cholesterol, LDL, triglycerides, and lipoprotein (a), and perhaps a slowing of the progression of atherosclerosis.[72] The technique has also been used in selected pediatric patients with success,[73] although the issue of vascular access is a difficult one. An interesting new medication approved for use in adults by the US Food and Drug Administration in late 2002 is ezetimibe, a selective inhibitor of cholesterol absorption that reduces LDL by approximately 20% in 12 weeks.[74] This trial included seven participants aged 12 to 17 years, with no particular mention of ill effects in these children; however, the medication has not yet been systematically studied in pediatric patients.

MULTIDISCIPLINARY LIPID CLINIC APPROACH

Because atherosclerosis has a complex and multifactorial pathophysiology, pediatric lipid treatment programs that employ a multidisciplinary approach are more likely to be successful. In our center, the approach is combined nutritional and aerobic activity counseling, along with risk assessment and lipid monitoring. Our impression is that lifestyle habits can be more malleable in children, and changes put into place in younger children might be more likely to have an impact for years to come. This is the prime rationale for seeing children at young ages, along with their families, even if they will not require medication before adulthood.

Contrary to the trend in adult lipid practice, we, along with most groups who see many children with hyperlipidemias, strive to avoid pharmacotherapy and only occasionally use medication in the most severely affected patients. Figure 47-2 describes one such approach to patient management.

Clinic sessions should include group and individual nutritional education, laboratory work (or a review of previously obtained laboratory results), and a session with a clinician. A 3-day food recall provides a basis for individual nutritional counseling at the initial visit and in follow-up. Patient and family group education can include the basics of "good" and "bad" cholesterol, saturated and *trans*–fatty acids, protein, sugars, and fiber, etc. Parents can be taught to read labels and to read between the lines on labels, and children can learn the concept of budgeting their fat and sugar intake so that birthday cake, for example, is not completely off limits but requires a lean period in compensation. It is useful to show children the actual amount of sugar in a can of soda or a serving of juice or the appearance of fat clogging a tube that represents an artery. Methods of "dieting" for children can include using the plate method (Figure 47-3). We stress that "diet" does not mean weight loss for slender patients with genetic hyperlipidemia, but weight loss is paramount in patients with moderate to severe obesity, even when genetic hyperlipidemia is present. In general, emphasizing substitution of foods, as opposed to restricting or eliminating food, is more positive and seems more effective. Table 47-4 presents some simple suggestions for dietary modifications in hyperlipidemia.

The physician or nurse practitioner portion of the visit should involve a review of family history, general medical history, level of physical activity (or lack thereof), and an evaluation of lipid values. Twelve-hour fasting lipid values are the most valuable for children referred to a specialist clinic as it is important to have accurate triglyceride and LDL levels, at least on one or two occasions. At the Children's Hospital, Boston clinic, a healthful breakfast is pro-

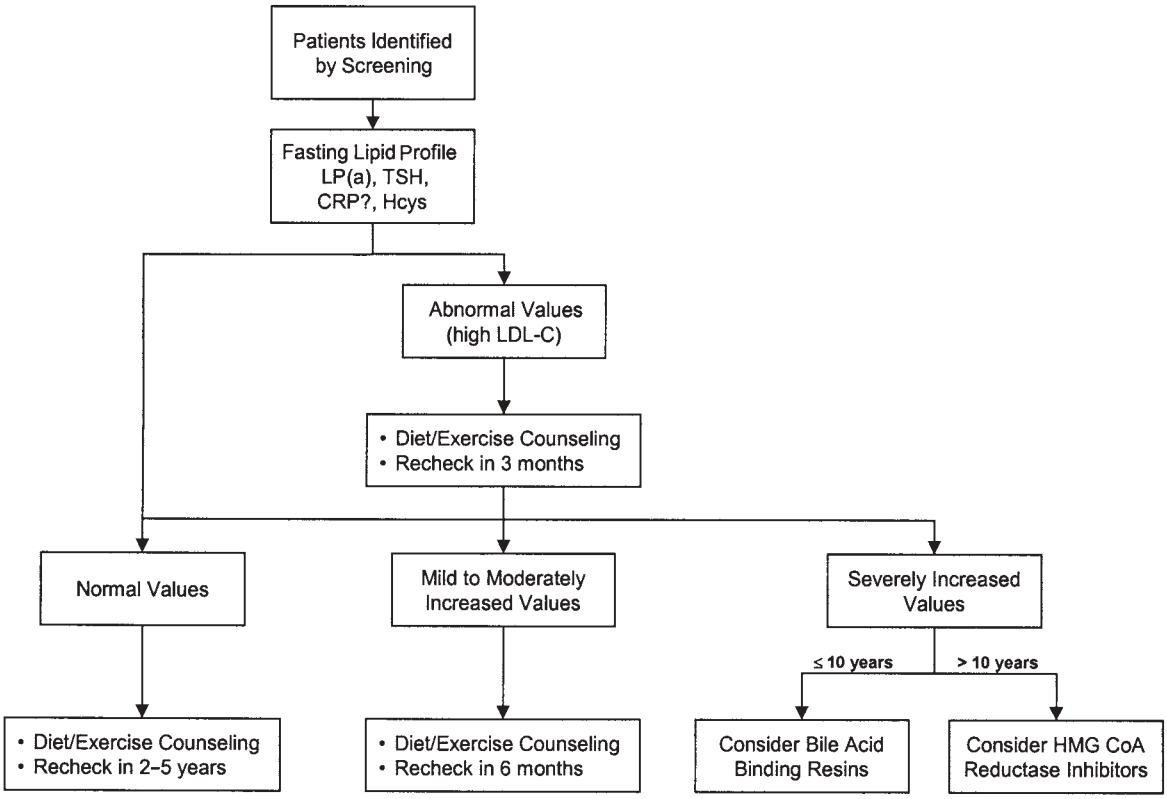

FIGURE 47-2 Proposed approach to young patients ascertained to have high cholesterol on screening. Thyroid-stimulating hormone (TSH) serves as an inexpensive screen for primary hypothyroidism. Lipoprotein (a) (Lp[a]) is an independent risk factor for premature atherosclerosis. The role of highly sensitive C-reactive protein (hsCRP) or homocysteine (Hcys) screening is not defined in pediatrics. HMG CoA = 3-hydroxy-3-methylglutaryl coenzyme A.

vided to children after their laboratory samples are drawn, allowing modeling of good eating habits. Because severely affected children in a pediatric lipid setting usually have severely affected parents, we have found that often the most pressing medical issue for the child is having his or her parents tested for hyperlipidemia. It is important to ask about cigarette smoke exposure, to encourage children not to smoke, and to encourage parents not to smoke around their children because it has been shown that children exposed to cigarette smoking have lower HDL levels.[75,76] We stress the need to find physical activities that the child will enjoy.

We try to emphasize that for most children, these issues are not an emergency but rather are long-term modifications that are important not for present health but for cardiovascular risk 30 to 40 years in the future (a nearly unimaginable length of time for most children). This helps parents and children to view this as a long-term project and removes the pressures of enforcing an immediate turnaround. Having only appropriate food in the home is helpful in making choices easier. Lifestyle changes seem to be more effectively made if the entire family joins in the effort. Often, suggested changes are indicated for multiple family members, even if only one child in the family was referred. Follow-up is crucial for monitoring progress, medication compliance, and somatic growth.

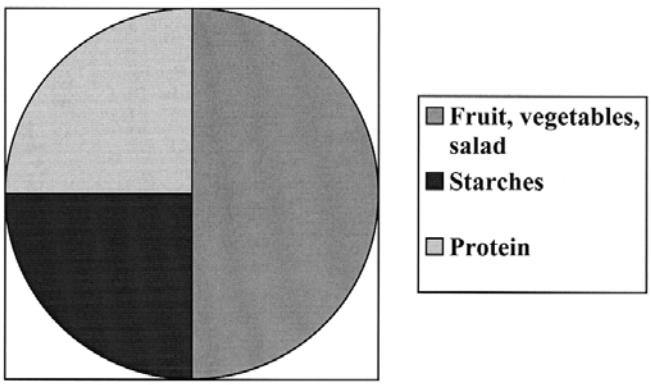

FIGURE 47-3 The "plate method" is a simple means for balancing the diet and reducing carbohydrate consumption without counting calories or grams of fat. The method is highly effective for hypertriglyceridemia and for obesity, if given with a few suggestions: (1) the entire family, not just the patient, should try the method for 4 to 6 weeks and then recheck lipids and weight; (2) the patient must finish the entire plate before having second helpings; and (3) "seconds" cannot be just starches but must again be balanced.

SUMMARY

Pediatric lipid disorders contribute to future cardiovascular risk and as such should be addressed aggressively. Yet at the same time, in the majority of cases, pediatric hyperlipidemias might be most safely, and perhaps most effectively, treated with a multidisciplinary approach that includes aerobic activity, nutritional counseling, and individualized interventions. Care should be exercised to prevent the establishment of negative behavioral patterns because the health implications of dyslipidemias are, for

the most part, far in the future. Future research should focus on longer-term evaluation of antihyperlipidemic medications in young patients and on developing markers of preclinical disease that can be used to evaluate the efficacy of interventions for atherosclerosis prevention.

CHAPTER 48

CARBOHYDRATE ABSORPTION AND MALABSORPTION

Martin H. Ulshen, MD

Carbohydrates are a major dietary source of energy, accounting for 50 to 60% of the calories ingested in the average Western diet after early infancy. The disaccharide lactose is the principal carbohydrate offered to most young infants, whether they are nursed or fed commercial cow's milk formula. Throughout the first year of life, however, sucrose and starch are introduced progressively into the diet as solids and juices; by early childhood, starch will have become the major dietary carbohydrate.

The proportion of newborns in the United States who breast-feed has been increasing.[1–4] In 1971, only about 6% of 6-month-old infants nursed. However, by 1995, about 60% of new mothers initiated breast-feeding and 25% of 6-month-old infants continued to nurse. During the first 6 months of life, human milk and commercial formula account for more than 50% of the total calories in the diet in the United States.[5,6] Human milk has a very high lactose content compared with the milk of other mammals; human milk and commercial formulas contain about 37 and 42% of their calories, respectively, in the form of carbohydrate.[7] Use of soy-based formulas has increased over the past 30 years; as many as 25% of infants in the United States now receive these formulas.[8–10] Soy-based formulas contain carbohydrate as cornstarch, cornstarch hydrolysate, tapioca starch, or sucrose rather than lactose.[8] The carbohydrate content of these formulas is similar to human milk and cow's milk–based formulas.

Baby foods provide less than 10% of the calories ingested by an average 3-month-old infant, with half of this amount coming from cereal.[6] During the entire first year of life, about 20% of the total caloric intake is provided by baby foods. By 12 months of age, table foods account for more than 50% of the calories in an infant's diet.[5] Of the solid foods, fruits become a significant source of carbohydrate by 4 months of age and remain the highest nonformula source of carbohydrate throughout the first year of life (G. H. Johnson, unpublished data). In an average diet for an older child or adult, about 50% of the carbohydrate is in the form of starch; lactose accounts for a decreasing proportion of the total carbohydrate calories, becoming only a minor fraction for many adults.

CARBOHYDRATE DIGESTION AND ABSORPTION

Although carbohydrate is ingested largely in the form of starch and disaccharides, only monosaccharides are actually able to move from the intestinal lumen through the mucosal barrier. Therefore, digestion of complex carbohydrates (ie, hydrolysis) is required for assimilation to occur.

Starch

Most dietary starch consists of either straight chains of glucose with α-(1,4) links (amylose) or straight chains with additional α-(1,6) branches accounting for about 5% of the total linkages (amylopectin). Amylopectin is the major form of starch in the human diet. The primary enzyme of starch digestion, α-amylase, acts only on the interior α-(1,4) linkages of starch. The oligosaccharides released are maltose (2 glucose units), maltotriose (3 glucose units), and the α-limit dextrins, oligosaccharides consisting of up to 6 glucose units with one or more α-(1,6) links, which come from amylopectin. The glucose released is negligible; therefore, the products of starch hydrolysis require further digestion prior to absorption. Amylase is unable to cleave the α-(1,6) linkages of amylopectin and the α-limit dextrins or the β-(1,4) linkage of cellulose.

Carbohydrate digestion begins with the oral exposure of starches to salivary α-amylase (Table 48-1). The role of salivary α-amylase in starch digestion has been uncertain because this enzyme is inactivated at gastric pH. However, starch and the oligosaccharide products of starch digestion have been found to protect the activity of salivary amylase in this pH range, even in the presence of pepsin.[11,12] In neonates, saliva is likely to be an important source of amylase activity, even though salivary enzyme activity is low in premature infants.[12] This function of salivary α-amylase appears to be analogous to the role that lingual lipase serves in fat digestion in newborns.[13]

Human milk, unlike cow's milk, is rich in α-amylase activity (the sum of several salivary isoenzymes).[14,15] This amylase, like salivary α-amylase, may partially compensate for the low level of pancreatic α-amylase activity

TABLE 48-1 Principal Enzymes of Carbohydrate Digestion in Humans and Their Common Substrates

Enzyme	*Substrate*
α-Amylase	
Pancreatic	Starch (interior α-l,4 links)
Salivary and human milk (may be important in neonates)	
Oligosaccharidases	
Sucrase-isomaltase (α–dextrinase)	Sucrose Maltose Maltotriose α-Limit dextrins (α-1,4 and α-1,6 links)
Maltase-glucoamylase	Short glucose polymers (α-1,4 links, activity is greatest for linear polymers) Maltose Maltotriose Starch (α-1,4 links)
Lactase	Lactose

in the duodenum of newborns (see below), in a manner similar to the role that human milk lipase appears to have in neonates.[16] During the first 3 months of life, the α-amylase activity in duodenal fluid is actually lower than the activity in an equivalent volume of the milk ingested by a nursing infant. Amylase activity levels do not vary between preterm and term human milk, throughout a feeding, or between feedings.[17] Storage of expressed human milk for at least 24 hours does not reduce amylase activity levels, even at 15°C to 25°C.[18] Pasteurization of human milk results in only a 15% reduction of activity (in contrast to lipase activity, which is completely abolished).[19]

In the adult, the pancreas secretes α-amylase in marked excess of the normal requirements for starch hydrolysis.[20] When intestinal contents reach the distal duodenum, hydrolysis is essentially complete. Although α-amylase will adhere to the intestinal brush border, intraluminal activity is more than adequate to account for the total amount of starch digested. In fact, adults with pancreatic insufficiency and secondary steatorrhea are usually able to digest starch adequately despite decreased levels of pancreatic α-amylase as well as the absence of electrophoretically identifiable salivary amylase in the duodenal fluid. Auricchio and colleagues demonstrated that infants less than 6 months of age typically have a low concentration of α-amylase activity in the duodenal fluid and a concomitant inability to completely hydrolyze amylopectin following a test meal containing this starch.[21] This pattern of low α-amylase activity in the first 6 months of life has been confirmed by others as well.[22,23] Infants can digest various cooked starches in limited quantities: at 1 month of age, 10 g per day (comparable the amount of starch in formula), and at 3 months of age, 23 g per day (comparable to the quantity of starch taken in cereal and formula at this age).[24] After the first year of life, children have high concentrations of α-amylase activity in their duodenal fluid, and their capacity for digestion of a test meal of starch is comparable to that of adults.

In healthy adults, the form in which starch is offered will greatly influence the degree to which it is digested.[25,26] As much as 10 to 20% of the carbohydrate in a bread composed of wheat flour may not be absorbed in the small intestine, whereas the starch from low-gluten wheat or rice bread (even with added gluten) appears to be completely absorbed. Wheat flour consists of granules of starch surrounded by a protein shell, and this layering effect may interfere with starch digestion. Variable susceptibility to digestion of the starches from a number of cereals has also been shown in vitro.[27] Amylase-resistant starch is a good substrate for colonic fermentation, resulting in short-chain fatty acids (see "Consequences of Carbohydrate Malabsorption" below) and has been used in the treatment of diarrhea.[28]

OLIGOSACCHARIDES

Oligosaccharides, including the products of starch digestion and the dietary disaccharides, are not absorbed intact but must first be split into monosaccharides. Hydrolysis of the oligosaccharides occurs at the luminal surface of the small bowel and is catalyzed by a group of enzymes, the oligosaccharidases (also, although less accurately, called the disaccharidases). These enzymes reside on the exterior surface of the brush border (the microvillus membrane) of the surface epithelium (enterocytes) of the small intestine. The oligosaccharidases are glycoproteins and consist of about 30 to 40% carbohydrate by weight, covalently linked to a protein moiety.[29] These enzymes are composed of a hydrophobic region, which serves as an anchor in the lipid-rich brush border membrane, and a hydrophilic region, which extends into the small bowel lumen and contains the active site.[30]

The surface of the small bowel is covered by a continuous sheet of epithelium. The epithelium proliferates in the crypts and migrates to the villus tips over a period of 3 to 5 days. During this migration, the epithelial cell or enterocyte matures both morphologically and functionally. Oligosaccharidase activity is associated with the mature villus enterocytes but not with the crypt cells. In addition to the normal variation in oligosaccharidase activity along the villus-crypt axis, activity varies along the length of the small intestine, with maximal levels in the proximal jejunum and minimal levels in the proximal duodenum and terminal ileum.[31] The process of synthesis of the oligosaccharidases within the enterocyte and their subsequent transport to the brush border, a region devoid of its own apparatus for protein synthesis, is incompletely understood but has been best studied with the enzyme complex sucrase-isomaltase.[32–34] There is evidence that this protein is synthesized and partially glycosylated in the endoplasmic reticulum. Further glycosylation takes place in the Golgi apparatus, and the nascent enzyme is subsequently incorporated into the brush border membrane.[35] Sucrase and isomaltase are synthesized as one large polypeptide, which is incorporated into the brush border membrane and then split into two subunits by exposure to pancreatic proteases.[33,34,36]

The developmental changes in both sucrase and lactase activities in the neonatal period and the distribution of activity along the small intestine in rodents correlate with the abundance of sucrase-isomaltase and lactase messenger ribonucleic acids (mRNAs), respectively.[37–39] In both rodents and humans, sucrase-isomaltase and lactase mRNAs appear to be absent from crypt epithelial cells and most prominent in the lower to midvillus enterocytes, demonstrated by in situ hybridization, correlating with the distribution of activity.[40–42] As shown in Table 48-1, a number of the oligosaccharidases have the ability to cleave to more than one substrate. The oligosaccharidases are classified as α-glucosidases (including sucrase-isomaltase and maltase-glucoamylase) and a β-galactosidase (lactase), depending on the type of carbohydrate linkage that is split. Many factors are known to influence enzyme activity, including the presence of substrate, hydrolytic products, pancreatic enzymes, and bile, as well as damage to the brush border. Ingestion of a diet rich in substrate sugar generally leads to an elevation in the complementary disaccharidase activity.[43–45] The reduction in sucrase-isomaltase activity associated with elimination of sucrose and starch from the diet can be accounted for by conversion of the enzyme to an inactive protein.[46] Lactase appears to be an exception, and the influence of chronic ingestion of a diet rich in lactose on lactase activity is small and probably not of physiologic importance.[47] It does not appear that this enzyme can be induced by diet in individuals with lactase deficiency, nor does lactase activity drop in individuals with normal levels when given a lactose-free diet.[48,49]

The half-life of the oligosaccharidases in vivo is in the range of 4 to 16 hours. Because migration of the enterocyte to the villus tip occurs over several days, there must be continued synthesis and degradation of these enzymes by the mature enterocyte. It appears that pancreatic proteases, and possibly bile acids and lysolecithin as well, play a key role in the degradation of these enzymes.[50–52] After removal of pancreatic enzymes or bile from the intestinal lumen in laboratory animals, the level of activity of the oligosaccharidases rises, and turnover of enzyme protein is decreased.[50,52] Paradoxically, lactase activity rises in the proximal bowel but falls in the mid–small bowel on removal of these secretions.[53] Treatment of pancreatic insufficiency with enzyme replacement returns the oligosaccharidase activity to normal. With the exception of lactase, this elevation of enzyme activity in pancreatic insufficiency has been demonstrated in humans as well.[54]

During fetal life, there is a characteristic pattern of development of the activities of each of the oligosaccharidases in the small bowel.[55] In humans, lactase is the last of these enzymes to reach the level found in full-term newborns. Because lactose is the major carbohydrate in human milk and most infant formulas, this observation has potential importance when the tolerance of dietary carbohydrate by premature infants is considered.

The oligosaccharidases, with the exception of lactase, have the capacity to hydrolyze substrates at a rate more rapid than the rate at which the resultant monosaccharide products can be absorbed.[56,57] Therefore, monosaccharide absorption, rather than oligosaccharide digestion, is the rate-limiting step for assimilation of these sugars. However, lactose is split at a rate that is lower than that of the mucosal uptake of the glucose and galactose products.[56] Therefore, lactase activity is rate limiting for lactose absorption. Furthermore, in normal individuals, the level of activity of lactase is always lower than the level of activity of sucrase. Lactose hydrolysis has been shown to be inhibited by monosaccharide products but by fructose as well, suggesting that the presence of other disaccharides (eg, sucrose) may also inhibit lactose hydrolysis.[58,59] All of these phenomena contribute to the observation that lactose intolerance is the most common of the acquired oligosaccharide intolerances.

The α-limit dextrins that result from amylopectin hydrolysis are digested by the complementary action of three brush border oligosaccharidases: sucrase, isomaltase (α-dextrinase), and glucoamylase.[60] Glucose monomers are removed in sequence from the nonreducing end of the oligosaccharide. Although all three enzymes are capable of splitting α-(1,4) links, isomaltase appears most active when four or more glucose residues remain; sucrase is most active for three or fewer glucose residues (ie, maltotriose and maltose). Only isomaltase is capable of splitting the α-(1,6) branches. Glucoamylase is especially active for straight-chain glucose polymers with about six glucose units.[61] Studies done in humans suggest that starch and disaccharides ingested in test meals are essentially completely absorbed by the time the intestinal contents reach the distal jejunum.[20,62,63]

Monosaccharides

Most of the monosaccharide that is presented to the intestinal surface during digestion results from hydrolysis of dietary starch and oligosaccharides. Monosaccharides released at the brush border by the oligosaccharidases can either be absorbed directly or can diffuse back into the lumen of the intestine to be absorbed at another site. Because of the size and hydrophilic nature of the monosaccharides, they are not able to move across the brush border membrane by diffusion. Glucose and galactose appear to be absorbed by the same carrier-mediated active process, whereas fructose appears to move across the brush border membrane by facilitated transport in association with a different carrier.[64,65] Infants less than 1 year of age have a decreased capacity for glucose absorption in comparison with adults.[66]

Evidence from in vitro studies has made a strong case for Na+-coupled active transport as the primary mechanism for absorption of glucose and galactose.[64] In the human intestine, about 95% of the dietary glucose ingested by an adult is absorbed by carrier-mediated transport.[67] This finding is in contrast to earlier studies, which had suggested a more important role for passive absorption. Transport of each sugar is saturable, and competitive inhibition suggests that both sugars are transported by the same membrane carrier. All of the sugars transported by this carrier have closely related structures. D-Xylose,

although a pentose, can be transported by the glucose-galactose carrier.

Glucose absorption by enterocytes occurs in two steps: (1) The Na+/glucose cotransporter (SGLT1), a transmembrane protein that is believed to aggregate as a homotetramer, is responsible for active transport across the brush border membrane.[68,69] Glucose is able to bind to the extracellular domain of this protein complex only in the presence of Na+; this interaction causes a conformational change in this transmembrane protein, moving glucose into the cell.[69] (2) Glucose moves out of the enterocyte by facilitated diffusion across the basolateral membrane in association with the transporter GLUT 2.[70] Both carriers have been cloned, sequenced, and expressed.[68,70] In studies in rabbit intestine, SGLT1 mRNA can be found by in situ hybridization in villus but not crypt epithelial cells, and abundance of this mRNA increases sixfold from the base to the tip of the villus.[71] SGLT1 protein has been found only associated with the brush borders of mature enterocytes.[71] Expression of both transporters is increased by exposure to glucose.

Although glucose is absorbed down a concentration gradient during meals, absorption continues as intraluminal glucose concentrations drop below tissue levels. Sodium concentration gradients appear to be the driving force for this transport system. The basolateral membrane transporter GLUT 2 maintains a low intracellular concentration. Therefore, although glucose movement is against a concentration gradient, it is coupled to Na+ movement down an electrochemical gradient. In studies in which Na+ has been removed from a solution bathing the intestine, in vivo or in vitro, glucose transport has been reduced or eliminated.[72,73]

Fructose absorption occurs by facilitated diffusion (ie, carrier mediated but not active transport). Fructose assimilation occurs at the brush border in association with a high-affinity transporter, GLUT 5.[74] Fructose then crosses the basolateral membrane associated with the carrier GLUT 2.[75] Expression of both transporters is increased by the presence of fructose. The capacity of the small intestine to absorb fructose in humans is limited and can be surpassed in some individuals during ingestion of a diet rich in fructose.[76] Excess fructose in the diet of infants, in addition to sorbitol, can be a factor in the development of toddler's diarrhea.[77]

There is another membrane transport mechanism that has been demonstrated for monosaccharides: the hydrolase-related transport system.[78] When intestinal preparations have been studied under conditions in which glucose transport has been saturated, further absorption of glucose could be achieved by introducing a glucose-containing disaccharide into the bathing solution. This transport is Na+ independent. Both glucose and fructose can be transported by this system when the disaccharide is sucrose; however, it is doubtful that this system is of physiologic importance.

CONSEQUENCES OF CARBOHYDRATE MALABSORPTION

The pathophysiologic consequences of carbohydrate malabsorption are similar for all carbohydrates and all underlying etiologies. The range of symptoms and the nutritional effects of carbohydrate malabsorption have been well characterized. The net capacity of the small bowel for carbohydrate absorption is influenced by several variables: (1) the functional capacity of the bowel mucosa for each of the steps of carbohydrate assimilation, (2) the amount of small bowel surface area available (influenced by bowel resection or mucosal damage), and (3) the rate of transit of luminal contents through the intestine. In the past, the small intestine was thought to be the only region of the gastrointestinal tract in which carbohydrate could be absorbed. However, the work of Bond and Levitt (described below) indicates that the colon is capable of conserving malabsorbed carbohydrate and has changed some of our ideas about the factors that influence the consequences of carbohydrate malabsorption.[79–81]

The complete symptom complex of carbohydrate malabsorption can include nausea, crampy abdominal pain, intestinal gas, bloating, abdominal distention, and watery diarrhea. However, not all of these symptoms need occur in every individual with carbohydrate intolerance. Patients may have abdominal pain with little or no diarrhea. Likewise, diarrhea may be present without other symptoms. Because a delay in the onset of symptoms after carbohydrate ingestion can occur, the association may not be obvious.

The surface of the gastrointestinal tract provides a hydrophobic barrier to the passive diffusion of carbohydrate. Therefore, if any step in the assimilation of carbohydrate is blocked, carbohydrate remains in the luminal contents and passes distally. The stomach and proximal small bowel are permeable to water and electrolytes; therefore, nonabsorbed carbohydrate in the lumen of the proximal gastrointestinal tract is diluted with water and electrolytes that have moved across the mucosa to maintain isotonicity. When a mixture of lactose and a nonabsorbable marker, polyethylene glycol (PEG), has been fed to normal individuals, dilution of PEG occurs in the duodenum, and progressive concentration of PEG is found in aspirates from the distal small bowel (Figure 48–1).[82] The increased concentration of PEG represents a decrease in intraluminal volumes resulting from net fluid absorption because PEG does not cross the small-bowel surface. For lactose-intolerant individuals, dilution of the lactose solution occurs in the duodenum as well; however, the concentration of PEG remains low throughout the distal small bowel, suggesting a lack of subsequent reabsorption of intraluminal water. Although net absorption of fluid does occur in the colon in these subjects, it is at a decreased rate. Furthermore, increased transit through the small bowel has been found to occur when carbohydrate is incompletely absorbed.[83] The net secretion of fluid and electrolyte in the small bowel, decreased reabsorption in the colon, and possibly the rapid transit through the small bowel all contribute to the production of a watery diarrhea rich in electrolyte. This has been called an osmotic diarrhea because the diarrhea results from the presence of a poorly absorbed osmotically active solute in the intestinal lumen.[84] These diarrheas are characterized by (1) the fact that they stop when the solute is removed from the diet and (2) a stool osmolality that is at least 50 mOsm/kg greater than twice the sum of stool sodium

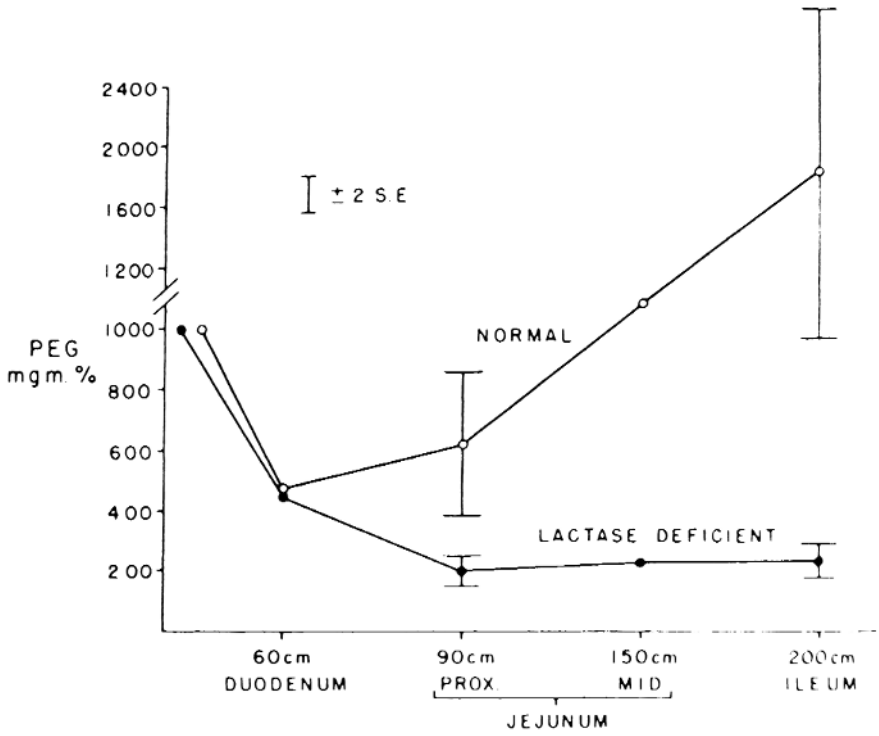

FIGURE 48-1 Polyethylene glycol (PEG) concentration is shown in different regions of the small bowel following ingestion of lactose and PEG by two normal and five lactase-deficient individuals. The small intestinal contents have become diluted in proximal bowel and then concentrated in distal bowel of normal but not lactase-deficient individuals. Reproduced from Christopher NL and Bayless TM.[82]

and potassium concentrations (ie, there is another osmotically active solute present in addition to electrolyte).[83,84]

Unabsorbed carbohydrate reaching the colon is fermented by bacteria, which produce short-chain fatty acids, CO_2, hydrogen (H_2), and methane. This process increases the osmolality of the colonic contents and stool by splitting carbohydrate into smaller units. Gas production and the increased fluid volumes in the intestine probably cause abdominal cramps by distention and altered motility. It is estimated that 1 g of malabsorbed carbohydrate (including the resultant short-chain fatty acids) results in an increase in stool weight of about 30 to 35 g.[85,86]

Bond and Levitt estimated that normal subjects absorbed 92 to 100% of a 12.5 g lactose load in the small bowel, whereas subjects with lactase deficiency absorbed only 22 to 60% of the load. This estimate was derived by collecting ileal contents after ingestion of a mixture of ^{14}C-labeled lactose and a nonabsorbable marker.[80] However, only about 15% of the ^{14}C from the malabsorbed lactose was recovered in the stool, suggesting further assimilation in the colon. Debongnie and colleagues obtained similar results offering subjects cow's milk, except that in two of their four lactase-deficient subjects, lactose malabsorption was not demonstrable (ie, only 0 and 7% of the ingested lactose was recovered from the ileum).[83]

The influence of lactose malabsorption on the absorption of other nutrients has been controversial. One can find studies that suggest that lactose intolerance either does or does not lead to malabsorption of protein or fat. Although small amounts of protein and fat may be malabsorbed along with lactose, this finding does not appear to be nutritionally important.[83] Lactose malabsorption is associated with increased recovery of calcium, magnesium, and phosphate from the ileum, suggesting that there is increased loss of these minerals with lactose malabsorption. Although lactose intolerance has been associated with osteoporosis in adults, causality has not been demonstrated. In situations in which gastrointestinal tract function is compromised (eg, the short-bowel syndrome), steatorrhea secondary to lactose intolerance may become clinically apparent.

Much of the carbohydrate malabsorbed in the small bowel may be conserved in the colon. In patients with lactose intolerance, a greater amount of ^{14}C from radiolabeled lactose is recovered in ileal aspirates than in the stool.[80] In germ-free rats, carbohydrate is not absorbed intact in the colon; fecal bacteria must first ferment the carbohydrate to short-chain fatty acids (including acetic, propionic, and butyric acids), which are then rapidly absorbed.[81,87] Absorption of ^{14}C-labeled sucrose has been compared in healthy subjects and patients with jejunoileal bypass (ie, short bowel).[79] The bypass patients were unable to absorb up to 84% of a 50 g dose of ^{14}C sucrose. For most of these patients, more than 60% of the ^{14}C that passed the ileum was absorbed in the colon. The normal individuals absorbed 95 to 98% of the sucrose load in the small bowel, and less than 1% of the ^{14}C was recovered in the stool. These studies suggest that in clinical situations in which there is malabsorption of carbohydrate, a large proportion of the carbohydrate can be salvaged in the colon by fermentation to short-chain fatty acids, which are then absorbed. Of the ^{14}C that remained in the feces, the major portion was nondialyzable (either incorporated into macromolecules or bound to nondialyzable components of the feces) and was, therefore, neither available for absorption nor osmotically active. It has been calculated that up

to 540 kcal per day in the form of short-chain fatty acids may be absorbed in the colon of an adult.[87] In the normal subjects, the amount of sucrose reaching the terminal ileum was only a small part of the total dose but was great enough to cause an osmotic diarrhea if not removed in the colon. Variability of the factors influencing this mechanism of colonic conservation of carbohydrate (eg, changes in colonic flora) may explain, in part, the wide range of symptoms that can occur with similar degrees of carbohydrate malabsorption. Variability of other gastrointestinal disorders such as irritable bowel, chronic constipation, and antibiotic-related diarrhea may have a similar basis.

TESTS OF CARBOHYDRATE INTOLERANCE

A wide array of tests are available to identify carbohydrate maldigestion and malabsorption. Each test has advantages and disadvantages, but none correlates perfectly with clinical symptoms. Most tests evaluate bowel function by measuring carbohydrate absorption or malabsorption, although disaccharidase assays measure mucosal enzyme activity directly. Clinical suspicion of a carbohydrate intolerance may be aroused when the introduction of a particular carbohydrate or group of carbohydrates into the diet results in diarrhea or abdominal pain. A typical example would be diarrhea that starts when sucrose-containing solids (eg, fruits) are introduced into the diet of an infant with congenital sucrase-isomaltase deficiency. Similarly, the resolution of diarrhea with the removal of a carbohydrate from the diet may be a clue to the diagnosis. As an example, diarrhea following a viral gastroenteritis may be secondary to a transient lactose intolerance and, if so, will resolve when lactose is removed from the diet.

Screening tests for carbohydrate intolerance include evaluation of stool-reducing substances and pH, as well as measurement of stool osmolality and electrolyte concentration. Examination of stool for reducing sugars is a simple bedside test that is especially useful in infants.[88] The test is done using Clinitest tablets (Ames), and the method is similar to that for measuring glucose in the urine. Five drops of stool are mixed with 10 drops of water, and a Clinitest tablet is added. Trace or 0.25% is not considered abnormal, but a greater reaction is considered a positive test. It must be remembered, however, that sucrose is not a reducing sugar. Therefore, it is recommended that if the patient has been given a sucrose-containing diet, the stool must first be heated to boiling with 0.1 normal HCl, instead of water, to hydrolyze the sucrose. The test is then carried out as described previously. Unfortunately, the proportion of both false-positive and false-negative reactions is high when the stool is evaluated for sucrose.[89] Breast-fed neonates will normally have some lactose in the stool; therefore, a positive Clinitest reaction in this group is not necessarily abnormal. We have seen a purple Clinitest reaction, occurring in an infant with phenolphthalein-induced, factitious diarrhea.[90] Presumably, this color was a combination of a blue negative reaction of the Clinitest plus a pink indicator reaction on alkalinizing the stool with Clinitest. If the amount of carbohydrate malabsorbed is small, the diarrhea is mainly secondary to the osmotic effect of luminal organic acids and associated cations; however, as the amount of malabsorbed carbohydrate becomes greater, unmetabolized carbohydrate makes a large contribution to the diarrhea.[91] This may explain some of the false-negative stool Clinitest reactions in individuals with carbohydrate malabsorption and diarrhea. Stool pH may also be a sign of carbohydrate malabsorption. As described previously in the section on consequences of carbohydrate malabsorption, when carbohydrate reaches the colon, it is fermented by bacteria, and organic acids (short-chain fatty acids) are produced. Depending on the buffering capacity of the stool, this process may lower the pH. A fecal pH < 5.6 has also proved to be a reliable screening test for carbohydrate malabsorption, as demonstrated in human volunteers with diarrhea induced by nonabsorbable carbohydrates.[84,89] The pH may occasionally be abnormal during carbohydrate malabsorption, despite a negative Clinitest, and this additional information can be useful.

The measurement of stool osmolality, as well as sodium and potassium concentration, will identify osmotic diarrhea of any etiology. As noted previously, if the osmolality of a stool is greater than two times the sum of the sodium and potassium concentration in the stool (this number includes the associated anions), an osmotic diarrhea is likely. Malabsorbed carbohydrate and osmotic cathartics are the two most common groups of solutes to cause an osmotic diarrhea.

Starch malabsorption is rarely a clinical problem, and no routine clinical studies specifically identify this disorder. Duodenal α-amylase activity can be quantitated using a standardized secretin-pancreozymin test.[22,23]

Carbohydrate Tolerance Tests

Carbohydrate tolerance tests have been among the most readily available and most widely performed tests of carbohydrate absorption in the past. Following ingestion of a carbohydrate, the patient is evaluated for a rise in blood sugar, which, when present, suggests that absorption has occurred. Symptoms that develop during the test can also be correlated with the results. The advantages of this test include its simplicity, lack of sophisticated equipment, relatively noninvasive character (compared to small-bowel biopsy), and potential correlation with symptoms. The disadvantages are not insignificant, however, and include a high rate of both false-positive and false-negative studies as well as the necessity of drawing repeated blood specimens. Factors other than an individual's capacity for carbohydrate absorption can alter the blood sugar level and include the rate of gastric emptying, hormonal influences on blood glucose, and the rate of peripheral metabolism of glucose. Delayed gastric emptying has been a common cause of false-positive tolerance tests in children. This problem can be circumvented by administering the carbohydrate directly into the duodenum using a nasoduodenal tube; however, this method reduces the simplicity of the test.

Tolerance tests have been used most commonly to study absorption of glucose, xylose, lactose, and sucrose. None of these tests has been well standardized. The quan-

tity of sugar administered can vary from 0.5 to 2.0 g/kg (maximum 50 to 100 g), usually given in a 10% aqueous solution. The timing for collection of blood samples varies from as frequent as 0, 15, 30, 45, 60, 90, and 120 minutes to a single sample 45 to 60 minutes after ingestion. Generally, a rise in blood sugar of 20 mg/dL is interpreted to represent adequate absorption. Both glucose and xylose require the glucose-galactose carrier system for uptake; malabsorption of these sugars has generally been used as an indirect measure of mucosal damage or decreased surface area (eg, the short-bowel syndrome). Glucose metabolism is influenced so greatly by factors other than mucosal absorption that D-xylose, a pentose that is not metabolized, has been used preferentially. Commonly, xylose is given as 0.5 g/kg; fasting and 1-hour blood samples are collected for measurement of blood xylose levels. In older children and adults, a 5-hour urine sample can be collected and analyzed to determine the percentage of the dose of xylose that is excreted. However, there are studies both supporting and questioning the usefulness of xylose absorption as a screening test for mucosal damage.[92–95] The most common clinical situation in which this test might be of use is in evaluating a patient for celiac disease. Unfortunately, one cannot always rely on an adequate rise in blood xylose level to exclude celiac disease.

Disaccharide tolerance tests have been useful in screening for lactase and sucrase deficiencies. However, the breath H_2 test, which is described below, is simpler and more accurate and has largely replaced the use of tolerance tests. Because glucose is released on hydrolysis of both lactose and sucrose, absorption should lead to an elevation of blood glucose. In one study of the standard lactose tolerance test performed in adults with normal lactase activity (demonstrated by small-bowel biopsy), 28% of the subjects had a maximal rise of blood glucose of less than 20 mg/dL.[96] When the administration of 50 or 100 g of lactose was compared, there was no difference in the percentage of individuals with normal curves. In 50% of the individuals, the blood glucose value had peaked at 15 minutes. Some investigators have felt that the reliability of this test can be increased by the use of capillary samples rather than venous blood.[97] An older test, which is rarely used now, involves the simultaneous ingestion of lactose and ethanol. The ethanol inhibits conversion of galactose to glucose, and the blood galactose level is then measured.

Disaccharidase Assay

Quantitation of oligosaccharidase activity in the mucosa of the small intestine has been the standard against which other tests of disaccharide intolerance have been measured. Tissue from the distal duodenum or proximal jejunum is obtained for study by capsule or endoscopic biopsy.[98,99] If the tissue is immediately frozen, these enzymes will remain stable for months. Assays are done by homogenizing the tissue in buffer, incubating the homogenate with the appropriate substrate (usually a disaccharide) at 37°C, and measuring the quantity of glucose released during a given period of time.[100] Although disaccharidase assays are generally performed in this manner, there are minor variations among laboratories, including the type of buffer used and the pH at which the incubation is done. Therefore, mean values and ranges may vary somewhat from one laboratory to another for any substrate studied, but these figures ought to be fairly consistent within the same laboratory. The enzyme activities most commonly assayed are sucrase, lactase, and maltase, using the substrates for which they are named. The substrate frequently used for the measurement of isomaltase activity has been palatinose because highly purified isomaltase is not readily available. Activities are usually expressed per gram wet weight of the mucosa and per gram mucosal protein (ie, specific activity).

Disaccharidase activities are easily quantitated in this manner. However, activity levels may not always correlate well with symptoms.[101] Although the small-bowel biopsy sample is taken from a region of the bowel that ought to exhibit near-maximal disaccharidase levels, it is, nevertheless, a sample of only a small area and may not be representative of the total bowel activity. This problem may occur with a disorder that causes patchy damage to the bowel or with the short-bowel syndrome. Alterations in the colonic conservation of carbohydrate will also influence symptoms.

Breath Hydrogen Test

The breath hydrogen test remains the most widely used method of analysis of carbohydrate intolerance. Carbohydrate that is malabsorbed in the small bowel will be fermented by bacteria in the colon, releasing hydrogen, CO_2, and methane gas. A portion of this gas is absorbed and subsequently expired in the breath (about 15 to 20% of the H_2 produced in the colon).[102,103] Although the original technique of measuring expired H_2 involved a continuous, closed, rebreathing system for collection, sampling is now usually done at 30-minute intervals, and a rise in H_2 content of more than 10 to 20 ppm over the fasting value (measured by gas chromatography) is considered consistent with carbohydrate malabsorption. The measurement of breath hydrogen content is therefore an indirect, semiquantitative test of carbohydrate malabsorption. It offers the advantage of being a simple, noninvasive, and sensitive study.

The method of collection of breath samples has been adapted for use with infants and children.[104] In addition, samples may be collected in the field and stored for later analysis. In fact, many of the most recent epidemiologic studies of lactose intolerance have incorporated this technique.

Breath methane concentration has been used to enhance the reliability of breath testing for carbohydrate malabsorption. However, the likelihood of methane production is low before 3 years of age. Individuals who produce methane and not H_2 gas are rare, and the sensitivity and specificity of the breath methane test are lower than those of the breath hydrogen test for lactose malabsorption.[105]

Bond and Levitt demonstrated the excellent correlation of breath H_2 content with lactose malabsorption by studying lactose-tolerant and -intolerant adults who had ingested 12.5 g of radiolabeled lactose.[80] Lactose malab-

sorption in the small bowel was determined by measuring the radiolabeled lactose in aspirates from a peroral tube placed in the distal ileum. Simultaneous breath samples were collected and analyzed for H_2 content. For each subject, breath hydrogen was also analyzed after the ingestion of a standard amount of nonabsorbable carbohydrate (lactulose). Comparison with this standard made it possible to quantitate the amount of carbohydrate malabsorbed by an individual through measurement of the H_2 excreted in the breath. The resultant plot of lactose malabsorption, shown in Figure 48–2, demonstrated the excellent correlation of breath H_2 excretion with ileal aspiration of malabsorbed lactose (coefficient of correlation = .94).

For infants and children, it is generally possible to identify either lactose or sucrose intolerance by collecting samples at 30-minute intervals for a total of 90 minutes after ingestation of 1 to 2 g/kg and up to 50 g of the sugar of interest.[105,106] A rise in breath H_2 content of either 10 or 20 ppm has been recommended as the cutoff for a positive test; a threshold of 10 ppm is associated with greater sensitivity but lower specificity compared with 20 ppm.

Many uses have been described for the breath hydrogen test and include the identification of isolated lactose or sucrose intolerance, small-bowel mucosal damage or decreased surface area (eg, short bowel), and bacterial overgrowth. However, potential problems in interpretation of the breath hydrogen test exist. As with all of the other tests for carbohydrate intolerance, a positive study is not always accompanied by symptoms (or even a history of previous symptoms). Because breath hydrogen analysis is a more sensitive measure of carbohydrate intolerance than many of the previously available tests, it is likely that identification of subclinical carbohydrate malabsorption will occur more frequently. Conversely, about 2% of the population lack the bacterial flora necessary to produce hydrogen gas in the colon and can therefore have a negative test despite carbohydrate malabsorption.[107] The use of antibiotics shortly before the test may alter the intestinal flora and influence colonic fermentation, thereby reducing the breath hydrogen level. If the ability of an individual to produce hydrogen gas is in question, this problem can be settled by performing a breath hydrogen study following the administration of lactulose. Ingestion of this poorly absorbed sugar should lead to hydrogen production, and a negative result indicates a lack of ability to produce hydrogen gas. A diarrheal illness or the presence of rapid transit may affect results as well. In addition, the breath hydrogen concentration rises during both sleep and cigarette smoking. Finally, a lower rate of H_2 production has been demonstrated when lactose has been given in whole milk rather than in an aqueous solution.[108]

PRIMARY DISORDERS OF CARBOHYDRATE ABSORPTION

Starch Intolerance

Clinically apparent starch malabsorption is uncommon. Infants less than 6 months of age normally have very low levels of α-amylase activity in the duodenum and therefore do have the potential for starch malabsorption.[22] Although starch malabsorption is uncommon, Lilibridge and Townes have described an infant with chronic diarrhea that appears to have been secondary to starch intolerance.[109] In a 1-month-old infant, starch provided 7% of the infant's dietary calories, and this proportion had increased to 16% by age 4 months. However, no α-amylase activity was found in a duodenal aspirate. Treatment by removal of starches from the diet resulted in improved stools, accelerated growth, and a drop in the intake from 300 to 120 kcal/kg/day. When the infant reached 1 year of age, the duodenal fluid contained low levels of α-amylase activity. At that time, starches were reintroduced into the diet without incident. In addition to this child, a patient with isolated absence of pancreatic amylase activity from the duodenal fluid and with chronic gastrointestinal symptoms suggesting malabsorption has been described by Lowe and May.[110] Although this patient had low trypsin activity, lipase activity was normal. In addition, salivary amylase was present.

Lebenthal and colleagues found reduced glucoamylase activity in 3% of assays performed in small-bowel biopsy samples from 511 children with chronic diarrhea.[111] In about 40% of the small group with reduced activity, glucoamylase deficiency was considered to be secondary to mucosal damage, and in the remainder, it was considered to be a primary deficiency. A subgroup of the children with glucoamylase deficiency was studied, and in some but not all of the children, symptoms appeared to be related to starch ingestion.

As mentioned previously, Anderson and colleagues have demonstrated that when starch is offered in the form of wheat flour, adults frequently have evidence of small-bowel malabsorption.[25] This observation has raised the possibility that some of the "functional" bowel diseases

might be caused or at least influenced by starch malabsorption. In addition, these investigators have suggested that the symptoms of some organic bowel diseases (eg, inflammatory bowel disease) might be potentiated by wheat in the diet.

Primary Disaccharidase Deficiencies

Primary Lactase Deficiency Lactose intolerance is the most frequent of all of the clinical syndromes of carbohydrate malabsorption. Although secondary disorders of lactose digestion are common in infancy, the primary disorders are of greater importance in older children and adults. There are three primary disorders of lactase deficiency: (1) developmental, (2) congenital, and (3) late onset (adult onset).

Lactase, unlike the other commonly measured disaccharidases, develops to the level of activity seen in full-term newborns late in the third trimester of gestation only.[55] Therefore, it is thought that premature infants commonly have low levels of lactase activity proportionate to their degree of immaturity.

MacLean and Fink evaluated a group of 22 healthy infants, ranging from 29 to 38 weeks of gestational age, who received a commercial infant formula containing lactose.[112] Serial measurements of breath hydrogen excretion were made. It was found that hydrogen excretion increased during the first 3 weeks of life and that, by this age, all of the infants were excreting levels that would be consistent with lactose intolerance in an older infant. The lack of evidence of lactose intolerance in some of the younger infants probably reflected the small volumes of formula taken initially. This study suggests that all premature infants probably do malabsorb lactose, although this is rarely symptomatically significant. Calculations based on the H_2 excretion over a period of time after feedings suggested that an average of about 65% of the lactose ingested by these infants reached the colon. However, all of the infants gained weight well, and the mean stool output was only 6 g per day. This finding suggests that colonic conservation of carbohydrate (see "Consequences of Carbohydrate Malabsorption") was likely to have been operative in these infants. In addition, there was no evidence that feeding the infants lactose stimulated more rapid development of lactase activity. It appears, therefore, that lactose malabsorption may be a normal event in premature infants, although it is usually not associated with symptoms. In fact, this process may encourage the development of a fecal flora, which prevents colonization of the colon with enteropathogens. It may not be necessary or even optimal to restrict lactose ingestion by asymptomatic premature infants.

Congenital lactase deficiency is an extremely rare disorder that has been infrequently reported, in contrast to late-onset hypolactasia, which is common (discussed later).[113–115] Diagnosis of the congenital form requires severely reduced or absent small bowel lactase activity in the newborn period, in association with normal mucosal histology and normal levels of the other disaccharidases. Lactase activity remains abnormal throughout life. The low levels of lactase activity that can be found in this disorder have been thought to be secondary to nonspecific hydrolysis of lactose by lysosomal acid–β-galactosidase rather than brush border lactase.[116] The former enzyme does not appear to play a physiologic role in lactose digestion. In a study in which brush border proteins from four children with congenital lactase deficiency were separated on polyacrylamide gels, the protein band corresponding to lactase was markedly reduced or absent in each case.[117] The mobility of the lactase band was normal, suggesting that activity was reduced because of decreased amounts of enzyme protein but not because of the synthesis of an altered protein.

The most common and most extensively studied of the disaccharide intolerances has been adult-onset hypolactasia (also known as adult-onset or late-onset lactose intolerance). Although this entity is never apparent at birth, it is a primary disaccharidase deficiency that appears later in life. Epidemiologic evidence suggests that this deficiency is an autosomal recessive characteristic, although this has not been definitely confirmed.[118–120] Late-onset lactose intolerance actually is not an abnormality or disease; if one considers the world's population, only a minority of people have the persistence into adulthood of the elevated lactase levels of infancy. Lactose intolerance beyond weaning, in fact, is typical of all mammals other than humans. Therefore, it is the people who have persistence of these high levels of lactase activity into adulthood who really are "atypical" or "abnormal." Nevertheless, because humans continue to eat and drink dairy products beyond infancy, they have the potential for the development of symptoms from lactase deficiency.

One of the most interesting aspects of late-onset hypolactasia is the variable prevalence of this trait among different racial and ethnic backgrounds. Lactose intolerance is common among adult Semitics, Asians, Africans, Eskimos, and American Indians (North and South), occurring in up to 80 to 90% of unmixed populations.[121] However, it is rare in Northern Europeans as well as in several tribes from Africa and India, occurring in only 10 to 20% of unmixed populations.[120] In the United States, up to 70% of blacks but less than 20% of whites have been found to be lactose intolerant.[122]

Two explanations have been offered for the difference in lactose tolerance among populations. One explanation is that lactase activity might be induced by substrate and that certain populations have had high levels because they ingest greater amounts of lactose. The bulk of the evidence in studies of animals and humans suggests that lactase is not an enzyme that can be induced to any useful extent.[48,123] The alternative explanation has been that lactose tolerance is genetically determined and has had a selective advantage in groups that historically have consumed dairy products as a major component of their diet. This hypothesis is consistent with the dietary practices of those populations that are known to be largely lactose tolerant.

A number of studies have confirmed the impression that lactose intolerance is inherited as an autosomal recessive trait.[118,119,124] In a study of Nigerian families, if both parents were lactose intolerant (21 families), only 1 offspring in

56 was lactose tolerant.[119] If one parent was lactose tolerant, 55% of the offspring were lactose tolerant. In a study including 156 American Indians, the likelihood of having lactose intolerance, identified by breath hydrogen excretion following an oral lactose load, was in direct proportion to the percentage of Indian blood of an individual.[118]

Despite the name "late-onset hypolactasia," the age of onset of this entity is quite variable among ethnic backgrounds and often occurs in early childhood. In Thailand, nearly all native adults have been lactose intolerant. In a study of 172 Thai infants and children, lactose intolerance was demonstrated to occur by 2 years of age in about 85% of this group; a standard lactose tolerance test was used.[125] Some of the children had sucrose or glucose tolerance tests as well, and these tests were virtually always normal, suggesting that the lactose intolerance was not secondary to generalized mucosal damage. The levels of lactase activity measured in small-bowel biopsies from a limited group of the Thai children supported the impression that lactase deficiency was widespread in this group. The age of onset of lactose intolerance was delayed in village children compared with institutionalized children, although still usually less than 2 years of age. The investigators speculated that environmental factors might have influenced the age of onset and specifically noted that, although nutrition was comparable in the two groups, episodes of acute enteritis were more common in the institutionalized children. Newcomer and colleagues studied a group of American Indians (Leech Lake Indian Reservation, Minnesota) in which 66% of the subjects demonstrated lactose intolerance using the breath hydrogen test.[118] Lactose intolerance was already present by 5 years of age, the youngest subjects studied. Johnson and colleagues demonstrated intolerance in 7 of 11 Pima Indians, aged 3 to 5 years, using a lactose intolerance test.[126]

Late-onset hypolactasia, identified by the standard lactose tolerance test, has been found to develop in blacks in the United States between the age of 6 and the teenage years.[127] Although Welsh and colleagues have suggested that the reduced lactase levels of late-onset lactose intolerance may develop by as early as 3 years of age in blacks, this finding has not been well documented. Both Lebenthal and colleagues and Welsh and colleagues have found that among whites, abnormal lactase levels are not seen before 5 years of age.[128,129] As in blacks, the incidence of symptomatic late-onset lactose intolerance probably increases gradually into the teenage years. These findings have led to the observation that if evidence of lactose intolerance (by breath hydrogen or standard lactose tolerance test) is found in a black under 3 years of age or a white under 5 years of age, one should always consider the possibility that there has been damage to the intestinal mucosa.[130]

The identification of lactose intolerance by screening tests does not necessarily correlate with the presence of symptoms and has resulted in confusion in the interpretation of these tests. Although the quantity of lactose that an individual ingests influences the degree of symptoms of lactose intolerance, the threshold for development of these symptoms varies among individuals. This observation may result from variation in the levels of residual lactase activity along the length of the bowel but is more likely to be related to factors that influence the colonic conservation of carbohydrate. Among individuals with late-onset lactose intolerance, symptomatic tolerance for lactose may range from the quantity present in half a glass up to 1 quart or more of milk. Bedine and Bayless evaluated the threshold for symptoms of lactose malabsorption among 20 adults with lactose intolerance (6 of whom were asymptomatic).[131] Of this group of subjects, 75% developed symptoms, which included abdominal fullness, bloating, flatulence, or diarrhea, within 3 to 4 hours after ingesting 12 g or less of lactose (Figure 48–3). This amount is equivalent to the quantity of lactose in one glass of milk. However, only about two-thirds of the subjects who developed these complaints had a previous history of symptomatic intolerance in association with the ingestion of one glass of milk. Above the threshold for an individual, symptoms became more severe with greater amounts of lactose. Interestingly, the threshold did not appear to correlate well with the jejunal lactase level. Similar findings have been observed in a study from Denmark.[132] However, more recently, individuals who considered themselves to have severe lactose intolerance were able to tolerate as much lactose as in an 8-ounce glass of milk daily without symptoms.[133] Individuals who do become symptomatic with the ingestion of lactose should tolerate an equivalent amount of a glucose and galactose mixture without any problem.[122]

Studies of schoolchildren and hospitalized adults suggest that lactose-intolerant individuals as a group do tend to drink less milk than individuals who are lactose tolerant.[122,134] Newcomer and colleagues found that among individuals with lactase deficiency, symptomatic lactose intolerance is more common in adults than in children.[118] Likewise, when subjects were given 50 g of lactose (or 2 g/kg if this were lower), children were less likely to develop symptoms than adults at an equivalent quantity of lactose per kilogram of body weight (Figure 48–4). In a double-blind study of the symptoms associated with lactose intolerance among healthy teenagers (including 42 lactose-tolerant and 45 lactose-intolerant individuals), no statistical difference was found for the occurrence of symptoms noted by either group after drinking 8 ounces of either a lactose-containing or placebo drink.[135] After ingesting 16 ounces of the lactose drink, however, 16% of the intolerant subjects did have symptoms that seemed to be related to the lactose.

As described in the section on consequences of carbohydrate malabsorption, Bond and Levitt demonstrated in their study of lactose absorption that lactose-tolerant individuals malabsorbed up to 8% of a 12.5 g lactose load, whereas intolerant individuals malabsorbed 42 to 75% of the load in the small bowel (Figure 48–5).[80] However, only a small fraction of the lactose was actually recovered in the stool because of bacterial degradation of the sugar and colonic absorption of the resultant short-chain fatty acids.

The extent to which late-onset lactose intolerance contributes to the etiology of recurrent abdominal pain of childhood (RAP) has been an area of great interest. RAP is probably the most common chronic symptom of child-

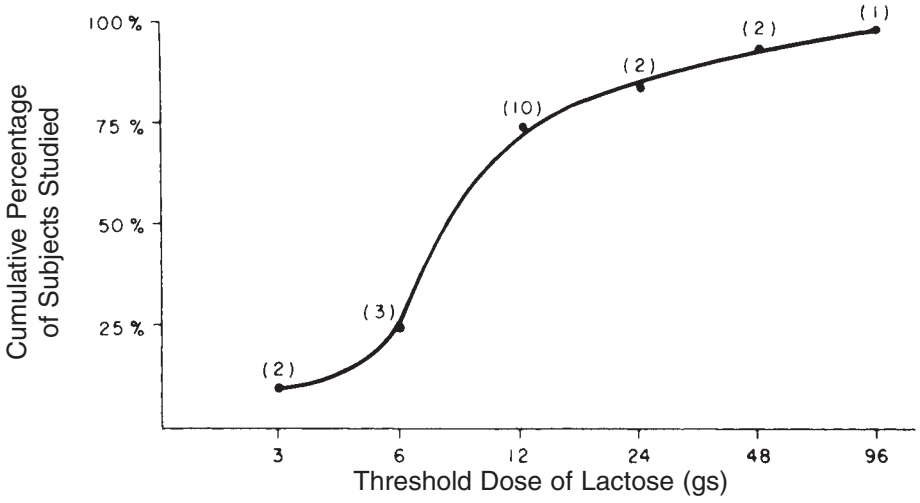

FIGURE 48-3 Cumulative percentage of subjects developing symptoms with increasing quantities of lactose. The number of subjects first symptomatic at each dose is given in parentheses. From Bedine MS and Bayless TM.[131])

hood, occurring in more than 10% of school-aged children.[136,137] Yet it is often not possible to identify an organic etiology. In 1971, Bayless and Huang described a group of five children (6 to 13 years of age) with RAP that appeared to be caused by lactose intolerance, despite the absence of diarrhea.[138] These observations and others have stimulated speculation that lactose intolerance might be the etiology for a large segment of RAP in childhood. Barr and colleagues reported that 40% of a group of 80 children with RAP studied prospectively were lactose malabsorbers, as defined by the breath hydrogen test.[106] However, among these lactose-intolerant children, it was not possible by history to associate symptoms with lactose ingestion. Although there was a trend toward more frequent symptoms following a lactose load among the lactose-intolerant individuals, 68% of the tolerant individuals complained of symptoms that could have been associated with lactose malabsorption as well. Of the malabsorbers, 28 participated in diet trials with and without lactose; 71% reported more frequent symptoms on the lactose-containing diet. Although this study suggests that lactose intolerance might have an important etiologic role in RAP, the diet trial was neither blinded nor controlled. In addition, two subsequent studies have not confirmed this hypothesis. Lebenthal and colleagues found that although about 40% of a group of patients with RAP had resolution of symptoms on a milk-elimination diet continued for 1 year, this percentage was no greater than the frequency of resolution of symptoms in groups of lactose absorbers fed either a similar or an unrestricted diet for the same period of time.[139] Wald and colleagues reported a prospective study of 40 children with RAP.[140] They demonstrated that 30% of the children were lactose malabsorbers when defined by a breath test using a load of 2 g/kg (maximum of 50 g) of lactose. This lactose load and the response were similar to those reported by Barr and colleagues[106]; however, when the breath tests were repeated using 12.5 g of lactose (equivalent to one glass of milk), only about 30% of the individuals previously identified as malabsorbers had abnormal studies. The presence of symptoms during the breath test did not discriminate between lactose-tolerant and lactose-intolerant individuals. Patients were then given lactose-elimination diets without knowledge of the results of their breath hydrogen tests. Although 25% of the lactose malabsorbers showed improvement in their symptoms of pain, 18% of the lactose absorbers also improved, and these response rates were not statistically different from one another. In addition, none of the three children who demonstrated abnormal breath hydrogen tests when given only 12.5 g of lactose improved during the lactose-free period. Considering all of these

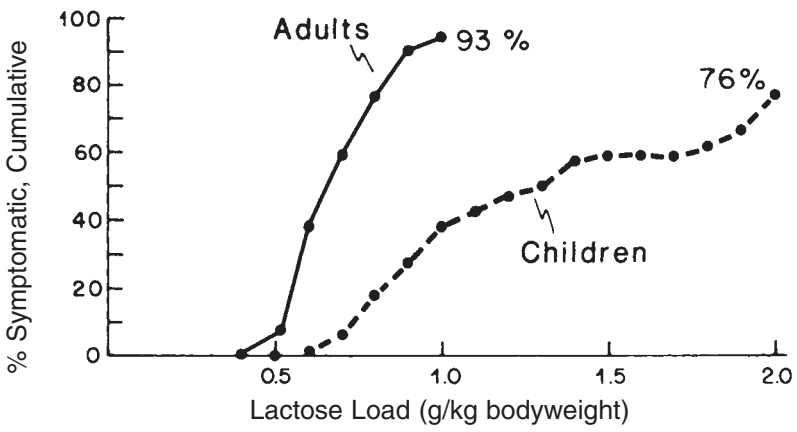

FIGURE 48-4 Cumulative percentage of subjects developing symptoms with increasing quantities of lactose (expressed g/kg body weight) is compared for adults and children. From Newcomer AD et al.[118]

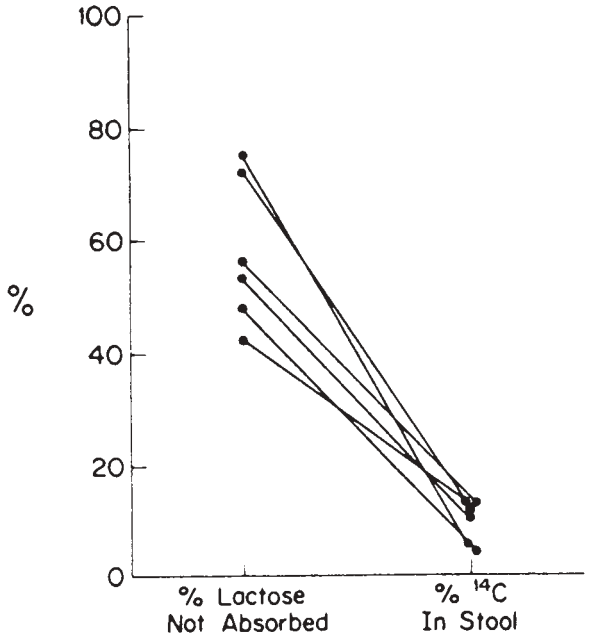

FIGURE 48-5 Comparison of the quantity of lactose not absorbed as determined by ileal aspiration with that derived from stool ^{14}C after ingestion of radiolabeled lactose by six lactase-deficient subjects. From Bond JH and Levitt MD.[80])

studies, it seems that lactose intolerance is undoubtedly the cause of RAP in a small proportion of patients but probably not in the 30 to 40% of these patients originally described. The extreme sensitivity of the breath hydrogen test, the large lactose loads used in these studies, and the high rate of placebo effect of diet treatment have probably led to an overestimation of the importance of lactose intolerance as a primary etiology of RAP.

Perhaps of greater importance is the possibility that lactose intolerance might exacerbate the symptoms of other gastrointestinal disorders (eg, inflammatory bowel disease [IBD]). Because late-onset lactose intolerance is common, it is inevitable that among individuals with another disorder, a subgroup will have lactose intolerance as well. This finding has led to some confusion about the role of lactose intolerance in the production of symptoms in patients with other gastrointestinal disorders. Despite the clinical impression that lactose intolerance can at times contribute to symptoms in IBD, lactose intolerance has been observed to be no more common in a group of children with IBD than in a group with RAP.[141] Although a comparison with normal subjects was not made, the prevalence of lactose intolerance is probably no greater in patients with IBD than in a healthy population of similar ethnic background. As mentioned previously, normal individuals commonly malabsorb small amounts of ingested lactose in the small bowel.[80] Patients with other gastrointestinal diseases, such as IBD, may be unable at times to compensate for even the small quantity of lactose that normally reaches the colon, and this factor may contribute to their symptoms.

It has been demonstrated that lactase enzyme from the small bowel of individuals with late-onset lactose intolerance has normal motility on polyacrylamide gel electrophoresis, but the enzyme is present in the brush border in decreased quantities.[117] Subsequently, similar observations have been made using the more sensitive technique of crossed immunoelectrophoresis.[142] Although decreased amounts of lactase protein were found in brush border membranes, the enzyme had normal activity per unit of enzyme protein, and no variants with abnormal mobility were found. This study suggests that individuals with late-onset lactose intolerance have either decreased synthesis or increased degradation of brush border lactase but do not produce an inactive enzyme.

In individuals without adult-onset hypolactasia (ie, those who have persistently high small-bowel lactase activity as adults), lactase mRNA is found uniformly in all villus enterocytes, and lactase protein, as well as lactase activity, is present uniformly at the brush border.[42] Individuals with adult-onset hypolactasia may have different patterns of development of lactase deficiency as a result of alterations at the transcriptional or translational level.[143–146] Even on a single villus from an individual with adult-onset hypolactasia, some enterocytes may have (1) no detectable lactase mRNA, (2) lactase mRNA but no detectable brush border lactase protein, (3) lactase protein but no activity, or (4) lactase protein and lactase activity.[42,147] Some enterocytes contain as much lactase mRNA as seen in the enterocytes of individuals without hypolactasia. Thus, enterocytes with different phenotypes are present on the same villus. Enterocytes with different patterns of lactase expression occur in a patchy distribution, indicating that they are not arising in a clonal pattern. The mechanism of this variable expression remains to be elucidated. Perhaps differences in the proportion of enterocytes with each pattern of expression explain the differences in mechanisms of adult-onset hypolactasia among individuals.

Studies of Finnish families with adult-onset hypolactasia have found no DNA variations in the coding or promoter region of the lactase gene but instead a variant of a *cis*-acting element roughly 14 kb upstream from the lactase gene. Evaluation of additional DNA samples from four different populations demonstrated the same pattern.[148] Studies indicate that the mutation causing the rare disorder congenital lactase deficiency lies outside the region of the lactase gene as well.[149]

Congenital Sucrase-Isomaltase Deficiency In humans, a congenital deficiency of small intestinal sucrase is always associated with a deficiency of isomaltase, and this entity is known as congenital sucrase-isomaltase deficiency.[150–154] This deficiency is much less common than late-onset lactose intolerance. It is found in about 0.2% of North Americans and in up to 10% of Greenland Eskimos.[153] Congenital sucrase-isomaltase deficiency appears to be hereditary and transmitted as an autosomal recessive trait. The association of these two enzyme deficiencies is, in fact, no surprise because these enzymes are synthesized together, inserted into the brush border membrane as one large protein, and subsequently cleaved into two units, which continue to remain closely associated.[32,34,36]

Characteristically, congenital sucrase-isomaltase deficiency first presents at the time of introduction of sucrose into the diet. This sugar may be introduced in a sucrose-containing formula (usually soy based) or in solid foods (especially fruits). The symptoms are typical of all of the syndromes of carbohydrate malabsorption: diarrhea, bloating, flatulence, and cramps. Failure to thrive may be a prominent component in young infants. On clinical presentation, these infants may be mistakenly thought to have gluten-sensitive enteropathy; however, they can also present with mild symptoms and adequate growth, suggesting chronic nonspecific diarrhea.[150,151] A rarer presentation has been protracted diarrhea in infants fed glucose polymer formula.[152] Older children with congenital sucrase-isomaltase deficiency can develop an aversion to sucrose-containing foods, which limits their intake of this sugar.

A suspicion that this disorder may be responsible for a patient's symptoms can first arise from the results of routine screening tests for sugar intolerance. The diagnosis should be confirmed by the characteristic pattern of small-bowel disaccharidase activity: extremely low or absent levels of activity of sucrase and isomaltase coincident with a normal level of lactase activity. Typically, the activity of lactase is the most sensitive to mucosal damage and the most greatly reduced in secondary disaccharidase deficiency. Therefore, the enzyme pattern seen with congenital sucrase-isomaltase deficiency should not be confused with the pattern of mucosal damage.

There have been conflicting hypotheses about the molecular basis of congenital sucrase-isomaltase deficiency. Dubs and colleagues, in 1973, reported studies of patients with this disorder, which included immunofluorescent staining of small-bowel biopsies with an antibody against the human sucrase-isomaltase complex.[155] They were able to demonstrate the presence of an immunoreactive protein in the brush border region of the villi of most of the patients studied and believed that this demonstrated the presence of an inactive enzyme. In 1974, Preiser and colleagues reported studies in which they performed gel electrophoresis with small intestinal brush border preparations from two siblings with congenital sucrase-isomaltase deficiency[156]; they observed the absence of the protein band usually associated with sucrase-isomaltase activity. Because no new protein band was identified, these investigators believed that this disorder resulted from a decrease in the amount of sucrase-isomaltase protein rather than the presence of an altered enzyme. In 1976, Gray and colleagues used a sensitive radioimmunoassay to demonstrate the complete absence of enzyme protein (both active and inactive) in seven patients with congenital sucrase-isomaltase deficiency.[153] A curious observation was that the fraction of total enzyme protein in the inactive form was greater for relatives of patients with congenital sucrase-isomaltase deficiency than for normal individuals. The investigators suggested that voluntary sucrose restriction in the diet of these family members might have influenced enzyme activation.

Several phenotypes of sucrase-isomaltase deficiency have been identified by localization of sucrase-isomaltase protein in small-bowel biopsies using monoclonal antibodies.[157] In different individuals, enzyme protein accumulates in the endoplasmic reticulum or Golgi or is transported to the brush border with reduced activity. These findings suggest the likelihood of at least three mutations causing different phenotypic expressions of sucrase-isomaltase deficiency. Consistent with this observation, mutations of the sucrase-isomaltase gene have been demonstrated to result in sucrase-isomaltase proteins that are either secreted and lost at the cell surface or retained in the endoplasmic reticulum and Golgi.[158–160]

Congenital Trehalase Deficiency Trehalase deficiency is a common disaccharidase deficiency in Greenland, occurring in about 8% of the population.[161] However, this deficiency does not appear to have nutritional importance.

Primary Monosaccharide Intolerance

Glucose-galactose malabsorption is the only known primary monosaccharide intolerance. It is an extremely rare disorder, with less than 25 cases having been reported.[162] Infants with this disorder present with diarrhea shortly after the first feeding that contains glucose, galactose, or any oligosaccharide composed of either of these sugars. Lactose, the principal carbohydrate of human milk, consists of glucose and galactose subunits; therefore, infants with this disorder will not be spared symptoms by nursing. Furthermore, infants with congenital glucose-galactose malabsorption will not tolerate sucrose (glucose-fructose), invert sugar (glucose + fructose), or glucose polymers. In fact, this diagnosis should be considered when a neonate has diarrhea in association with carbohydrate malabsorption and is found to tolerate fructose alone. The disorder is thought to be hereditary with an autosomal recessive mode of transmission, and many of the children reported have been the products of consanguineous matings.[162]

In vitro studies with radiolabeled glucose and galactose have demonstrated that the small-bowel mucosa from patients with congenital glucose-galactose malabsorption cannot concentrate these sugars, in contrast to the mucosa from normal subjects.[163,164] Small-bowel perfusion studies have also demonstrated decreased absorption of these sugars in vivo.[162] The mucosal histologic appearance and the capacity for absorption of fructose have both been shown to be normal. It is thought that this disorder represents a deficiency or defect in the specific glucose-galactose carrier protein of the brush border of the small intestine. Although the transport of glucose and galactose is markedly reduced in this disorder, no further decrease in uptake occurs with the in vitro introduction of phloridzin, which competitively binds to the carrier.[163] This observation has raised the possibility that there is a defect in the binding site of the glucose-galactose carrier. With the cloning of SGLT1, two siblings have been described with a mutation in the *SGLT1* gene leading to a defect in the Na+/glucose cotransporter and secondary glucose-galactose malabsorption.[165] Remission of symptoms with increasing age has been described even though active jejunal glucose transport remains absent in these patients.[166]

Patients with primary glucose malabsorption have been identified using the breath hydrogen test with a relatively small glucose challenge (0.1 g/kg), in the absence of any associated symptoms.[162] With greater quantities of glucose or galactose (0.5 or 1.0 g/kg, respectively), loose, acidic stool developed and contained reducing substance; however, fructose (2.0 g/ kg) was well tolerated.

SECONDARY DISORDERS OF CARBOHYDRATE ABSORPTION

Many forms of injury to the mucosa of the small bowel may lead to transient carbohydrate intolerance. Often histologic abnormalities will be noted to be concomitant with the carbohydrate intolerance; however, the mucosa can appear relatively normal by light microscopy, especially with a transient disaccharide intolerance. Infants seem to be more prone to secondary disorders than older individuals, and carbohydrate intolerance commonly occurs in association with infantile gastroenteritis. Intolerance for disaccharides alone or in combination with monosaccharides may occur, but the former is more common. Acquired monosaccharide intolerance usually suggests severe small-bowel mucosal damage, manifested as moderate to severe villous atrophy on light microscopy and damaged microvilli on electron microscopy.[167]

During acute infantile diarrhea, malabsorption of both monosaccharides and disaccharides has been demonstrated by small-bowel intubation studies.[168] Occasionally, transient lactose intolerance can persist for a period of months. The likelihood that this will occur seems to correlate with the severity of the diarrheal illness and the degree of malnutrition.[169] Aside from this association with transient lactose intolerance, there is a suggestion that malnutrition may potentiate the initiation of late-onset lactose intolerance at an earlier age.[170] A substantial proportion of childhood infectious diarrhea is caused by viruses (primarily rotavirus); the pathogenesis of this diarrhea involves acute damage to mature villus epithelial cells with replacement by rapidly migrating but immature crypt epithelial cells.[171] These immature epithelial cells exhibit decreased disaccharidase activity as well as decreased capacity for glucose absorption. When a group of patients with rotavirus gastroenteritis were evaluated with a lactose breath hydrogen test during the acute illness, an abnormal study was noted in most of these children, but 1 week later, the test was normal in all.[172]

Bacterial overgrowth in the small intestine may be associated with both mono- and disaccharide intolerance.[173] In fact, this overgrowth may be the mechanism of the sugar intolerance that occasionally follows gastrointestinal surgery in neonates.[174] An animal model for bacterial overgrowth, which has been extensively studied, has been surgically prepared blind loops of bowel in the rat.[175–178] A reduction of disaccharidase activity in these blind loops appears to be secondary to an increase in brush border glycoprotein degradation rather than decreased synthesis.[176] Although increased amounts of deconjugated bile salts have been thought to be a mediator of the disaccharidase deficiency in bacterial overgrowth, this may not be the case.[177] Bacterial extracts prepared from anaerobic organisms isolated from blind loops have been shown to have the ability to remove disaccharidases from isolated brush borders, most likely as a result of an elastase-like protease activity.[178]

Some species of *Bacteroides* have been shown to have what appears to be a unique ability to secrete proteases, which release maltase and sucrase when incubated with human brush borders.[179] Similar protease activity has been found in fluid aspirated from the small intestine of patients with bacterial overgrowth. Other clinical disorders that have been associated with secondary carbohydrate intolerance include giardiasis, gluten-sensitive enteropathy, cow's milk protein intolerance, and protracted diarrhea of infancy. Recently, an association of abnormal lactose breath hydrogen tests with cancer chemotherapy has been demonstrated.[180] Therefore, a wide variety of agents may produce damage to the small bowel mucosa and secondary carbohydrate intolerance, which can occasionally be slow to resolve.

TREATMENT OF CARBOHYDRATE INTOLERANCE

Attempts to induce enzyme activity as a treatment for patients with oligosaccharidase (disaccharidase) deficiencies have not been successful. Chronic ingestion of lactose by individuals with late-onset lactose intolerance does not alter their ability to digest lactose or their level of small-bowel lactase activity.[48,123,125] Although the ingestion of a diet rich in fructose will stimulate an increase in the level of small bowel sucrase activity in normal individuals,[181] Greene and colleagues were able to demonstrate only a slight rise in sucrase activity, which did not reach a normal level, when a child with congenital sucrase-isomaltase deficiency was given a diet rich in fructose.[182]

The most direct method of treatment of sugar or starch intolerance has been the elimination of the malabsorbed carbohydrate from the diet. For young infants, special formulas are available that are lactose, sucrose, or even carbohydrate free. The carbohydrate-free formulas require an added sugar. In addition, formulas are available with glucose polymers (five to nine glucose units in length). The use of these polymers rather than an equivalent amount of glucose results in a reduction in the intraluminal osmolality in the small bowel.[183] Infants with an acquired monosaccharide intolerance caused by small-bowel mucosal damage will exhibit net fluid secretion during perfusion of the jejunum with glucose.[184] If the glucose is replaced with an equal concentration of a short-chain glucose polymer, the secretion will be decreased or even reversed.[184] Presumably, the lower osmolality of the polymer improves fluid balance. However, there is at least one case report in which an infant recovering from chronic protracted diarrhea tolerated oral glucose but not a glucose polymer.[185]

Infants with congenital glucose-galactose malabsorption tolerate dietary fructose well.[163,164] However, a secondary monosaccharide intolerance will usually involve all of the monosaccharides, and, if severe, a period of total parenteral nutrition (TPN) may be necessary. The use of a modular formula will allow a gradual increase in dietary

TABLE 48-2 Comparison of Lactose Content of Various Milk Products

Product	*Lactose (g)*
1 cup (approximate)	
Milk	11–12
2% milk (low fat)	9–13
Skim milk	12–14
Chocolate milk	10–12
Buttermilk	9–11
Low-fat yogurt	11–15
Cottage cheese	5
Cottage cheese (low fat)	7–8
Ice cream	9–10
Sherbet, orange	4
1 ounce (approximate)	
Cheddar cheese	0.4–0.6
American cheese	0.5
Swiss cheese	0.4–0.6
Cream cheese	0.8
Parmesan cheese (grated)	0.8
Butter (2 pats)	0.1

monosaccharide, as tolerated, and a simultaneous decrease in the proportion of calories provided by TPN.[186]

For carbohydrate intolerance, restriction of other carbohydrate-containing foods and drinks becomes critical once infants are no longer taking formula alone. Lists are available that provide the lactose or sucrose content of common foods (Tables 48–2 and 48–3),[150,187] but it is often useful to have a trained dietitian help with diet planning. How vigorously the diet needs to be restricted will depend on the individual's symptomatic response to dietary treatment. The use of commercially prepared lactase enzyme to split the lactose in milk (described later) has simplified the treatment of lactose intolerance. Of course, a combined secondary lactase and sucrase deficiency is more difficult to treat because the diet becomes so restrictive. It should be mentioned that although congenital sucrase deficiency is always associated with isomaltase deficiency and isomaltase is active in starch digestion (especially in the digestion of α-limit dextrins), starch intolerance is generally not a problem in this disorder, and there is usually no need for restriction of starch intake.

Lactase-deficient individuals tolerate yogurt with fewer symptoms than anticipated, considering the amount of lactose in this milk product (see Table 48–2). A lactase enzyme has been identified in yogurt, which is inactive prior to ingestion but active at body temperature (37°C) and small intestinal pH (7).[188] This enzyme is active in small-bowel contents and allows lactase-deficient individuals to absorb a large fraction of the lactose in a yogurt meal. The use of probiotic agents has been considered in the treatment of lactose intolerance, but efficacy has not been established.[189,190]

In addition to food intolerances, it is important to remember that medications contain sugars, which may be a source of symptoms for some patients. Lists of sugar-free drugs are periodically available in the pharmaceutical literature, and drug companies should be consulted directly if there is concern about a specific medication.[191] Patients with disaccharide intolerance will usually tolerate sugar substitutes, although it is important to keep in mind that the use of these products does restrict the caloric intake. Sorbitol, a poorly absorbed polyalcohol sugar used in many "sugar-free" products, may produce an osmotic diarrhea as well as gas, bloating, and cramps.[192] For patients on low-sugar diets, it is important to consider sorbitol as a potential cause of chronic symptoms suggestive of a sugar intolerance.

Commercially produced lactase enzyme products are available to add to foods or take with meals containing lactose to reduce symptoms.[193] This enzyme is prepared by extraction of bacterial or yeast β-galactosidases. If added to cow's milk at room or refrigerator temperature and when allowed to sit for a specified period of time, it will hydrolyze up to 95% of the lactose. Taste acceptance of the milk prepared in this manner is good. This kind of product allows for bulk production of low-lactose dairy products. This technical advance may have excellent possibilities in areas of the world where the majority of individuals are lactase deficient and where cow's milk products could be an important staple in the diet (see Appendix, Tables A-16 and A-24).[98] Sacrosidase, an enzyme with sucrase activity isolated from *Saccharomyces cerevisiae*, has been studied in the treatment of congenital sucrase-isomaltase deficiency.[194] This

TABLE 48-3 Food with Low Sucrose Content

Foods	*Less Than 1% Sucrose*	*Between 1% and 2% Sucrose*
Fruits, fruit juices	Gooseberries	Boysenberries
	Blackberries	Cherries (Bing)
	Currants	Grapes (Tokay or Thompson seedless)
	Lemon	Guava
	Rhubarb	Lime juice
	Pomegranate	Pear
	Cranberries	Figs
	Loganberries	Raspberries
		Strawberries
Vegetables	Tomato	Beans (lima)
	Tomato juice	Carrot
	Bamboo shoots	Rutabaga
	Beans (snap, string, green)	Squash (golden, crookneck)
	Cabbage	Bean sprouts
	Cauliflower	Black-eyed peas
	Celery	
	Corn	
	Cucumber	
	Eggplant	
	Lettuce	
	Potato (white)	
	Pumpkin	
	Radishes	
	Squash (Hubbard, butternut)	
Grains, cereals, nuts, sweetening agents	Corn meal	Wheat flour
	Puffed rice	Whole-grain cereals, crackers with whole wheat
	Rice (brown, white)	
	Wheat flour (patent)	
	Macaroni, spaghetti	Honey
		Pecans

CHAPTER 49

NUTRITIONAL ANEMIAS

Paul Harmatz, MD, Ellen Butensky, RN, MSN, PNP, Bertram Lubin, MD

Anemia is defined as an inadequate circulating red cell mass to prevent tissue hypoxia. Anemia can be related to blood loss, decreased red cell production, increased red cell destruction, or a combination of these events. When anemia occurs as a consequence of a nutritional deficiency, any of these pathologic processes may be involved. Vitamin deficiencies that have been implicated as causes of anemia in humans include vitamin A, members of the vitamin B group (pyridoxine, riboflavin, folic acid, and vitamin B_{12}), vitamin C, and vitamin E. Among minerals, iron and copper are recognized as essential for optimal erythropoiesis. Complex nutritional disturbances, such as those observed in starvation and protein-calorie deficiency states, can also result in anemia.

Hemoglobin, hematocrit, and red cell indices (mean cell volume [MCV], mean corpuscular hemoglobin [MCH], and mean corpuscular hemoglobin concentration [MCHC]) are the initial laboratory assessments used to diagnose anemia. It is important to recognize and adjust for the age-related changes in these parameters when assessing anemia in the pediatric age group (Table 49-1). An initial evaluation of these parameters can help to classify the anemia as one caused by decreased red cell production versus increased red cell destruction, acute blood loss, or impaired hemoglobin production. If the anemia is secondary to inhibited hemoglobin synthesis, the anemia will be microcytic and hypochromic (decreased red cell indices). Conversely, if the anemia results as a consequence of a disturbance in cell maturation, the anemia may be macrocytic (increased red cell indices). If the deformability of the red cell membrane is altered, the anemia will have a hemolytic component, an elevated reticulocyte count, and normocytic or macrocytic red cell indices. Nutritional deficiency states may result in a combination of decreased hemoglobin synthesis, abnormal red cell maturation, and increased red cell destruction. In some nutritional deficiency states, such as protein-calorie malnutrition, decreased red cell production is also noted.

The most common nutritional deficiency responsible for anemia is iron deficiency. Nutritional deficiencies of folic acid or vitamin B_{12} are also occasionally encountered, and patients with chronic illness may have other vitamin, mineral, and protein deficiencies contributing to anemia. This chapter reviews relationships between nutritional deficiencies and anemia and discusses responsible mechanisms. The etiology of many of the vitamin and mineral deficiencies is not discussed in detail as this information is provided elsewhere in this book

VITAMIN DEFICIENCY ANEMIAS

Vitamin A Deficiency

Chronic deprivation of vitamin A results in an anemia with certain characteristics similar to those observed in iron deficiency. Mean red cell volume and MCHC are reduced, anisocytosis and poikilocytosis may be present, and serum iron values are low.[1–4] Unlike iron deficiency, however, liver and marrow iron stores are increased, serum ferritin values are normal, serum transferrin concentration is usually normal or decreased, and the administration of therapeutic doses of iron may not correct the anemia. These findings suggest that the basis for this hypochromic, microcytic anemia may be related to a failure of iron transport from storage sites to active metabolic pools.

Nutritional surveys conducted in developing countries have supported a relationship between serum concentration of vitamin A and blood hemoglobin concentration.[5] An excellent correlation was demonstrated in a study of 532 children in Karachi, Pakistan, between retinol levels and hemoglobin, hematocrit, and red blood cell levels.[6] A correlation between plasma retinol and hemoglobin was observed experimentally in adult men in the United States with induced vitamin A deficiency confirming a causal relationship of vitamin A to anemia.[2] Finally, studies in underdeveloped countries with a high prevalence of vitamin A deficiency have shown that treating anemia with vitamin A in combination with iron is more effective than treatment with iron alone, supporting a causal relationship.[2,7–10]

Pyridoxine Deficiency

The vitamin B_6 group includes pyridoxal, pyridoxine, and pyridoxamine. These substances are all phosphorylated to pyridoxal-5-phosphate, which is an essential cofactor in heme biosynthesis mediated by d-aminolevulinic acid synthetase.[11,12] In some experimental animals, pyridoxine deficiency produces anemia and ringed sideroblasts.[13] Experimental induction of vitamin B_6 deficiency in two infants was associated with a hypochromic, microcytic anemia,[14] and a malnourished patient has been described whose hypochromic anemia failed to respond to iron therapy but subsequently responded to the administration of vitamin B_6.[15]

TABLE 49-1 Red Blood Cell Values at Various Ages: Mean and Lower Limit of Normal (–2 SD)*

	Hemoglobin (g/dL)		*Hematocrit (%)*		*RBC Count (10^3/L)*		*MCV (fL)*		*MCV (pg)*		*MCHC (g/dL)*

Male	15.5	13.5	47	41	5.2	4.5	90	80	30	26	34	31

*These data have been compiled from several sources. Emphasis is given to recent studies employing electronic counters and to the selection of populations that are likely to exclude individuals with iron deficiency. The mean ± 2 SD can be expected to include 95% of the observations in a normal population. Adapted from Dallman PR. In: Rudolph A, editor. Pediatrics. 16th ed. New York: Appleton-Century-Crofts; 1977.
MCH = mean corpuscular hemoglobin; MCHC = mean corpuscular hemoglobin concentration; MCV = mean corpuscular volume.

Nutritional deficiencies of pyridoxine are extremely rare, although occasionally patients receiving therapy with antituberculosis drugs such as isoniazid, which interferes with the transport of pyridoxine to cells,[13,16,17] develop a microcytic anemia, which can be corrected with large doses of pyridoxine.[18,19] A small percentage of patients who have congenital or acquired sideroblastic anemia improve while on pharmacologic doses of pyridoxine.[20,21] There are also reports of sideroblastic anemia owing to vitamin B_6 deficiency in patients on hemodialysis.[11] Coadministration of pyridoxine with isoniazid or during dialysis should decrease the risk of these complications.

Riboflavin Deficiency

Although anemia secondary to riboflavin deficiency has been demonstrated in several animal models, it has been difficult to establish a direct casual role in humans.[22] The best evidence is provided by experimental studies. Human volunteers with malignancies maintained on a riboflavin-deficient diet and fed the riboflavin antagonist galactoflavin develop pure red cell aplasia.[23] Vacuolated erythroid precursors are evident prior to the development of aplasia. Red cell indices are normal, and the reticulocyte count is low. This anemia can be corrected by the administration of riboflavin. Confirmation of this response to riboflavin supplementation has been seen in both human adult and pediatric populations with anemia.[24,25] Riboflavin-deficient children given riboflavin demonstrated a decrease in serum iron and transferrin saturation accompanied by an increase in hemoglobin if the initial hemoglobin was below 13.5 g/mL, suggesting a relationship between riboflavin and iron use.[25]

Rat studies have shown that riboflavin deficiency is associated with reduced iron absorption and increased iron loss.[26,27] It has been proposed that this enhanced iron loss is the result of an accelerated rate of epithelial turnover in the small intestine.[28] In addition, ferrokinetic studies in humans receiving the riboflavin-deficient diet and galactoflavin demonstrated prolonged plasma clearance and distribution of iron primarily to liver and spleen in contrast to bone marrow in normals. Clearly, riboflavin has an important role in erythropoiesis probably by altering iron metabolism.

Riboflavin deficiency produces a decrease in red cell glutathione reductase activity.[29,30] Glutathione reductase is necessary for glutathione peroxidase to effectively regulate cellular redox potential.[31,32] Under normal conditions, the decrease in glutathione reductase activity is not associated with an increased sensitivity of the red cell to oxidant-induced injury.[33] It is possible that certain conditions in conjunction with riboflavin deficiency will leave the red cell vulnerable to oxidation injury, causing hemolytic anemia; however, this has not been described in humans.

Vitamin C (Ascorbic Acid) Deficiency

It is still unclear whether ascorbic acid has a direct role in hematopoiesis or whether the anemia observed in subjects with ascorbic acid deficiency, scurvy, is a result of the interactions of ascorbic acid with folic acid and iron metabolism. Although approximately 80% of individuals with scurvy are anemic,[34] attempts to induce anemia in human volunteers by severe restriction of dietary ascorbic acid have been unsuccessful.[35,36] Confusion arises because the anemia observed in subjects with scurvy may be hypochromic, normocytic, or macrocytic, and the marrow may be hypocellular, normocellular, or hypercellular. In about 10% of patients, the marrow is megaloblastic.[34]

Ascorbic acid is required to maintain folic acid reductase in its reduced, or active, form. Impaired folic acid reductase activity results in an inability to form tetrahydrofolic acid, the metabolically active form of folic acid. It has been demonstrated that patients with scurvy and

megaloblastic anemia excrete 10-formylfolic acid as the major urinary folate metabolite. Following ascorbic acid therapy, 5-methyltetrahydrofolic acid becomes the major urinary folate metabolite in these patients. This observation has led to the suggestion that ascorbic acid prevents the irreversible oxidation of methyltetrahydrofolic acid to formylfolic acid.[37] Failure to synthesize tetrahydrofolic acid or to protect it from oxidation in scurvy ultimately results in the appearance of a megaloblastic anemia. Under these circumstances, ascorbic acid therapy will produce a hematologic response only if sufficient folic acid is present to interact with the ascorbic acid.[38]

Iron deficiency in children often occurs in association with ascorbic acid deficiency. Scurvy may cause iron deficiency as a consequence of external bleeding. Iron balance may be further compromised by ascorbic acid deficiency because this vitamin facilitates intestinal iron absorption.[39] Ascorbic acid increases the bioavailability of iron through two mechanisms. First, it can reduce Fe^{3+} to Fe^{2+}, which is more soluble and less likely to form insoluble hydroxides at low pH than Fe^{3+}. Second, it forms a stable complex with iron, preventing iron from complexing with dietary constituents, such as tannins and phytates, which block transport into gastrointestinal mucosal cells.[40] Patients with scurvy, particularly children, often require both iron and ascorbic acid to correct a hypochromic, microcytic anemia,[41] and, rarely, a combination of iron, ascorbic acid, and folate may be required.[42]

Despite the evidence linking ascorbic acid deficiency to alterations in either folic acid or iron metabolism, many patients with scurvy have a normocytic, normochromic anemia accompanied by a persistent reticulocytosis of 5 to 10%. Ascorbic acid has antioxidant properties, and it is possible that a deficiency of this vitamin renders the cell susceptible to oxidant injury. This is of particular interest in regard to the possible reducing effects of ascorbic acid on oxidized vitamin E, much like those described above for folic acid.[43] Administration of ascorbic acid to patients with scurvy who have hemolysis produces an initial increase in reticulocyte count, followed by a rise in hemoglobin concentration and an ultimate correction of hematologic abnormalities.[44]

Folic Acid and Vitamin B_{12} Deficiencies: The Megaloblastic Anemias

The fundamental biochemical defect that results from deficiency of either folic acid or vitamin B_{12} is decreased synthesis of deoxyribonucleic acid (DNA). This decreased synthesis of DNA appears to be the result of the inadequate conversion of deoxyuridylate to thymidylate and is largely owing to inadequate quantities of 5,10-methylenetetrahydrofolate for participation in the necessary single-carbon transfer reaction.[45] Vitamin B_{12} is required for the release of folate from its circulating and stored methyl form so that it can return to the tetrahydrofolate pool for conversion to 5,10-methylenetetrahydrofolate. In vitamin B_{12} deficiency, folate is trapped as methylfolate, which is metabolically inactive. This event is known as the "folate trap" hypothesis.[46–48]

The morphologic representation of this decreased DNA synthesis is the megaloblast. Megaloblasts are nucleated red blood cells that display a lacy nuclear chromatin and prominent parachromatin pattern and an apparent dyssynchrony of maturation between the nucleus and the cytoplasm. This dyssynchrony is produced by the slow DNA synthesis in the nucleus in relation to the near-normal synthesis of ribonucleic acid (RNA) in the cytoplasm. Although the morphologic abnormalities present in the maturing erythroid precursors are regarded as the hallmark of folic acid or vitamin B_{12} deficiency, morphologic abnormalities are also evident in the myeloid and megakaryocytic cell lines, resulting in morphologic abnormalities in granulocytes and platelets. Owing to the involvement of multiple cellular elements in marrow, the diagnosis of megaloblastic anemia can be confused with the diagnosis of acute myelogenous leukemia.

Nutrient deficiency of either folate or vitamin B_{12} will eventually result in a similar megaloblastic anemia. However, not all megaloblastic anemias are attributable to a lack of these vitamins because any abnormality that limits DNA synthesis can produce megaloblastosis. Other examples include orotic acid, which is a precursor of uridine, thiamin deficiency, Lesch-Nyhan syndrome, congenital dyserythropoietic anemias, and as a complication of chemotherapeutic agents (methotrexate and cytosine arabinoside), antimalarial agents, and antibacterial agents (trimethoprim). Some of these antifolates have an affinity for dehydrofolate reductase (DHFR), and when intracellular folate concentrations are low, they may inhibit DHFR activity and cause folate deficiency.

In an established case of megaloblastic anemia, the circulating red cells are macro-ovalocytic, and their MCV is increased to a range of 105 to 160 fL. The presence of simultaneous iron deficiency may obscure the macrocytosis, resulting in a normocytic anemia. In either folate or vitamin B_{12} deficiency, polychromia and fine basophilic stippling of the erythrocytes are observed, and Howell-Jolly bodies, which are nuclear remnants normally extruded from the erythrocyte during cell maturation, may be present. The concentration of serum iron is usually increased owing to impaired erythrocytosis. The red cell life span is modestly reduced, perhaps owing to an abnormality in membrane properties related to the dyserythropoietic state. A significant degree of ineffective erythropoiesis is present.[49] This may be reflected by an increase in the serum bilirubin concentration and an increase in serum lactate dehydrogenase (LDH).[50] Unconjugated serum bilirubin concentration may reach a range of 2.0 to 3.0 mg/dL.

The earliest morphologic change in the megaloblastic anemias is alteration in the circulating granulocytes. The polymorphonuclear leukocytes are hypersegmented. In the normal child, 2.6 segments are the average; in patients with folate or vitamin B_{12} deficiency, the average number of nuclear lobes generally exceeds a mean value of 3.0. In the normal subject, fewer than 3.0% of the circulating leukocytes have five lobes; in contrast, in megaloblastic anemias, nuclear hypersegmentation will result in the presence of polymorphs with six or more nuclear segments.[50] In severe forms of deficiency, both neutropenia and thrombocytopenia can be present.

Folate or vitamin B_{12} deficiency may occur as a result of inadequate ingestion, absorption, or use owing to congenital or acquired defects or increased requirement, excretion, destruction, or loss of these nutrients. Deficiencies of either folate or vitamin B_{12}, from any mechanism, are uncommon in the pediatric population in the United States.

Folic Acid Deficiency

The folic acid molecule consists of a pteridine moiety, coupled by a methylene bridge to a *p*-aminobenzoic acid molecule, which, in turn, is covalently bound to a glutamic acid residue. Natural folic acid occurs primarily as polyglutamates. These polyglutamates must be broken down to monoglutamates before intestinal absorption can occur. This reaction requires the presence of the enzyme γ-glutamylcarboxypeptidase (conjugase), which is present in the mucosal border of the small bowel. A folate binder exists on the enterocyte surface. Monoglutamates are absorbed through both active and passive mechanisms. An etiologic and pathophysiologic classification of folate deficiency is shown in Table 49-2.

Most of the folate in the blood is in the form of 5-methyltetrahydrofolic acid and is transported in free form or loosely associated with serum proteins.[51] Specific folate binding proteins also have been found in plasma and tissues that have similarities to receptors on the surface of some cells.[52] Only small quantities of folate are normally found in the urine; this excretion of 1 to 10 μg per day is a result of both the tight plasma binding of folate and the tubular resorption of any filtered vitamin. The fecal content of folate may be as high as 500 mg/day and is a consequence of bacterial synthesis, which occurs primarily in the large bowel. Some folate is lost daily in sweat and desquamated skin. Patients with severe burns have extensive loss of folate through the skin.

The clinical manifestations of folate deficiency include megaloblastic changes (not necessarily anemia or pancytopenia); gastrointestinal symptoms such as glossitis, anorexia, gastrointestinal discomfort, or occasional diarrhea; humoral and cellular immune defects; and neurologic abnormalities including depression, poor judgment, and some affective disorders.[53]

The Adequate Intake (AI) of folate for infants is 65 μg/day until 6 months of age and 80 μg/day from 7 to 12 months. The Dietary Reference Intake (DRI) for children is 150 μg/day from 1 to 3 years of age, 200 μg per day from 4 to 8 years of age, 300 μg/day from 9 to 13 years of age, and 400 μg/day from 14 years to adulthood.[54] Folate is present in a wide variety of foods. Cow's milk, human milk, and proprietary infant formulas normally provide approximately 50 μg L. In contrast, goat's milk contains only 2 to 11 μg/L, and the feeding of goat's milk to infants as the sole source of nutrition will result in the appearance of a megaloblastic anemia.[55] Although dietary folic acid deficiency is a common cause of megaloblastic anemia in developing countries, it appears to be unusual in the United States, where folic acid deficiency is more likely to be the result of defective absorption, increased requirements, or impaired use.

TABLE 49-2 Etiologic and Pathophysiologic Classification of Folate Deficiency

Nutritional causes
Decreased dietary intake
Poverty and famine (associated with kwashiorkor, marasmus)
Institutionalized individuals (psychiatric and nursing homes)
Chronic debilitating disease
Goat's milk, special diets (phenylketonuria, maple syrup urine disease, slimming)
Cultural/ethnic cooking techniques (food folate destroyed) or habits (folate-rich foods not consumed)
Decreased diet and increased requirements
Physiologic
Pregnancy
Lactation
Prematurity, infancy
Pathologic
Intrinsic hematologic disease (extrinsic: AIHA, drugs; malaria, hemoglobinopathy; SCD, thalassemia; membrane defects; HS, PNH)
Abnormal hematopoiesis (leukemia, lymphoma, MDS, agnogenic myeloid metaplasia with myelofibrosis)
Infiltration with malignant disease
Dermatologic (psoriasis, methotrexate dermatopathies)
Folate malabsorption
With normal intestinal mucosa
Some drugs (controversial)
Congenital folate malabsorption
With mucosal abnormalities
Tropical sprue
Nontropical sprue
Regional enteritis
Defective cellular folate uptake
Familial aplastic anemia
Inadequate cellular use
Folate antagonists (methotrexate)
Hereditary enzyme deficiencies involving folate
Drugs (multiple effects on folate metabolism)
Alcohol
Sulfasalazine
Triamterene
Pyrimethamine
Trimethoprim-sulfamethoxazole
Anticonvulsants (diphenylhydantoin, barbiturates)
Acute folate deficiency

Adapted from Antony A. Megaloblastic anemias. In: Hoffman R, et al, editors. Hematology: basic principles and practice. New York: Churchill Livingstone; 1991.
AIHA = autoimmune hemolytic anemia; HS = hereditary spherocytosis; MDS = myelodysplastic syndrome; PNH = paroxysmal nocturnal hemoglobinuria; SCD = sickle cell disease.

Developmental changes in folate balance are seen during infancy. Serum and red cell folate concentrations are higher in both preterm and term infants than in normal adults.[56] After birth, serum values decline rapidly, but the decline is most rapid and most severe in infants weighing less than 1,700 g at birth. Approximately two-thirds of low birth weight infants may display subnormal serum folate concentrations between 1 and 3 months of age, but they rarely have a megaloblastic anemia. Administration of supplemental folic acid, in the absence of megaloblastic anemia, has not been demonstrated to produce any increase in the hemoglobin concentration. The normal preterm infant absorbs folic acid without difficulty. The dietary provision

of 20 to 50 μg/day appears adequate to prevent the development of a deficiency. The presence of chronic infection or diarrhea may impair absorption or increase needs in these small infants. Overcooking of foods or boiling of milk can reduce the folate content by approximately 50%.[57]

Folate deficiency may accompany kwashiorkor, and its incidence has been found to range from 10 to 70%. This variation presumably reflects regional dietary practices. Both malabsorption and chronic infection may also contribute to this folic acid deficiency.

Because folate is absorbed primarily from the upper third of the small intestine, structural or functional damage in this area can reduce absorption sufficiently and result in folate deficiency. In chronic diseases, such as gluten enteropathy, tropical sprue, and active Crohn's disease, a megaloblastic anemia may occur. In many of these disorders of the small bowel, there is an apparent loss of intestinal conjugase activity because a small dose of monoglutamate folate produces a prompt hematologic response; large doses of polyglutamate folate, such as those present in food, are poorly absorbed. Impaired absorption has also been described in chronic congestive heart failure and skin disorders such as dermatitis herpetiformis.

Folate malabsorption may be induced by a number of drugs. Patients taking anticonvulsants such as phenytoin (Dilantin) may develop a folate-responsive megaloblastic anemia. It has been proposed that this anemia is a result of phenytoin-induced inhibition of intestinal conjugase, thus interfering with the conversion of dietary polyglutamate to the absorbable monoglutamate form.[58] Folic acid antagonists (folate analogs) such as methotrexate, pyrimethamine, pentamidine isethionate, and trimethoprim, which inhibit the reduction of folate to its metabolically active tetrahydrofolate derivative, may produce a megaloblastic anemia. In addition, a variety of genetic deficiencies of enzymes required for folate metabolism have been described. Some of these patients demonstrate mental retardation, and many, but not all, have a megaloblastic anemia.[59,60]

Folate requirements appear greater per kilogram in the newborn infant and young child[48]; in pregnant women, in whom folate is shunted to the developing fetus and urinary folate loss is increased; and in lactating women, who secrete 50 μg or more into each liter of milk.[43] The folate content of breast milk does not correlate with the mother's plasma folate[61] because folate is concentrated in milk above the level of plasma folate. Some milk folate is bound to the folate binding protein, as indicated above. Other groups of patients with higher than normal folate requirements include persons with sprue and other diseases of the small intestine, persons taking antiepileptic medication, women taking birth control pills, and persons with hemolytic anemia, including those with sickle cell anemia and thalassemia.[53]

Laboratory Diagnosis of Folate Deficiency

In addition to the characteristic laboratory findings of megaloblastic anemia, such as macrocytosis with or without neutropenia, multilobulated polymorphonuclear cells, increased LDH and bilirubin, bone marrow showing megaloblastic changes, increased plasma iron content and saturation of transferrin, and decreased serum cholesterol and lipids, several specific measurements provide direct evidence of deficiency of folate. These include decreased serum folate, decreased erythrocyte folate, homocystinemia and sometimes homocystinuria, and abnormal deoxyuridine suppression test in bone marrow corrected in vitro by addition of *N*-5-methyltetrahydrofolate or other folates and excretion of formiminoglutamate in the urine.[53]

Measurement of folate activity of serum and red blood cells is the most direct and reliable way to determine the folic acid status of the patient. The measurement of serum folate concentration alone reflects short periods (2 weeks) of folate deficiency. Herbert produced folate deficiency by self-experimentation and convincingly demonstrated that a fall in serum folate concentrations precedes the appearance of any other hematologic manifestations (Table 49-3).[62] The concentration of red cell folate is far more useful for documenting the presence of a long-standing deficiency. Only reticulocytes and nucleated red cell precursors are capable of taking up the vitamin from tissue stores. The folate in the mature erythrocyte is nonexchangeable; thus, reduction in red cell folate indicates a deficiency of at least 3 to 4 months duration.

The normal range of serum folate is 3 to 15 ng/mL. Serum folate values in the 1.5 to 3.0 range are regarded as "indeterminate." The red cell folate normally ranges from 150 to 600 ng/mL, and values of less than 150 ng/mL are diagnostic of deficiency. Normal values for the first year of life are depicted in Table 49-4. Microbiologic assays using *L. casei* will produce spuriously low results if the serum used for assay contains antibiotics or chemotherapeutic agents that inhibit the growth of the organism. A therapeutic trial, using 100 μg/day of folic acid, may also be used to make a presumptive diagnosis.

Vitamin B_{12} Deficiency

Vitamin B_{12}, or cobalamin, is an organometallic complex consisting of two major moieties: a corrin nucleus containing a covalently bound cobalt atom and a nucleotide base lying at right angles to the corrin nucleus. The vitamin B_{12} coenzymes, which activate intracellular metabolism, are 5-adenosylcobalamin and methylcobalamin. Hydroxycobalamin is the predominant dietary form of the vitamin. Vitamin B_{12} is synthesized by bacteria and is not present in plants; therefore, it does not occur in vegetables or fruit.

Only two metabolic functions for the vitamin B_{12} coenzymes have been identified in humans. The first of these is

TABLE 49-3 Time Sequence of Hematologic Changes in the Development of Nutritional Folic Acid Deficiency

Hematologic Finding	*Time to Appearance (wk)*
Reduced serum folate	2
Hypersegmentation of leukocytes	6
Reduced red cell folate	17
Macro-ovalocytosis	18
Megaloblastic bone marrow	19
Anemia	19–20

the conversion of L-methylmalonyl-coenzyme A (CoA) to succinyl CoA, a reaction catalyzed by methylmalonyl-CoA mutase and requiring 5-adenosylcobalamin. Defects in the conversion of L-methylmalonyl-CoA to succinyl CoA result in methylmalonicacidemia (MMA) and methylmalonicaciduria. The second reaction in which vitamin B_{12} is a cofactor is the homocysteine 5-methyltetrahydrofolate methyltransferase reaction. This reaction generates methionine from homocysteine using methionine synthase and produces tetrahydrofolic acid from 5-methyltetrahydrofolic acid.[63]

Dietary vitamin B_{12}, primarily in the form of hydroxycobalamin, is absorbed in the terminal ileum and requires the presence of intrinsic factor that has been secreted in the parietal cells of the stomach. Nutritional deficiency of vitamin B_{12} is extremely rare in infants and children. An etiologic and pathophysiologic classification of vitamin B_{12} deficiency is shown in Table 49-5.

It is estimated that the adult and older child require 1.0 μg of vitamin B_{12} per day and the infant 0.1 μg per day to maintain normal erythropoiesis. The normal diet usually contains far more vitamin B_{12} than this minimal requirement. Western diets usually contain 5 to 10 μg daily. The highest concentrations are found in liver, kidney, meat muscle, fowl, shellfish, and dairy products. There is probably no vitamin B_{12} in fruits, vegetables, nuts, or cereal unless they are contaminated with vitamin B_{12}–producing bacteria. Vitamin B_{12} is usually not destroyed by cooking. Under alkaline conditions and the presence of ascorbic acid, some vitamin B_{12} may be lost when milk is boiled or when meat is overcooked.

The average daily vitamin B_{12} output in breast milk is approximately 0.3 μg and closely parallels the serum vitamin B_{12} concentration of the mother.[64] The term infant receives approximately 30 μg of vitamin B_{12} from the mother during the course of gestation. Liver stores are about 26 μg in term infants but only 10 μg in premature infants.[65] Serum vitamin B_{12} values in the newborn are normally much higher than those of the mother. Because of this adequate endowment, vitamin B_{12} deficiency owing to inadequate ingestion in the first year or two of life is seen only when an infant is born to a severely vitamin B_{12}–deficient mother and is exclusively breast-fed by her or placed on a strict vegetarian diet. Megaloblastic anemia in the infants of strict vegetarian mothers has been reported from India.[66] Megaloblastic anemia in breast-fed infants of mothers who either have untreated pernicious anemia or are on vegetarian diets has also been observed in 5- to 6-month-old infants in the

TABLE 49-4 Normal Serum and Red Cell Folate Values during the First Year of Life: Mean (Range)

Age	*Red Cell Folate (ng/mL)*	*Serum Folate (ng/mL)*
Neonate	598 (196–1,256)	24.5 (3–59)
3–4 mo	283 (110–498)	12.2 (5–30)
6–8 mo	247 (100–466)	7.7 (3.5–16)

TABLE 49-5 Etiologic and Pathophysiologic Classification of Cobalamin (Cbl) Deficiency

- Nutritional Cbl deficiency (insufficient Cbl intake)
  - Strict vegetarians, vegans
  - Breast-fed infants of mothers with pernicious anemia
- Abnormal intragastric events (inadequate dissociation of Cbl from food protein)
  - Atrophic gastritis
  - Partial gastrectomy with hypochlorhydria
- Deficient or defective intrinsic factor (IF) molecules (IF-Cbl complex not formed; therefore, Cbl not absorbed)
  - Deficient IF
    - Congenital IF deficiency
    - Loss or atrophy of gastric oxyntic mucosa
      - Partial gastrectomy
      - Autoimmune destruction
        - Adult pernicious anemia
        - Juvenile pernicious anemia
      - Caustic destruction (lye)
      - Total gastrectomy
  - Defective IF
    - IF with no abnormal susceptibility to acid pepsin/trypsin
    - IF with 60-fold lower affinity for IF receptor
- Abnormal events in small bowel lumen
  - Inadequate pancreatic protease (Cbl complex not degraded; therefore, Cbl not transferred to IF)
    - Insufficient pancreatic protease (pancreatic insufficiency)
    - Inactivation of pancreatic protease by gastric hypersecretion (Zollinger-Ellison syndrome)
  - Usurpation of luminal Cbl (inadequate Cbl binding to IF)
    - By bacteria
      - Stasis syndromes (blind loops, pouches of diverticulosis, strictures, fistulae, anastomoses)
      - Impaired bowel motility (scleroderma pseudo-obstruction)
      - Hypogammaglobulinemia
    - By *Diphyllobothrium latum* (fish tapeworm)
- Disorders of ileal mucosa/IF receptors (IF-Cbl not bound to IF receptors)
  - Diminished or absent IF receptors—surgical conditions (ileal bypass, resection)
  - Abnormal mucosal architecture/function—medical conditions (tropical/nontropical sprue, Crohn's disease, tuberculous ileitis, infiltration by lymphomas)
  - Defective IF receptors/post-OF receptor defects
    - Imerslund-Graesbeck syndrome
    - Transcobalamin (TC) II deficiency
    - Drug-induced effects (slow K, biguanides, cholestyramine, colchicine, neomycin PAS)
- Disorders of plasma Cbl transport (TC II-Cbl complex not delivered to TC II receptors)
  - Quantitative deficiency (congenital TC II deficiency)
  - Qualitative deficiency of TC II with decreased Cbl binding
  - Defective binding of TC II-Cbl to Tc II receptors
- Metabolic disorders (Cbl not used by cell)
  - Inborn errors—mutations A–G
    - Cbl A: defective reduction of Cbl II to I
    - Cbl B: defective conversion of Cbl I to Ado-Cbl
    - Cbl C, Cbl D: defective reduction of Cbl III to II
    - Cbl E: inability to maintain Cbl bound to MS in reduced state
    - Cbl F: inability to transport Cbl from endosome/lysosome to cytoplasm
    - Cbl G: defect in MS catalyzed reaction
  - Acquired disorders: Cbl I oxidized to III-N2O inhalation

Adapted from Antony A. Megaloblastic anemias. In: Hoffman R, et al, editors. Hematology: basic principles and practice. New York: Churchill Livingstone; 1991.

United States.[67,68] In many of these cases, the infant presents with evidence of neurologic involvement as well as a macrocytic anemia. Both resolve following treatment with vitamin B_{12}. As yet, megaloblastic anemia owing to dietary vitamin B_{12} deficiency has not been reported in children in the United States as a result of a vegetarian diet if the infant was born of a nutritionally sufficient mother.

The absorption of vitamin B_{12} requires gastric secretion of intrinsic factor, normal pancreatic exocrine secretion, and normal ileal function. The gastric disorders producing inadequate or absent secretion of intrinsic factor include congenital pernicious anemia, juvenile pernicious anemia (with or without one or more endocrine disorders), and extensive gastric resection (Table 49-6). Children with congenital pernicious anemia are born with absence of intrinsic factor and no other abnormalities. The stomach is normal on biopsy and produces normal quantities of gastric acid. There are no antibodies to intrinsic factor or parietal cells. Patients with this disease generally present between 4 and 28 months of age with a megaloblastic anemia or neuropathy. The disease is inherited as an autosomal recessive disorder. One variant of this disorder has been described in which the patient was found to have an immunologically normal, but biologically inert, intrinsic factor.[69] The defective molecule binds vitamin B_{12} normally but attaches poorly to the ileal receptor site.

The juvenile form of pernicious anemia resembles that seen in adults. These children have gastric atrophy, gastric achlorhydria, absent intrinsic factor, and a high incidence of antibody against intrinsic factor. Some children with pernicious anemia, like adults, have associated endocrinopathies such as hypoparathyroidism, hypothyroidism, and Addison's disease. An association of selective immunoglobulin A deficiency with juvenile pernicious anemia has also been observed.

Failure of absorption of vitamin B_{12}–intrinsic factor complex in the ileum may also produce a megaloblastic anemia. This problem has been observed following ileal resection or ileal atresia; in association with celiac syndrome, regional enteritis, severe chronic pancreatitis, and lymphosarcoma of the terminal ileum; and in Imerslund-Graesbeck syndrome. In this latter disorder, which is familial, there is a series of defects in transport of vitamin B_{12} across the enterocyte despite the presence of a structurally normal ileum and intrinsic factor. Vitamin B_{12} absorption is not corrected by the addition of normal human intrinsic factor with vitamin B_{12}.[63]

Inadequate absorption of vitamin B_{12} may also be the result of competition for the vitamin in the gut from intestinal parasites, such as the fish tapeworm, or bacteria in association with the blind loop syndrome or trichobezoar.[55] Inadequate use of the vitamin B_{12} may occur in congenital enzyme deficiencies of vitamin B_{12} metabolism and congenital lack of the vitamin B_{12} transport protein transcobalamin II. In addition, several rare metabolic genetic defects affecting vitamin B_{12} metabolism have been reported. Because these deficiencies do not represent nutritional deficiencies, the reader is advised to consult other sources for more detailed information regarding these inherited abnormalities.[55,63,70]

The biochemical changes associated with vitamin B_{12} deficiency include MMA and methylmalonicaciduria of a magnitude determined by the flow of odd-chained fatty acids, valine and threonine, through the pathway. The secondary effects of MMA accumulation include acidosis, hyperglycinemia, and possibly inhibition of other enzymes and of bone marrow stem cells by accumulated MMA.[71–74] Homocystinemia and homocystinuria can be found. Inadequate levels of tetrahydrofolate in cells, producing defective rates of polyglutamyl folate synthesis and deficiency of folates required for some intracellular reactions, are observed. Defective thymidylate synthesis, defective synthesis of endogenous purines, defective detoxification of formate, and accumulation of formiminoglutamate, 5(4)-amidoimidazole-4(5) carboxyribonucleotide, and other intermediates of folate-dependent reactions are present. Biochemical central nervous system changes, which might relate to defective methylation of myelin basic protein, have been reported.[75–77] Finally, intracellular folate levels are lower than expected for the concentration of folate in plasma.[53]

Clinical Manifestations of Vitamin B_{12} Deficiency

The onset of symptoms is often insidious and may include pallor, apathy, fatigability, and anorexia. These symptoms are not specific for vitamin B_{12} deficiency. A beefy red and sore tongue with papillary atrophy may be observed. Pares-

TABLE 49-6 Vitamin B_{12} Malabsorption in Childhood

	Age at Onset (yr)	*Inheritance*	*Gastric Mucosa*	*Acid Secretion*	*Intrinsic Factor*	*Parietal Cell and Intrinsic Factor Antibodies*	*Associated Abnormalities*

thesias may be reported in the older child. Signs of subacute dorsolateral degeneration are uncommon in children, but loss of vibration and position sense may be seen. When neurologic disease is present, the lower limbs are more severely affected. The neurologic changes may precede the appearance of anemia. A number of gastrointestinal symptoms have been reported. The peripheral blood findings and bone marrow findings in vitamin B_{12} deficiency resemble those observed with folic acid deficiency.

Diagnosis of Vitamin B_{12} Deficiency The general findings secondary to megaloblastic anemia are similar to those indicated above for deficiency of folic acid. Specific measurements for vitamin B_{12} deficiency include decreased serum cobalamin, excess methylmalonic acid in the urine or serum, homocystinemia and sometimes homocystinuria, and abnormal deoxyuridine suppression test in bone marrow, corrected in vitro by addition of MeCbl or 5-formyltetrahydrofolate but not by methyltetrahydrofolate.

The serum vitamin B_{12} level is deficient when it is less than 100 pg/mL (normal 200 to 800 pg/mL). If the dietary history indicates a normal vitamin B_{12} intake, absorption of cobalt-labeled vitamin B_{12} should be performed by the Schilling test. For this purpose, a standard dose of the labeled vitamin (0.5 μg) is given orally after an overnight fast, and then a "flushing dose" of 1,000 μg of vitamin B_{12} is given parenterally 2 hours after the oral dose. Less than 7% of the labeled dose will appear in the urine during the 24-hour collection period if there is a lack of intrinsic factor or malabsorption of vitamin B_{12} for any other reason. If absorption is impaired, the Schilling test is repeated with the simultaneous administration of both intrinsic factor and labeled vitamin B_{12}. Improvement in the urinary excretion of the labeled ascorbic acid confirms the diagnosis of intrinsic factor deficiency. Gastric biopsy, the measurement of gastric acid secretion, and assay of intrinsic factor in gastric juice all help to categorize the nature of the underlying disturbance.

A therapeutic trial may be employed for the diagnosis of vitamin B_{12} deficiency. A dose of 0.5 μg of cyanocobalamin or hydroxycobalamin is given parenterally for 7 to 10 days. A reticulocytosis and increase in hemoglobin concentration should be observed. If the diagnosis has been firmly established, a therapeutic trial may be omitted and the patient treated with daily doses of 25 to 100 μg. If the patient has any form of vitamin B_{12} malabsorption rather than a primary nutritional deficiency, maintenance therapy should consist of monthly injections of 50 to 1,000 μg, depending on the patient's age and weight.

Vitamin E Deficiency

Vitamin E, α-tocopherol, a lipid-soluble antioxidant, was first discovered in 1922. Although a need for vitamin E in human nutrition has been established, precise requirements, the means of determining vitamin E sufficiency, the spectrum of diseases produced by vitamin E deficiency, the interrelationships between vitamin E and other nutrients, and its precise mechanism of action have been topics of continued debate and the subject of excellent reviews.[78–81]

The human fetus at 5 months gestation has a total-body vitamin E content of only 1 mg.[82] The fetus at term has a body vitamin E content of 20 mg. The increase in body vitamin E content during gestation can be linearly related to total body weight or total body fat and averages 3 to 7 mg/kg. The normal adult male averages 50 mg/kg, and the female averages 160 mg/kg. This difference in the ratio of body vitamin E to body weight presumably reflects differences in body fat composition. The ratio of vitamin E to fat remains relatively constant throughout gestation and averages 0.27 mg of vitamin E per gram of lipid; ratios of 0.24:1.00 have been described for adult males and 0.46:1.00 for adult females.[83,84]

Plasma vitamin E levels average close to 0.9 mg/100 mL in the mother at term, with a corresponding value of only 0.2 mg/100 mL in the infant.[85] Although there is a direct relationship between the plasma level of vitamin E in the infant at birth and that of the mother, infants are not born with values above 0.6 mg/100 mL, the value regarded as the lower limit of normal for older children and adults. When vitamin E concentrations are expressed as vitamin E-to-lipid ratios, perhaps a more nutritionally valid means of determining vitamin E deficiency, differences between mothers and their infants disappear. The vitamin E-to-total lipid ratio of mothers at term has been found to average 1.57:1.00, with a ratio of 2.40:1.00 in cord blood.[86]

Infants, both term and preterm, who are fed colostrum and human milk achieve normal plasma vitamin E concentrations by 1 week of age.[46,87] Most of the simulated human milk formulas presently available will produce vitamin E concentrations within the normal adult range when fed to infants during the first 2 weeks of life. The relationship between iron content and vitamin E in the diet may determine the turnover of vitamin E as iron-mediated reactions stimulate lipid peroxidation and increase the requirements for vitamin E.

Hemolytic Anemia and the Premature Infant Prior to 1967, despite the fact that it was recognized that most proprietary formulas fed to low birth weight infants resulted in a prolonged period of vitamin E deficiency, no hematologic abnormalities could be demonstrated.[88,89] In 1967, the presence of a hemolytic anemia that could be corrected by vitamin E or prevented by maintaining vitamin E sufficiency from early infancy was described.[90]

This syndrome was seen almost exclusively in infants with birth weights of less than 1,500 g and was most pronounced during the period of 6 to 10 weeks of life. The hematologic findings consisted of anemia with hemoglobin of 6 to 8 g/dL, reticulocytosis of 4 to 5% or greater, and thrombocytosis. Red cell morphologic changes included the presence of anisocytosis, poikilocytosis, red cell fragments, and irregularly contracted erythrocytes and spherocytes. The hydrogen peroxide hemolysis test was abnormal, and the red cell life span was reduced.[90,91] These findings were all consistent with alterations in the membrane caused by oxidant injury. Treatment with vitamin E, in total doses ranging from 200 to 1,000 mg, produced a prompt rise in hemoglobin, a reduction in the reticulocyte

count, and a gradual decline in the platelet count to the normal range. In addition to the hematologic abnormalities, many of the small infants also displayed edema of the lower legs and scrotum, watery nasal discharge, and, on occasion, tachypnea. The mechanisms responsible for these changes are not known.

Melhorn and Gross studied infants of less than 36 weeks gestation receiving a commercial formula and found that, at 6 to 10 weeks of age, infants who had been supplemented with 25 IU of vitamin E per day from day 8 of life had significantly higher hemoglobin concentrations and lower reticulocyte counts and hydrogen peroxide tests than the unsupplemented infants.[92] It was also found that the daily administration of ferrous sulfate, 10 to 12 mg/kg/day from day 8, exaggerated the hemolytic anemia in the infants not receiving the vitamin E supplement. Williams and coworkers demonstrated that hemolytic anemia owing to vitamin E deficiency occurred in infants receiving iron-fortified formulas only if the formula was unusually rich in polyunsaturated fats.[93]

It has been hypothesized that hemolysis occurs in vitamin E deficiency as a consequence of peroxidation of lipid components of the red cell membrane. The peroxidation is initiated by the generation of a free radical (an unpaired electron) and proceeds autocatalytically in the absence of an antioxidant. Iron, in the reduced state, particularly in the presence of ascorbic acid, is recognized to generate free radicals. The requirements for lipid peroxidation include the presence of a suitable substrate (eg, a long-chain unsaturated fatty acid), a lack of antioxidant (eg, vitamin E), and a source of a free radical generating system (eg, heavy metals, molecular oxygen). Most proprietary formulas have now reduced their polyunsaturated fatty acid (PUFA) content and increased their vitamin E concentration, resulting in vitamin E-to-PUFA ratios in excess of 0.6:1.00, a value generally regarded as sufficient to prevent the development of vitamin E deficiency.[78] The potential for the development of vitamin E deficiency anemia is present when infants receive intravenous lipid preparations without adequate vitamin E supplementation.

The diagnosis should be suspected in an infant who displays anemia in the presence of persistent reticulocytosis, nonspecific red cell morphologic abnormalities, and thrombocytosis. Confirmation of the diagnosis requires (1) evidence of a reduced plasma vitamin E concentration (< 0.5 mg/dL) or a reduced vitamin E-to-total lipid ratio (< 0.6), (2) an abnormal hydrogen peroxide hemolysis test (usually > 30% hemolysis with a normal laboratory value of < 10%), and (3) an increase in hemoglobin and a fall in reticulocyte count after vitamin E therapy. Response should be apparent within 10 days, provided that correction of criteria 1 and 2 has occurred.

Miscellaneous Conditions Patients with various forms of malabsorption will become vitamin E deficient. These include patients with exocrine pancreatic insufficiency (cystic fibrosis), congenital biliary atresia, abetalipoproteinemia, and extensive small-bowel resections. In patients with reduced concentrations of plasma vitamin E, the red cell half-life is usually shortened,[61,79] although anemia is usually not evident or, when present, is usually not correctable by the administration of vitamin E alone. The relative anemia observed in most patients with chronic lung disease with cystic fibrosis will not respond to iron alone but may improve when iron and vitamin E are given concurrently.[94]

Anemia of Starvation

Studies conducted during World War II with conscientious objectors demonstrate that semistarvation for 24 weeks resulted in a mild to moderate normocytic, normochromic anemia.[95] Marrow cellularity was usually reduced and was accompanied by a decrease in the erythroid-to-myeloid ratio. Measurements of red cell mass and plasma volume suggested that dilution was a major factor responsible for the reduction in hemoglobin concentration. In persons subjected to complete starvation, either for experimental purposes or to treat severe obesity, anemia was not observed during the first 2 to 9 weeks of fasting.[96] Starvation for 9 to 17 weeks produced a fall in hemoglobin and marrow hypocellularity.[97] Resumption of a normal diet was accompanied by a reticulocytosis and disappearance of anemia. It has been suggested that the anemia of starvation is a response to a hypometabolic state, with its attendant decrease in oxygen requirements.

Anemia of Protein Deficiency (Kwashiorkor)

From the series of Delmonte and coworkers on the anemia of protein deficiency in rats, it was deduced that oxygen consumption and, therefore, erythropoietin production are reduced.[98] Other studies confirmed this observation but related the reductions to caloric deprivation, with its associated decrease in the blood level of triiodothyronine and thyroxine.[99] As a result, erythropoiesis decreases, and the reticulocyte count falls. The plasma iron turnover and red cell uptake of radioiron are markedly reduced, and the red cell mass gradually declines.[100] Protein deficiency also produces a maturation block at the erythroblast level and a slight decrease in the erythropoietin-sensitive stem cell pool.[101] If exogenous erythropoietin is provided, normal erythropoiesis is restored despite protein depletion,[102] an observation that has explained the empiric but successful use of starved rats in the bioassay for erythropoietin.

In infants and children with protein-calorie malnutrition, the hemoglobin concentration may fall to 8 g/dL of blood,[103,104] but some children with kwashiorkor are admitted to the hospital with normal hemoglobin levels, probably owing to a decreased plasma volume. The anemia is normocytic and normochromic, but there is a considerable variation in the size and shape of the red cells on the blood film. The white blood cells and the platelets are usually normal. The marrow is most often normally cellular or slightly hypocellular, with a reduced erythroid-to-myeloid ratio. Erythroblastopenia, reticulocytopenia, and a marrow containing a few giant pronormoblasts may be found, particularly if these children have an infection. With treatment of the infection, erythroid precursors may appear in the marrow, and the reticulocyte count may rise. When nutrition is improved by feeding high-protein diets (pow-

dered milk or essential amino acids), there is reticulocytosis, a slight fall in hematocrit owing to hemodilution, and then a rise in hemoglobin, hematocrit, and red blood cell count. Improvement is slow, however, and during the third or fourth week, when the children are clinically improved and the serum proteins are approaching normal, another episode of erythroid marrow aplasia devoid of giant pronormoblasts may develop. This relapse is not associated with infection, does not respond to antibiotics, and does not remit spontaneously. It does respond to either riboflavin or prednisone, and unless treated with these agents, children who develop this complication may die suddenly. It has been suggested that the erythroblastic aplasia is a manifestation of riboflavin deficiency.[105]

Although the plasma volume is reduced to a variable degree in children with kwashiorkor, the total circulating red cell mass decreases in proportion to the decrease in lean body mass as protein deprivation reduces metabolic demands.[104] During repletion, an increase in plasma volume may occur before an increase in red cell mass, and the anemia may seem to become more severe, despite reticulocytosis. The erythropoietin level increases as the hemoglobin concentration falls[106] and, more importantly, as oxygen demand increases. The increased oxygen demand may, in part, account for the reticulocytosis. Also, during the repletion period, occult deficiencies of iron, folic acid, and, occasionally, riboflavin, vitamin E, and vitamin B_{12} may become manifest unless these essential nutrients are supplied in adequate amounts.

METAL DEFICIENCIES

Iron Deficiency

Iron deficiency continues to be the most common nutritional cause of anemia worldwide, affecting as many as 4 to 5 billion people.[107] The prevalence of iron deficiency has been declining in industrialized countries over the last few decades, at least partly owing to an increase in breastfeeding and fortification of infant formulas and cereals.[108] Unfortunately, most of the rest of the world has not experienced such a decline; an estimated 90% of cases occur in developing countries, impacting significantly on morbidity, mortality, and national development.[107]

Anemia, a treatable condition, is the most common clinical problem associated with this deficiency. However, the real public health concerns are the cognitive and behavioral impairments seen in infants and children,[109–113] the fatigue and decreased work capability in older children and adults,[109] and the association of severe iron deficiency anemia in pregnant women with prematurity, perinatal mortality, and low birth weight infants.[114–116] Because long-term iron supplementation is an impractical solution, providing fortified staple foods and working to increase the bioavailability of iron in various foods are steps toward decreasing the prevalence of iron deficiency worldwide.[117]

Iron deficiency occurs in various stages. First, there is depletion of iron stores in the body. This stage is unlikely to be diagnosed by any routine screening laboratory tests. Next, there is iron deficiency with anemia, initially with a normal MCV. As the deficiency continues, erythropoiesis is significantly impaired, and the diagnosis becomes more evident with obvious hypochromia and microcytosis on peripheral blood smear, in conjunction with some of the nonhematologic manifestations of this condition.

The body, based on its needs, attempts to maintain a balance between iron stores, recycled iron, and dietary iron intake. One-third of an infant's iron needs come from dietary sources; the remainder is recycled from red blood cell breakdown. Over time this changes, so that by adulthood, an even greater proportion of iron needs come from recycled iron such that there is less reliance on the diet for iron.

Iron is a vitally important nutrient that serves multiple functions in the body. It is the functional group in hemoglobin for oxygen transport and use in the red blood cell and helps with storage of oxygen in myoglobin in muscle. Iron is also present in peroxidase, catalase, and the cytochromes. Excess iron is stored primarily as ferritin and hemosiderin for use when the requirements of the body are greater than the combination of the dietary intake and the available recycled iron.

Fetal-Maternal Relationships The iron content of the normal newborn infant is approximately 75 mg/kg, as determined by carcass analysis of stillbirths.[119] Studies performed during various stages of pregnancy indicate that the iron content of the fetus and the weight of the fetus increase proportionately with age; thus, through gestation, the fetus tends to maintain a constant iron content. Under usual circumstances, 66 to 75% of the infant's iron is present in the red cell mass. Storage iron in the liver and spleen, although subject to great variability, makes up approximately 6% of the total iron, whereas nonhemoglobin iron in the form of cytochromes, myglobin, and other iron-containing enzymes account for approximately 24%.[120]

The bulk of the infant's iron endowment at birth is represented by the red cell mass. As a result, the amount of iron in the body at the time of birth depends on the blood volume and the hemoglobin concentration, and any complications during pregnancy or the perinatal period that result in fetal blood loss will compromise the infant's iron endowment. Unless extreme, the presence of maternal iron deficiency does not appear to compromise the iron endowment of the fetus. The hemoglobin concentration in the cord blood of infants born to anemic iron-deficient mothers does not differ from that of infants born to iron-sufficient mothers until maternal hemoglobin values fall below 6.0 g/dL.[121] With extreme maternal iron deficiency anemia, the placenta is small and the cord blood hemoglobin concentration is reduced. Some studies have observed that women with low serum iron values tend to have infants with lower than normal serum iron levels[122]; other studies have found no difference in the state of the infant's iron nutrition at 6, 12, and 18 months of age regardless of whether their mothers had received iron supplementation during pregnancy.[123,124] The relationship between maternal iron status and pregnancy outcomes is discussed further in Chapter 24, "Maternal Nutrition and Pregnancy Outcome."

Employing plasma ferritin concentrations as an index of iron sufficiency, Rios and coworkers were unable to document any correlation between plasma ferritin concentrations in mothers with high and low values and the plasma ferritin concentrations of their infants at birth or at $1^1/_2$ months of age.[125] It may be concluded from these studies that, except in the most unusual circumstances, maternal iron deficiency by itself does not result in iron deficiency anemia in the infant, either at birth or later in the first year of life. Factors such as rate of growth relative to birth weight, initial iron endowment that has been compromised by blood loss, and infant nutrition seem to be far more important in determining the later appearance of anemia.

At birth, the newborn has a large number of reticulocytes and a relatively high hemoglobin concentration with a mean of 16.6 g/dL.[126] The hemoglobin increases over the first few days and then, as erythropoiesis slows in the marrow and extramedullary spaces, the hemoglobin falls, reaching a nadir in 6 to 8 weeks. Erythropoiesis is then stimulated and the hemoglobin rises to 12.5 g/dL, which is the mean throughout infancy.[126] Preterm infants have a more dramatic fall in hemoglobin to a mean of about 9 g/dL at the nadir, although the marrow recovery is good, and at 6 months of age, these infants have the same mean hemoglobin concentration as a term infant.[127]

Iron Requirements Iron requirements are age dependent. It is rare for a term infant to become iron deficient before 4 months of age, but a preterm infant can become deficient by 2 to 3 months because of relatively faster growth and smaller iron stores at birth.[126] From birth through adolescence, children need iron for growth and increasing blood volume, as well as to replace losses. Although the amounts are small, in an infant averaging 20 μg/kg/day, iron is lost in sweat, urine, bile, and desquamation of skin and intestinal cells and through hair and nail loss.[108] The Committee on Nutrition of the American Academy of Pediatrics made the following recommendations for daily iron requirements for infants, based on approximately 10% absorption[128]: term infant, 1 mg/kg to maximum 15 mg/day, beginning by 4 months; low birth weight infant, 2 mg/kg to maximum 15 mg/day, beginning by 2 months. The DRI is 1 to 3 years: 7 mg/day; 4 to 8 years: 10 mg/day; 9 to 13 years: 8 mg/day; 14 to 18 years: boys, 11 mg/day; girls, 15 mg/day; pregnancy: 27 mg/day.[54]

Etiology Iron is found in many different food sources; however, the bioavailability is highly variable. Studies have shown that breast milk and cow's milk each contain 1 mg/L of iron. However, the bioavailability of iron to the infant is drastically different, with 49% absorption of the former and only 20% absorption of the latter.[129] The absorption from fortified formula is only 3 to 4%, but it contains 12 mg of iron/L.[125] Because the amount of iron in breast milk is not consistent over a long period of time, the addition of iron-fortified cereal is recommended for all infants by 4 to 6 months of age to help keep up with needs and prevent depletion of iron stores. These cereals are fortified with an electrolytic iron powder, resulting in 0.45 mg of iron/g of cereal. Thus, one portion contains 5 mg of iron, but only about 4% is absorbed.[130]

Shortly after starting cereals, most infants also start other foods. Heme iron, from animal sources, is absorbed more efficiently than nonheme iron from vegetable sources. The difference is 15 to 20% compared with 5%. The mechanism of absorption is different. Heme iron enters the intestinal mucosa cell in the intact protoporphyrin. Nonheme iron is absorbed as free iron or protein bound, which makes it more susceptible to influence from other factors that assist or inhibit absorption.

The absorption of iron is affected by the combination of foods and drinks ingested together. For example, orange juice facilitates absorption, whereas tea hinders it. Some of the other enhancers of iron absorption are ascorbic acid, fructose, certain amino acids, meat, fish, and poultry. Inhibitors include phosphates, phytates (common in vegetarian diets), tannins, and oxalates.[117,131] Interestingly, the iron in eggs is not efficiently absorbed, and it also inhibits the absorption of iron from other sources.[131]

By the age of 12 months, infants switch over to whole cow's milk from formula and may or may not continue to be breast-fed as well. It is important to restrict this intake to less than three-quarters of a liter per day because too much can cause milk-induced exudative enteropathy, with blood loss and malabsorption leading to hypoproteinemia, iron deficiency, and anemia, which can be significant.[132] The acidic environment of the stomach helps to convert ferric iron to the more soluble ferrous form of iron. Thus, conditions that affect this acidity, such as partial or total gastrectomy (rare in children), achlorhydria, and antacids, also decrease iron absorption. Rapid gastric emptying, celiac disease, and inflammatory bowel disease also cause malabsorption.[117,118]

Manifestations With the decline in iron deficiency anemia in industrialized countries, children with the manifestations of severe long-standing iron deficiency anemia are rare. Sadly, they are still seen elsewhere. Mild to moderate iron deficiency anemia is most common. Frequently, the first signs and symptoms of iron deficiency anemia are pallor, fatigue, exercise intolerance, and, occasionally, palpitations. The pallor is most notable in the nail beds, conjunctiva, and palms, especially if the individual has dark skin. Fatigue and exercise intolerance have been best documented in studies of adults employed at physical labor, revealing that even mild anemia can affect exercise tolerance in settings involving strenuous energy expenditure and that correction of the anemia increased exercise tolerance.[133–135] The usual phenomenon of pica or compulsive consumption of non-nutritional items such as dirt, clay, cornstarch, laundry detergent, or ice is a characteristic finding of iron deficiency anemia. Ingestion of these items usually exacerbates the underlying iron deficiency by further impairing absorption.[136]

The recognition that iron deficiency produces a broad array of systemic effects has attracted increasing attention.[118,137] A partial list of nonhematologic manifestations of iron deficiency is provided in Table 49-7.[138] Over time, glossitis, stomatitis, and angular cheilosis may develop. These symptoms may be the result of tissue iron deficiency

rather than the anemia itself.[139] Koilonychia, or spooning of the fingernails, is caused by abnormal proliferation of the cells of the nailbed. Other features of severe long-standing iron deficiency anemia can actually make treatment with oral iron supplementation difficult. The presence of esophageal webs, or Plummer-Vinson syndrome, impairs swallowing; atrophic gastritis and abnormal duodenal mucosa can both decrease absorption.

There have been numerous studies investigating immune function associated with iron deficiency anemia.[109,140–149] Interestingly, iron overload has also been shown to impair normal immune function, decreasing lymphocyte proliferation and the ability of macrophages to kill intracellular pathogens.[150] Similarly, both iron deficiency and iron therapy have been associated with increased infection. In one study, anemia was associated with malaria, acute respiratory infection, and diarrhea,[151] and two other studies found fewer episodes of infection in children treated with parenteral or oral iron.[152,153] However, other studies show that individuals with malaria, hepatitis C virus infection, and human immunodeficiency virus infection have worse outcomes if they have excess iron or are treated with iron.[154–156] This conflict may be attributable, in part, to the difficulty in establishing cause and effect and accounting for mediating variables.

Iron plays an important role in brain development, and many studies have indicated that iron deficiency is associated with cognitive impairment, poor motor development, and behavioral problems.[109–112,157–159] This is particularly disturbing as these problems may continue long term, even after correction of the anemia. However, it should be noted that a causal relationship has not been established as important potential confounding variables have not been fully accounted for. It is also not clear that central nervous system effects can be remedied by iron therapy as many of the clinical trials have failed to demonstrate benefit from therapy. A more detailed discussion of the relationship between iron status and behavior, including study limitations, is presented in Chapter 22, "The Behavior of Children."

TABLE 49-7 Nonhematologic Manifestations of Iron Deficiency

Impaired growth
Skin and mucous membranes
Koilonychia
Angular stomatitis
Glossitis
Gastrointestinal tract
Anorexia
Dysphagia with postcricoid webs
Gastric achlorhydria
Malabsorption
Beeturia
Exudative enteropathy and occult bleeding
Central nervous system
Irritability
Decreased attention span
Poor performance in standardized developmental testing
Breath-holding spells
Impaired exercise tolerance
Immunologic response
Impaired lymphocyte mitogen response
Decreased leukocyte killing

Iron is essential to the metabolism of certain amine neurotransmitters.[109] Children with iron deficiency anemia have increased catecholamines in their urine, which return to normal levels after iron therapy.[160] There have been animal studies suggesting abnormal dopamine receptor function in association with iron deficiency anemia.[161] The exact meaning of these findings and how they relate to cognitive and behavioral development remain unclear.

Laboratory Findings The diagnosis of iron deficiency anemia is rarely made based on a single laboratory test but rather on a combination of several tests and the comparison to age-specific norms reflecting the changes that occur as a child grows. Commonly used tests assess the iron storage, erythropoiesis, and severity of the anemia (Table 49-8). Together these tests can help to rule out other causes of anemia.

Peripheral Smear. Often microscopic examination of the blood smear can be normal early in iron deficiency, but as the anemia progresses, hypochromia, microcytosis, anisocytosis, and occasional target cells and elliptocytes are seen.

Hemoglobin. Anemia starts when this value is < 95% for age. Thus, it is essential to use age-based mean hemoglobin values for accurate interpretation of these results.

Red Cell Distribution Width. This is a valuable index to note, especially as a clue early in iron deficiency anemia, because it is a sensitive test, although not very specific.[162] It represents the variation in size of the red blood cells. In thalassemia, infection, and inflammation, it is usually normal, but in iron deficiency anemia, this value is elevated and can be > 20%.[118]

Mean Corpuscular Volume. This value represents the average size of the red blood cell and varies with age. When anemia becomes significant enough to interfere with hemoglobin synthesis, microcytosis occurs (low MCV). This is one of the red cell indices readily available from an electronic counter in the laboratory.

Mean Corpuscular Hemoglobin. As with the MCV, this index is available from an electronic counter. Initially, with iron deficiency, the MCH is normal, but with advancing anemia, the red blood cell becomes more hypochromic, and this change is evident by a low MCH.

Serum Ferritin. Iron inside the cell can be toxic. Ferritin, a protein, helps to compartmentalize it. The serum level correlates with total-body iron. As an acute-phase reactant, ferritin is increased by inflammatory, infectious, and malignant processes, and correlation with body iron stores becomes less reliable. Although a few conditions, including vitamin C deficiency, reduce serum ferritin, values < 10 μg/L are generally indicative of iron deficiency anemia. Scurvy, or ascorbic acid deficiency, should be evaluated as a potential cause of low ferritin.

Serum Iron. This is not a reliable test for iron deficiency anemia because it has a diurnal pattern with a peak in the morning and a trough in the evening. As with serum ferritin, it can be elevated by many other conditions. The concentration is usually low in iron deficiency anemia.

TABLE 49-8 Laboratory Measurements of Iron Status

Storage iron depletion
Bone marrow iron stain (decreased)
Serum ferritin (decreased)
Serum transferrin (increased)
Transferrin receptor (increased)
Serum iron (decreased)*
Iron deficiency erythropoiesis
Transferrin saturation (decreased)
Total iron-binding capacity (increased)
Free erythrocyte protoporphyrin (increased)
Zinc protoporphyrin (increased)
Red cell mean corpuscular volume (decreased)
Red cell mean corpuscular hemoglobin (decreased)
Red cell distribution width (increased)
Reticulocyte heme (decreased)
Iron deficiency anemia
Hemoglobin (decreased)
Therapeutic trial with increase in hemoglobin concentration

*See text.

However, even a single dose of iron within the 24 hours prior to the test can cause a transient elevation in the serum iron level, thus possibly masking an underlying iron deficiency anemia.[139]

Total Iron-Binding Capacity. Most circulating iron is bound to a plasma protein called transferrin. Total iron-binding capacity (TIBC) is a measure of the total transferrin. As the serum iron decreases, the TIBC increases, and the ratio of these variables in iron deficiency anemia is less than 1:6.[162]

Transferrin Saturation. This value is the ratio of serum iron to TIBC multiplied by 100 to yield a percentage. It represents the percentage of transferrin that is saturated with iron. A low percentage is suggestive of iron deficiency.

Transferrin Receptor. This receptor is bound to transferrin in circulation and is indicative of the concentration of the cellular transferrin receptor. Because receptor synthesis increases with iron deficiency but not with anemia of chronic disease, it may prove to be a more sensitive indicator of iron deficiency.[163] It is also elevated in the presence of ineffective erythropoiesis and sideroblastic anemias. This must be taken into account and evaluated appropriately.

Erythrocyte Protoporphyrin. Under normal circumstances, iron combines with protoporphryin in the red blood cell to form heme, a reaction catalyzed by the enzyme ferrochelatase. In iron deficiency anemia, there is an elevation in erythrocyte protoporphyrin (EP), usually > 35 μg/dl,[164] because there is less iron for heme production. Lead poisoning, which often causes a higher level of EP than iron deficiency, does so by inhibiting ferrochelatase. Inflammatory, infectious, and/or malignant processes also can raise the EP level.[139]

Zinc Protoporphyrin. In iron deficiency and lead poisoning, zinc protoporphyrin is formed instead of EP because zinc fills the iron pocket in the protoporphyrin molecule. This is a sensitive, inexpensive test that will show an elevation in iron deficiency even before anemia is present.[165] When iron stores are sufficient, the ratio of iron-to-zinc incorporation into protoporphyrin is 30,000 to 1.[166] Alone this test does not differentiate between iron deficiency and lead poisoning, so further tests must be done. The issue is complicated because iron deficiency increases the absorption of lead so that in many situations, the two disturbances exist together. A lead level and a therapeutic trial of oral iron therapy may be necessary to sort things out.

Reticulocyte Heme. Reticulocyte hemoglobin content measurement by automated flow cytometry assesses the iron status of red blood cells when they are released from the bone marrow as reticulocytes.[167] It can be used to detect early iron deficiency and has been found to be the strongest predictor of iron deficiency when compared with other commonly used laboratory parameters.[168]

Bone Marrow Biopsy. If the usual tests are equivocal or there are confounding factors making the diagnosis of iron deficiency difficult, such as infection or inflammation, the bone marrow iron stores can be assessed. Staining the specimen with Prussian blue and counterstaining with safranin O helps to show the characteristic paucity of ferritin and hemosiderin, the final breakdown product of iron and ferritin.[127] Normally, 10 to 20% of red cell precursors in the marrow contain iron granules; however, in iron deficiency, few, if any, will be present.[169]

Therapy If iron deficiency is diagnosed or suspected based on some or all of the laboratory tests discussed above, treatment with iron should begin immediately. In most circumstances, oral iron supplementation is used because it is inexpensive and easily absorbed. The dose of iron for infants and children is 4 to 6 mg/kg of elemental iron, depending on the severity of the anemia, divided into two to three doses per day. For adolescents, the dose is 100 to 300 mg of elemental iron per day.[170] Traditionally, three-times-daily dosing has been used, but recent research has demonstrated that once-daily dosing results in similar treatment of anemia,[171] and once- or twice-weekly dosing results in similar improvement in hemoglobin but not ferritin.[172] Further work in this area is ongoing in an attempt to reduce side effects, simplify treatment, and improve compliance.

Ferrous iron is more easily absorbed than ferric iron; thus, the usual treatment for infants and children is ferrous sulfate. Premature infants are frequently vitamin E deficient owing to decreased intake, decreased stores, and poor absorption of vitamin E. Because iron therapy inhibits absorption of vitamin E, this deficiency must be corrected before iron therapy is started.[173] The absorption of iron on an empty stomach is about twice that of a full stomach; therefore, it is recommended that the dose be given about an hour prior to a meal.

The duration of treatment is 2 to 4 months after the hemoglobin has returned to a level normal for age in order to replenish the iron stores.[118] If these stores are not replenished because iron therapy is discontinued too soon, a rapid recurrence of iron deficiency anemia may result. Thus, the importance of completing the full recommended course of treatment must be emphasized to the parents or caretakers of the affected child and to the affected child who is old enough to understand.

Response to treatment is initially evident by a reticulocytosis peaking in 5 to 10 days from the onset of treat-

ment. During the first week of therapy, the hemoglobin rises about 0.25 to 4 g/dL/day and then slows to about 0.1 g/dL/day.[170] It is important to follow up no more than a month later to see if there is improvement because if there is no change in that period of time on an adequate dose and compliance is not an issue, further studies must be done to determine the underlying problem.[118] Failure of oral iron therapy can be the result of impaired absorption, incorrect diagnosis, ongoing blood loss greater than hemoglobin generation, inadequate dose, ineffective iron preparation, superimposed malignancy or inflammatory disease, or, most commonly, simple noncompliance. Compliance can be an issue because of the taste of iron, gastrointestinal distress, or concern of parents that the drops will stain the infant's teeth. These problems can be dealt with by giving the iron with a small amount of food or liquid, preferably something that will enhance the absorption, and by giving the drops in the back of the mouth. If noncompliance is suspected but denied, the stool can be examined. In the presence of iron supplements, it should be black. The stool can also be tested specifically for iron if necessary.

Parenteral iron therapy has greater side effects and therefore is reserved for only specific circumstances. These include true intolerance to oral iron (extremely rare), severe gastrointestinal disease that prevents absorption and may be exacerbated by oral iron therapy, chronic bleeding, or repeated noncompliance.[174,175] The dose is calculated to correct the anemia and replenish the iron stores. The formula is:

$$\frac{\text{Normal Hgb} - \text{Initial Hgb} \times \text{blood volume} \times 3.4 \times 1.5 = \text{mg iron}}{100}$$

The normal hemoglobin (Hgb) should be based on the age. Blood volume is approximately 80 mL/kg of body weight. The value 3.4 converts the grams of hemoglobin to milligrams of iron, and the factor 1.5 provides a little extra iron to supply the iron stores.[174,175]

The side effects of this therapy must be considered before starting. The most significant, although rare (< 1%), is anaphylaxis. Therefore, whenever this treatment is used, a test dose must first be given, and if there is no sign of reaction 5 minutes after the test dose, the therapeutic dose may be started. Epinephrine should be kept at the bedside, as well as resuscitation equipment. Less severe side effects are hypotension and flushing (2%), phlebitis (10%), and a delayed rash with or without arthritis (20%).[174,175] Most often, this is given intravenously; however, if there is extravasation or if it is given through the very painful intramuscular route, the iron can stain the skin, and this stain takes a long time to resolve.

In extreme iron deficiency anemia with a very low hemoglobin and/or cardiovascular instability, a packed red blood cell transfusion is given first to stabilize the patient. This is usually followed by oral iron therapy. In this situation, the transfusion is given slowly, at 5 cc/kg over 4 hours to start. Depending on how much more blood is necessary to increase the hemoglobin to the desired level, the rest of the transfusion can be broken into aliquots and given slowly or at the usual rate for a transfusion.[170]

Copper Deficiency

Copper is present in a number of metalloproteins. Among the cuproenzymes are cytochrome-*c* oxidase, dopamine-β-hydroxylase, urate oxidase, tyrosine and lysyl oxidase, ascorbic acid oxidase, and superoxide dismutase (erythrocuprein). More than 90% of the copper in the blood is carried bound to ceruloplasmin, an α_2-globulin with ferroxidase activity.

Copper appears to be required for the absorption and use of iron. It has been proposed that copper, in the form of ferroxidases, converts and maintains iron in the Fe^{3+} state for its transfer by transferrin.[176]

Copper deficiency has been described in malnourished children[177] and in both infants[178] and adults[179] receiving parenteral alimentation. Copper deficiency in humans is characterized by (1) a microcytic anemia that is unresponsive to iron therapy, (2) hypoferremia, (3) neutropenia, and usually (4) the presence of vacuolated erythroid precursors in the marrow. In infants and young children with copper deficiency, radiologic abnormalities are generally present. These abnormalities include osteoporosis, flaring of the anterior ribs with spontaneous rib fractures, cupping and flaring of long bone metaphyses with spur formation and submetaphyseal fractures, and epiphyseal separation. These radiologic changes have frequently been misinterpreted as signs of scurvy.

The diagnosis of copper deficiency can be established by the demonstration of a low serum ceruloplasmin or serum copper level. Adequate normal values for the first 2 to 3 months have not been well defined and are normally lower than those observed later in life. Despite these limitations, a serum copper level of less than 40 μg/dL or a ceruloplasmin value of less than 15 mg/dL after 1 or 2 months of age can be regarded as evidence of copper deficiency. In later infancy, childhood, and adulthood, serum copper values should normally exceed 70 μg/dL.

Preterm infants are at risk owing to their lower hepatic copper stores, which largely accumulate in the third trimester.[180] Low serum copper values may be observed in hypoproteinemic states, such as exudative enteropathies and nephrosis, as well as in Wilson's disease. In these circumstances, a diagnosis of copper deficiency cannot be established by serum measurements alone but instead requires analysis of liver copper content or clinical response after a therapeutic trial of copper supplementation.

The anemia does not respond to iron but is quickly corrected by administration of copper. Therapy in a dose of 0.2 mg/kg of body weight will cause a prompt reticulocytosis and rise in the leukocyte count. This can be given as a 10% solution of copper sulfate ($CuSO_4 \cdot 5\ H_2O$), which contains about 25 mg of copper/mL.

The daily requirement of copper is 0.1 to 1 mg for infants and 1.0 to 5.0 mg for children and adolescents. Copper intake in infants is usually low because breast milk contains only 0.2 to 0.4 mg copper per liter and infant formulas are generally fortified to 0.4 to 0.6 mg/L; however, copper defi-

ciency is rarely seen in healthy term infants. Older infants and children tend to have increased copper intake as cereals and other foods provide more copper than milk.[180]

SUMMARY

This chapter describes how deficiencies of specific nutrients such as iron, copper, vitamin B_{12}, folate, and vitamins A, C, and E can produce anemia. Although a deficiency of iron is the most common nutritional cause of anemia, it is important to recognize that multiple nutrient deficiencies may be present, and correction of a single deficiency alone will not necessarily correct the anemia. Careful examination of a routine hemogram can suggest the likely underlying nutrient deficiency and can certainly help direct initial diagnostic procedures. Anemia is a well-recognized major world health problem, leading to low birth weight and premature delivery, poor educational performance in childhood, lost work productivity, and decreased quality of life. Early recognition, diagnosis of specific nutrient deficiencies, and provision of effective therapy are immediate medical goals, whereas effective nutrient supplementation of at-risk populations is an important long-range public health goal.

CHAPTER 50

FUNCTION AND NATURE OF THE COMPONENTS IN THE ORAL CAVITY

James H. Shaw, DMD, PhD, Linda Nelson, DMD, MScD, Catherine Hayes, DMD DMSc

The position of the oral cavity at the entrance to the gastrointestinal tract requires that it perform functions that need diverse tissues and specialized structures. The foods and other items that children eat and drink vary widely in their particle size and texture, degree of hardness, pH, and other chemical stimuli, as well as wide ranges of temperature. These different characteristics produce stresses on the oral components that must be moderated before swallowing. In the mouth, food items must be subdivided by chewing and simultaneously diluted and buffered with saliva until the bolus is suitable to swallow and pass on to the esophagus and lower areas of the gastrointestinal tract. The amount and composition of saliva secreted on each occasion are in response to the whole experience of eating—from the initial seeing, smelling, and anticipating to the tasting, chewing, and swallowing.[1,2] Especially in young children, many undesirable materials are taken into the mouth, which contribute various kinds of microorganisms and/or other dangerous entities.

The temperature and humidity of the oral cavity, as well as the frequent presence of all required nutrients for cellular growth and multiplication in food and drink, result in the mouth being an ideal incubator for many types of microorganisms from birth onward. An important source of the infant's flora is the primary caregiver.[3] There is evidence of matrilineal transmission of mutans streptococci in very early childhood. Strong correlations between salivary mutans streptococci counts in mothers and their children have been reported. Maternal salivary levels of mutans streptococci infection may influence infection rates of mutans streptococci in their children at ages 6 to 18 months and at 4 to 5 years. Salivary concentrations of 10^5 colony forming units mutans streptococci per milliliter of maternal saliva were associated with a 52% infection rate in their children compared with only a 6% infection rate when the maternal saliva concentration was 10^3 or below.[4,5] The presence of caries in the mother and siblings increases risks for the child, but the most consistent predictor of risk of caries (dental decay) in children is past caries experience.[6] Nutrients and the foods that provide them have numerous relationships to the oral tissues and structures, and these relationships vary depending on the nature of the tissue or structure itself. Some relationships differ from those elsewhere in the body. For example, sugars, when metabolized throughout the body, are wholesome sources of energy for the cells' many and varied functions. However, in contrast to this vital systemic relationship, the sugars have an undesirable local effect in the mouth. On the surfaces of dental enamel, sugars support the metabolism of microorganisms in dental plaque with the production of acid.

In the life history of the soft tissues, a transition occurs at birth as a result of the new, stressful exposure of their outer surfaces to microorganisms and food, meanwhile still being nourished systemically. A much more striking transition occurs for the teeth, especially the enamel surfaces, at the time of their eruption into the oral cavity. Prior to eruption, the external surfaces of enamel are surrounded by the enamel cap, including the enamel-forming cells of ectodermal origin, the ameloblasts; the inner surface of the dentin is covered by the layer of odontoblasts, the dentin-forming cells, which are embryonically of mesodermal origin. Both enamel and dentin throughout their formation and mineralization are related fully to the systemic environment. At eruption, the enamel cap is ruptured, and the outer surfaces of enamel become exposed to the oral milieu of saliva, microorganisms, and food. The odontoblastic layer remains intact in contact with the capillaries of the pulp and continues to metabolize slowly with the centripetal formation of secondary dentin at the expense of the connective tissue in the pulp. The latter process accelerates when toxic metabolites from a deep carious lesion in the dentin trigger a protective response with more rapid production of secondary dentin.

Structure of Enamel

Enamel and dentin are characteristically different from other tissues in the body. When fully mature, enamel contains only about 1% organic material and 2% water. Its tiny organic component consists of proteins chemically similar

to the keratins of skin and is dispersed throughout the inorganic crystals as a network of extremely delicate and intricate fibrils.[7] The rest of enamel is the complex calcium-phosphorus salt hydroxyapatite, which varies somewhat in its composition, depending on the concentrations of anions and cations in the extracellular fluids at the time it crystallizes in the embryonic organic matrix. The hydroxyapatite in enamel has more perfectly formed crystals than those in dentin and bone. After its eruption, enamel contains no cells and is cut off from systemic influences other than through saliva, which bathes it continuously throughout life. Elements in saliva exchange with those on the outer surface of the enamel, especially in the period shortly after eruption.[8] Owing to its acellular nature, enamel has no ability to heal or remodel, with the exception that remineralization of early (precaries) surface lesions with the incorporation of calcium and phosphorus from saliva can occur under suitable conditions.[9,10]

Structure of Dentin

Dentin contains about 20% protein of the collagen family comparable to bone. About 70% of dentin is hydroxyapatite. Although dentin continues to form centripetally at a slow rate, like enamel, it is unable to remodel or repair itself as it does not contain anything comparable to the haversian system of bone. Any developmental errors in the formation of enamel and dentin remain throughout life as chemical or histologic artifacts in the kymographic record.

NUTRITIONAL STUDIES ON THE ORAL TISSUES AND STRUCTURES

Soft Tissues

The soft tissues, mucosa, gingiva, tongue, and taste buds, are especially susceptible to local stresses. Their metabolic activity is high. Oral mucosal cells in rats, for example, are replaced in 3 to 5 days by rapid cell division in the basal layer and sloughing of the surface cells; in contrast, the turnover rate in cheek skin is about 10 days.[11] This high metabolic activity accounts for the rapid healing of injuries to soft tissues within the mouth. However, the high metabolic activity of oral tissues results in a high susceptibility to nutritional deficiencies as adequate nutrients must be available to support the rapid cell multiplication and replacement.

In the early decades of nutrition as a discipline, deficiencies were often recognized first as clinical entities because of manifestations in the oral cavity; scurvy (vitamin C) and pellagra (niacin) are the prime examples.[12] The ease of oral examination for abnormalities with minimal violation of the subject's privacy also contributed to early recognition of nutritional deficiencies that affected oral components.

The increased understanding of nutrition and the attention to preventive nutrition, including legally required fortification of foods, such as niacin for the prevention of pellagra, have led to the almost total elimination of such nutritional deficiencies in children of the industrialized nations. However, in the developing nations of the third world, especially in times of famine, such deficiencies still occur.

Mineralized Tissues

In early experimental studies with rats, severe deficiencies of vitamin A caused abnormalities in the ameloblasts, which led to hypoplastic enamel.[13] Severe vitamin C deficiency in guinea pigs, which, unlike rats, require preformed vitamin C in their diets, produced a syndrome in which the odontoblasts produced much less dentin.[14] As a result, the erupting teeth were thin and fragile. Acute deficiencies in rats and dogs of vitamin D or calcium or grossly abnormal calcium-to-phosphorus ratios resulted in inadequate mineralization and hypoplasia of the teeth.[15,16] Little evidence exists to suggest that moderate deficiencies of these nutrients are of clinical significance in children in industrialized countries, although we still see cases of vitamin D–resistant ricketts. In severely malnourished children in developing countries, a linear enamel hypoplasia (natal line) has been described in the anterior teeth of the primary dentition (Figure 50-1), which is much less frequent or absent in better nourished children in the same communities.[17,18] The poorly mineralized ring around the teeth in this syndrome was being formed about the time the children were born and was highly susceptible to dental caries. All children at birth had low serum vitamin A levels.

Low protein intake during the reproductive cycle of white rat dams resulted in delayed eruption of the molars of their offspring. Their teeth were smaller and more susceptible to tooth decay than those of the offspring of

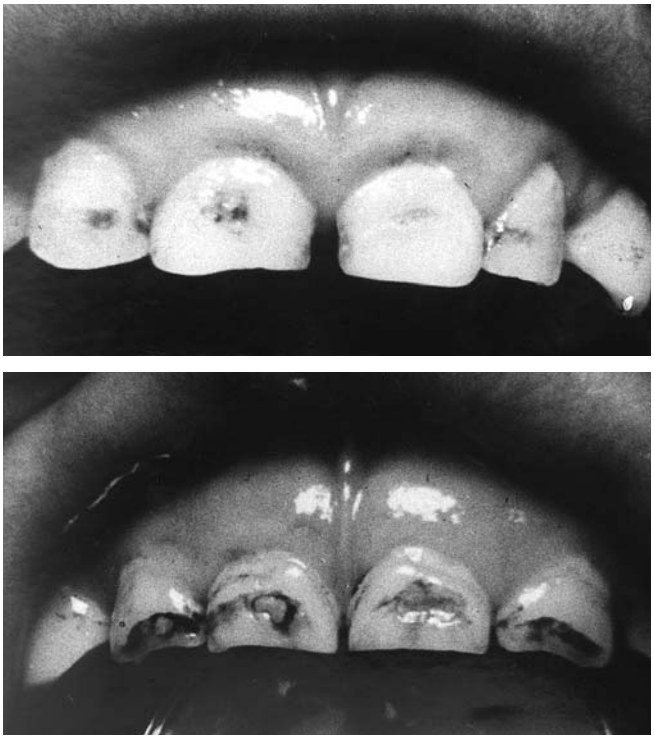

FIGURE 50-1 Photographs of linear hypoplasia of the anterior teeth of Guatemalan children. These hypoplastic areas are prone to develop dental caries. Reproduced with permission from Sweeney EA et al.[17,18]

closely related females provided with adequate protein.[19] The increased caries susceptibility in the deprived rats may be attributable to structural abnormalities in the salivary glands produced by the protein deficiency.[20]

Alvarez conducted two cross-sectional and one longitudinal study among Peruvian children in whom malnutrition in early life was prevalent.[21] He studied the influence of malnutrition on the time of tooth eruption and of deciduous tooth exfoliation and the susceptibility of both deciduous and permanent teeth to dental caries. As in the earlier studies with rodents, tooth eruption was delayed significantly among malnourished children. Because rodents have only a single dentition, exfoliation could not be studied in the laboratory. Among the malnourished Peruvian children, their deciduous teeth exfoliated appreciably later than those in better-nourished children in the same communities. When the length of time that the deciduous teeth were exposed to the oral environment was considered, instead of the traditional method of considering only the chronologic age of the children, the deciduous teeth of malnourished children were observed to have a higher incidence of caries than those of the better-nourished children. Even a single episode of moderate malnutrition before 1 year of age also resulted in a higher incidence of dental caries of the permanent incisors and first molars, which were being formed and were starting to mineralize during that interval. The increased incidence of dental caries among these children again paralleled the rodent studies conducted three decades earlier. Alvarez suggested that this observation may result from imperfect formation of dental enamel early in life.

Several studies, in animals and humans, have evaluated the effect of nutrition and nutrients on the growth and development of oral structures. The conclusion of many studies is that adequate nutrition is essential from the earliest periods of development. Further, a firm diet enhances proper growth and development compared with a soft diet. Specifically, the effect of diet consistency has been shown to affect growth of the mandible and maxilla and proper tooth eruption. Ongoing research on the harmful effects of nutrition on oral growth indicates that excess vitamin A can be a potent teratogen that may contribute to oral defects such as cleft palate. Protective effects of folic acid have been shown in animal studies but not in humans as yet, probably owing to the complexity of other factors also involved.[22]

Adequate amounts of all nutrients should be provided throughout the long periods of tooth formation in children to ensure their normal development, that is, from the last trimester of pregnancy through 16 years of age.

DISEASES OF THE ORAL CAVITY

The two principal diseases of the oral cavity are dental caries (cavities, carious lesions) and periodontal disease (destruction of the tissues that support the teeth in the jaws). Although the latter is the chief cause of tooth loss in adults, juvenile periodontitis occurs infrequently in children, is much more localized than in adults, and may be associated with an immunologic defect in some children. Both diseases are of multifactorial origin, are chronic in nature, and progress slowly and intermittently. Nutrition is not known to have a relationship to juvenile periodontitis except possibly through dietary influences on the dental plaque.

Etiology of Dental Caries

A carious lesion results from an interaction between the carbohydrates in food, especially the sugars, with cariogenic microorganisms in the dental plaque on tooth surfaces and the tooth surface in the presence of saliva; the gross anatomy of the tooth, the composition of the enamel and dentin, and the quantity and quality of saliva all vary in ways that influence the rate of progression of tooth decay. The most serious adverse influence on the ability of the teeth to be maintained in the oral cavity is any reduction in the flow of saliva owing to salivary disease, radiation, or drug use that modifies the ability of the salivary glands to function.[23,24]

Under certain circumstances, the acidic metabolic products of the microorganisms on the tooth surfaces from sugars reduce the pH of plaque sufficiently to demineralize enamel and, later, the dentin progressively until a carious lesion (dental decay) is produced. The epidemiologist commonly speaks of this type of disease production as the relationship of the agent (microorganism[s]), host (the tooth and the person in which it functions), and environment (the components in the milieu around the tooth and the home and community in which the individual lives) (Figure 51–2).[25] All three parameters must simultaneously be in a caries-producing mode for carious lesions to be initiated and progress to become visually detectable. Periodontal disease also results from the interaction of food, the microorganisms in the crevices between the teeth and the gingiva, and the tissues in the area.

Agent The microorganisms producing carious lesions are able to colonize the surfaces of the teeth and/or the pits

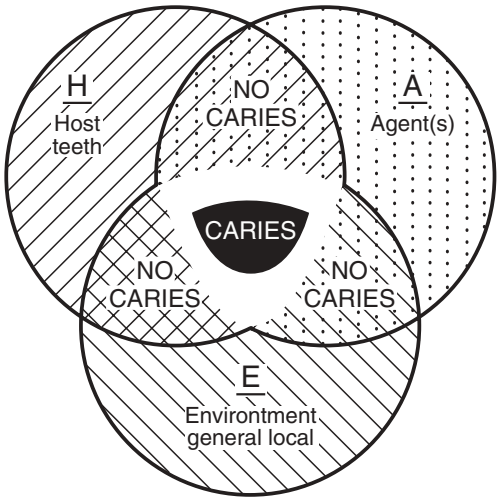

FIGURE 50-2 Diagrammatic illustration of the three major parameters simultaneously required for the initiation and progression of carious lesions. Reproduced with permission from Keyes AH and Jordan HV.[25]

and fissures of the biting surfaces.[26] These microbiota are able to produce sufficiently acidic environments (pH around 5) on the tooth surfaces when metabolizing actively to demineralize enamel and later dentin. They must be able to continue to metabolize actively at these low pH values as the lesion progresses deeper into the tooth. The primary sources of energy required by these organisms are the sugars. *Streptococcus mutans* is of special interest because it produces mutans, a polysaccharide of glucose, which enables it to adhere to smooth surfaces and to build up colonies in dental plaque. The nature of plaque is such that the microbial metabolites are produced in close proximity to enamel with restricted access to buffering saliva. In the human mouth, plaque contains numerous species of microorganisms with acid-producing capabilities. The complex nature of the oral milieu makes it virtually impossible to fully apply Koch's principles for identification of a specific causative organism. Probably more than one species is involved in most situations, but especially as lesions progress more deeply into the tooth with the need to metabolize in a strongly acidic environment.

Host Evidence of genetic determinants of caries resistance is limited in humans, yet a variety of subtle indications of genetic influences have been reported. Early suggestions that large differences in caries experience between national groups were genetically determined have been largely discredited. The caries prevalence in industrialized nations tended to be routinely higher than in developing countries; however, as the dietary customs of the high-caries industrialized nations were adopted in developing countries with increased sugar consumption and more frequent eating, their low-caries experience has been increasing. Meanwhile, in the last 20 years, dental caries prevalence in the industrialized nations has been decreasing significantly.[27]

Comparison of the dental caries experience of twins indicated that identical twins had more similar caries experiences than fraternal twins.[28] This may not be a truly genetic influence as such environmental experiences as food preferences, frequency of eating, and tooth brushing techniques may be more similar for identical than for fraternal twins. Similarities in dental caries for twins reared separately were considered to be about 50% attributable to genetic influences.[29]

Numerous trials have been conducted to develop animal strains of divergent caries resistance. Superficially, differences attributable to heredity seemed to be produced. However, when so-called resistant strains were heavily challenged early in life with cariogenic microorganisms, carious lesions developed readily, although not always as extensively as in the seemingly more susceptible strains.

Mandel suggested three avenues through which genetic influences may be mediated: (1) salivary components that buffer plaque acids elevating the pH and influencing the bacterial ecology of plaque, (2) immunologic and nonimmunologic constituents of oral fluids that have the capacity to alter the ability of cariogenic bacteria to attach to enamel, and (3) protein-bound lipids on the surfaces of teeth that may alter the permeability to acids produced in plaque.[30]

Environment The single most important variable in the oral environment is the frequency of consuming foods containing sugars that adhere to tooth surfaces. The absolute amount of sugars consumed is less important than the frequency of eating. In the 1930s and 1940s, numerous studies were conducted on the relation of frequency of eating to caries experience (Figure 50-3).[31] Almost invariably, the conclusion was that caries experience increased as frequency of food consumption, especially of between-meal snacks, increased. More recently, this type of trial has been less frequent and the above relationship has not been as readily demonstrable. Since the earlier studies, food habits have changed dramatically. At that time, most food was prepared and eaten at home, and the amount of sugar used was controlled by the homemaker. Between-meal snacks were usually candy and cookies. Today, relatively little food is prepared at home; many items are commercially prepared, with the amount of sugar controlled industrially on the basis of the amount needed for "best" taste. In addition, a much higher percentage of meals is consumed away from the home. Snack consumption is much more frequent, and less dependence is placed on three main meals a day.

The amount of sugar available per capita in a country is a reasonable index of the prevalence of dental caries among its children (Figure 50-4).[32] The information supporting the pivotal role of sugars in the etiology of dental caries

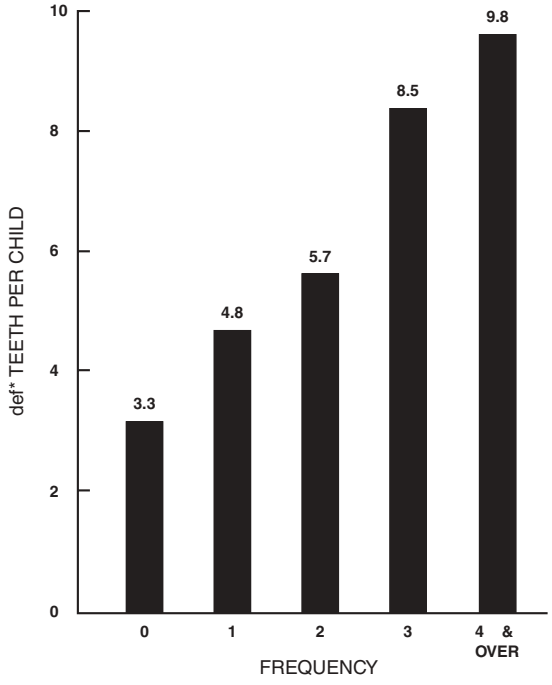

FIGURE 50-3 This bar graph compares the number of decayed, missing, and filled deciduous teeth with the frequency of between-meal eating in preschool children in Tennessee. Reproduced with permission from Weis RL and Trithart AH.[31]

was considered by 1977 to be sufficiently conclusive that Horowitz stated that in human dental experimentation,

> the control group should not be asked to engage in any practice that may have a harmful effect on the dentition or its surrounding tissues. For example, subjects in a control group should not be given or asked to use chewing gum sweetened with sucrose, nor should they be asked to use sucrose rinses or other agents to produce decalcification of tooth enamel or initiate carious lesions, unless the investigators are certain that they can completely "reverse" the defects.[33]

Mandel stated that little disagreement exists that differences in amount, form, and frequency of readily fermentable carbohydrates can affect the rate of caries attack, but considerable variation between children exists when intake appears to be generally comparable.[30]

Foods are complex mixtures of many chemicals. As yet, it has not been possible to devise a series of animal trials and evaluations in the human oral cavity that dependably estimate the caries-producing value of a specific food.[34] Some food items that contain relatively little sugar but substantial amounts of starch are more capable of producing caries lesions than expected; others containing high amounts of sugar are less capable of supporting the caries process than expected.

A special case of rampant dental caries limited to the maxillary anterior deciduous teeth and posterior molars has become known as early childhood caries. This problem occurs in young children who are put to bed at night or for rests during the day with a bottle of formula or sweetened juice. When they go to sleep, salivary secretion decreases drastically, and the fermentable carbohydrates in the milk or juice are not diluted or washed away but are readily available to the microorganisms on tooth surfaces.[35] It is believed that the tongue affords protection to the mandibular anterior teeth so that they are pathognomonically not affected. Excessive on-demand breast-feeding is also capable of causing the same problem. The sugar, lactose, in human milk is clearly able to support the caries process.

Pediatricians and pediatric dentists on a preventive basis need to urge mothers of young infants to follow feeding practices in which excessive exposure to sweetened fluids and breast milk does not occur. When early childhood caries is already present, appropriate dietary corrections need to be made by less frequent feeding and the use of fewer sweet snacks of all kinds. Appropriate professional dental care is needed, probably including topical fluoride applications, such as a fluoride varnish, coupled with strong oral hygiene procedures at home.[36] The latter will

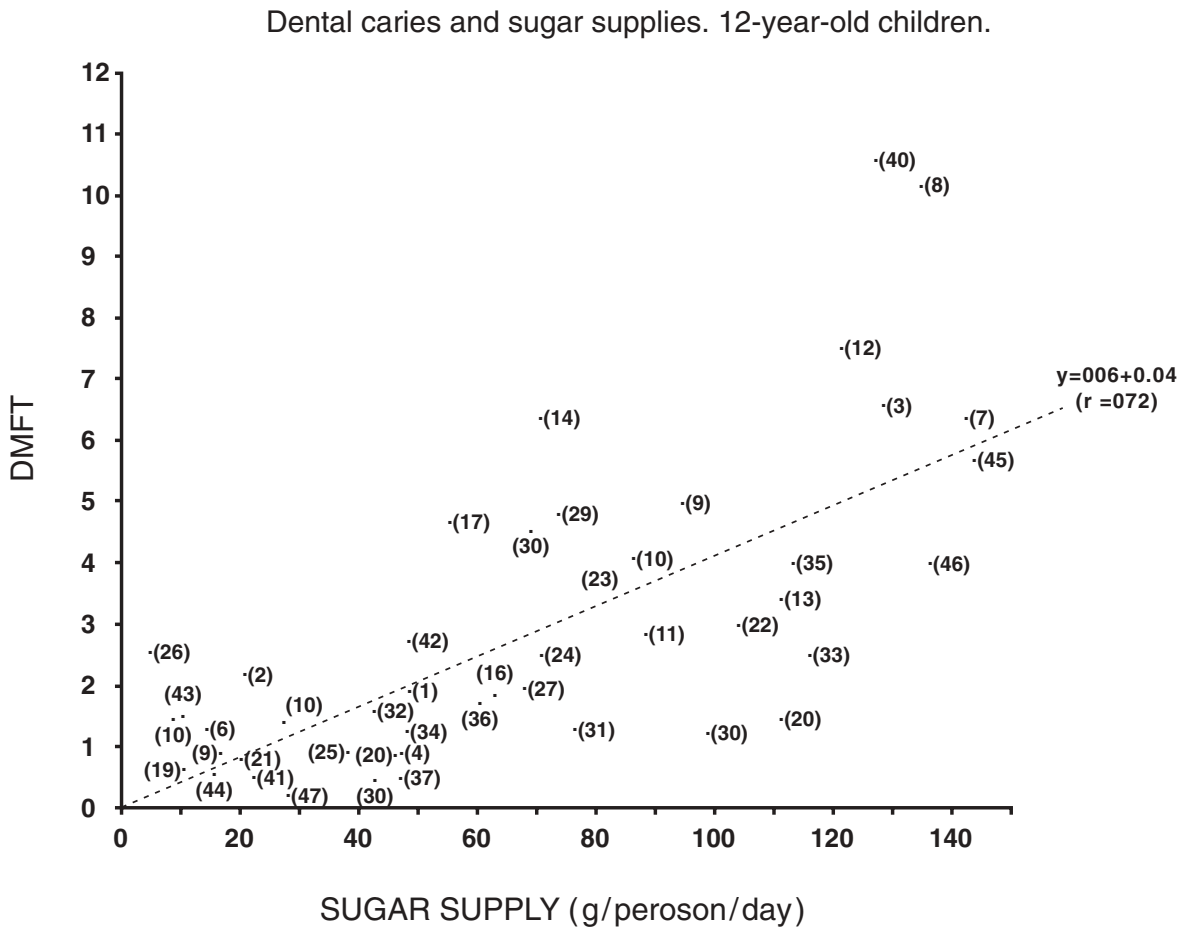

FIGURE 50-4 This graph represents a comparison of the number of decayed, missing, and filled permanent teeth with the sugar supply in grams per person per day for 47 countries. Reproduced with permission from Sreebny LM.[32])

include the parent's brushing of the infant's teeth with fluoridated toothpaste. Care is needed so that excess fluoride is not swallowed.

The importance of maintaining the deciduous teeth is not to be underestimated. They are needed as "space maintainers" as the jaws grow in order that there will be adequate room for eruption of the permanent teeth. Increased likelihood of orthodontic problems accompanies the early loss of deciduous teeth. High levels of untreated caries in the deciduous teeth provide reservoirs of cariogenic microorganisms from which the permanent teeth become quickly infected when they erupt into the oral cavity.

Reduced Ability of Polyols to Support Caries Measurement of the pH of dental plaque in vivo with tiny, sensitive electrodes has become a convenient means of evaluating how various solutions and foods in the oral cavity affect the metabolism in the dental plaque in proximity to the tooth surface. In 1944, Stephan reported on a sharp depression in the pH of dental plaque after a glucose rinse was swished around the mouth.[37] This depression from the resting value with a pH around 6.6 to 7.0 (the range observed in saliva) to 5.0 or less within minutes after the start of the glucose rinse lasted for a few minutes and then slowly returned to the resting value. Plots of results from this kind of evaluation have become known as Stephen curves (Figure 50-5).[37,38] The consensus from the Stephen curve concerning the relation of plaque pH to caries production is shown in Table 50-1.

Both the equipment and the procedures for intraoral tests have been refined and are used widely today. For example, certain varieties of cheese eaten shortly after a sugar rinse or a sweet food prevent the rapid pH drop in dental plaque (Figure 50-6).[38] Likewise, chewing a gum sweetened with a polyol, sorbitol or xylitol, does not result in a pH decrease, whereas chewing a gum sweetened with sucrose causes the typical caries-producing decrease (Figure 50-7).

TABLE 50-1 Relation of Plaque pH to Caries Production

Plaque pH	*Potential for Caries Initiation and Development*
Above 6.0	Safe area; low solubility of enamel; calcium and phosphorous adequate to saturate environment
6.0–5.5	Doubtful or very slow progression
Below 5.5	Danger area; high solubility of enamel; calcium and phosphorous inadequate to saturate environment

Adapted from Stephen RM and Edgar WM.[37,38]

Oral microorganisms have greatly limited abilities to metabolize the polyols, xylitol (5 carbon), sorbitol, and mannitol.[39,40] The effect of sugar substitutes on changes in caries rates has been evaluated in several observational studies as well as clinical trials, with results consistently demonstrating a protective effect of xylitol on caries incidence. Sorbitol was also shown to decrease caries rates compared with controls; however, the reductions in caries rates were greatest when xylitol was the sugar substitute. Some limitations of these studies include a lack of radiographs in caries diagnosis, high loss to follow-up, potential confounding, and bias owing to the nature of long-term community intervention studies. The criteria for causality—consistency, strength association, biologic plausibility, temporal sequence, and dose-response relationship—should be considered. First, these studies are remarkably consistent both in terms of the magnitude of the effect observed as well as the consistent demonstration that xylitol was superior to sorbitol in decreasing the risk of dental caries. Second, the relative risks observed are considered strong (0.19–0.4). It is biologically plausible that xylitol can reduce dental caries because the pH of plaque is lowered with xylitol compared with sucrose. Fourth, a dose-response trend was observed in the two studies that evaluated different concentrations of xylitol,

with the greatest effect observed in the subjects using the strongest xylitol preparations. The evidence to date suggests a strong caries-protective effect of xylitol.[41]

In vivo pH testing has been used extensively in Switzerland, not only in basic research but also in the estimation of the potential of a specific product to cause dental caries when used excessively. When a product has been evaluated by approved methods for in vivo testing and is found not to cause an excessive decrease in pH, the Swiss Health Authority grants permission to identify the product as "zahnfreundlich" (friendly or safe for the teeth) and imprint a distinctive logo on the label (Figure 50-8).[42] This procedure has not been adopted elsewhere because of the inability to find a consensus that this procedure is adequate for the intended purpose.

FLUORIDES AND HUMAN HEALTH

Because fluoride has relationships to dental caries through both the host and the environment, a separate section for fluoride discussion is appropriate. Fluoride ion from any salt of the highly reactive halogen fluorine occurs ubiquitously in water supplies, soils, and foods. Fluoride is also present in all body fluids and tissues, even when the amount of fluoride ingested is low. Probably no nutrient demonstrates more clearly the physiologic spectrum from the influence of an insufficient intake, through normal to toxic levels of ingestion.

Toxicity of Excess Fluoride: Mottled Enamel

Toxic manifestations of excess fluoride ingestion were observed before recognition of its benefits, unlike other nutrients, for which the effects of deficiencies were described first. In 1901, Eager, a physician in the US Public Health Service stationed in Naples, Italy, described an esthetically disfiguring problem of dental enamel in otherwise healthy adults.[43] Their enamel was variously mottled with brown stains; he attributed the problem to local geologic conditions. In striking contrast, he recognized that the enamel of teeth in young children in the area was normal, which he postulated might be attributable to a recent change known to have occurred in the water supply.

Subsequently, descriptions of mottled enamel were reported from numerous parts of the world in humans as well as in domestic animals.[44] Evidence became increasingly clear in humans that this esthetically disfiguring problem was caused by some agent in community or home water supplies. In animals, the problem sometimes was caused by their water supplies and in other situations was related to rock phosphate supplements added to their feeds as a source of calcium and phosphorus.

By 1931, reports from several widely separated laboratories established that the mottled enamel in humans and experimental animals was attributable to excess ingestion of fluoride from drinking water that contained more than 1.5 ppm fluoride, that is, 1.5 mg/L of water.[45–47] At this point, the popular name, mottled enamel, was superseded by the scientific descriptor, chronic endemic dental fluorosis.

This abnormality was determined to result from some as yet undefined altered relationship(s) in the deposition of crystals of hydroxyapatite in the organic matrix formed by ameloblasts, the enamel-forming cell of ectodermal origin. This developmental interrelationship is apparently the most sensitive process to excess fluoride in the extracellular fluids of any in the body. Higher intake (20 mg) of fluoride per day in industrial exposure causes abnormal calcification in the spine and, after 20 years, serious crippling fluorosis.[48]

Classification System for Mottled Enamel

Dean developed a classification system to describe the various visual levels of enamel pathology and a weighting system to provide a community fluorosis index.[49] He used the terms (1) questionable—slight aberrations from the normal glossy translucency of enamel, which the examiner could not be certain was pathologic (weight = 0.5); (2) very mild—small, dull, paper-white areas scattered irregularly over the tooth surface but covering less than 25% of its area (1.0); (3) mild—more extensive white opacities but less than 50% of the area involved (2.0); (4) moderate—all surfaces affected with marked wear on the chewing surface accompanied by brown stains (3.0); and (5) severe—all surfaces affected with marked hypoplasia, discrete or confluent pitting, and widespread brown stains

FIGURE 50-8 The "safe for teeth" logo approved for use on the label of an approved product in Switzerland. Reproduced with permission from Guggenheim B.[42]

(4.0). The community fluorosis index was calculated by combining the weight for each child with the frequency of occurrence of each grade in the child population. A community fluorosis index over 0.5 was considered undesirable, indicating the need to reduce the water fluoride level.

As shown in Figure 50-9, mottled enamel does not become a problem until in excess of 1.5 ppm fluoride in drinking water was ingested during tooth development.[50] However, water concentrations beyond this amount caused increasingly severe fluorosis and increasing frequency. As a public health measure, excessively high fluoride amounts must be reduced or a new lower fluoride water supply found. It must be emphasized that mottled enamel cannot result from consuming excessively high amounts of fluoride after the teeth are formed because this abnormality is completely of developmental origin.

Dental Benefits of Naturally Available Fluorides

One of the earliest observers of enamel fluorosis in this country, McKay, in Colorado Springs, where the water supply was later shown to contain 2.0 ppm fluoride, reported that teeth with mottled enamel did not seem to have an increased susceptibility to dental caries despite the surface irregularities.[51] In the late 1920s and 1930s, several small studies suggested that fluorosis appeared to be associated with reduced dental caries experience.

A combination of the need to know the permissible upper limit of fluoride in drinking water plus the increasing concern about the generally high incidence of dental caries among American children led to many extensive epidemiologic surveys among children. Numerous increasingly large surveys in the 1930s and 1940s indicated the strong correlation between fluoride ingestion during tooth development and tooth decay. For example, Dean and colleagues reported on data for 7,257 12- to 14-year-old children in 21 cities in four states.[52,53] Figure 50-10 indicates the convincing relationship between fluorides during development and dental caries experience. They also considered other factors that might be related—composition of diet, hours of sunshine, and hardness of the water—and concluded that none could explain the naturally available fluoride–dental caries relationship.

Dental Benefits of Water Fluoridation

By 1945, the dental benefits of fluoride in communal water supplies had been demonstrated to the satisfaction of almost all investigators and many health-related professional organizations. The possibility of pathology elsewhere in the human body or of increased susceptibility to other diseases had been thoroughly studied, with negative results with one exception, the crippling fluorosis described above, which has never been observed at the optimal level for caries reduction.

Hence, in 1945, three clinical trials were initiated to adjust the fluoride concentration of community water supplies to an optimal level, with the expectation that 10 years would be needed for demonstration of the benefits. Grand Rapids, Michigan, was selected as one trial community, with Muskegon, Michigan, to serve as the unfluoridated control city and Aurora, Illinois, as a natural fluoride city. A second study was initiated in Newburgh, New York, with nearby Kingston as the unfluoridated control. The third community was Brantford, Ontario, with Sarnia, Ontario, as the unfluoridated control and Stratford, a nearby community with an optimal fluoride level naturally present. The data soon demonstrated that the results from water fluoridated in the distribution system duplicated those observed where fluoride was naturally present, with caries reductions from 50 to 60% in permanent teeth (Figure 50-11).[53–57] The benefits in teeth developed during the study began to show up sufficiently rapidly that Muskegon dropped out as the control community for Grand Rapids before the 10-year test period ended and initiated its own water fluoridation program. In addition, some unexpected reductions in caries initiation were observed among the

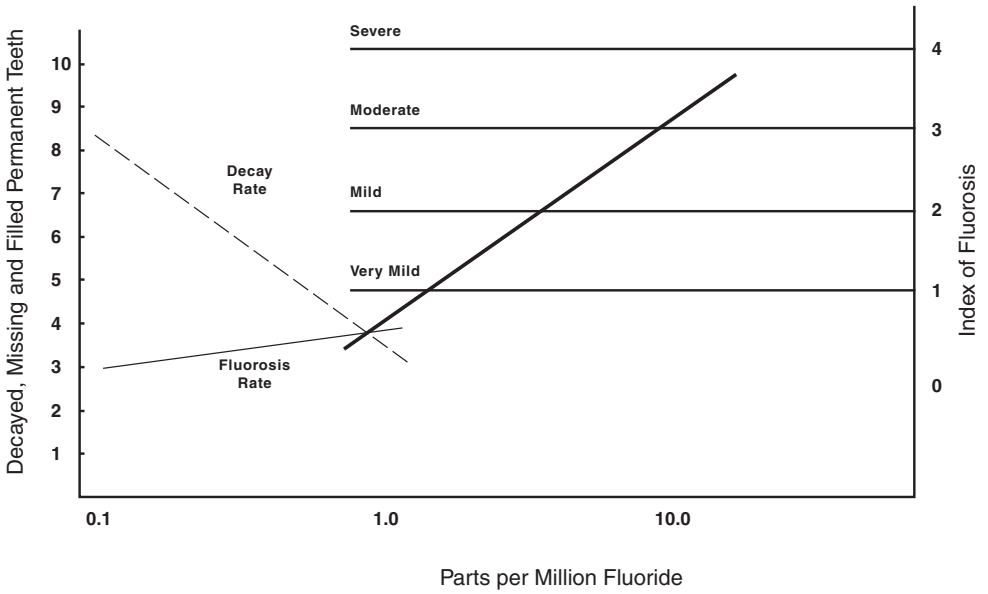

FIGURE 50-9 Relation between decayed, missing, and filled permanent teeth (*broken line*), severity of dental fluorosis (*solid line*), and fluoride concentration in the public water supply, with the latter on a logarithmic scale. Reproduced with permission from Hodge HC and Smith FA.[50]

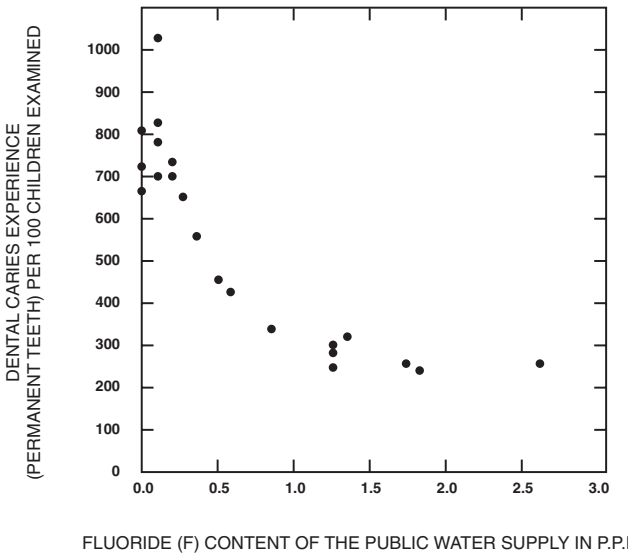

FIGURE 50-10 Relationship between the fluoride content naturally available in public water supplies and the number of decayed, missing, and filled permanent teeth per 100 children 12 to 14 years old. Reproduced with permission from Dean HT et al.[52,53]

teenage population in teeth formed before fluoridation was begun; this observation suggested that an oral environmental influence was occurring in addition to the expected systemic influence on developing teeth. As in communities with naturally available fluoride, the greatest benefit was for the smooth surfaces of the anterior teeth and the least for the carious lesions that develop in the developmental pits and fissures on the grinding surfaces of the posterior teeth. No evidence of esthetically disfiguring mottling was observed in these trials.

Fluoridation of water supplies has been widely adopted in the United States as a valuable and inexpensive public health measure. The Fluoridation Census in 1992 reported that 134.7 million individuals on communal water supplies in 8,572 communities received water fluoridated in the water processing system; in addition, 10.0 million individuals lived in 1,924 communities where the water contained at least 0.7 ppm fluoride naturally.[58] The total percentage of the population benefiting from fluoride in the water in the United States was 62.1.

Metabolism of Fluorides

The varying evidence of mottled enamel within the child population of any community in both natural fluoride areas and areas where fluoridation is practiced has been the subject of much interest since the first evidence of the fluoride relationships. Some variation undoubtedly occurs in the amount of water consumed by individual children; the amounts of canned fish with bones and the use of tea, the only foods with substantial amounts of fluoride, constitute additional variables.

Fluorides from soluble salts are readily absorbed from the gastrointestinal tract.[59] In the presence of high concentrations of cations that produce much less soluble salts of fluoride, its absorption is reduced. When much less soluble sources of fluoride are ingested, absorption of fluoride is also reduced.

The kidneys are the major route for fluoride removal from the body, which is characterized by variable degrees of tubular resorption. A range in resorption has been

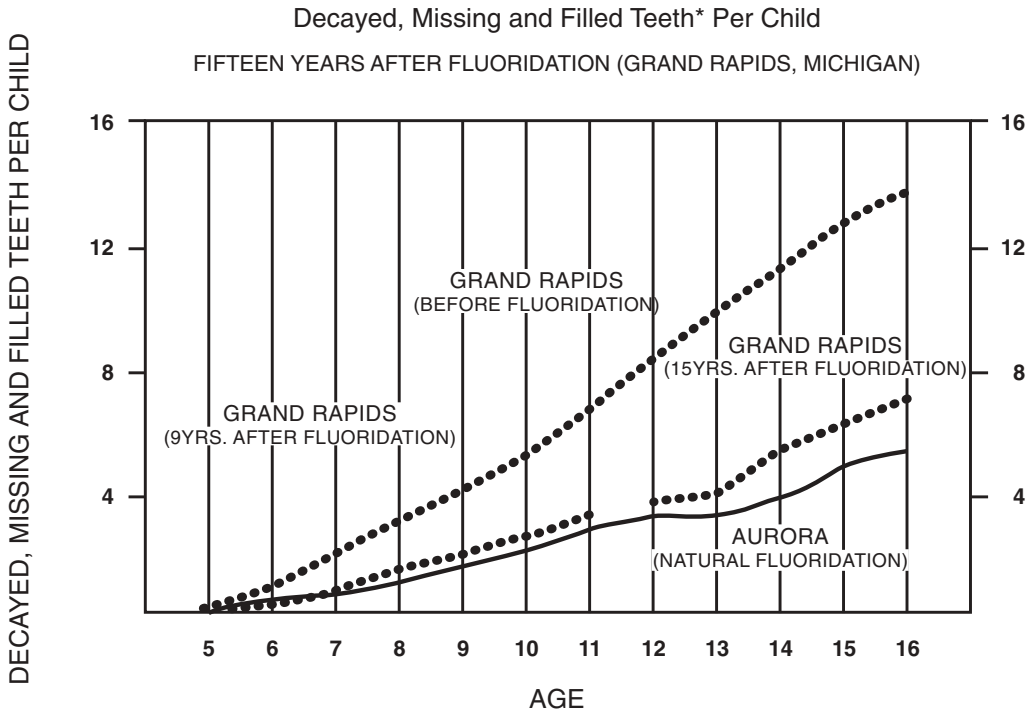

FIGURE 50-11 The benefits of fluoridation of the communal water supply in Grand Rapids, Michigan, are shown for the deciduous teeth after 9 years and for the permanent teeth after 15 years. The inclusion of the data for Aurora, Illinois, where the water naturally contains an adequate comparison of how similar the benefits are between natural fluoride and fluoride introduced at the water treatment facility. Reproduced with permission from Arnold FA et al.[54–57]

reported in humans; in four studies, the average resorption of fluoride after filtration into the tubules varied from 23 to 38%.[60] In general, fluoride clearance tended to increase with increased urinary flow rate. Urinary pH also influenced fluoride excretion. In rats with a urinary pH less than 5.6 induced by administration of ammonium chloride, urinary excretion was less than 5% of the amount filtered; alkaline pH as high as 8.0, induced by administration of sodium bicarbonate, resulted in fluoride excretion approaching 70%. Various factors can chronically alter the acid-base status and affect fluoride relationships. The composition of the diet is normally the major determinant of acid-base balance and urinary pH. In addition, various metabolic and respiratory disorders, level of physical activity, and altitude of residence contribute to acid-base status.

The combination of slightly different levels of fluoride ingestion by children with the above factors, which modify excretion in the urine, is probably adequate to explain the different degrees of mottled enamel in children within the same community.

Dental Benefits of Fluoride Tablets, Toothpastes, and Oral Rinses

Tablets or drops are recommended for children when fluoride is not available in the public water supply or when the water supply is from an individual well.[61] Fluoride analysis of the water in use needs to be made to be certain that it is too low to be beneficial. The levels recommended by the American Academy of Pediatric Dentistry for different ages and levels of fluoride in the water supply are shown in Table 50-2.[62] Fluoride supplementation is especially important for breast-fed infants irrespective of the fluoride level of the local water supply. The amount of fluoride secretion in human milk is low even when the local water supply contains an adequate fluoride level. Because young children are prone to swallow toothpaste, use of fluoridated toothpaste (usually containing 1,000 ppm fluoride, ie, 1 mg F per gram) contributes to the level of fluoride ingested. Therefore, it must be used sparingly; the size of a pea on the brush is adequate.

Fluoride toothpaste is an important part of the preventive approach for all children. Investigations have shown that fluoridated toothpastes and oral rinses, as well as application of concentrated fluoride solutions to enamel surfaces in the dental office or clinic, demonstrate substantial ability to prevent dental caries even in areas where the water is fluoridated.

The extent to which the various uses of fluorides contribute to the dental health of the United States is demonstrated by a statement by Harold Varmus, Nobel laureate and director of the National Institutes of Health, at a Senate Appropriations Subcommittee Hearing on March 17, 1994.[63] In response to Senator Harkin's question, "Does medical research contribute to long-term cost savings?" Varmus stated that his favorite example of the benefits of research concerned the use of fluorides to prevent dental caries, which alone saves the taxpayer several billion dollars per year.

TABLE 50-2 Dietary Fluoride Concentration in the Water Supply

	Fluoride Concentration in the Water Supply		
Age of Child	*Less than 0.3 ppm F*	*0.3–0.6 ppm F*	*More than 0.6 ppm F*
Birth–6 mo	0	0	0
6 mo–3 yr	0.25 mg	0	0
3–6 yr	0.50 mg	0.25 mg	0
6 yr up to at least 16 yr	1.0 mg	0.50 mg	0

Adapted from Pediatr Dent.[62]
The possibility of mild fluorosis has been reported with the above regimen, but no consensus has been reached about reducing these levels. Pediatricians and dentists may want to halve the above levels for children considered to have a low caries risk.

Mechanisms of Action of Fluorides

When the dental benefits of fluoride were first observed, systemic mechanisms of action were sought. The degree of crystallinity of hydroxyapatite in enamel increased as its fluoride concentration increased. Acid solubility of hydroxyapatite decreased as its fluoride concentration increased. Enamel surfaces had particularly high fluoride concentrations.[64]

Saliva contains about 0.019 ppm fluoride (1 μmol/L), about one-fiftieth of the concentration in communal water fluoridated at 1 ppm.[65] Even this low concentration appears to be important in the maintenance of the integrity of the tooth surface and in the remineralization of precarious lesions in the enamel. The mechanisms of action of fluoride in caries inhibition include the following: (1) the enhancement of remineralization during the repeated cycles of demineralization/remineralization in the early stages of the caries process, (2) the inhibition of glycolysis by which sugar is metabolized by bacteria to produce acid, and (3) pre-eruptive fluoride exerts some degree of caries inhibition; it acts by incorporation into the developing enamel hydroxyapatite crystal, thus reducing enamel solubility.[66]

Treatment of Carious Lesions

Because a visually detectable carious lesion is rarely self-limiting, it continues to progress until the pulp is infected, with the probable loss of the tooth, unless specific action is taken to interrupt the progress of the lesion. Decayed enamel and dentin must be removed and replaced with an inert material that is able to resist the forces of mastication and the influences of the oral milieu.

Pit and fissure sealants have been demonstrated to be effective in the primary prevention of caries, and their effectiveness remains strong as long as the sealants are maintained.[6] Sealants are intended to protect caries-susceptible tooth surfaces, which are benefited least by fluoride. They should be placed as soon as possible after the tooth erupts and isolation to prevent moisture contamination during placement can be achieved.

Identification of early carious lesions and treatment with preventive resin restorations have moved dentistry into a new era. This very conservative treatment allows for

the removal of just the small pit and fissure lesion and subsequent restoration with esthetic composite resin to which a sealant can be applied. By removing only the carious enamel and dentin, the preventive resin technique provides a restoration with a minimum of tooth reduction while ensuring the prevention of future caries in other pits and fissures through sealant placement.[67]

Amalgam is the least expensive restorative material to purchase and insert. The new high-copper amalgams are expected to last over 30 years. Questions have been raised in a few publications about the safety of amalgams because of their gradual release of mercury vapor. The media picked up this concern and exaggerated the problem with regard to both its severity and its frequency. Berglund estimated that 1.7 μg of mercury vapor was inhaled from 12 amalgam fillings in a 24-hour period.[68] He noted that the World Health Organization threshold limit value for mercury vapor in the workplace is 100 times greater than this amount.

Osborne stated that allergies to amalgam have been reported in the literature infrequently but that it is speculative as to which component(s) of amalgam (mercury, silver, tin, or copper) is causative.[69] Owing to their frequent handling of amalgam, dentists and their staffs are exposed to more mercury than any patient. Even though the profession urges great care in amalgam handling and ventilation of dental offices, guidelines that are followed by most dentists, dentists still accumulate a greater body burden of mercury than do nondentists. However, dentists have 2½ years longer life expectancies than the population in general, including physicians. Dentists and their staffs do not have elevated levels of spontaneous abortions, and their children do not have a higher incidence of birth defects.[70]

SUMMARY AND RECOMMENDATIONS

Typical of all areas of the body, the mouth and each of its components require a nutritionally well-balanced diet containing adequate amounts of all essential nutrients throughout development and maintenance.

Attention must be drawn to one special requirement for the adequate development and maintenance of the teeth throughout their entire life histories, namely, a source of fluoride. The easiest and least expensive way to provide fluoride is through a communal water supply containing 1.0 ppm fluoride that is present naturally or is added in the local water treatment plant. If, for any reason, water fluoridation is not possible, a proprietary source of fluoride in tablets or drops should be used. However, it is imperative that the diet should not be supplemented if the water already contains 0.7 ppm or more fluoride; an undesirable level of mottling is likely to occur with fluoride from two sources.

Consumption of sticky snacks containing sugars should be kept to a minimum and be replaced whenever possible by such noncariogenic snacks as fresh fruits and vegetables, cheese, or nuts. Candy and gum sweetened with a polyol are good substitutes for products sweetened with sugar.

Good oral hygiene habits need to be followed at least once a day using a small amount of fluoridated toothpaste. Use of a fluoride oral rinse or varnish is appropriate, especially when the child has a high degree of susceptibility and when there is a problem of reduced manual dexterity.

Visits to a dentist regularly are essential to detect and treat early lesions. Usually, every 6 months is sufficient, but when the child is especially susceptible, more frequent visits are important, as suggested by the dentist. Preventive procedures, such as topical fluoride applications to the tooth surfaces and the use of sealants to flow into and fill the susceptible pits and fissures on the occlusal surfaces of the posterior teeth, are to be encouraged.

Children who have had radiation of the head or neck or chemotherapy may have a reduced salivary flow, which is probably the most serious deleterious influence on caries initiation and progression. Special attention to frequent and careful oral hygiene and frequent use of oral fluoride rinses are imperative.

CHAPTER 51.1

ADOLESCENCE: HEALTHY AND DISORDERED EATING

Ellen S. Rome, MD, MPH, Isabel M. Vazquez, MS, RD, LD, Nancy E. Blazar, RD, LD

Adolescence consists of a period of rapid and often dramatic changes in the teen's physical, cognitive, and emotional states. The pubertal growth spurt, surpassed only by the growth rate in the first 2 years of life,[1] forces each teen to deal with changing body habitus, with resultant shifts in body image. Simultaneously, each teen must deal with the development of primary and secondary sexual characteristics, alterations in mood, and differentiation of cognitive ability.[2,3] Because the onset and speed of these changes can vary considerably, adolescents can be particularly sensitive about their appearance.[4] Many teens attempt to gain control or a sense of mastery over their changing bodies and environment through changes in dietary habits or behaviors.[5–7] Others may engage in exercise for a variety of reasons, ranging from recreation to fitness to use as a means of weight control.[8] Nutrition during this period of rapid growth can be critical for adolescents in ensuring a healthy progression through puberty and achievement of full height, optimal bone density, and, for girls, initiation/continuation of normal menstrual cycles.

Adolescent diets have been shown to contain inadequate amounts of calcium, iron, and other essential nutrients.[9] Teens also may ingest protein, total fats, saturated fats, and cholesterol in higher than recommended doses.[10] Young athletes with higher energy demands may also consume nutrients that are inadequate to ensure growth and development. Moreover, aberrant eating patterns can have their antecedents prior to or early in adolescence, at which point, eating disorders can emerge.[11] A fine line often exists between pursuit of fitness and "healthy" exercising and the more obsessive hyperexercising seen in many teens with eating disorders. This chapter addresses the nutritional concerns of the healthy adolescent as well as the specific dietary concerns for those patients with eating disorders. Topics to be covered include the diagnostic criteria for anorexia nervosa, bulimia nervosa, and eating disorder not otherwise specified and a brief overview of the medical complications associated with these conditions. The role of exercise will also be addressed, including the issues of amenorrhea and osteopenia in the adolescent athlete with and without an eating disorder. Strategies for nutritional intervention in the office setting will be provided with the goal of prevention, early identification, and treatment of adolescents at risk for an eating disorder or experiencing the consequences of nutritional insufficiency.

GUIDELINES FOR THE DIETARY NEEDS OF THE HEALTHY ADOLESCENT

Adolescent dietary needs differ from the needs of younger children in the amount of required calcium, iron, most vitamins and minerals, and calories. The calorie and protein needs of adolescents are influenced by several factors, including gender, age, degree of maturation, and level of activity. The main nutritional goal is for the adolescent to ingest optimal nutrients in a balanced way to promote growth and health. Sometimes this nutritional goal is not achieved owing to adolescent eating practices, lifestyle, behaviors, and, in some cases, inadequate food and income.

Recommended daily caloric and nutrient requirements by age are seen in Appendix Table A-8. To look at energy needs in a different way, many dietitians and clinicians use calories and protein per unit height instead of per unit weight as this method takes into account growth better than would a calculation based on weight.[12,13] For instance, if an adolescent girl with anorexia nervosa had her caloric needs estimated by weight, we might underestimate her needs; conversely, an obese adolescent might overestimate caloric needs if using kcal/kg body weight as the basis for determining energy needs. The Recommended Dietary Allowances (RDAs) categorized the calorie and protein needs by chronologic age, without taking into account height. Table 51.1-1 shows the comparison between estimated calories based on weight versus height. A concrete example might be the calculation of energy needs for a 15-year-old girl at a weight of 50 kg (110 pounds) and a height of 160 cm. Based on weight, her calorie needs would be 50 kg × 40 kcal/kg = 2,000 kcal. Protein needs based on weight would be 50 kg × 0.08 g/cm = 40 g of protein. Based on height, the calcula-

tions change to 160 cm × 13.5 kcal/cm = 2,160 kcal, and for protein, 160 cm × .27 g/cm = 43.2 g protein per day.

The use of the kcal/cm provides a quick formula by which to calculate daily needs. For a longer method that takes into account weight, height, and age, basal energy expenditure can be used. The basal metabolic rate (BMR), estimated by the resting energy expenditure (REE), represents the minimum amount of energy needed by the body at rest in the fasting state; measuring REE is usually expensive and inconvenient for the office setting. Estimations of the standard REE for an individual prove more useful for the health care provider and can be calculated from the Harris Benedict equation[14]:

$$\text{For females, REE} = 665 + (9.6 \times \text{wt in kg}) + (1.7 \times \text{ht in cm}) - (4.7 \times \text{age in years})$$

$$\text{For males, REE} = 66 + (13.7 \times \text{wt in kg}) + (5 \times \text{ht in cm}) - (6.8 \times \text{age in years})$$

Above REE, energy requirements are also determined by activity level and the need for weight gain above basal requirements. Correction factors for activity levels and various disease states are seen in Appendix Table A-12.[15–18] Total energy requirements are estimated by multiplying REE by the activity and stress correction factors. The Mayo Clinic Nomogram can also be used to calculate total energy expenditure from surface area, age, and sex.[19]

Adolescents have high intakes of protein, total and saturated fat, and cholesterol. The intake of fat in a typical adolescent diet is around 33%, which is higher than the amount recommended by the American Heart Association (30% calories from fat). In general, adolescents consume more fat than recommended, and their food intakes are deficient in important vitamins and minerals such as calcium and iron.[20–24] A subset of adolescents are overly concerned about their weight and their appearance.[25] Many are dissatisfied with their weight, especially girls who want to lose weight and boys who are underweight and want to be heavier, with more muscle mass. Many adolescents follow unsafe practices to control their weight and to lose weight. Such practices included the use of diet pills, laxatives, vomiting, diuretics, fasting, and strict diets that can compromise the health and growth of the adolescent.[26] In our health-conscious society, the norm for this subset of teens may be a low-fat diet. These teens, along with their mothers and/or families, may falsely assume that "low fat" should mean "no fat." Actually, a low-fat diet for a child, teen, or young adult needs to include a minimum of 30 to 50 g of fat per day. In terms of calories, the ideal balance for the average teen should be as follows:

Regular diet:	*Low-fat diet:*
50–55% carbohydrate	50–55% carbohydrate
15–20% protein	15–20% protein
30% fat	20–25% fat

So, a teen consuming a 2,100-calorie diet might require 70 g of fat (30% calories), 105 g of protein (20%), and 263 g of carbohydrate (50%). Fluid requirements can be calculated in terms of body weight, using the following formula:

Body weight	*Maintenance fluid needs per day*
1–10 kg	100 mL/kg
11–20 kg	1,000 mL + 50 mL/kg for each kg > 10 kg
Above 20 kg	1,500 mL + 20 mL/kg for each kg > 20 kg

Thus, an adolescent weighing 50 kg (110 pounds) needs around 1,500 mL + (30 kg × 20 mL/kg) = 2,100 mL fluid per day or the equivalent of 8.4 cups (8 oz/cup).

The adolescent athlete may ingest a higher carbohydrate-containing diet. However, if eating properly, the lower percentage of fat intake still meets the basic needs of 30 to 50 g/day because overall calorie intake for the elite athlete is presumably higher. Thus, the nutritionally restricting athlete may run into problems of not meeting basic energy, protein, or dietary fat needs, although sheer percentages may meet an 80 to 15 to 5% distribution. General guidelines for adolescent athletes can be found in Table 51.1-2.

During the pubertal growth spurt, the adolescent acquires 15% of adult height, 50% of adult weight, and 40% of adult total-body mineral content.[27] Over half of the adult bone calcium is normally deposited during adolescence, with bone calcium content reaching a maximum by age 30.[28] During this time, the daily intake of elemental calcium must be above a threshold level to meet the daily demands and add new calcium to bone, in other words, creating a positive calcium balance. Currently, the RDA for calcium in teenagers 12 to 18 years of age is 1,200 mg/day. Recent studies have suggested that this amount is insufficient to meet the needs of rapidly growing teens.[29,30] In a calcium balance study, Matkovic and Ilich found that the minimum daily intake of elemental calcium required by adolescents to reach the threshold level is 1,480 mg/day, significantly above the RDA of 1,200 mg/day. The authors recommended a daily intake of 1,600 mg/day to mineralize new bone without depleting current skeletal reserves in growing teens.[31] It is noteworthy that most healthy teenagers fail to meet the RDA of 1,200 mg/day,[32] and patients with eating disorders have been shown to ingest insufficient calcium. In teens with anorexia nervosa, intakes have ranged from 300 mg/day to 1,100 mg/day, with most in the range of 500 to 600 mg/day.[33–36]

To create a positive calcium balance, many teens with eating disorders will require calcium supplementation. Sev-

TABLE 51.1-1 Adolescent Nutritional Requirements: Comparison of Recommended Calorie and Protein Needs for Adolescents

		Calories		*Protein*	
	Age	*kcal/kg*	*kcal/cm*	*g/kg*	*g/cm*
Males	11–14	55	15.9	1.0	0.29
15–18	45	17.1	0.90	0.34	
19–24	40	16.4	0.80	0.33	
Females	11–14	47	14.0	1.0	0.29
15–18	40	13.5	0.80	0.27

TABLE 51.1-2 Guidelines for Adolescent Athletes

General recommendations
- Adolescent athletes need between 6 and 10 g of carbohydrate per kg of body weight per day.
- Food intake should emphasize the consumption of complex carbohydrates and moderate amounts of fat.
- Fat intake should be kept at 30% of calories from fat.
- Protein recommendations for endurance athletes are 1.2 to 1.4 g/kg body weight. For strength-trained athletes, the protein requirements may increase to 1.6 to 1.7 g/kg body weight per day. The increase in protein intake can be easily met through diet without the use of supplements.
- Fluids: Water is the best alternative for fluid. Diluted fruit and sports drinks are acceptable.
- Vitamins and mineral supplements are not recommended unless the adolescent is not consuming adequate amounts of food. Protein and amino acid supplements are not recommended.
- Vegetarian athletes may be at risk for low-calorie, protein, and micronutrients intake.
- There is no need to use vitamins/mineral supplements, amino acids, or protein mixtures.
- There is no scientific evidence to support the notion that supplements improve athletic performance. Supplements should be recommended only to athletes with poor nutrient intake.
- Adolescent athletes and nonathletes are at risk for iron deficiency and low intakes of calcium. Food intake should emphasize the consumption of those two nutrients.
- Adolescent athletes need adequate calories especially at the time of high-intensity training to support growth and to avoid muscle mass losses and menstrual dysfunction.

Before exercise
- Adolescents should eat a light meal about 3 hours prior to competition.
- Fluids: Adolescent athletes should drink between 14 and 22 oz of fluid 2 hours before exercise.
- Adolescent athletes should not eat sweet foods or drinks before participation in sports.
- A snack or meal before exercise should be high in carbohydrate, low in fat, moderate in protein, and low in fiber.

During exercise
- The most important goal when the athlete is doing exercise is to replace fluid losses and provide between 30 to 60 g of carbohydrate per hour, especially for endurance events that last over an hour.
- Fluids: 6 to 12 oz should be consumed every 15 to 20 minutes, depending on tolerance.

After exercise
- After exercise, the goal is to provide adequate fluids, energy, and carbohydrates.
- Provide a carbohydrate intake of 1.5 g/kg of body weight during the first 30 minutes and again every 2 hours for 4 to 6 hours.
- Fluids: After exercise, the athlete needs to drink between 16 and 24 oz of fluid for every pound of weight loss during exercise.
- After a strenuous competition, athletes should consume a mixed meal with adequate amounts of carbohydrate, protein, and fats.

eral acceptable forms are available, as outlined in Table 51.1-3. Calcium supplements vary in their ability to be absorbed. To test the quality of a particular supplement, the tablet can be placed in a glass of vinegar. If the tablet has not dissolved after 10 to 30 minutes, it is not an easily absorbed source of calcium.[37] To maximize absorption, clinicians should instruct their patients to take calcium carbonate supplements at mealtime as the presence of food in the stomach increases acid levels, helping with absorption. Although calcium carbonate supplements contain the highest percentage of elemental calcium, they may also cause constipation or flatulence. Calcium citrate supplements can be taken at any time, making them easier for patients on a busy schedule. Calcium phosphate can be found in calcium-fortified orange juice, soy milk, and rice milk. Nonchewable supplements should be taken with water to help them dissolve. Absorption is better when a patient ingests no more than 500 mg of calcium at a time. Women's multivitamins with calcium may contain up to 450 mg of calcium, whereas a typical multivitamin may contain no calcium. Other helpful hints include having patients avoid taking calcium with high-fiber meals as fiber reduces the amount of calcium the body can use; avoid preparations with bone meal, dolomite, and oyster shell as they may contain contaminants or toxic ingredients; and avoid taking iron and calcium supplements simultaneously as they may interfere with each other's absorption. The calcium content of some foods and drinks is seen in Table 51.1-4.

EATING DISORDERS: DEFINITIONS

Described as the "relentless pursuit of thinness,"[38] anorexia nervosa is characterized by extreme weight loss, distorted body image, and a morbid fear of obesity.[39,40] Diagnostic criteria have evolved over time, with the latest proposed revision outlined in Table 51.1-5. This table includes definitions for anorexia nervosa, bulimia nervosa, and eating disorder not otherwise specified. Of note, in the criteria from the *Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (*DSM-IV*),[41] anorexia nervosa can involve either weight loss leading to maintenance of body weight less than 85% of that expected or a failure to gain the expected amount of weight during a period of growth, leading to a body weight of less than 85% of that expected. In other words, a teen with a distorted body image who gains in height but maintains a given weight can cross weight centiles during that period of growth, alerting the astute clinician to a potential problem even before other symptoms have become apparent.

Typically, the adolescent who is either overweight or dissatisfied with current body image moves from a moderate effort to lose weight to an intense preoccupation with weight loss and eating; eventually, food-related activities interfere with socialization and family activities. School performance is often affected last, if at all. Restrictive anorexic adolescents are often characterized as obsessive-compulsive, perfectionistic, introverted, and emotionally inhibited.[42,43]

Bulimia nervosa, derived from the Greek root meaning "ox hunger,"[44] is characterized by the binge eating behavior, in which one "eats like a bull." Typically, bulimia nervosa begins in a teen who has been trying to control his or her weight with little success; he or she discovers, either spontaneously, from a friend or family member, or from the media, that self-induced vomiting, laxatives, or diet pills can control weight.[40] Binges may develop subsequently

TABLE 51.1-3 Available Calcium Supplements

Product	*Type of Calcium*	*Manufacturer*	*Elemental Calcium per Tablet (mg)*
Calcet	Calcium lactate, calcium gluconate, calcium carbonate	Mission Pharmacal	153
Calcet Triple Calcium + Vitamin D	Calcium lactate, calcium gluconate, calcium carbonate	Mission Pharmacal	300
Caltrate 600 Plus	Calcium carbonate	Lederle Laboratories	600
Caltrate 600 + Vitamin D	Calcium carbonate	Lederle Laboratories	600
Citracal	Calcium citrate	Mission Pharmacal	200
Citracal + Vitamin D	Calcium citrate	Mission Pharmacal	315
Citracal Liquitabs	Calcium citrate	Mission Pharmacal	500
One a Day for Women multivitamin	Calcium carbonate	Bayer	450
OsCal 500 chewable tablets	Calcium carbonate	Marion Laboratories	500
OsCal 500 + Vitamin D	Calcium carbonate	Marion Laboratories	500
Rolaids	Calcium carbonate	Warner-Lambert	220

*Do not use if patient has lactose intolerance.

and can involve the ingestion of up to 20,000 calories in a 1- to 2-hour period, with resultant abdominal discomfort, distress, or fatigue.[45] For other patients, a "binge" might consist of the same amount a healthy person would consider normal. In the patient with an eating disorder, this volume triggers an inordinant amount of guilt or negative feelings. Binges usually end with compensatory behavior, such as self-induced vomiting, exercise, and abuse of laxatives or diuretics. Other binges end with an exhausted food supply or interruption by family or friends. These patients often display other impulsive behaviors, including stealing, overspending, substance abuse, self-mutilation, and promiscuity.[46] A history of sexual abuse has also been reported in 20 to 50% of patients with bulimia nervosa.[47]

The teen with anorexia nervosa whose actions and thoughts appear to be egosyntonic or consistent with her inner self feels justified in her behaviors and is extremely resistant to therapy. This intrapsychic state depends on a severe level of cognitive denial and disappears when the denial is successfully challenged. In contrast to the adolescent with anorexia nervosa, the bulimic teen's thoughts and actions are egodystonic, causing her to have feelings of guilt, loss of control, and acute distress. Adolescents with bulimia are more likely to seek help, whereas adolescents with anorexia nervosa are often dragged in by concerned family or friends. However, changing the behavior can be just as difficult in a bulimic patient as in a patient with anorexia nervosa.

TABLE 51.1-4 Comparison of Calcium Content in Various Foods

Food	*Serving*	*Calcium per Serving (mg)*
Milk	1 cup	300
American cheese	1 oz	174
Cottage cheese	½ cup	77
Tofu	½ cup	434
Ice cream	½ cup	88
Yogurt	1 cup	345–415
Frozen yogurt	½ cup	104
Broccoli (cooked)	½ cup	89
Orange juice fortified with calcium	1 cup (8 oz)	300

EPIDEMIOLOGY

Incidence rates for anorexia nervosa have increased steadily from 1975 to 1991 in teens ages 10 to 19 years, although rates in adults have remained relatively constant.[48–50] The prevalence has been most recently estimated to be 0.5 to 3% of adolescent and young adult women, with an increasingly larger number of "healthy" girls expressing worrisome eating attitudes and weight concerns.[39,51–54] The classic image of the overachieving, "perfect little girl" from the upper middle class family is also being challenged, with more eating disorders seen in males (up to 5 to 10% of all cases) and in teens with a variety of backgrounds, ethnicities, and psychological profiles.[51,54–57] Eating disorders have been found in increasing numbers in Japan, China, and other countries.[58–60] In the United States, eating disorders are on the rise in minority groups such as Hispanics and native Americans.[61]

Anorexia nervosa continues to have two peaks of onset, one in early adolescence (ages 11 to 14 years) and a second peak in late adolescence (17 to 19 years),[39,62] whereas bulimia nervosa tends to begin in late adolescence with a teen of normal or high weight. The prevalence of bulimia nervosa has been estimated to be 1 to 19% using *DSM-IV* criteria.[46,48,51,63,64] Studies of female high school and college students have found symptoms of bulimia in 4.5% and 18%, respectively.[65,66] Higher rates of anxiety (43%), chemical dependency disorders (49%), bipolar disorders (12%), and personality disorders or personality trait disturbances

TABLE 51.1-5 Diagnostic Criteria for Anorexia Nervosa, Bulimia Nervosa, and Eating Disorder Not Otherwise Specified

Anorexia nervosa
- Intense fear of becoming fat or gaining weight, even when underweight
- Refusal to maintain body weight at or above a minimally normal weight for age and height (eg, weight loss leading to maintenance of body weight < 85% of that expected or failure to gain weight during a period of growth leading to body weight < 85% of weight expected)
- Disturbed body image, undue influence of weight or shape on self-evaluation, or denial of the seriousness of the current low body weight
- Amenorrhea or absence of at least 3 consecutive menstrual periods for those postmenarchal (also considered amenorrheic if periods inducible only after estrogen therapy)

Types
- Restricting = no regular binges or purges (self-induced vomiting or use of laxatives or diuretics)
- Binge eating/purging = regularly binges or purges in patient who also meets the above criteria for anorexia nervosa

Bulimia nervosa
- Recurrent episodes of binge eating, characterized by
  - Eating a substantially larger amount of food in a discrete period of time (eg, in 2 hr) than would be eaten by most people in similar circumstances during that same time period
  - A sense of lack of control over eating during the binge
- Recurrent inappropriate compensatory behavior in order to prevent weight gain, eg, self-induced vomiting, use of laxatives, diuretics, fasting, or hyperexercising
- Binges or inappropriate compensatory behaviors occurring, on average, at least twice weekly for at least 3 mo
- Self-evaluation unduly influenced by body shape or weight
- The disturbance does not occur exclusively during periods of anorexia nervosa

Types
- Purging = regularly engages in self-induced vomiting or use of laxatives/diuretics
- Nonpurging = uses other inappropriate compensatory behaviors, eg, fasting, hyperexercising, without regular use of vomiting or medicines to purge

Eating disorder not otherwise specified (those that do not meet criteria for anorexia nervosa or bulimia nervosa by DSM-IV*)*
- All criteria for anorexia nervosa except has regular menses
- All criteria for anorexia nervosa except weight still in normal range
- All criteria for bulimia nervosa except binges < twice/week or < 3 mo
- A patient with normal body weight who regularly engages in inappropriate compensatory behavior after eating small amounts of food (eg, self-induced vomiting after eating 2 cookies)
- A patient who repeatedly chews and spits out large amounts of food without swallowing
- Binge eating disorder: recurrent binges without the compensatory behaviors associated with bulimia nervosa

Adapted from the American Psychiatric Association, Diagnostic and Statistical Manual of Mental Disorders, 4th ed. Washington (DC): American Psychiatric Association; 1994.

(50 to 75%) have also been found in patients with bulimia nervosa.[46,67–71] Another series found that 50% of patients with anorexia nervosa and 30% of patients with bulimia nervosa met criteria for major depression.[72]

Many adolescents may show unhealthful eating behaviors even without evidence of a full-blown eating disorder. Adolescents and young adults who are required to reduce their food intake or follow a strict diet owing to a disease state are at high risk for developing an eating disorder.[73] In a study of 4,746 public middle school and high school students in Minnesota, healthful weight control behaviors were used by the majority of teens to control weight (85% adolescent girls, 70% adolescent boys).[74] These behaviors included cutting down on high-fat items and sweets, increasing fruits and vegetables, and exercise. Unhealthful weight control practices included fasting, restricting, using a food substitute (powder or special drink), skipping meals, and smoking more cigarettes; these behaviors were used by 57% of adolescent girls and 33% of adolescent boys. Extreme weight control behaviors, defined as use of diet pills, laxatives, diuretics, or vomiting to control weight, were used by 12% of the girls and 5% of the boys. The authors found that a high percentage of average-weight girls perceived themselves as overweight, desired to weigh less, and expressed body dissatisfaction.[74] Their data also found that obese adolescents recognized that they were overweight, with most reporting some steps taken to lose weight. Thus, prevention of both obesity and eating disorders may lie less in recognizing who is overweight and a superficial review of desirable weight control behaviors; rather, interventions may be more effective if more time is spent in building skills in how to engage in healthful weight control behaviors successfully.[74] Further strategies for eating disorder nutritional management are discussed in more detail later in this chapter.

In a study in Cleveland, Ohio, 1,268 urban, suburban, and rural high school students were given questionnaires asking about dieting and purging behavior.[5] Laxatives and diuretics were used more frequently by black girls than by white girls (10% versus 3% for laxatives, 5% versus 2% for diuretics). Vomiting was used more commonly by white girls, with 8% vomiting monthly compared with only 1% of black girls. It should be noted that 40% of the boys reported dieting, with similar dieting and purging behaviors between black and white boys. A survey of 36,320 Minnesota public school students in grades 7 through 12 revealed chronic dieting reported by 12.1% of the girls and 2.1% of the boys, with significantly greater numbers of girls dieting as they progressed from junior high through high school. Chronic dieters were more likely to report use of laxatives, ipecac, diuretics, self-induced vomiting, and other maladaptive behaviors.[7] Thus, clinicians should be alerted to the possibility that an adolescent who has reported chronic dieting may be developing an eating disorder.

Some male runners with compulsive exercise patterns have been shown to have bizarre preoccupations with food, concern about weight with strict monitoring of intake, and a high achievement orientation.[75] Such behaviors may indicate the presence of an eating disorder in the male athlete. In a group of 93 elite women runners, 13% had been diagnosed previously with anorexia nervosa, 25% displayed binge eating, 9% binged and purged, and 34% had atypical eating practices.[76] Among college athletes who often engage in highly intense competition, abnormal dietary patterns are prevalent. Self-induced vomiting has been reported in 14%, laxative abuse in 16%, routine use of diet pills in 25%, and at least one unhealthful eating habit in 32% overall.[77] A study of female college gymnasts

showed that 62% reported unhealthful eating behaviors, with two-thirds told by their coaches that they were too heavy.[78] Athletes whose coaches had commented on their weights were more likely to engage in unhealthful dietary practices. Athletes should be questioned by their clinicians about body image, weight concerns, menstrual patterns, and eating behaviors.

NUTRITIONAL ASSESSMENT OF THE TEEN WITH AN EATING DISORDER

A careful history and physical examination can reveal much information about the chronicity of the teen's illness, abnormal eating behaviors, and potential strategies for management. The clinician can start the history taking session by asking the parent and the teen individually why he or she is being seen. This information can be most helpful in revealing hidden agendas or different perceptions of parents and their teenagers. Ideally, the parent and teen each should be given time alone with the provider to promote a sense of individualized caring and listening to each one's needs. Confidentiality should be established immediately, with the explicitly stated caveat that the provider will break confidentiality if the situation is life-threatening or extremely dangerous. The clinician should ask the teen what is the most he or she has ever weighed and when. What is the least weight remembered and when? What is the current weight? For girls, at what age did periods start? When was her last period? Are menses regular, with or without cramps, and how long do they last? Has flow or duration changed? If periods have ceased, at what weight was she when she had her last period? Eating disorders can be associated with both primary and secondary amenorrhea. It is helpful to elicit the age of menarche and regularity of periods of the mother and the teen's female siblings.

The clinician should also ask questions about body image and self-esteem. For instance, does the teen feel underweight, overweight, or just right? At what weight would the teen like to be? Does he or she have any "trouble spots" or areas on the body that cause the teen particular discomfort or concern? With a reticent teen, the clinician might change the phrasing to state that most people have certain parts of their body that they would like to change and then ask the teen if he or she has any "trouble areas." Asking the teen how hard he or she struggles to lose or maintain weight simultaneously gives information on the effort placed in the abnormal eating behaviors and acknowledges the difficulty and stress the teen may feel over weight issues.

The clinician should specifically ask how the teen controls weight. Does the teen vomit to lose weight and, if so, using what methods (finger, toothbrush, or other tool)? A teen who can vomit at will without use of a finger or other item has probably been practicing this behavior frequently or for a long time. Does the teen use diet pills? Diuretics? Laxatives? If so, what kinds, how many per day, and how often? How often does the teen have bowel movements? Are they loose or formed? Any diarrhea or constipation? How much caffeine does he or she consume daily? The amount and kinds of fluids consumed also are important. Use of over-the-counter and illicit drugs, cigarettes, and alcohol should also be assessed.

The provider should determine the amount of time spent in exercise, what kinds of exercise and level of competition, and duration of involvement in a sport. Exercise can serve as another means of purging behavior. When women with eating disorders exercise, they tend to do so compulsively.[79] Many women pursue abnormally low body weights to participate in ballet, to compete in sports such as track or gymnastics, or to pursue a career in modeling.[80] Menstrual disorders have been associated with eating disorders in gymnasts, runners, ballet dancers, and models.[81] The amount of distress or any physical symptoms caused by missing a workout should also be assessed. The clinician should also ask the patient and family members whether the teen performs other "anxious" repetitive movements, such as pacing or foot tapping.

In obtaining a dietary history, the clinician can ask about the frequency and location of meals and snacks and about the quantity of food consumed. If she states that she eats a bagel for breakfast, ask how many bites she can manage; in this way, the provider acknowledges his or her awareness of the difficulty in consuming foods. Does the teen usually skip breakfast? Lunch? Dinner? Can the teen comfortably eat food prepared outside the home, for example, at school, restaurants, or friends' houses? Is he or she comfortable eating in front of friends and family? At home, who prepares the food, and are meals eaten alone or with other family members? How many nights a week is there a family dinner? Does he or she ever binge or "pig out?" What constitutes a binge? The provider and the patient may have different concepts about the definition of a binge, so explicit descriptions of the last binge can be helpful. How long does a binge last? Are they planned? What are the rituals around the bingeing?

The clinician should ask if the teen has any "taboo" foods or foods that she simply cannot or will not eat. Certain foods may be deemed "safe," whereas others are "unsafe"; for example, cake and cookies may be assiduously avoided, whereas many patients will eat muffins.[82] Other patients may be sophisticated label readers and eliminate all hidden fats, believing that if less fat is good, then none is better. Foods may be classified as absolutely good or bad, often with episodes of "magical thinking." Extreme examples include avoidance of all fat grams as they will automatically produce body fat, fear of talking about food on the telephone lest the calories move through the telephone and deposit themselves on the patient's body, or assumptions that restaurants or companies prepare foods in the most caloric way possible. Some patients may refuse to look in a particular mirror in the house because of the belief that the mirror literally added pounds to the teen's hips and buttocks. Such extreme delusional thinking often resolves with refeeding,[83] but many of the associated eating behaviors can be difficult to change. Families may note unusual use of utensils in eating or ritualistic behaviors, such as cutting food into minuscule pieces or chewing each bite multiple times.

Strict avoidance of fat grams, red meat, or other items can alert the clinician to potential nutritional insufficiencies while simultaneously painting a picture of how rigid the teen's diet currently may be. Many teens begin their eating disorder with a gradual switch to "healthful eating," often heralded by the weight-conscious family as a positive sign. For instance, the teen may cut out red meat, then move to lacto-ovovegetarianism, and then shift to be a "vegan," one who abstains from consumption of meat, fish, fowl, dairy products, and eggs.[84] Although a vegetarian diet can be healthful, the adolescent may use this diet as a means to restrict further, especially in the context of a nonvegetarian family who may be accepting of this seemingly healthful change and not realize the extent of the abnormal eating.

Another method for assessing daily intake is by 24-hour recall. Although this technique has achieved some popularity owing to its ease of use, its validity has been questioned.[85,86] Teens with eating disorders may exaggerate or minimize the amounts and types of food consumed, depending on whether they are restricting or bingeing. Having a parent in the room during this part of the interview may serve as a "reality check," with the body language and parents' interruptions "correcting" the teen's potential misrepresentation of amounts. Also, the meals of the teen's previous day may not be "typical," with a change in intake solely in anticipation of "reporting" to the health care provider. The main point of the 24-hour recall lies in distinguishing the types and amounts of foods consumed, including dairy products, fruits and vegetables, sources of fat and protein, and any junk foods. Patients with anorexia nervosa in particular should not be encouraged to count calories excessively as they may eat even less when attention is given to caloric contents, quantity, and quality of foods ingested.

For teens with disordered eating, a 3-day food record or a daily food journal can be a useful tool, not only during the dietitian's initial assessment but also to monitor the changes being made during recovery. Specific instructions on how to complete the food record can help improve accuracy of the information. The teen should be given advice on how to quantify food using standard measuring tools (eg, tablespoons or cups rather than "mouthfuls"). Patients with obsessive-compulsive tendencies may benefit from a more generalized approach to journaling and changing behavior patterns, helping them get away from strict calorie or fat gram counting, weighing, and measuring. In contrast, patients with bulimia nervosa can use the information obtained from the food record to identify foods or situations that trigger a binge (see Table 51.1-6). Attention can be placed on the emotional state during a binge, timing, or other pertinent aspects. For instance, if a teen always binges on arrival home after school, the clinician can suggest filling the time with more structured activities so that the teen does not automatically enter the kitchen at that time. Such simple interventions can sometimes provide a new behavioral pattern for a teen who is otherwise "stuck." Asking what the teen has tried, if anything, to avoid bingeing can also guide the clinician toward potentially useful interventions. The clinician should determine how the binge typically ends and whether they engage in compensatory behaviors after a binge. For purgers, the ability to postpone vomiting for even an hour may be a positive first step. Those patients who vomit should be advised to rinse their mouths with water with baking soda or mouthwash in lieu of brushing teeth after vomiting to minimize the impact of acid on the tooth enamel.

The clinician should also ask about more general symptoms. This review of systems should include questions about the level of energy or fatigue, change in mood, depression, and suicidal ideation. Tolerance to cold, irritability, and changes in skin should also be assessed. Level of school and family functioning should also be determined; patients with anorexia nervosa may slowly isolate themselves from peers and family, and all teens with eating disorders may show an extreme narrowing of interest.

TABLE 51.1-6 Sample Food Journal

Scale: 1 = hungry, 5 = comfortable, 10 = uncomfortably full.

Major losses or changes in the family structure can also trigger the onset of an eating disorder.

In the office setting, weights should be obtained in a hospital gown after voiding. Clinicians should be on the alert for weight manipulation during office visits, ranging from simple water loading for weight elevation to hiding of weights or other objects beneath the hospital gown or in various orifices. Many providers weigh patients backwards on the scale, especially if a patient will use a number on the scale to restrict further. A dipstick urinalysis can help assess specific gravity, with a value of 1.005 or less indicating water loading intentionally or perhaps a misguided view on fluid requirements. Urinalysis can also illuminate ketosis, proteinuria, and dehydration. Dehydration may result in an accelerated heart rate, masking a sinus bradycardia. Relevant findings on the physical examination of a patient with an eating disorder are listed in Table 51.1-7.

MEDICAL COMPLICATIONS OF EATING DISORDERS

Despite substantial malnourishment, adolescents with eating disorders may have remarkably few physiologic abnormalities at the time of presentation and in follow-up.[40] Medical complications of the eating disorder can be caused directly or indirectly by three processes: (1) caloric restriction, (2) purging behaviors, and (3) binges. Almost every organ system of the body can be affected by these behaviors.[87–90] Pure restrictors can have a different constellation of complications from those found in patients who purge; binges put the patient at risk for a separate set of problems. To clarify the myriad complications, the following sections divide the problems into those caused by caloric restriction, those caused by purging behaviors, and those related to bingeing.

Medical Complications of Caloric Restriction

The most serious sequelae of a prolonged starvation state include risk of sudden cardiac death, risk of arrhythmias, and myocardial wasting. In anorexia nervosa, thinning of the left ventricle and decreased cardiac chamber size have been reported,[91,92] along with the associated decreased blood pressure and reduced cardiac output.[39] The teen may complain of cold hands and feet, caused by diminished peripheral circulation owing to increased peripheral vascular tone in the face of decreased cardiac output.[93]

Sinus bradycardia, sinus arrhythmia, and hypotension can be seen as protective mechanisms or adaptations to a

TABLE 51.1-7 Physical Findings in Teens with Eating Disorders

Finding	*Cause*
Mouth	
Dental caries	Bingeing on sugar-containing foods
Enamel erosions on lingual and occlusal surfaces	Chronic vomiting
Dry mouth	Anxiety, decreased salivary output
Scratches on posterior pharynx or palate	Use of toothbrush, finger, or other object for vomiting
Skin	
Lanugo	Extreme weight loss (primitive response to warm body)
Russell's sign (calluses on the knuckle)	Use of finger for vomiting
Dry, cold, scaly skin	Decreased basal metabolic rate
Orange skin	Hypercarotenemia
Brittle hair and nails	Relative hypothyroidism
Petechiae	Thrombocytopenia from extreme malnutrition, on face from vomiting with Valsalva
Pedal or pretibial edema	Withdrawal from laxatives or diuretics; rapid refeeding
Sallow, loose, or sagging skin	Loss of subcutaneous fat
Callus formation or pressure sores	Pressure from sitting or exercising excessively
Eyes	
Conjunctival hemorrhage	Vomiting with Valsalva
Cheeks	
Parotid enlargement	Chronic vomiting
Cardiac	
Hypotension by pulse or blood pressure, bradycardia	Myocardial wasting, malnutrition
Breasts	
Atrophic tissue	Loss of subcutaneous tissue
Abdomen	
Scaphoid	Loss of subcutaneous tissue
Palpable loops of stool	Slowed gastrointestinal motility; constipation
Genitalia	
Dry, atrophic vagina	Hypoestrogenemia
Extremities	
Cold hands and feet; acrocyanosis	Poor circulation
Muscle wasting	Malnutrition
Other	
Loose-fitting clothes	To hide cachexia

state of malnutrition, occurring gradually over time; by themselves, these changes are not thought to be life-threatening.[94] In contrast, direct myocardial impairment can occur more quickly and can be lethal; examples include primary cardiovascular abnormalities such as prolonged corrected QT interval, ventricular dysrhythmias, and reduced myocardial contractility. Thus, the low heart rate of patients with anorexia nervosa is primarily a problem in association with a primary cardiovascular abnormality or electrolyte imbalance predisposing to arrhythmia. However, bradycardia, hypotension, and hypothermia are appropriately used as cues indicating medical compromise and the need for intervention. Varying heart rates (less than 40 to 60 beats per minute) have been used as a criterion for admission in various programs.[44,46,95,96] Gradual refeeding and bed rest under close observation remain the appropriate therapy for profound asymptomatic sinus bradycardia, with the cardiac abnormalities reversible when the teen returns to a more normal weight.[94] Rapid refeeding has been associated with congestive heart failure, probably caused by the large increase in afterload in patients with cardiac wasting.[97] Refeeding can also result in hypophosphatemia, caused by the combination of depletion of total-body phosphorus stores during catabolic starvation and increased cellular influx of phosphorus during anabolic refeeding.[98,99] This extracellular hypophosphatemia is often treated with 500 mg, orally twice a day, of a phosphorus replacement product such as Nutraphos (250 mg phosphorus, 164 mg sodium phosphate, 278 mg potassium phosphate; Willen), in a dose of two capsules orally twice a day, to provide the RDA of 1,000 mg phosphorus per day during acute refeeding.

Many patients develop a pattern consistent with the "euthyroid sick syndrome." Peripheral conversion of thyroxine (T_4) to triiodothyronine (T_3) is decreased, with a high or high-normal level of reverse T_3.[39,100] It is most likely that the decrease in T_3 represents another adaptive response to starvation by helping to reduce the metabolic rate in the face of decreased energy stores. Suggestive symptoms include bradycardia, cold intolerance, dry skin, coarse hair, slowed relaxation of reflexes, and hypercarotenemia.[39] Teens with anorexia nervosa should not be given thyroid hormone solely on the basis of a low T_4 level.[93]

As with other starved patients, growth hormone and cortisol levels are the only hormones typically above normal in anorexia nervosa.[93] Elevated levels of growth hormone probably reflect the associated decrease in insulin-like growth factor I, which normally inhibits growth hormone secretion at the level of the hypothalamus and the pituitary.[39] With refeeding, growth hormone levels fall to normal within a few days. Hypercortisolemia has been postulated as a cause of the osteopenia associated with eating disorders.[33]

Hematologic changes include pancytopenia, neutropenia without an apparent increased susceptibility to infection, and a normochromic or hypochromic anemia.[40] The bone marrow tends to be hypocellular.[39] Although many patients who have eliminated red meat from their diets may also have iron deficiency anemia, the anemia associated with their malnourished state often resolves with refeeding.

Gastrointestinal manifestations include delayed gastric emptying and slowed motility, with patients often describing feelings of early satiety, bloating, postprandial discomfort, and constipation.[89,90,101] Abnormal liver function tests may reflect fatty infiltration of the liver and usually normalize with weight gain. Teens with anorexia nervosa may also have transient hypercholesterolemia, also reversible with weight gain; in general, checking cholesterol levels in these teens should be avoided as they tend to use an elevated level as an excuse to restrict their daily fat intake further.

An elevated blood urea nitrogen level can also be observed, reflecting dehydration and a decreased glomerular filtration rate.[40] Starvation can also cause total-body sodium and potassium depletion, with 25% of patients with anorexia nervosa found to have peripheral edema with refeeding; it is most likely that this effect is caused by increased renal sensitivity to aldosterone and the action of increased insulin secretion on the renal tubules.[40] A minority of patients may have impaired or erratic release of vasopressin in response to osmotic challenge.[102] These patients may note mild polyuria. Remarkably, almost all patients who lose weight solely by caloric restriction tend to have normal electrolyte levels, even in the face of severe malnutrition.[51] The exception occurs in adolescents who restrict fluid to lower the weight and develop severe dehydration and in adolescents who load water to manipulate the weight prior to a visit to a health care provider and present with significant hyponatremia.

Amenorrhea, hypoestrogenism, and osteopenia occur commonly in girls with low weight as well as in patients with bulimia (see Chapter 51.3, "Adolescents: Bone Disease").

Medical Complications from Purging and Bingeing

Chronic, self-induced vomiting has been associated with hypokalemic, hypochloremic, metabolic alkalosis.[51,103,104] Loss of hydrogen, chloride, and water from gastric fluid results in chloride and volume depletion, triggering a secondary hyperaldosteronism. Consequently, tubular reabsorption of sodium and excretion of potassium increase. The loss of hydrogen ions, both from tubular excretion and from gastric fluid, further causes an exchange of hydrogen and potassium at the cellular level, with worsening hypokalemia. Sodium levels tend to be low or normal but can also be high. It is unclear why some teens who report vomiting over 20 times per day can have remarkably normal electrolytes, whereas those vomiting only three or four times per week can have values that are markedly abnormal.

Hypokalemia can also cause fatal or life-threatening arrhythmias. In a series of 37 patients with anorexia nervosa, 24% had prolonged corrected QT, with each case except one associated with hypokalemia, hypomagnesemia, or medications.[105] Adults with a protracted course of anorexia nervosa may be at greater risk for fatal arrhythmia.[106] Teens who use ipecac to purge are also at risk for irreversible myocardial damage as well as a diffuse myositis secondary to emetine toxicity.[40] If the myopathy is detected at an early stage, it may be reversible.[107] Diuretic abuse can also result in electrolyte abnormalities through tubular excretion of potassium and hydrogen; it has also

been associated with low levels of calcium, magnesium, and zinc in patients with eating disorders.[93,108] Laxative abuse causes loss of fluid and electrolytes in the stool. Those patients who combine vomiting with laxative and diuretic use are most at risk for severe electrolyte imbalances. Significant peripheral edema with accompanying fluid and electrolyte shifts can occur in patients who abruptly stop taking laxatives and diuretics, as might occur on admission to an inpatient unit.[51]

Vomiting can also cause parotid enlargement and a characteristic pattern of dental enamel erosion (perimolysis) on the lingual and occlusal surfaces of the incisors from repeated contact with gastric acid.[89,93] Patients may note thermal hypersensitivity when dental erosion has occurred. Bingeing on foods with high sugar content can also cause an increase in dental caries. Elevated amylase levels have also been found and are probably salivary in origin.[109] Vomiting in a state of decreased consciousness, as would occur in a patient using alcohol or drugs, may result in aspiration pneumonia.

Binge eating can cause acute gastric dilatation and even rupture.[110,111] A few patients who binge and vomit have also developed Mallory-Weiss tears and esophageal rupture.[109]

AMENORRHEA AND OSTEOPENIA

Recently, attention has been focused on the "female athlete triad," consisting of amenorrhea, osteopenia, and the presence of an eating disorder.[112] Amenorrhea, one of the cardinal signs of eating disorders, can also be seen in certain athletes, especially those participating in competitive sports that emphasize endurance and/or a slender physique with minimal body fat.[113–119] Binge-purging has also been shown to be a risk factor for secondary amenorrhea, with an odds ratio of 4.17.[120] In eating disorders and in long-distance runners, amenorrhea has been associated with hypothalamic dysfunction, weight loss, decreased body fat, excessive exercise, and stress.[121,122] Typically occurring after a 10 to 15% loss of body weight, amenorrhea can also precede weight loss in 50 to 75% of patients with eating disorders.[113,123,124] The basic mechanism appears to be an alteration in the regulation of gonadotropin-releasing hormone secretion by the hypothalamus, with changes in the dopaminergic and opioid systems found in patients with anorexia nervosa and in athletes.[113] Heavy training (over 18 hours per week) starting before and continuing throughout puberty has been shown to alter growth rate and to reduce growth potential in adolescent gymnasts. The proposed mechanisms include prolonged inhibition of the hypothalamic-pituitary-gonadal axis by exercise combined with the metabolic effects of dieting.[125]

"Athletic amenorrhea" can result in a hypoestrogenic state associated with decreased bone density in adults and delayed or interrupted puberty with decreased bone density in teens.[126,127] The osteopenia occurring with prolonged loss of menses has been associated with increased risk of stress fractures in both athletes and patients with eating disorders.[116,127] The risk factors for osteopenia in athletes and eating disorder patients can be seen as a negative net balance between bone resorption and formation.[127] Increased bone loss through resorption occurs with hypoestrogenism (amenorrhea) and hypercortisolemia (chronic stress). Decreased bone formation occurs with glucocorticoid excess and with inadequate calcium and protein intake. Excess glucocorticoids decrease calcium absorption from the gut and inhibit bone formation through direct, receptor-mediated osteoblast effects.[128,129] Acquisition of bone mineral normally continues through the second decade, with peak bone mass reached only in late adolescence or early adulthood.[130,131] Approximately 40 to 60% of bone mass is acquired during the pubertal growth spurt, occurring in females between the ages of 11 and 13 years; evidence suggests that as much as 5% may be acquired during the third decade.[34] This latter figure gains importance in that an extra 5% can account for a significant decrease in fracture risk.[34] Net gains are positively correlated with physical activity, weight, and calcium and protein intake and negatively associated with age.[34]

Osteopenia has been associated with amenorrhea of even a relatively short duration. Bachrach and colleagues found that 12 of 18 teens with anorexia nervosa had osteopenia, with half of this group having been diagnosed within the previous year.[130] The authors postulate that either osteopenia occurs relatively quickly or each patient had unrecognized illness for a longer period of time. Age at onset and duration of anorexia nervosa correlated significantly with bone density, whereas activity level, duration of amenorrhea, and calcium intake did not show a significant relationship with bone density. In contrast, Rigotti and colleagues found that exercise offered some protection against bone loss in anorexia nervosa.[35] Neither calcium supplementation nor vigorous exercise will protect against osteopenia in teens with severely abnormal eating behaviors.

Therapy for osteopenia and amenorrhea in athletes and patients with eating disorders has not been adequately studied. Estrogen replacement therapy can prove problematic for some teens with eating disorders and for athletes who are concerned about potential weight gain or the development of secondary sexual characteristics. Moreover, in teens who have not achieved final height and show significant pubertal delay, estrogen doses high enough to prevent osteopenia may cause accelerated fusion of the epiphyses, compromising final adult height.[130,132] Although estrogen may have an independent effect on bone mass in adolescents,[133] preliminary data suggest that hormonal replacement therapy alone may be insufficient to overcome the detrimental effect of low weight for height on bone density.[134] Weight gain with associated re-establishment of normal estrogenization appears to be the best means of increasing peak bone mass in teens with eating disorders, with increased bone mineral density seen even before the return of menses.[133,135]

Several noninvasive methods are available and have been used to assess bone density, analyzing either trabecular or cortical bone. Best measured in the vertebral spine, trabecular bone consists of plates traversing the internal cavities of the skeleton. Found in the distal radius and other areas, cortical bone forms the outer layer of the

skeleton.[113] Both cortical and trabecular bone mass increase during the pubertal growth spurt. In anorexia nervosa, trabecular bone appears to be most severely affected, with a relative sparing of cortical bone; this discrepancy is probably attributable to the more rapid turnover of trabecular bone, with resultant increased sensitivity to the metabolic changes caused by starvation or stress.[33,127,130] Single-photon absorptiometry, used in Rigotti and colleagues' study,[35] measures only cortical bone, whereas quantitative computed tomography of the spine exclusively measures trabecular bone. This latter method involves 75 times the radiation exposure of absorptiometry and thus has been used primarily in research studies.[136] Dual-photon absorptiometry, or dual-energy x-ray absorptiometry (DXA), measures trabecular bone of the axial skeleton (eg, the lumbar vertebrae or femur). DXA is currently the method of choice in assessing bone density in adolescents because of its precision, accuracy, and minimal dose of radiation.[113]

Several questions remain with respect to the triad of eating disorders, amenorrhea, and osteopenia. First, who should be studied with dual-energy absorptiometry or another methodology? For those with significant osteopenia, who should be treated and with what? Many centers consider obtaining bone density assessments of teens with eating disorders who have had amenorrhea for 6 to 12 months. The information can then be used as an impetus for weight gain and/or for improved compliance with calcium supplementation.

The decision for hormonal (estrogen/progestin) replacement should be made on an individual basis, taking into account potential final height and bone age. Bachrach and colleagues found that recovered anorexics displayed persistent osteopenia, suggesting that deficits in bone density acquired during adolescence may not be completely reversible.[133] The burden, then, should be placed on early detection of eating disorders, initiation of efforts to promote weight gain at the onset, calcium supplementation to ensure intake of 1,200 to 1,600 mg orally per day,[27] and consideration of hormonal replacement or other interventions after 6 to 12 months of hypoestrogenic amenorrhea.

FORMING A NUTRITIONAL PLAN

Treatment of eating disorders should involve a team approach, including a primary care provider to address medical concerns, a therapist, a registered dietitian, and often a family therapist or social worker.[44,90,96] Nutritional intervention is an essential part of treatment. The extreme thought disorder often accompanying severe malnutrition will not change with therapy alone; the initial step must ensure adequate nutrition before any therapy will be effective or even tolerated.[83]

In performing the anthropometric assessment, the clinician needs to determine if the patient weighs less than 85% of the weight expected for her age and height (ideal body weight [IBW]). The body mass index (BMI) is calculated as the weight in kilograms divided by the height in squared centimeters. In adults, a BMI less than 17.5 raises the suspicion of anorexia nervosa.[137] The newer growth charts now help track the BMI and can be found through the Centers for Disease Control and Prevention Web site (<www.cdc.gov/growthcharts.2000>). Adolescents with a BMI less than the 10th percentile are considered to be underweight; a BMI less than the 5% may indicate a higher risk for anorexia nervosa. The clinician should also consider the patient's weight history, body build (muscle versus fat), and stage of development when using the BMI.[55,56,137] The IBW initially can also be determined by using the 10th percentile weight for height (Appendix Tables A-1 and A-2) or, more commonly, the Frisch table at the 10th percentile (Table 51.1-8).[138] The latter table establishes a minimum weight for patients with both primary and secondary amenorrhea. The clinician should make clear to the patient that menses will not necessarily resume the moment the teen achieves the target weight; otherwise, the teen may inch herself up to that weight and not budge an ounce above it. The health care provider should emphasize a weight range, above which menses are most likely to return, remembering that the weight will probably be at or near that weight at which periods ceased.

Several other methods can be used to determine IBW for patients over 18 years of age. The 1959 Metropolitan Life Charts provide estimations for weight by age, sex, and appropriate frame size. The Hamwi formula provides a simple means of calculating desirable body weight.[139] For women of medium frame, allow 100 pounds for the first 5 feet and then add 5 pounds for every inch above. For example, a women who is 5 feet and 3 inches would have a Hamwi desired weight of 100 + (3 × 5) = 115 pounds (range 112–118 pounds given to the patient). For women of a large frame, add 10%, and for those with a small frame, subtract 10%. In men, the medium frame starting point is 106 pounds, with 6 pounds added per inch.

Overall goals for nutritional management should be spelled out clearly to the teen and family at the start of therapy. The dietitian may be viewed with some fear and mistrust by the adolescent initially[140]; the teen should be reassured that the dietitian hears and understands his or her concerns and will work with the teen to ease the transition back to health.[141] Recognition of the extreme variability between individual patients' diets and identification of the specific diet pattern exhibited by a particular teenager can have practical implications for planning individualized treatment.[142] Proceeding too quickly with nutritional changes may trigger anxiety and cause the patient to become more resistant to therapy.[143] The primary care provider, nutritionist, therapist, and other members of the care team must work together to allay these fears and to stabilize the patient medically and psychologically.

A food plan, developed collaboratively with the teen, will support the gradual transition to a normalized eating pattern. Initially, a daily intake of as little as 1,200 calories may be appropriate to prevent postprandial discomfort after prolonged starvation. Otherwise, a 1,500-calorie diet should be adequate to start, with calories added in 200 to 300 kcal increments to produce a rate of weight gain of 0.2 kg per day (⅓ pound) if hospitalized or ½ to 2 pounds per week in the outpatient setting.[89,90,144]

TABLE 51.1-8 Minimal Weight for Particular Height Associated with the Onset or Restoration of Menstrual Cycles

Adapted from Frisch RE and McArthur JW.[138]

Liquid supplements (Ensure, Boost, Resource, or other brands) may be used as needed in patients who initially cannot tolerate the addition of solid foods. If a teen has a 1,500 calorie a day meal plan and can manage only 750 calories as solid food initially, three cans of a supplement (250 calories each) could be substituted.

Nasogastric tube feedings and peripheral alimentation carry increased medical and psychological risks; their use should be limited to those patients unable to consume sufficient calories orally who need urgent or acute stabilization.[145,146] A protocol for inpatient nutritional stabilization is outlined in Table 51.1-9.

Metabolic rate or caloric demands may increase quickly in the refeeding anorexia nervosa patient. In one study, during several stages of anorexia nervosa, when weight remained stable, restricting anorexic patients needed to consume a greater number of calories than patients with bulimic anorexia nervosa.[147] Differences in activity did not account for these findings, and bulimic anorexic patients were found to have similar or greater activity than the restricting group. As patients transition from a hypometabolic state to a hypermetabolic state during refeeding, daily caloric intake may need to be increased to as high as 3,500 to 4,000 calories.

The clinician should establish safe ranges for intake of both macronutrients and micronutrients. RDAs for various nutrients are found in Appendix Table A-8. Protein should constitute 20% of total calories, with minimum intake equal to the RDA in g/kg of IBW. Carbohydrates should account for 50 to 55% of total calories, and the clinician can encourage intake of fluids and water-insoluble fiber to treat the constipation that often accompanies refeeding.[82] Many patients with anorexia nervosa eat a relatively large quantity of fruits and vegetables; fiber in other forms, such as whole-wheat breads, cereal, or other grains, should be recommended. The last 20 to 30% of calories should come from ingestion of fat to provide sources of essential fatty acids; in teens ingesting few or no fat grams initially, the nutritionist can use a starting goal of 15% fat intake. This latter dietary change is often the most traumatic for the teen and should occur with a gradual, sequential reintroduction of the patient to "normal" eating. Expanded food selections should be encouraged, but the addition of a multivitamin mineral supplement providing 100% of the RDA for most micronutrients will help ensure an adequate nutrient intake. Iron-containing preparations may aggravate constipation,[82] but the clinician can counter this effect with use of sufficient fiber.

An easy way to communicate these calorie and nutrient requirements is through the use of a food plan. Food plans offer structure and help eliminate the binge, purge, and restrict patterns common to teens with eating disorders. Food plans allow the teen to eat mechanically until he or she is able reliably to recognize hunger and satiety signals.

It is important for the teen to be comfortable eating a wide variety of foods without any fear, guilt, or anxiety. "Forbidden" foods should be gradually reintroduced into the diet. With the help of a parent, creating a list of foods liked and disliked prior to the onset of the eating disorder can help determine whether a food is now avoided out of fear or is one that has always been disliked. It is useful to

TABLE 51.1-9 Nutritional Treatment for the Patient with an Eating Disorder during an Inpatient Admission

I. Initial caloric and protein requirement
   a. Calorie intake at 1,500 kcal per day (females), 1,750 kcal per day (males), until assessed by nutritionist
   b. Maintenance calorie range for weight gain on a long-term basis is determined by adding 500–1,000 kcal to the initial estimated caloric requirement. In some cases, higher calorie levels are necessary.
   c. Minimum protein intake range is per RDA for age based on minimum weight goal and ideal body weight.
   d. Micronutrient supplementation (daily multivitamin)
   e. Nutraphos, 500 mg orally twice a day for 5 d
   f. Maintenance fluid requirements

II. Nutrition monitoring
   a. Daily weight in a hospital gown after voiding: expect 0.2 kg/d weight gain
   b. Adequate caloric provision, with 30 min bed rest after each meal
   c. Increase calories by 250 calories until steady weight gain is achieved.
   d. Supplements: if < 0.2 kg gain after 2 d in hospital, 250-calorie supplements are given, starting with two supplements initially, to be treated as medicine (non-negotiable). Each day that weight goal is not met, an additional can is added.

III. Patient education

RDA = Recommended Dietary Allowance.

then develop a hierarchy of identified fear foods and begin reintroducing the least "scariest" foods first.

Vegetarianism is an easy way to justify the elimination of meats, which are often feared because of their fat content. Adherence to a vegetarian diet, if begun with the onset of the eating disorder, should be discouraged during the recovery process to facilitate an adequate nutrient intake and promote comfort with eating a wide variety of foods.

The refeeding process can cause discomfort with bloating, flatulence, constipation, or diarrhea. The dietitian or clinician should remind teens that these symptoms, although bothersome, will gradually resolve as their body adjusts to the changes they are making. Bloating and gas can be reduced by limiting gas-producing foods. Constipation can be corrected by consuming adequate calories and fluids, as well as more soluble fiber found in whole grains.

There are several dietary modifications to consider when refeeding teens with anorexia nervosa. Limiting raw high-fiber foods and consuming only a moderate amount of fat help promote gastric emptying. Eating foods cold or at room temperature helps reduce the feeling of fullness. Choosing to eat smaller, more frequent meals will reduce bloating. Restricting the use of caffeine, gum, sugar substitutes, and diet beverages will improve the teen's ability to recognize hunger and satiety. Calorie and fat gram counting should be discouraged, and access to scales should be limited or prohibited. Social eating should be encouraged, and time limits should be placed on mealtimes to prevent the teen from being at the table all day.

Interventions for teens with bulimia nervosa should focus on creating feelings of satiety and implementing a structured eating behavior pattern. Selecting hot or warm foods with adequate amounts of fat enhances feelings of satiety. Buying foods in single servings whenever possible and avoiding "trigger" foods initially will help control the urge to binge. Eating meals and snacks sitting down and selecting foods that require the use of utensils will slow down the rate of eating and increase satiety. Skipping meals, eating on the run, and eating secretly should be discouraged. Binge purge behaviors should be stabilized before assisting an overweight teen with weight loss. Other helpful hints can be found in Table 51.1-10.

Attention can be placed on the emotional state during a binge, when and where it occurs, and how hungry the teen is at the time. For instance, if a teen always binges on arrival home after school, the clinician can help identify triggers and explore possible solutions with the teen. If boredom is the trigger, filling the time with more structured activities will be helpful. Effective strategies also include disrupting the automatic behavior chain by entering through a different door and changing the order of activities, for example, checking electronic mail or calling a friend before snacking. Deciding on a snack in advance, encouraging the teen to put leftovers away after assembling the food, sitting down at a predetermined location, and eating without distraction (eg, never in front of a television or computer) will help prevent a binge. If a teen arrives home overly hungry, it makes eating a moderate amount of food nearly impossible. Therefore, encouraging an adequate intake of calories at breakfast and lunch is important in preventing binge eating after school.

For teens with secondary amenorrhea, resumption of menses often occurs as they improve fat intake toward a range of 40 to 60 g per day, although, anecdotally, menses may resume at lower intakes. Hence, if an adolescent girl has regained weight to that weight at which periods had ceased but remains amenorrheic, one intervention could be to increase fat grams to 40 to 60 g of fat per day, a task difficult for many of these patients.

In addition to the above guidelines and concerns, adolescent athletes may also have specific nutritional issues. For instance, much mythology exists about the pre-event meal and the pros and cons of carbohydrate loading. Short-term, high-intensity activities, such as sprinting, diving, or high jump, rely on anaerobic fuel sources. Longer-term activities of lesser intensity, such as long-distance running or cross-country skiing, require aerobic energy sources.[149] Activities

TABLE 51.1-10 Guidelines for Adolescents with Eating Disorders

Individualize treatment
Avoid discussing numbers such as weight and calories
Encourage variety of foods
Slowly incorporate unsafe foods
Avoid fat gram and/or calorie counting
Limit meal time to 20–30 min per meal
Encourage small frequent feedings
Avoid gas-producing foods
Avoid diet beverages, sugar substitutes, gum, and caffeine
If patient is not eating fat, start with 15% calories from fat
Use multivitamin supplement with calcium
Provide concrete ideas to facilitate changes in eating behavior patterns

such as tennis, basketball, and soccer use both. A high-carbohydrate diet promotes muscle glycogen storage, which, over time, can enhance endurance. Caloric requirements may be as high as 2,400 to 4,500 calories daily in the high school or college athlete,[8] whereas skilled competitive cyclists riding 19 hours a day may need as many as 9,500 to 14,000 calories per day.[150] The metabolism of additional carbohydrates may also increase requirements of thiamin, riboflavin, and niacin, but a well-balanced diet should supply sufficient amounts of these nutrients. Large doses of vitamins and minerals will not enhance muscle mass or performance.

A strong emphasis on competition can make young athletes vulnerable to nutrition misinformation and unsafe practices thought to enhance performance. During prolonged, strenuous exercise, carbohydrate supplementation has been shown to improve performance.[151] However, carbohydrate ingested prior to competition has not had an effect on performance and, in past years, has even been considered detrimental.[149] One study showed that pre-exercise candy bar consumption does not cause premature fatigue or decreased endurance.[152] In counseling teens on nutrition to optimize performance, emphasis should be placed on a healthful, balanced diet, with adequate calories and fluids to prevent dehydration and electrolyte imbalances. Carbohydrates should be ingested within 2 hours after prolonged, strenuous exercise and preferably within about 20 minutes because glycogen synthesis rates are 50% higher than at 2 to 4 hours after exercise.[151] Complex carbohydrates are preferred as they facilitate faster gastric emptying when ingested in high concentrations, they are associated with less gastrointestinal stress than found with simple sugars, and they contain fiber, vitamins, and minerals.[153–155]

In sports such as wrestling and lightweight crew, the clinician should use the preparticipation physical as an opportunity to educate and intervene in any unhealthful eating practices detected at that time. Wrestlers have been shown to use profuse sweating, diuretics and laxatives, and spitting into a cup to keep from swallowing saliva as added water weight.[156] Tcheng and Tipton have recommended a desired minimum range of 7 to 10% fat for wrestlers; the athlete should not be allowed to compete below the weight recommended by the physician.[157] The athlete should be asked about desired weight goals, dieting practices, and training activities, with nutritional guidance and appropriate interventions occurring before, during, and after the season as needed.

Teens who engage in weight lifting and similar activities should be discouraged from use of anabolic steroids or protein supplements. Strenuous physical activity does not increase protein requirements[158]; athletes can easily meet their protein needs by following a balanced diet.[149] The RDA for protein is 0.36 kg protein per pound of body weight for the average adult or adolescent athlete[159]; a total of 0.45 g of protein per pound is recommended for marathoners. Diets that provide more than 0.9 g of protein per pound of body weight have not been shown to increase muscle strength.[160,161] Dehydration in combination with use of protein supplements can compromise kidney function with the added load of nitrogen; with nitrogen excretion, further water is lost.[162]

Strenuous physical activity or intense training has been associated with anemia, which can impair performance. Contributing factors include marginal iron intake, increased iron losses, and increased destruction of erythrocytes with extreme exercise.[163] Screening with a yearly hemoglobin or hematocrit is warranted in teenagers engaging in competitive or strenuous athletics.[164]

CONCLUSION

Adolescents with eating disorders or those who participate in athletics can have specific nutritional needs, most of which can be adequately provided through a healthful, balanced diet. Clinicians and nutritionists can work with patients and families and within the community to target high-risk eating behaviors and to do preventive education. Nutritional education for coaches, parents, and other individuals involved in teens' lives and activities can be provided within the school setting, church, or community. Teens who are deemed to be at high risk can be referred to appropriate centers for further counseling and treatment.

CHAPTER 51.2

THE ADOLESCENT ATHLETE: PERFORMANCE-ENHANCING DRUGS AND DIETARY SUPPLEMENTS

Jordan D. Metzl, MD

Practitioners in pediatric nutrition are often faced with the issue of optimal nutrition in the adolescent athlete. As sports have become more competitive, this issue has become increasingly important to young athletes and their families. In certain instances, young athletes will turn to performance-enhancing drugs and dietary supplements in an effort to improve sports performance. For the health practitioner, knowing how and when to deal with these issues, especially in terms of potentially injurious substances such as anabolic steroids, is of tremendous importance.

Performance-enhancing drugs, also known as ergogenic aids, are designed to give athletes a chemically induced advantage in athletic competition. The thought of pediatric and adolescent athletes using performance-enhancing drugs, once used only on Olympic and professional levels, was previously inconceivable. As the nature of youth sports has changed, the need to win at all costs has created an environment that encourages the use of performance-enhancing drugs and dietary supplements in children and teens. Unfortunately, child and adolescent athletes are using ergogenic aids to chemically improve sports performance.

There are few safeguards to discourage children and teens from taking performance-enhancing drugs, whereas Olympic, collegiate, and professional athletes are routinely tested as a means of active discouragement. Because young athletes who use performance-enhancing drugs are often remiss in discussing these issues, knowing how, when, and where to address drug use is essential for pediatricians with athletic patients in their practices. Pediatric and adolescent athletes who take performance-enhancing drugs will rarely discuss these issues with their health care providers unless asked directly and even with direct questioning might be tempted to provide misinformation. The opportunities for meaningful intervention and prevention are few.

Performance-enhancing drug use in children and adolescents is of tremendous concern for both health and social reasons. From a health perspective, the effects of all performance-enhancing substances are not presently known in the pediatric and adolescent age group because none of these products have ever been tested in these groups. Neither short-term nor long-term effects of these products are known, and they are potentially harmful to young users. From a social perspective, the use of chemicals to enhance sports performance is against the very nature of healthful competition that youth sports are meant to encourage.

The effective education of young athletes who might be considering the use of performance-enhancing drugs is of paramount importance. The health practitioner who deals with the young athlete population should take aggressive measures to educate the athletic and parent community about the ill effects of many of the supplements that young athletes are using. This chapter examines the issue of performance-enhancing drugs in the young athlete and provides helpful ideas on how to recognize, counsel, and thoughtfully discourage use in the young athlete.

YOUTH SPORTS: CHANGING NATURE

The past 25 years have witnessed a significant change in the nature of youth sports. In the "old days," sports participation in young athletes was generally considered a pastime, a helpful way to encourage health and fitness in children and teens. Often this type of activity consisted of children playing on neighborhood sports teams, usually in local recreational leagues.

In the past 25 years, however, a youth sports explosion has changed the demographics of the young athlete population. These changes are most visible in three domains: gender, number of competitors, and the nature of competition. Spurred on by Title IX, a federal regulation passed in 1972 that guaranteed an equal ratio of scholarships for men and women at the collegiate level, there has been a substantial increase in the number of female athletes of all ages. Initially this was restricted to the collegiate level, but as the number of available college scholarships for female athletes increased, so did the number of female athletes on all levels. In 1972,

there were approximately 25,000 high-school female athletes; in 2000, there were more than 3 million.[1] Figure 51.2-1 illustrates these trends, including a dramatic increase in female athletes as well as an overall increase in high-school sports participation.

At present, there are more than 30 million children and teens under the age of 18 playing on some form of organized sports teams in the United States.[2] For pediatricians, the increasing number of young athletes has translated into an increase in the amount of sports medicine practiced in the pediatric office. This includes the evaluation of both medical and orthopedic issues related to the young athlete.

As the number and makeup of the young athlete population has grown, the very nature of athletic competition in children and teens has changed as well. The "win at all costs" mentality has become the norm in many youth sports leagues around the United States. Although competition is a favorable aspect of youth sports, excessive competition can have unfavorable manifestations in children and adolescents.

When winning is defined as the only acceptable outcome for athletes, this can encourage them to look for any available means of improving athletic performance. When winning is defined as the only goal of athletics, children and teens are most susceptible to using performance-enhancing drugs.

HISTORY OF PERFORMANCE-ENHANCING DRUG USE IN SPORTS

The issue of performance-enhancing drugs in sports is not a new phenomenon. In 300 BC, two competitors were barred from the first Olympiad in Greece because of illegal ingestion of animal protein.[3] As the technology and the science of performance-enhancing substances have improved over the past 2,000 years, so have the methods that athletes use to chemically improve sports performance.

Initially, professional and Olympic athletes used performance-enhancing substances primarily because they had the most to gain in terms of wealth and fame from athletic success. A survey published in *Sports Illustrated* in 1996 asked US Olympic athletes the question, "If you could take an undetectable performance-enhancing substance, win every competition for 5 years, and then die, would you?" More than 50% said "yes."[4] As performance-enhancing substances became more available, use was popularized in college athletics. More recently, high-school and junior-high athletes have admitted to taking performance-enhancing substances. Two studies have shown the user rate of anabolic steroids in the high-school athlete population to be approximately 10%.[5,6] A study published in 1998 found a 3.5% user rate for anabolic steroids in the junior-high population.[7] Clearly, the issue of performance-enhancing drugs, once confined to elite athletes, has trickled down to the youth sports world.

MAJOR CATEGORIES OF PERFORMANCE-ENHANCING SUBSTANCES

There are many categories of performance-enhancing drugs and dietary supplements. This section concentrates on several of the major categories of products used by adolescent athletes.

Anabolic Steroids

Anabolic steroid use is a major health risk to the adolescent athlete. As previously mentioned, the user rate of anabolic steroids in the male high-school athletic population is approximately 10%. Anabolic steroids were invented in the 1950s and use was popularized in the 1970s, mainly in Olympic and professional athletes.[8] Anabolic steroids are available in several forms, including oral, injectable, and topical. The most popular forms of these products include nandralone and methandrostenolone (Dianabol).

The biochemical basis for anabolic steroid effectiveness rests in the increased levels of testosterone that these products produce. Unlike pure testosterone, which causes a degree of secondary sexual characteristic growth, such as deepening voice and facial hair, roughly equivalent to anabolic effect on muscle, anabolic steroids are chemically altered testosterone derivatives that emphasize anabolic growth.[9] Anabolic steroids that have been developed thus far can only preferentially encourage anabolic effect but cannot totally isolate muscle and bone growth. Therefore,

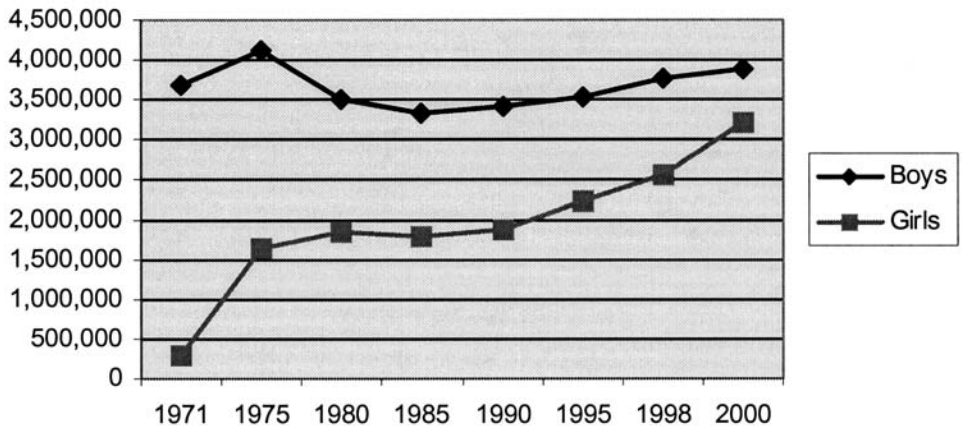

FIGURE 51.2-1 High-school sports participants, 1972–2000. Adapted from the National Federation of Youth Sports.[1]

users of anabolic steroids will show significant increase in muscle mass but will also show signs of secondary sexual characteristic development. The major effects of anabolic steroids are listed below.

- Increased muscle mass
- Hirsutism
- Deepened voice
- Acne
- Psychological lability ("testosterone rage")
- Increased risk of hepatic cancer
- Increased risk of cardiovascular disease
- Increased ratio of low-density lipoprotein to high-density lipoprotein
- Impotence

Physician Intervention Young athletes, both boys and girls, are using anabolic steroids. The active discouragement of anabolic steroid use is the responsibility of every health professional who encounters this issue. A helpful principle for the pediatrician to remember is that cases are rarely isolated. If one athlete on a team is implicated, chances are that teammates are aware of the problem and might also be using these drugs.

The keys to successful intervention in anabolic steroid use include a careful review of known side effects of these dangerous drugs and a discussion with the athletic director of the school where the athlete is participating. When the athletic department is involved in the active discouragement of use, there is generally much more success in addressing the problem.

A final point with regard to discouragement is the need to recognize that these products work. Anabolic steroids have been proven to increase muscle mass, so discouragement in the "just say no" model is generally ineffective.[10] Using an honest approach, admitting to the athlete that anabolic steroids do work but that the health risks are significant is the most effective method of discouragement.

Diuretics

Use of diuretics, including furosemide and hydrochlorothiazide, has been popularized primarily in wrestling, where rapid weight-loss practices—losing 5 to 10 pounds over several days to meet criteria for a certain weight class—have been a significant cause of concern. The exact user rates are not known, but the known side effects of diuretic use include rapid weight loss owing to diuresis and significant electrolyte abnormalities. In some episodes, these electrolyte abnormalities have led to fatal cardiac arrhythmia.[11]

The setting of wrestlers struggling to "make weight" is the most common scenario for the use of diuretics in sports. As is the case with anabolic steroids, these drug-use outbreaks generally occur in groups. Therefore, if a case of diuretic abuse is discovered, discussion with both the patient and the athletic community is required. Furthermore, a discussion with the athletic director at the local school is important to explain the dangers of unsafe weight-loss practices. The American Academy of Pediatrics has a helpful position statement on healthful weight-control practices in young athletes that can assist the pediatrician in providing guidelines for this discussion.[12]

The hallmark signs of diuretic abuse include excessive urination, rapid weight loss over a short period of time, and syncope owing to orthostatic hypotension. Unfortunately, cases of diuretic abuse are often discovered when the situation has become serious enough to draw a complication to medical attention. It is best to address the issues of safe weight loss with wresting teams before the season begins rather than wait for complications to occur.

Dietary Supplements

Dietary supplements are performance-enhancing substances that have become popular with pediatric and adolescent athletes for two main reasons. First, they are readily available and can be purchased in most health-food stores and over the Internet. Second, they are marketed as "safe and natural" ways to improve sports performance. With the Proxmire amendment of 1993, jurisdiction over the use of nutritional supplements was removed from the US Food and Drug Administration (FDA).[13] The nutritional supplement market has since exploded, with advertising campaigns targeted at young athletes. These campaigns have included professional athletes endorsing these products through direct campaigns, clothing, and commercials. Much like cigarette advertising campaigns of the early 1960s and 1970s, in which cigarette use was encouraged to promote health, vitality, and vigor, nutritional supplements have been promoted to the general population today with scant attention to scientific research or safety.

Despite protestations to the contrary, often from companies or scientists who produce these compounds, none of the nutritional supplements has ever been shown to be safe and/or effective in pediatric or adolescent subjects. Nutritional supplement use in young athletes is a significant health concern. There have been several cases in which supplements that were perceived to be "safe and natural" were found to be dangerous. The most recent case involved ma huang, a nutritional supplement that was very popular until 2000, when it was found to be the causative factor in 23 cases of death or permanent disability in a study performed over a 2-year period in California.[14] In addition, because the FDA does not regulate these products, there is no guarantee that the compounds listed on the bottle are the exact contents of the pills or tablets inside.

There are hundreds of nutritional supplements, and more are developed each year. None of these products are approved for use in pediatric or adolescent subjects. The next section discusses two popular products, creatine and androstenedione.

Creatine

Creatine remains the most popular nutritional supplement in young athletes, with sales of more than $400 million (US) yearly.[15] A recent study of 1,103 children and adolescents in grades 6 to 12 found that 5.6% of student athletes were using creatine, with a stated goal of improving sports performance in 75% of cases. In this study, users were

found at all grade levels, including sixth- and seventh-grade students.[16]

Creatine is a naturally occurring compound and is synthesized by the liver, kidneys, and pancreas. Creatine is also found in chicken, meat, and fish. The total daily requirement for creatine is 2 g.[17] When creatine loading, athletes routinely take three to four times the recommended daily amount. Creatine is thought to increase muscle strength in short bursts of activity in some athletes.[17] Thus far, there have been two reported cases of renal failure linked to creatine use, but the wider concern about unknown side effects in the future is a more significant cause for concern.[18,19] Because of the lack of any scientific data that support safety, the American College of Sports Medicine does not recommend creatine use in any adolescent under the age of 18 years.[20] Therefore, the pediatrician should discourage creatine use in any adolescent patient and should document in the medical record if this advice is given.

Androstenedione

Androstenedione, otherwise known as andro, is a "natural" supplement that was popularized in 1998 when professional baseball player Mark McGwire used the product to enhance strength during his home-run record-setting year. Androstenedione is a testosterone precursor, a step on the biosynthetic pathway of testosterone. In 1999, in the aftermath of the McGwire home-run controversy, Major League Baseball commissioned a study of the effects of androstenedione on serum testosterone concentrations. This study found that in doses greater than 300 mg/day, androstenedione was capable of raising serum testosterone levels.[21] The implications of this study are significant, particularly for the pediatric and adolescent user.

Androstenedione is a steroid precursor that raises the level of testosterone, a side effect that can have potentially significant complications, particularly for the preadolescent male and the postadolescent female. The preadolescent boy with exogenous amounts of testosterone added to his baseline testosterone level will begin puberty prematurely, thus effectively reducing adult height through premature physeal closure. In addition, concern about long-term testosterone production is also important for the prepubescent boy. The postadolescent female who uses this product exposes herself to increased amounts of androgen and can develop undesirable side effects, such as hirsutism and acne. Although androstenedione might produce increased amounts of skeletal muscle mass, the risks for children and adolescents are significant, and its use should be discouraged.

THOUGHTFUL DISCOURAGEMENT, THE KEY TO PREVENTION

Effective discouragement of the use of performance-enhancing drug and dietary supplements requires a well-founded argument to convince most adolescents to change their habits. For that reason, the best approach, *thoughtful discouragement*, requires the physician to give both pertinent advice to counsel the teen athlete against these potentially harmful products and healthful alternatives to drug use to help achieve improved strength and sports performance.

The first part of the solution to the issue of performance-enhancing drug use in pediatric and adolescent patients is recognition. Most adolescent athletes are remiss in admitting use of these substances to their pediatricians and will offer this information only when asked. This is most easily and naturally accomplished during the preparticipation examination with the addition of a simple question, "Are you using any substance to improve your sports performance?" This often leads to a broader discussion with the athlete and his or her family.

Once recognition of the problem is accomplished, the next step is educational. A well-known sports adage says, "The best defense is a good offense." This point is especially true concerning the prevention of performance-enhancing drug use in young athletes. As has been mentioned, the increasingly competitive climate of youth sports encourages the use of performance-enhancing drugs. Unlike at higher levels, where athletes are routinely tested for performance-enhancing drug use, the most effective means of discouragement in the adolescent athlete population is aggressive intervention with education, on both the personal and global levels. There has been recent discussion about the possibility of instituting drug testing in the adolescent athlete community as a means of discouraging use of performance-enhancing drugs. Although this might serve as a minor deterrent, the main approach to effective discouragement is education of the parent and athletic communities.

When faced with a young athlete who asks about performance-enhancing drugs in the office, discussing the most recent research and case reports on the side effects of these products, with mention of the lack of any significant information regarding product safety, is helpful. On a more general level, the pediatrician can make a significant difference by speaking to the athletic director or local school administrator and recommending that the school, and coaches, adopt a policy against use of any type of performance-enhancing product.

In the spectrum of performance-enhancing drugs, the pediatrician faced with an athlete who is using nutritional supplements such as creatine or androstenedione is placed in an especially difficult position. These compounds are perceived as safe and natural, and product use is sometimes encouraged by various factions, including coaches, trainers, or fellow athletes. The effective discouragement of use in the adolescent athlete is often difficult. Encouraging patients who are taking performance-enhancing drugs, and particularly nutritional supplements, to seek consultation with a sports nutritionist who is well versed in pediatric sports nutrition can encourage healthful caloric intake to maximize muscle growth.

Finally, recognizing that athletes who are taking performance-enhancing drugs are doing so to improve strength and sports performance, pediatricians need to provide an alternative to drug use for children and adolescents. Rather than using discouragement alone—the "just say no" approach—it is essential to offer a healthful alter-

native for increasing muscle strength. This lies in the form of pediatric strength training. Endorsed by organizations such as the American Academy of Pediatrics and the American College of Sports Medicine, strength training in children as young as 8 years is a safe and effective method of increasing baseline strength and improving athletic performance.[22] The program should be supervised and needs to emphasize repetition rather than maximum weight lifting, but the results can be tremendously gratifying for children and teens and can include a baseline strength increase of 30 to 40%.[23]

CONCLUSION

The use of performance-enhancing drugs in young athletes is an issue that is important for pediatricians and nutritionists to address with their athletic patients. This is particularly important in today's youth sports climate because increasing competitiveness encourages the use of performance-enhancing drugs to help athletes gain an advantage. Recognition of performance-enhancing drug use is most effectively accomplished during the preparticipation examination. Once the issue of performance-enhancing drug use is identified, thoughtful discouragement is the most effective method of intervention. This involves a combination of individual and local education and the encouragement of alternative methods of increasing baseline strength, such as strength training. If these steps are taken, pediatricians can make a significant difference in the health and safety of the young athlete and can better serve their athletic adolescent patients.

CHAPTER 51.3

ADOLESCENCE: BONE DISEASE

Keith J. Loud, MD, CM, Catherine M. Gordon, MD, MSc

Adolescence is a critical period for lifetime bone health. Evidence has accumulated that an individual's peak bone mass (PBM), which is the strongest predictor of his or her future risk of osteoporosis, is reached by early adulthood. At least half of all adult mineralized calcium is laid down during the adolescent years, with the most rapid bone accretion occurring in late childhood and early adolescence.[1,2] Any condition that impairs this process may create a deficit in bone mass that will have permanent ramifications for future risk of osteoporosis, which afflicted over 10 million Americans and cost more than $15 billion in direct medical expenditures just for fracture care in 2001.[3]

Unfortunately, there are several disease states, each related to nutritional deficits, that can inhibit bone accretion at this crucial time, including rickets, anorexia nervosa (AN), the "female athlete triad," inflammatory bowel disease (IBD), celiac disease, and cystic fibrosis (CF). In this section, these conditions are discussed in detail. Adolescence itself may also prevent maximal PBM attainment as the dietary habits of many modern teenagers do not optimize calcium and vitamin D intake.

NORMAL BONE PHYSIOLOGY AND DEVELOPMENT

Bones are the fundamental units of the skeletal system, providing an adaptable frame that supports and protects the major organ systems of the body while allowing for locomotion. Because of its role in calcium and phosphate homeostasis, bone can also be considered an organ system. The skeletal system is the reservoir for the calcium used in essential mechanisms ranging from the regulation of cardiac electrical activity, contraction of muscles, and varied inter- and intracellular messaging systems. Each bone, housing lymphoid and myeloid precursor cells within the marrow, is also an organ unto itself. Finally, these organs are composed of a unique tissue substance that is once again called "bone."

Types of Bone

Bone, as a tissue, takes on two forms in normal health: cortical (dense) and trabecular (cancellous or spongy) bone. Cortical bone, which makes up 80% of the skeletal bone mass, is found in the diaphysis (shaft) of long bones such as the femur, as well as the "walls" of almost all other bones, including the vertebrae. It provides strength against tensile, torsional, and shear forces. The remaining 20% of bone mass consists of trabecular bone, found in the metaphyses (ends) of long bones and the entire bodies of the vertebrae. It is well suited to resist compressive forces. Because of its high surface area-to-volume ratio, trabecular bone occupies greater than 20% of the volume of the skeletal system and has approximately eight times the metabolic activity of cortical bone.[4] Owing to its higher metabolic availability, trabecular bone is more significantly affected by disease states.

Histology: The Building Blocks of Bone

Regardless of its structure or ultrastructure, on a microscopic level, bone consists of thin layers, or lamellae, of a mineralized protein matrix. This mature lamellar bone is 70% (by dry weight) mineral, predominantly calcium and phosphate in the form of hydroxyapatite crystals [$Ca_{10}(PO_4)_6(OH)_2$] and a less pure, carbonate-rich analogue called bone apatite, which is more soluble and thus more available for metabolic activity. The remaining 30% of the mass is an organic substance called osteoid, primarily protein in the form of type I collagen. Cellular elements, which produce all of the metabolic activity of bone, make up only 2% of the osteoid.

Osteoblasts are bone-forming cells derived from fixed-tissue osteoprogenitor cells. Osteoblasts synthesize osteoid on the surface of already mature lamellar bone, periosteum, or endosteum. They then regulate the process of mineralization of the collagen matrix through the actions of bone-specific alkaline phosphatase (BSAP), which is different from the alkaline phosphatase produced in the liver and can be distinguished from it by special assays.

Once the osteoid matrix has mineralized, it is considered bone. The osteoblasts, which are synchronized in such a way as to create the parallel lamellae, become trapped inside small caverns called lacunae and mature into osteocytes that communicate via long processes with each other to direct mineral homeostasis.

Osteoclasts are multinucleated cells from the marrow monocyte-macrophage cell line. Producing lysosomal enzymes such as acid phosphatase, osteoclasts break down the mineralized bone matrix, mobilizing calcium and phosphorus for participation in homeostasis, in a process called bone resorption.

Growth and Remodeling: Bone Cycle

Bone is a dynamic tissue. Growth in long bones occurs at the physes (growth plates) and apophyses (secondary centers of

ossification) by a process known as enchondral ossification in which osteoblasts lay down bone on a cartilaginous framework that is ultimately resorbed by osteoclasts. Even after skeletal maturity, osteoblasts respond to structural stresses in bone by laying down new matrix. Osteoclasts concomitantly resorb areas of bone under less stress. Thus, bone is constantly remodeling. At times of growth, bone formation by osteoblasts is greater than resorption by osteoclasts. With disuse, osteoclasts outpace osteoblasts and bone mass decreases. Otherwise, osteoblasts and osteoclasts are tightly "coupled" to keep formation and resorption equally balanced in what is known as "the bone cycle."[5]

Importance of Adolescence

Bones grow at different rates throughout the skeleton. The extremities (appendicular skeleton) have largely completed growth by the time of the pubertal growth spurt (peak height velocity [PHV]). Increases in estrogen and testosterone during puberty result in growth of the trunk and spine (axial skeleton). These increases in vertebral bone size are accompanied by dramatic increases in bone mineral density (BMD) in cross-sectional studies.[6,7] This trabecular bone reaches its peak BMD by age 20 to 30 years but steadily declines thereafter.[8] Alarmingly, one animal model showed that calcium restriction in adolescence resulted in a decreased bone volume throughout life, even after restoration to recommended calcium intake in young adulthood.[9]

Adolescence is an essential time for significant bone accretion. Over half of adult bone calcium is laid down during the teenage years.[1] Maximal rates of bone mineral accretion follow PHV by 6 to 12 months.[10–12] As a consequence, at the time of PHV (Tanner pubertal stage II–III in girls, Tanner stage III–IV in boys), teenagers have reached approximately 90% of their adult height but have acquired only 60% of their adult total-body mineral content, resulting in relatively less mineralized bone.[11] In North America, these pubertal stages are reached by age 11 to 14 in girls and 13 to 17 in boys. Studies by Thientz and colleagues are consistent, showing that girls' BMD may plateau by age 16 (or 2 years postmenarche) and boys' BMD by age 20.[2] This is a much earlier window of opportunity than was previously suspected. In fact, 95 to 100% of PBM may be attained by the end of adolescence.[13,14]

Factors Affecting Bone Health

Genetics Intrinsic factors dominate the determination of bone density (Figure 51.3-1). Males have a higher bone mass than females at nearly all ages.[8] Black children demonstrate an approximately 10% higher BMD by dual-energy x-ray absorptiometry (DXA) than do children of other ethnicities,[15] even after correcting for bone size.[14] An interesting finding among black and white girls was that their spinal BMD was similar until puberty, at which point the black girls had an increase of 34%, whereas the white girls improved only 11%.[16] Family history of osteoporosis in postmenopausal women predicts lower BMD for their daughters,[17] and both elderly men and women have an increased risk of osteoporosis when other family members have been affected.[18] In all, 60 to 80% of the variance in PBM is attributed to heritable factors.[8] Polymorphisms in the genes encoding receptors for vitamin D,[19] estrogen, type I collagen,[20] insulin-like growth factor I (IGF-I), transforming growth factor β, and interleukin-6 (IL-6) are being studied,[21] but none have been able, singly or in combination, to account for more than a small percentage of this variance in PBM.

Hormonal Status A normal hormonal milieu is essential to attain and maintain normal bone formation. Early menarche and regular menses are strong predictors of increased bone mass in women,[22] demonstrating the importance of estrogen. Among adolescent girls, an estimate of estrogen exposure was positively correlated with spine BMD.[8] Estrogen deficiency may also slow growth in axial bone size when it occurs during adolescence, a time when truncal growth typically accelerates.[23–25]

Androgens exert independent and positive effects on PBM.[26] Men with a history of delayed puberty[27] or documented low serum androgen levels[28] have been shown to have decreased BMD. Testosterone replacement over 18 months normalized BMD rapidly in a study of men with

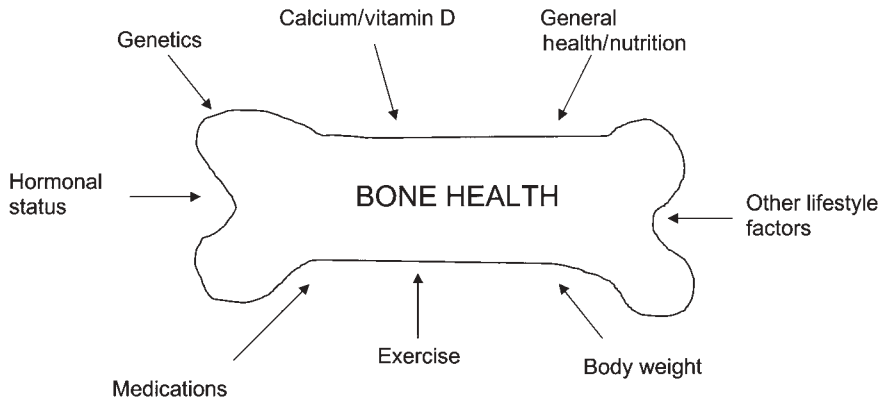

FIGURE 51.3-1 Factors affecting bone health. Reproduced with permission from Loud KJ, Gordon CM.[169]

acquired hypogonadism.[28] Patients with androgen insensitivity have a mutation in the androgen receptor, with consequent impaired androgen action, such that there is resistance to even elevated androgen levels. Previous reports have shown that affected individuals have decreased bone mineralization.[29–31] Even after administration of estrogen replacement therapy (ERT) in these individuals, BMD did not significantly increase, again highlighting the importance of androgens in bone physiology.[29] Women with androgen excess also have been shown to have a higher BMD.[32,33]

Children and adults with childhood-onset growth hormone (GH) deficiency have lower BMD than controls.[34,35] Studies have shown that patients on adequate replacement doses of GH have increased BMD compared with GH-deficient patients,[36,37] although young adults who had received GH replacement during childhood but who discontinued the medication at the completion of linear growth demonstrated decreased spine and hip BMD in long-term follow-up.[8] The actions of GH are likely mediated by IGF-I, an anabolic factor that stimulates osteoblast function directly.

Exercise Patients with impaired activity owing to central nervous system or neuromuscular disease develop disuse osteoporosis.[38] Several studies now suggest that individuals engaged more intensely in weight-bearing activities have higher measured BMD than less active controls.[39–43] Even among women with amenorrhea, those who are more athletic have higher bone density.[44] Unfortunately, swimmers do not consistently reap this benefit as their activity is largely weightless, highlighting the importance of weight-bearing activities.[45] The increases in BMD are site specific; for example, runners and ballet dancers have higher proximal femur (hip) BMD than controls, whereas gymnasts have higher measured radial (arm) BMD.[46] These gains in BMD persist years after these athletes have retired from sports.[47–49] Intervention trials have not consistently duplicated these findings but have been hampered by the relatively small sample sizes and the short duration of these studies.[50]

General Nutrition and Health In addition to participating in weight-bearing exercise, individuals must maintain appropriate weight. At most weights, there is a direct relationship between body mass index (BMI) and BMD, with underweight individuals at increased risk for lower BMD.[51] Adolescent girls with low weight owing to AN have decreased BMD, as discussed below. Excessive BMI may also have a deleterious effect on BMD. A case-control study of boys found that those with distal forearm fractures had an increased prevalence of obesity (BMI > 85th percentile for age) and a lower BMD than age-matched controls.[52] These associations were hypothesized to be attributable to the increased adiposity of the overweight boys.[52]

The carbohydrate, fat, and protein macronutrients are essential to provide the building blocks for growth and attainment of appropriate BMI to maximize BMD. These nutrients also provide energy for the muscle contractions that mechanically load bone, thereby stimulating bone formation. In addition, lipids are substrates for the synthesis of prostaglandins, which are cytokines that may play an essential role in regulating bone metabolism.[53] Proteins are particularly important as the fundamental elements of muscle tissue, as well as the predominant components of osteoid, the unmineralized precursor to bone. In one study, protein intake and bone mass gains were positively correlated in children, possibly mediated by IGF-I production,[54] although ongoing research continues in this area.

Other nutrients with putative, but not studied, influences on bone density include magnesium, phosphorus, copper, manganese, zinc, and vitamins C and K. Approximately 60% of the body's magnesium and 85% of the phosphorus are in bone. Magnesium may decrease the brittleness of bone by modulating the size of hydroxyapatite crystals. The other minerals and vitamins are important cofactors in the synthesis, folding, and cross-linking of the proteins found in bone, including collagen, elastin, and osteocalcin.[53]

Medical conditions that impair bone density are shown in Table 51.3-1. Many of these act by causing malnutrition, with concomitant decreases in BMI and absorption of important nutrients. Some are described in detail later in this section. Tobacco (by decreasing osteoblast function)

TABLE 51.3-1 Conditions Predisposing to Osteoporosis in Children and Adolescents

Chronic illnesses Mechanisms = malnutrition, cytokines, endocrinopathies, medication effects, decreased activity	Inflammatory bowel disease (Crohn's disease, ulcerative colitis), celiac disease, asthma, chronic renal failure
Organ transplantation Mechanisms = malnutrition, cytokines, immunosuppression, endocrinopathies, medication effects, decreased activity	Bone marrow, heart, lung, kidney, pancreas, liver
Endocrine abnormalities	Genetic sex hormone deficiency, Turner's syndrome, acquired sex hormone deficiency, anorexia nervosa, exercise-induced amenorrhea, premature ovarian failure, irradiation, chemotherapy, other endocrine abnormalities, Cushing's syndrome, hyperparathyroidism, hyperthyroidism, growth hormone deficiency, hyperprolactinemia, diabetes mellitus
Medications	Corticosteroids, anticonvulsants, cyclosporine A, lithium, gonadotropin-releasing hormone agonists, heparin, methotrexate
Family history	Osteoporosis, frequent fractures
Female athlete triad Definition = disordered eating, amenorrhea, and osteoporosis	Any female athlete, but particularly those in activities that emphasize lean physique
Prolonged immobilization	

and excessive alcohol use increase the risk of lower BMD in young women, although these factors have not been thoroughly studied in younger adolescents.[55]

Calcium and Vitamin D As described above, bone is a calcified tissue that derives its compressive strength from its calcium-phosphate crystal structure and, in turn, serves as the body's vast reservoir of calcium. Enormous gains are made in total skeletal calcium over childhood and adolescent development, from approximately 25 g at birth to 900 (females) to 1,200 g (males) at skeletal maturity.[10,12] It follows that calcium is an essential nutrient for skeletal as well as general health. Dairy products are an important source of dietary calcium, providing approximately 75% of the calcium in a typical North American diet.[53] Epidemiologic data suggest that osteoporosis is more prevalent in regions where dairy intake is low and that milk consumption in childhood and adolescence correlates with postmenopausal BMD.[56–59] There is some evidence that calcium is a necessary, but not sufficient, element for bone accretion. In one study, women consuming greater than 1,000 mg of calcium daily made no significant gains in their BMD if they did not concomitantly increase their activity patterns.[60]

Vitamin D is the important partner of calcium in dairy products. The active form of vitamin D, 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], is necessary for normal mineralization of bone. In addition to being absorbed though the gut, vitamin D is also synthesized endogenously in the skin under the influence of ultraviolet sunlight. It is converted to 25-hydroxyvitamin D [25(OH)D] in the liver and then to 1,25$(OH)_2$D in the kidney. Activated 1,25$(OH)_2$D facilitates absorption of calcium and phosphate from the duodenum and jejunum, as well as reabsorption of calcium from the renal tubules. At high levels in the serum, it can stimulate osteoclasts to resorb bone, but this action is mediated via receptors on osteoblasts.[61]

Vitamin D deficiency has been clearly linked to fractures in postmenopausal and osteoporotic women.[62,63] Plasma 25(OH)D levels, the most sensitive clinical index of vitamin D status, are positively correlated with BMD in middle-aged and elderly women.[64,65] Even serum 25(OH)D levels in a range suggesting subclinical vitamin D deficiency are associated with a reduced bone mass.[63] Seasonal variation of vitamin D metabolites, with high summer/fall and low winter values, has been established in adults and is generally more pronounced in northern latitudes, where there is reduced cutaneous production of vitamin D for up to 6 months of the year.[66–72] Some, but not all, studies have indicated a similar seasonal difference in BMD.[73–76,77] In postmenopausal women with low intakes of vitamin D, BMD significantly decreases in winter, which can be prevented by vitamin D supplementation.[76]

The effects of calcium and vitamin D are difficult to separate. When calcium intake is sufficient, non–vitamin D–dependent passive absorption predominates. However, in the face of low calcium intake, vitamin D–dependent active transport becomes the major route for calcium absorption. Thus, the effect of vitamin D deficiency on calcium bioavailability is critical when it coexists in the setting of low dietary calcium intake.[78,79] Fortunately, such a deficit can be easily treated, and the incidence of fractures possibly decreased, with combined vitamin D and calcium supplementation.[80–83]

NUTRITIONAL INFLUENCES ON BONE ACCRETION IN ADOLESCENCE

CALCIUM

Although calcium intake would be a seemingly obvious factor promoting increased BMD, the literature is not uniform. In growing children, the influence of calcium availability on gains in bone density has been demonstrated. Dietary calcium is one of the most significant predictors of bone mass in cross-sectional studies of children and adolescents.[84–86] Controlled supplementation trials in healthy children and adolescents, including twin studies, have generally shown increased gains in BMD in at least some subgroups of those supplemented with calcium, milk extract, or dairy products.[87–94] However, the response to calcium varied among studies with respect to skeletal site, pretreatment calcium consumption, pubertal stage, and genetic factors.[50] There is also uncertainty in how well the gains are maintained after supplementation is discontinued as only one of the studies demonstrated persistence of the increase more than 1 year later.[95] This is an area of ongoing study, but the available data on potential benefits justify endorsement of the recommended daily intakes, for adolescents, in the range of 1,300 mg of elemental calcium (Table 51.3-2).

VITAMIN D

In a study of hospitalized adults, Thomas and colleagues reported that 57% of the men and women screened were vitamin D deficient on serum testing.[96] Research in Scandinavia has shown that dietary intake of vitamin D in children, even when combined with vitamin stores from the

*AI: Adequate Intake: used if sufficient scientific evidence is not available to derive a Recommended Daily Allowance (RDA).

summer, is not sufficient to sustain healthy vitamin D levels during the winter.[97,98] The prevalence of vitamin D deficiency among otherwise healthy American adolescents is currently unknown. A concern is that vitamin D deficiency can result in an increase in the bone remodeling rate, which could impair bone density achievement during skeletal growth.[99]

Dietary vitamin D intake of some of the patients identified as deficient in the Thomas and colleagues study exceeded the Recommended Daily Allowance (RDA), and many had no apparent risk factors for vitamin D deficiency. To address this issue, investigations are ongoing into the mechanisms of vitamin D action. One such area is the role of the vitamin D receptor gene in calcium absorption and bone mass accretion. One study noted a significantly lower spinal BMD in girls with a homozygous recessive (BB) genotype at one restriction site when compared with heterozygous (Bb) or dominant (bb) genotypes.[100] Thus, alleles for this receptor may influence an individual's response to calcium intake and other environmental factors.

Disturbances in Adolescent Nutrition with Implications for Bone Health

General Nutrition It should be remembered that rates of gastrointestinal calcium absorption and urinary excretion significantly influence the bioavailability of calcium. Foods high in oxalic acid such as spinach, beans, sweet potatoes, and rhubarb, which are not typically major components of the average teenager's diet, may inhibit calcium absorption.[53] Otherwise, calcium absorption is relatively high and excretion relatively low in adolescents when compared with adults. The typical adolescent's high-salt diet may negate this advantage, however, as each gram of urinary sodium excretion obligates a loss of 26 mg of urinary calcium.[101,102]

Dairy Intake A survey in the United States showed that although adolescents overwhelmingly (> 90%) believed that calcium is healthy and important for bones, few (19%) were aware of the RDA for calcium and even fewer (10%) knew how to meet this goal with dairy products.[103] It is not surprising, therefore, that less than 16% of adolescent girls in the United States meet the Dietary Reference Intake (DRI) of calcium of 1,300 mg/day.[104–106] The mean calcium intake for girls aged 9 to 13 years is approximately 890 mg/day, or 69% of DRI; this value drops to approximately 710 mg/day, or 55% of DRI, in 14- to 18-year-old girls.[53] Similarly, mean magnesium intake is approximately 93% and 60% of the RDA for the respective age groups, probably largely owing to lack of dairy consumption.[53]

Carbonated Beverages Wyshak and Frisch have shown that consumption of carbonated beverages, particularly cola (phosphoric acid–containing) drinks,[107] in teenaged girls may be associated with increased risk of bone fractures.[108] The association was not found to hold for teenaged boys.[107] The pathophysiology is not completely understood but is felt to be attributable, in large part, to the substitution of carbonated beverages for milk. Cola drinks may be particularly implicated because they create a high phosphoric acid load, which both chelates calcium and may increase parathyroid hormone (PTH) secretion. High intake of calcium was protective in the study,[107] but it is noted that between 1970 and 1997 in the United States, per capita consumption of carbonated beverages increased by 118% at the same time consumption of milk declined by 23%.[109]

BONE DISEASES

Osteomalacia

Rickets, or vitamin D–deficient osteomalacia, is a classic example of the detrimental effect of malnutrition on bone and continues to be a problematic condition for growing children in North America and worldwide. Evidence is beginning to accumulate that vitamin D deficiency may be prevalent among American adolescents and young adults, particularly those who live in northern latitudes.

Low levels of $1,25(OH)_2D$ lead to low levels of serum calcium, which stimulates PTH secretion. Under the stimulus of PTH, osteoclasts increase the rate of bone resorption to maintain calcium homeostasis. Osteoblasts respond to the increased osteoclast activity by increasing osteoid formation. Owing to the relative lack of calcium and phosphate, this osteoid is poorly mineralized. As a consequence, vitamin D deficiency impacts negatively not only on trabecular bone, which is more hormonally responsive and more commonly affected by such deficiencies, but also on cortical bone.

In addition to poor dietary intake, vitamin D deficiency can be caused by inadequate exposure to sunlight. Anticonvulsants cause increased hepatic breakdown of vitamin D. Patients with renal disease may have decreased activation of 25(OH)D to $1,25(OH)_2D$, in addition to increased tubular losses of calcium and phosphate. Use of aluminum-containing antacids impairs phosphate absorption. Other gastrointestinal conditions also impair absorption of vitamin D, calcium, and phosphate, as will be described.

Clinical manifestations of rickets in skeletally immature children include flaring of the metaphyses and growth retardation. In skeletally mature adolescents and adults, findings are more subtle, including bone pain, susceptibility to fracture, and pseudofracture. Serum levels of 25(OH)D are a reliable measure of total vitamin D stores. However, the desirable level for 25(OH)D, including what constitutes the threshold stimulus for rises in PTH, is a subject of debate.[78,83,98] Recent data by Haden and colleagues showed that PTH levels start to increase at a 25(OH)D level of 25 ng/mL, higher than the threshold of 12 to 15 ng/mL previously established for vitamin D deficiency.[110] Treatment consists of ensuring adequate dietary intake of vitamin D, with supplementation as necessary. A commonly prescribed replacement dose for adolescents and young adults with rickets is ergocalciferol (vitamin D), 2,000 IU by mouth once daily. Parenteral weekly dosing of 50,000 IU intramuscularly is also used but must be undertaken cautiously, with assurance of

adequate calcium intake and appropriate monitoring of vitamin D and PTH levels.

Osteoporosis

Definitions In contrast to *osteomalacia*, which refers to a condition in which the bone matrix is poorly mineralized regardless of the actual mass of bone tissue produced, *osteoporosis* is defined as a systemic skeletal disease characterized by low bone mass and microarchitectural deterioration of bone tissue, with a consequent increase in bone fragility and susceptibility to fractures.[111] A related term, *osteopenia*, is used to describe a significant reduction in bone mass for age and sex. In each of these conditions, the osteoid is mineralized normally to form calcified bone, but there is less of it and its structural arrangement is abnormal.

Diagnosis Adult osteoporosis is defined by the World Health Organization (WHO) as a BMD below 2.5 standard deviations from the mean peak BMD attained for gender (ie, *t*-score < –2.5) as measured by DXA. Osteopenia is the term reserved for BMD with a *t*-score between –1.0 and –2.5.[112] Using these definitions, DXA scanning has become the gold standard for diagnosing abnormalities in bone tissue in adults. Unfortunately, these WHO definitions currently exist only for postmenopausal women and are not available for children and adolescents.

Dual-Energy X-Ray Absorptiometry DXA uses x-rays of two differing photon energies passing through the body to a sensitive detector. The beams are attenuated differentially depending on the tissues through which they pass. A computer then calculates body composition, bone mineral content (BMC), and BMD based on the attenuation. DXA scanners report BMC in grams of mineralized calcium and BMD in grams per area of bone region in squared centimeters (g/cm^2). Advantages of DXA scanning include relatively rapid scanning times (approximately 5 minutes for each scan), low levels of radiation exposure (one-tenth the radiation of a chest radiograph), and precision in the range of 1%. For these reasons, DXA can be used in children, with reliable normative data available consistently by 8 years of age, with some databases including children as young as 4 years.[113]

Limitations of DXA for Adolescents The major limitation of DXA is that it uses a two-dimensional technique to quantify a three-dimensional structure. Density is, by definition, a measure of mass per unit volume. The BMD reported by DXA scanners is areal, or per unit area in g/cm^2. The significance of this calculation is more than academic as the mechanical properties of bone are dependent on its architecture and geometry, as well as its composition. Good mathematical models have been developed to calculate approximate volumetric BMDs known as bone mineral apparent densities in g/cm^3, although their prognostic value is not well established.[114]

These limitations of DXA are more significant in adolescents. First, not all DXA scanners are equipped with the proper software to evaluate pediatric body composition and, therefore, BMD. Even comparing a single adolescent with himself or herself on a single machine with reliable pediatric software is subject to flaws. Presumably, one could measure serial DXA scans over time to assess the effect of a disease state or treatment on BMD. Unfortunately, the growth of the child complicates interpretation. To illustrate, consider quantifying the density of a tree trunk by measuring the shadow cast by the tree in the sun. After 1 year of growth, the tree trunk casts a wider (and perhaps darker) shadow, but it may be no denser than it was previously. Using DXA, the "shadow" or areal BMD (aBMD) of this tree would be reported as greater than it was the previous year. The same phenomenon occurs when measuring a growing child's bones. The opposite phenomenon, that of a growing child's measured aBMD remaining constant, should therefore appear ominous to the clinician. Unfortunately, limitations on the actual scores reported for BMD do not allow the clinician to quantify the degree of risk. Fortunately, bone grows stronger as it increases in diameter, even at the same BMD.[115]

As mentioned, interpreting even reliable values for BMD is challenging. The *t* (or standard deviation) score, which compares an individual adult's BMD to the mean peak BMD (or PBM) attained by young adults of the same gender, provides a valid estimate of the risk of fracture for that adult. The z-score compares an individual's BMD to the mean BMD (in standard deviation units) for his or her age and gender, which is useful to grade patients with respect to their peers but has no prognostic significance. Reliable pediatric databases report *t*- and z-scores, but the *t*-scores are not informative as most children and adolescents have not reached their peak young adult BMD. Uniform definitions of osteoporosis or osteopenia based on z-scores do not yet exist. Furthermore, as bone mass accretion is strongly influenced by Tanner stage, which does not directly correlate with chronologic age, comparing BMDs based on age alone may be problematic. Finally, most databases include predominantly or exclusively white populations, which makes the interpretation of BMD data more difficult for patients of different ethnic groups.[113]

Other Imaging Techniques Quantitative computed tomography is a technique of bone densitometry that can generate measures of bone volume and thus a more accurate volumetric BMD. Pediatric algorithms are available, but the increased time required and significantly increased radiation doses limit its use in this age group. A newer technology, quantitative ultrasonography, shows promise as it has no associated radiation exposure and has been validated in Israeli and Korean adolescents with reasonable precision.

Serum Markers Bone turnover markers are used infrequently in the assessment of metabolic bone disease, primarily for research purposes, to gauge the relative contributions of bone formation versus bone resorption in the bone remodeling cycle. Some endocrinologists also use them to monitor treatment response. Serum alkaline phosphatase levels, particularly BSAP, reflect osteoblast func-

tion, as does serum osteocalcin, an osteoblast-specific product. Serum tartrate-resistant acid phosphatase is an osteoclast equivalent for BSAP, whereas collagen type I cross-linked N-telopeptide (NTx), which, as a breakdown product of bone, reflects osteoclast activity and can be measured in the urine. Adult studies have shown these markers to be inferior to bone densitometry for diagnosing osteoporosis and monitoring skeletal health, and pediatric reference ranges are limited as growth, puberty, and diurnal cycling cause wide variation in these values.

NUTRITIONAL DISEASE STATES ASSOCIATED WITH OSTEOPOROSIS

Anorexia Nervosa

Patients with AN are at risk for profound deficits in BMD that are often irreversible, even with a return to appropriate weight. Previous research has shown that patients with chronic AN have a sevenfold increased incidence of fractures and are at increased risk for developing early osteoporosis.[116–120] Because the incidence of anorexia increases during the years of attainment of PBM, the lifelong impact on skeletal health in maturity is particularly concerning. The mechanisms of this bone loss are certainly related to decreased dietary intake of calcium, vitamin D, and other macronutrients. Women with AN also develop hypothalamic amenorrhea, which results in low circulating levels of estrogen.

It is hypothesized that estrogen helps regulate bone mass by impairing osteoblast-mediated bone resorption. Oral contraceptive (OCP) use by young women with AN was shown in a retrospective cross-sectional study to be associated with a higher BMD.[121] In a small pilot study of women with AN and hypothalamic amenorrhea, ERT resulted in increases in BMD.[122] Unfortunately, ERT alone has not consistently been shown in other controlled studies to be able to reverse the bone loss in patients with AN, with the possible exception of those most profoundly affected (below 70% of ideal body weight).[123] Despite the fact that its effects on bone accretion have been disappointing, ERT remains one of the standard therapies used to help maintain skeletal health in patients with AN,[124] along with psychological support. Ultimately, nutritional rehabilitation and weight restoration are necessary to return menstrual function, circulating estrogen levels, and bone formation to normalcy. Even prior to attainment of menstrual regularity, however, bone density increases with weight gain in adolescent girls with AN.[125]

It has been suggested that bone formation is more profoundly decreased than resorption is increased in patients with AN.[118] This "uncoupling" of the normal bone cycle has led investigators to address both sides of the formation-resorption dyad.[120,126–128] Serum levels of IGF-I have been found to be decreased in patients with AN.[128] Short-term randomized controlled trials of IGF-I administration showed significant increases in bone formation in patients with AN, with greatest improvement in those also given OCPs, arguing for a synergistic effect between ERT and IGF-I.[129,130] Unfortunately, use of this agent in children and adolescents may be limited owing to its availability only as an intravenous or subcutaneous preparation. Longitudinal data are also awaited to determine long-term efficacy.

Nutritional Supplements: Dehydroepiandrosterone Like IGF-I, levels of the adrenal steroid dehydroepiandrosterone (DHEA) are low in patients with AN.[131–133] DHEA is positively correlated with BMD in adults and parallels the pattern of bone accretion in that secretion of DHEA peaks during the same adolescent years as bone mass acquisition accelerates.[131,134–141] DHEA is thought to increase levels of IGF-I, thereby increasing bone formation by stimulating osteoblasts, and also decreases mediators of osteoclast-mediated resorption.

Recent studies of administration of short-term oral DHEA, which is currently sold as a nutritional supplement, in adolescent girls with AN have shown that this agent is well tolerated. The adolescents who were given DHEA showed significant decreases in concentration of NTx, a marker of bone resorption, and increases in osteocalcin, a marker of formation.[142] The effect of DHEA on BMD in these patients is still under study. Because it is unregulated by the US Food and Drug Administration, DHEA is widely available, but it is potentially unsafe, depending on the preparation and dosing. For both of these reasons, DHEA cannot be recommended at this time as a therapy for patients with bone loss secondary to AN.

The Female Athlete Athletic participation has become increasingly common among adolescent girls since the enactment of Title IX of the Educational Amendments Act in 1972, which required women's intercollegiate athletic offerings to be proportional to their representation in the student body. As noted previously, an active lifestyle has the potential for improved skeletal health. Unfortunately, some female athletes may develop patterns of unhealthful eating, irregular menstrual cycles, and an ensuing state of low estrogen levels, which can undo the beneficial effects of exercise on bone density.[143] In 1992, 20 years after Title IX, the American College of Sports Medicine coined the term "female athlete triad" to define this interrelatedness of disordered eating, amenorrhea, and osteoporosis in certain female athletes.[144,145] Owing to its relatively recent definition, the prevalence of the entire female athlete triad has not been well established. Studies have shown, however, that 3.4 to 66% of female athletes have experienced amenorrhea compared with only 2 to 5% in the general population, and 15 to 62% of female college athletes demonstrate disordered eating compared with a 5 to 10% prevalence of eating disorders in the general population.[146–150]

Complete epidemiologic characterization of the female athlete triad may prove elusive as most athletic women with menstrual irregularities do not meet the criteria for osteoporosis or frank eating disorders. Some of these women even consume adequate calories, leading some clinicians to use the term "athletic amenorrhea," believing it is caused by the stress of exercise. Loucks and colleagues have disputed this concept, showing that low energy availability, defined as a failure to match food intake directly to

exercise energy expenditure, not stress of exercise, alters luteinizing hormone (LH) pulse frequency and amplitude.[151] These disturbances in LH pulsatility can cause amenorrhea or more subtle menstrual dysfunction, including irregular, anovulatory, and short luteal phase cycles, all of which can cause a relative estrogen deficiency and increased bone resorption. Work with elite gymnasts and runners has shown that even within-day, hourly energy deficits cause changes in body composition, with greater amplitude and frequency variations in energy balance correlating with increased body fat percentage.[152] The authors suggest that these wide swings also predispose to menstrual dysfunction.[152]

An alternative but complementary hypothesis is that cognitive dietary restraint, defined as the intention to limit food intake to control body weight, regardless of actual food limitation, is associated with higher levels of cortisol, which, in turn, impairs bone mass accretion by directly decreasing osteoblast activity and indirectly increasing osteoclast activity. In studies by McLean and colleagues, exercising women with high dietary restraint measures by questionnaire had similar BMI and menstrual cycle length to those with low restraint but higher urinary cortisol excretion[153] and lower total-body BMC.[154] In either case, it is important to counsel adolescent female athletes to maintain positive energy balance throughout the day with frequent appropriate pre-, post- and between-exercise meals.

Celiac Disease

Celiac disease is a disorder of nutrient absorption in the small intestine that affects as many as 1 in 250 people of European descent. In susceptible individuals, an immunologic reaction to gluten (a protein found in wheat, barley, and rye) leads to a chronic enteropathy of the proximal intestine. Low BMD is a common complication of celiac disease, caused by general malnutrition secondary to anorexia (reduced dietary intake) and impaired absorption of nutrients, especially calcium and vitamin D,[155] among other etiologies.

A gluten-free diet (GFD) is the mainstay of treatment for celiac disease, decreasing intestinal manifestations and improving BMD in adults and, in short-term trials, children. A recent long-term longitudinal study in children and adolescents showed that spinal BMD in patients with celiac disease was significantly lower than in controls at the time of diagnosis. After long-term GFD treatment (4 years), patients had regained BMC and BMD to levels similar to controls, with significant "catch-up" gains made in the first year of GFD treatment. Of note, the effects were most pronounced in the subgroup most compliant with GFD.[155]

Inflammatory Bowel Disease

Like patients with celiac disease, adolescents with IBD are at risk for low BMD. Patients with Crohn's disease (CD) have a higher incidence of osteopenia than those with ulcerative colitis (UC),[156] likely related to the more widespread distribution of intestinal inflammation in the former versus the latter diagnosis. In addition to malabsorption of calcium, phosphate, and vitamin D, these patients have generalized malnutrition. They may also have delayed puberty, leading to inadequate levels of estrogen and/or testosterone to promote adequate bone accretion. High concentrations of circulating inflammatory cytokines IL-1β, tumor necrosis factor α, and IL-6 that occur in IBD may have direct stimulating effects on osteoclasts, increasing bone resorption. Finally, extensive mucosal disease or surgical resection of the small bowel, particularly the terminal ileum, seen in CD further impairs calcium and vitamin D absorption.

The magnitude of corticosteroid use is the single greatest predictor of osteopenia in patients with both UC and CD.[157] Steroids directly decrease bone formation by inhibiting osteoblast activity. Indirectly, corticosteroids decrease the secretion of estrogen and testosterone, which are necessary for bone accretion, as well as decrease the absorption of calcium in the gut and reabsorption of calcium in the kidneys.

These adverse effects of corticosteroids are a concern for other patients with systemic steroid-dependent diseases such as juvenile rheumatoid arthritis (JRA) and collagen vascular diseases and solid organ transplant recipients. A recent study has shown a dose-related loss of BMD at the hip in premenopausal adult women using inhaled glucocorticoids for treatment of their asthma.[158] Although there is a similar concern for children and adolescents, it is largely speculative as the studies in these age groups are few and have not shown significant differences in BMD between patients on inhaled corticosteroids and controls.

Cystic Fibrosis

Patients with CF are at increased risk for significant bone disease. A review of the literature from 1988 to 1998 has shown relative BMD decreases for patients with CF, with measured z-scores ranging from –0.31 to –2.14 in studies with varying age populations and densitometry methods. This decrease in BMD translates into measurable increases in fracture rates and kyphosis (compression of the thoracic vertebrae) in CF patients aged 6 years and older.[159]

Once again, the pathophysiology of bone loss in these patients is felt to be multifactorial, with malabsorption of calcium and vitamin D, general malnutrition, inflammatory cytokines, and systemic corticosteroid use all playing roles. Vitamin D is a fat-soluble vitamin that relies on pancreatic enzymes for optimal absorption and reabsorption via enterohepatic circulation. Patients with CF have been shown to have a high prevalence of vitamin D deficiency, even after exogenous supplementation.[159] CF patients additionally have decreased levels of IGF-I and growth impairment, with height deficits as great as one standard deviation when compared with controls, which impairs maximal bone mineral accretion and may warrant GH replacement.[159,160] Pubertal delay and hypogonadism ensue, even in adulthood, leading to deficits in the estrogen and testosterone necessary to optimize the bone cycle. The decreased levels of IGF-I may also have direct deleterious effects on bone density. An additional

consideration in CF can be a lack of exercise tolerance in patients owing to their respiratory disease. Because bones require mechanical loading for remodeling, lack of weight-bearing activity further hinders normal bone mineral acquisition.

EVALUATION AND MANAGEMENT

The conditions described above are only a few of those that predispose children and adolescents to osteoporosis (see Table 51.3-1). The wide variety of conditions that impair skeletal health necessitates a high index of suspicion and heightened level of concern for bone health on the part of the pediatric health care or nutrition practitioner. The limitations of DXA scanning in pediatric populations detailed earlier have delayed its widespread use. Therefore, there is little evidence on which to make general recommendations as to when and how frequently specific groups of children should have bone density measurement by DXA. Standard practice in the authors' clinic is to perform DXA scans on girls and young women with AN after 6 months of hypothalamic amenorrhea. It is reasonable to perform a baseline DXA scan at the time of diagnosis on patients, age 8 years and older, with celiac disease, IBD, JRA, and CF. Bone density measurement is also recommended for patients with multiple fractures, regardless of etiology, pathologic or atraumatic fractures, and stress fractures. A higher level of suspicion should also be raised in any patient with a strong family history of osteoporosis or with long-term use of systemic corticosteroids. DXA scans should then be repeated over time, but not more frequently than annually in clinical practice as the changes noted over a shorter period are unlikely to be significant.

Patients found to have subnormal BMD on DXA scanning should have a screening evaluation of calcium homeostasis in addition to any clinically indicated laboratory assessments of their underlying medical conditions. A panel including serum calcium, phosphorus, magnesium, 25(OH)D, PTH, and thyroid-stimulating hormone, as well as a urinary spot calcium-to-creatinine ratio (normal < 0.2), would be sufficient. Any abnormalities, or BMD z-scores < –2.5, warrant referral to a provider (eg, an endocrinologist) experienced in calcium metabolism and skeletal health.

MANAGEMENT

Management of bone disease in patients with the chronic illnesses described consists primarily of optimizing nutritional status, particularly with respect to calcium and vitamin D, and ensuring a normal hormonal milieu, with exogenous replacement of estrogen, testosterone, and GH, as warranted. GFDs have already been mentioned for patients with celiac disease. Systemic corticosteroids should be used judiciously but should not be withheld if that would jeopardize management of the underlying disease process. As with many decisions in clinical medicine, potential risks and benefits must be balanced for each individual case.

The uses of DHEA and IGF-I in patients with AN have already been discussed. The positive effects of each on bone formation may make them attractive candidates for use in other diseases, particularly IGF-I for CF. However, long-term improvements in BMD, as well as solutions to the limitations mentioned above (nonstandard preparations for DHEA, parenteral administration for IGF-I), will need to be demonstrated before widespread use can be recommended.

Another class of agents being explored in several clinical trials of patients with AN and some of the other subgroups mentioned above is the bisphosphonates. These investigations have been prompted by the successful use of the bisphosphonate pamidronate in children with osteogenesis imperfecta,[161] as well as increasing experience with the bisphosphonate alendronate in postmenopausal women with osteoporosis. Bisphosphonates are potent and irreversible inhibitors of bone resorption that become incorporated permanently into the mineralized bone matrix. Until the introduction of alendronate, an oral preparation, bisphosphonates were limited by the same considerations as IGF-I. Alendronate may cause significant esophageal erosions, which can be mitigated by the recent development of once-weekly dosing. Concerns still exist around use of bisphosphonates in pediatrics, especially with respect to possible inhibition of primary remodeling of growing bone, increased risk of osteomalacia, long half-life in bone (> 10 years), and unknown effects on the growing fetus. Additionally, despite increases in BMD, there is concern that bone matrix, intercalated with bisphosphonate, may not provide normal mechanical strength. Therefore, although there is great promise to translate their established benefits in the elderly to younger patients, at the present time, these agents should not be used outside of research studies, with the possible exception of use by experienced and skilled providers for patients with diseases causing severe osteopenia or osteoporosis.

Finally, early recognition of the conditions that predispose to osteopenia and early identification of patients at risk are essential to the prevention of bone loss in adolescents with chronic illnesses, which may be the most effective way to manage bone disease in these patients.

PREVENTION

In addition to managing the skeletal complications of chronic illnesses, one of the most important goals of adolescent nutrition is the potential prevention of osteoporosis by maximizing skeletal health in otherwise healthy teenagers. It is essential to ascertain family history of osteoporosis, especially early-onset osteoporosis, or frequent fractures. Dietary sources of calcium and vitamin D should be assessed and inadequacies addressed. Recommended age-appropriate daily calcium, magnesium, phosphorus, and vitamin D intake guidelines have been developed in the United States by the National Institutes of Health and National Academy of Sciences (see Table 51.3-2) and should be endorsed.[106] Metabolic studies of calcium retention in adolescent girls showed such large

variation, however, that it might be necessary to individualize calcium requirements based on postmenarcheal age.[162,163] Others have argued that gender and physical activity should also modify recommendations for optimal calcium intake.[164]

The consensus recommendation for vitamin D intake is also subject to modification. The efficiency of conversion of 25(OH)D in the kidney increases during puberty, suggesting that requirements for vitamin D in adolescents are no higher than in adults.[165] But, as mentioned above, the prevalence of subclinical vitamin D deficiency in adolescents (or adults) is not known. Higher 25(OH)D levels than previously believed may be needed to protect against secondary hyperparathyroidism. Both of these questions are the subject of current research. In the meantime, it is recommended that adolescents consume 400 IU of vitamin D daily.

The success shown by a single supplementation trial in maintaining increases in BMD several years after discontinuation of concentrated milk protein as the primary calcium source may suggest the superiority of milk over other sources,[95] but further study is necessary to confirm this finding. Adolescent girls may need to be reassured that consuming dairy products instead of calcium supplements will not increase their weight or percent body fat, as shown in a 4-year longitudinal study.[166] Some examples of dietary sources of calcium and vitamin D are listed in Table 51.3-3. For those who cannot or will not consume adequate dairy products, calcium supplements are a suitable alternative (see Table 51.3-3). Despite concerns to the contrary, chronic consumption of high levels of calcium has not been shown to impair absorption of such essential nutrients as iron, magnesium, and zinc as long as the intake is held below 2.5 g (2,500 mg) daily.[53,167]

CONCLUSIONS

The growing body of literature highlighted in this section should alert clinicians in all disciplines to the adverse effects of chronic illnesses and inadequate nutrition on the skeletal health of adolescents. Most clinicians should find the solutions less obscure, however, as the promotion of skeletal health is ultimately no more than the promotion of good general health, including recommending balanced general nutrition, moderate weight-bearing exercise, and avoidance of alcohol and tobacco for all adolescents. The challenge is in helping teenagers modify their behaviors to meet these goals.

TABLE 51.3-3 Examples of Dietary Sources of Calcium

Food	*Calcium*	*Serving Size*
Milk	300	8 oz
Low-fat yogurt	300–415	8 oz
Calcium-fortified orange juice	300	8 oz
Cheddar cheese	300	1.5 oz
Cooked broccoli	35	½ cup

CHAPTER 52

FAILURE TO THRIVE: MALNUTRITION IN THE PEDIATRIC OUTPATIENT SETTING

Robert Markowitz, MD, Christopher Duggan, MD, MPH

HISTORY, BACKGROUND, AND DEFINITION OF TERMS

Pediatricians have described malnourished children with the words "failure to thrive" since at least the nineteenth century.[1] There continues to be a notable lack of progress regarding a valid and reliable definition of the term.[2] A review of general pediatric and pediatric nutrition textbooks failed to find a consensus definition, with various anthropometric and nonquantitative descriptive terms being employed.[3] Vinton and Dietz have rightly suggested that the term is a mere euphemism for undernutrition.[4]

Indeed, the child termed "failed to thrive" in the office of a pediatrician in industrialized countries would more likely (and more accurately) be described in developing countries as malnourished or suffering from protein-energy malnutrition.[5] The continued use of vague terminology such as failure to thrive limits the ability to scientifically study the nutritional status of a population and is likely symptomatic of the medical profession's unwillingness or inability to recognize and treat nutritional disorders among their patients.

Nonetheless, if only owing to the strength of historical precedent, the term failure to thrive will continue to be used to describe infants and young children with malnutrition. It is therefore recommended that quantitative criteria be specifically employed as well. Commonly used criteria include (1) a child whose weight (or weight for height) is more than 2 SD below the mean for sex and age and/or (2) a child whose weight curve has crossed more than 2 percentile lines on the Centers for Disease Control and Prevention (CDC) growth charts after having achieved a previously stable pattern.

Alternative wordings of the first criterion include "less than the 3rd percentile" or "a weight-for-age (or weight for height) z score (or standard deviation score) less than –2.0." z-scores are calculated by the following formula:

$$\text{z-score} = \frac{\text{actual weight} - \text{median weight}}{\text{standard deviation}}$$

where standard deviation is the age- and sex-specific standard deviation of weight and median weight is the median value for age and sex. It should be noted that expressing anthropometric measures in terms of z-scores is recommended by the World Health Organization (WHO), especially when describing groups of subjects.[6] Z-scores allow more precision in describing anthropometric status than does the customary placement "near" or "below" a certain percentile curve. For example, the phrase "below the 3rd percentile" does not distinguish between a child just below this point (whose z-score may be –2.1) from one with severe growth faltering (whose z-score may be –3.5 or lower) (Figure 52-1). Similarly, 3% of normal children will weigh less than the 3rd percentile, but a z-score significantly lower than –2.0 clearly indicates a growth problem. The CDC has established computer programs that calculate anthropometric data such as weight for height for age and weight for height; these are expressed as percentiles, z-scores, and percentage of the median without making recourse to plotting points by hand.[7] Software for palm-based computers is also available.

The second criterion is a more functional definition of growth failure that takes into account the fact that weight loss or even lack of normal growth during infancy and childhood is abnormal. Thus, these patients should not await the attainment of the low anthropometric scores noted above before appropriate evaluation and treatment are instituted. What constitutes a "stable pattern" can be difficult to define, although Edwards and colleagues addressed this issue by defining the true percentile as the maximum achieved between 4 and 8 weeks of age because weight at this point was found to correlate more strongly with weight at age 12 months than did birth weight.[8] They proposed a functional definition of failure to thrive as "a child whose weight deviates downwards across two or more major centiles from the maximum centile achieved at 4 to 8 weeks for a period of a month or more."

Anthropometric assessment of nutritional status can also be categorized to help determine chronicity of nutritional deprivation. The simple use of a weight-for-age cut-

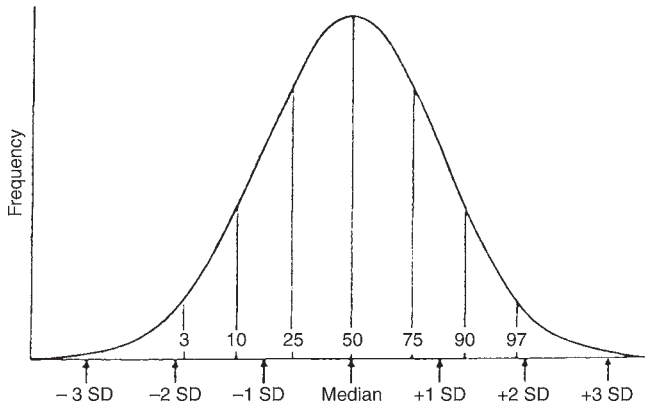

FIGURE 52-1 Comparison of percentiles versus standard deviation or z-scores. Two SDs below (or above) the mean corresponds to the 3rd (or 97th) percentile. Adapted from Jeliffe DB et al.[15]

off to define malnutrition is obviously nonspecific because patients included can be either well proportioned and just constitutionally small or truly of low weight. A classic distinction between acute malnutrition ("wasting" or low weight for height) and chronic malnutrition ("stunting" or low height for age) was proposed by Waterlow and has been widely adopted.[9] Table 52-1 recounts this classification scheme, in which percentage of the median is calculated by the following formula:

$$\% \text{ median} = \frac{\text{actual weight} \times 100}{\text{median weight}}$$

where median weight is the median value for age and sex.

An important caution should be noted when a subject's height faltering is used to call attention to nutritional status. Clearly, genetic and constitutional causes of short stature need to be ruled out before implicating chronic malnutrition as the cause of poor height growth. Elicitation of family history and interpretation of growth parameters in light of midparental height and parental growth patterns can be helpful in this regard. In addition, strict adherence to standard growth curves should not be expected. Smith and colleagues underlined the fact that the National Center for Health Statistics (NCHS) standard curves are mathematical averages based on large numbers of children (ie, cross-sectional curves) and not growth lines along which individual children should be expected to grow (ie, longitudinal).[10] They also demonstrated that infants manifest a growth rate at birth that is predominantly determined by maternal factors. They then shift to one that is increasingly determined by their genetic background. Thirty percent of healthy, full-term, white infants crossed one percentile line and 23% crossed two lines as they moved from birth to age 2 years. Children whose birth lengths were near the 10th percentile but whose subsequent lengths were closer to the 50th percentile tended to catch up at an average of 11.5 months; those born near the 90th percentile and moving down to the 50th percentile did so at an average age of 13 months (Figure 52-2). Karlberg and colleagues analyzed the length curves of healthy children in the first 3 years of life.[11] Children were found to have nonlinear decelerations in their growth rates starting during infancy. During the second year of life, the variation in the growth rate was found to increase, with greater gains in linear growth during the spring/summer than autumn/winter. During the third year, the growth pattern stabilized. Thus, fluctuations in length percentiles are a normal phenomenon in infant growth and, especially in the face of normal weight gain, should not prompt evaluation for nutritional disease. Horner and colleagues have demonstrated that a more significant decline in the linear growth rate occurs in children with constitutional short stature.[12] This fall in the growth rate generally first became apparent in the first 6 to 9 months of life and was greatest during the first 2 years. These children fell more than 2 SD below the mean for height by 3 years of age. Subsequently, their growth rate was the same as that of normal children but below and parallel to the 3rd percentile.

Alternative or supplemental anthropometric criteria for failure to thrive have been proposed, including decreased weight velocity, low triceps skinfold (TSF) values, and midarm circumference (MAC). For example, data have been published on incremental gains in the length and weight of the infants enrolled in the Iowa and Fels studies.[13] Measurement and interpretation of skinfold thickness and growth velocity have the disadvantage of requiring special equipment and/or graphically represented standards and may not add specificity or sensitivity to the screening criteria noted above. Depleted fat stores and slowed growth velocity are often concomitant findings in the patient with malnutrition, and their presence or absence can be noted on detailed clinical evaluation. In some settings, for example, in refugee camps or in famine situations, a quick assessment of nutritional status is provided by the MAC because this value is relatively independent of patient age and correlates well with risk of death, especially when adjusted for height.[14] However, for standard screening purposes in most US settings, the anthropometric measurements of weight, height, and age are usually sufficient.

Certainly, any diagnosis of malnutrition requires accurate measurements of weight, length, head circumference, and age. Infants' lengths should be measured supine on a length board until age 2 years, after which time they should be measured upright. Infants and children should

TABLE 52-1 Waterlow Criteria for Categorizing Type and Chronicity of Malnutrition

Type of Malnutrition	*Acute (Weight for Height) (% of Median)*	*Chronic (Height for Age) (% of Median)*
Normal	> 90	> 95
Mild	80–90	90–95
Moderate	70–80	85–90
Severe	< 70	< 85

Abnormalities of weight for height are termed "wasting" and those of height for age are called "stunting." Adapted from Waterlow JC.[9]

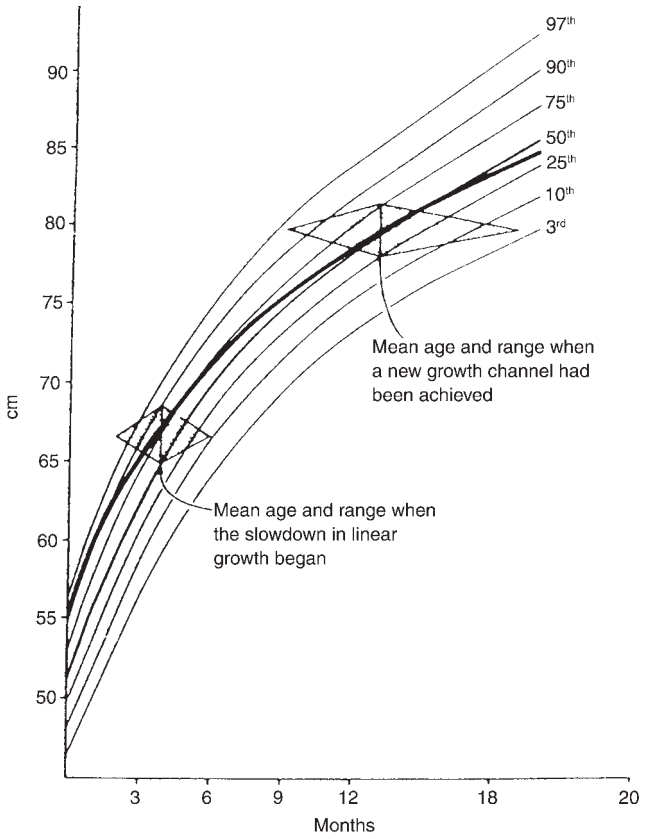

FIGURE 52-2 Mean linear growth curve of 16 healthy infants who crossed percentile lines during infancy. Whereas at birth they were at the 90th percentile, by age 2 years, they had reached the 40th percentile. This shift generally occured between 3 and 13 months. Adapted from Waterlow JC.[9]

be weighed with minimal clothing on scales accurate to at least 100 g. If possible, one person in the office should be designated as solely responsible for weighing and measuring patients. Detailed summaries of anthropometric techniques have been published elsewhere.[15]

These measurements should be plotted on appropriate graphs (see Appendix). When plotting infants with a history of premature birth, their chronologic age should be corrected by gestational age until 24 months for weight, 40 months for length, and 18 months for head circumference.[16]

The NCHS standards have previously been recommended and used worldwide since 1978 by the WHO regardless of racial or ethnic origin.[17,18] In 2000, the CDC developed new standards for infants from birth to 36 months and for children from 2 to 20 years of age.[19] These standards are now recommended for use in the United States. The new growth charts were developed to address some of the concerns raised about the 1977 NCHS curves.[19] The new CDC curves are more representative of a cross-section of the ethnicity of the children living in the United States. Data from breast-fed infants are also included so that the mix of formula-fed and breast-fed infants is more accurately represented. The distribution of birth weights now more closely matches the national distribution. Statistical methods have been employed to smooth the disjunction between length and height. Finally, the body mass index (BMI) is now available for children from ages 2 to 20 years. On the NCHS charts, weight-for-stature charts are available but stop at age 10 years for girls and 11 years for boys.

A somewhat misleading distinction in the medical literature is still written of concerning organic versus nonorganic failure to thrive (eg, Rosenn and colleagues[20]). The former is that type of malnutrition attributable to an underlying medical condition that has presumably limited the intake, absorption, or use of adequate calories. Nonorganic failure to thrive, in contrast, implies a primary social dysfunction of the family or societal unit whose net result is that the child is not offered adequate calories. Berwick and colleagues reviewed the records of 122 children between the ages 1 and 25 months who were hospitalized for failure to thrive.[21] Thirty-three percent had no specific diagnosis, 32% were felt to have a social or environmental explanation, and 31% were given a specific medical diagnosis. Because the vast majority of childhood undernutrition in the United States is attributable to so-called nonorganic causes, the discussion of therapy will be directed at identifying and rectifying these reasons (see below). It has also been written that a so-called mixed failure to thrive category exists in which both organic and psychosocial factors are responsible or one may result from the other, resulting in the poor nutritional status.[22,23] This is not surprising and reflects the difficulty in any attempt to dichotomize between physiologic and social influences on health in general and nutrition specifically.

EPIDEMIOLOGY

Significant pediatric undernutrition in the United States is often cited to occur in 10% of low-income children.[24] The prevalence of underweight children can range from 1 to 10%, depending on the clinical setting.[25] Unfortunately, the definitions of malnutrition used to support such claims include well-established anthropometric criteria but also terms as inclusive and perhaps biased as "[failure to thrive] noted on the problem list or in the clinic notes."[26] Other factors that can interfere with an accurate survey of failure to thrive infants have been reviewed.[27]

National surveys have been undertaken that provide information on the prevalence of inadequate growth.[25] The National Health and Nutrition Surveys (NHANES I [1971–1974], II [1976–1980], and III [1988–1991]) studied the prevalence of low height for age and weight for height among 2 to 5 year olds. In the 1988–1991 survey, the prevalence was found to be 5.2% and 2.7%, respectively. The Pediatric Nutrition Surveillance System (PedNSS) measured the prevalence of inadequate growth in predominantly less than 5-year-old low-income children who participated in publicly funded nutrition and public health programs. In 1996, the prevalence for low height for age was 5.8% and low weight for height was 2.6% in 2 to 5 year olds. Furthermore, the PedNSS reported in 1996 that infants from birth to 2 months experienced the highest prevalence for both indicators. In this group, 12% had low height for age and 4.1% low weight

for height. Finally, blacks had the highest rates for both of these indicators.

In recent years, pediatric health care providers have encountered growing numbers of international adoptees and the children of new immigrants. Every year, 3 million children ages 0 to 19 years of age immigrate to the United States mainly from Asia, Western Europe, and North Africa.[28] Immigrant children have been found to be deficient for height for age and weight for age.[29] They may also have developmental delays, infectious diseases, a variety of health problems, and psychosocial stressors.[28–30] Fifteen thousand foreign-born children are adopted by American citizens each year.[28] Since 1990, the majority were adopted from China and the countries of the former Soviet Union.[28] Among the children adopted from China, z-scores were ≤ –2 SD in 39% for height, 18% for weight, and 24% for head circumference.[30] Developmental delays, both global and in specific areas, were common, as were infestations, infections, and chronic medical conditions.[30]

TABLE 52-2 Risk Factors for the Development of Failure to Thrive

Infant characteristics
Any chronic medical condition resulting in
Inadequate intake (eg, swallowing dysfunction, central nervous system depression, or any condition resulting in anorexia)
Increased metabolic rate (eg, bronchopulmonary dysplasia, congenital heart disease, fevers)
Maldigestion or malabsorption (eg, AIDS, cystic fibrosis, short gut, inflammatory bowel disease, celiac disease)
Premature birth (especially intrauterine growth retardation)
Developmental delay
Congenital anomalies
Intrauterine toxin exposure (eg, alcohol)
Plumbism and/or anemia
Family characteristics
Poverty
Unusual health and nutrition beliefs
Social isolation
Disordered feeding techniques
Substance abuse or other psychopathology (including Munchausen syndrome by proxy)
Violence or abuse

MEDICAL RISK FACTORS FOR MALNUTRITION

There are many well-known medical and psychosocial risk factors for the development of failure to thrive (Table 52-2), which can generally be viewed as relating to the infant or to the family. Almost all chronic medical conditions in a child can lead to poor weight gain by a variety of factors.[31] These include decreased caloric intake (anorexia, food withholding, altered mental status), increased caloric requirements (fever, infections), and/or inefficient use of ingested calories (maldigestion, malabsorption, and metabolic disorders). The nutritional implications of hospitalization for the treatment of medical or surgical conditions are almost uniformly detrimental, and the nutritional status of hospitalized pediatric patients is poor (see Chapter 11, "International Nutrition").[32] Nutritional recommendations for specific disease states are found elsewhere in this textbook.

An important medical risk factor for undernutrition in childhood is premature birth. Growth data are available for low birth weight preterm infants (see Appendix).[33–36] Recently, growth curves for the use with hospitalized very low birth weight growth curves have been developed.[37] Standard growth curves should be used once the infant has achieved a gestational age of 40 weeks. As noted above, correction for prematurity should be done when plotting an infant's anthropometric measurements on the CDC growth curves to correctly assess growth. Even with correction for gestational age, however, Casey and colleagues have shown that patients who were both low birth weight and premature have smaller mean lengths, weights, and head circumferences than their term counterparts in the first 3 years of life.[34,35] The lower the birth weight, the greater the depression of the mean.

Having plotted growth parameters, the clinician should keep in mind the myriad potential complications of prematurity that can lead to malnutrition, including chronic lung disease, necrotizing enterocolitis and intestinal resection, developmental delay, retinopathy of prematurity, and other sensorineural abnormalities. In addition, behavioral abnormalities of some premature infants (including irritability and oral aversion) can predispose to poor postnatal growth.

The infant who is small for gestational age is a special case because prenatal factors may have already exerted a deleterious effect on somatic growth. The reasons for in utero growth failure include both genetic problems (such as chromosomal aberrations), environmental influences (such as maternal smoking, malnutrition, or exposure to drugs or other toxins), and infection. Infants with symmetric growth retardation (in which weight, height, and head circumference are equivalently depressed) are less likely to respond to nutritional supplementation with catch-up growth. Conversely, asymmetrically growth-retarded infants (whose weight is disproportionately low) have more truly suffered in utero malnutrition and can therefore be expected to achieve better growth after birth.[38] Strauss and Dietz have observed that many infants who are labeled intrauterine growth retarded (IUGR) often have mothers and non-IUGR siblings who are smaller and lighter and come from families in which there is an increased prevalence of IUGR infants.[39] They concluded that some of these infants may be genetically small, which may limit their catch-up growth.

A prospective case-control study of premature infants has identified some risk factors for poor weight gain after hospital discharge among this population.[40] Among 914 infants with birth weights ≤ 2,500 g, 19.7% were diagnosed with failure to thrive at some point in the first 3 years of life. Multivariate analysis revealed that among infants with growth failure, significantly more had birth weights less than 1,500 g, were small for gestational age, had an abnormal neurologic examination at 40 weeks gestational age, or had a mother whose height was less than 5 feet

2.5 inches. Interestingly, infants born to mothers who were college graduates or who were living with the infant's father had a higher risk of developing failure to thrive than those without these characteristics. Family income, prenatal care, and maternal race were found not to be significant factors.

The child with neurologic disease is also at special risk for poor growth. Children with cerebral palsy are especially at risk for abnormalities of growth and nutritional status (see Chapter 34).[41–44] Many children with developmental delay are short for their age, and although stunting owing to chronic malnutrition is a possible cause, genetic programming owing to the underlying condition and/or altered neuroendocrine axis can also be an etiology. In addition, children with developmental delay may suffer from swallowing dysfunction, gastroesophageal reflux, constipation, and other gastrointestinal diseases that, in addition to their underlying neurologic dysfunction, may alter their caloric intake. Children with hypertonia and movement disorders can have excessive energy expenditure, which may be an additional factor contributing to poor growth. Conversely, children with cerebral palsy often have limited physical activity and therefore lower energy requirements than similarly aged children, thereby placing them at risk for obesity.

Anthropometric evaluation of children with spastic cerebral palsy can be difficult owing to contractures or scoliosis, and interpretation of growth should be done in light of the growth potential of any known diagnosis or syndrome. Because of these difficulties in correctly measuring and interpreting linear growth, emphasis should instead be placed on obtaining adequate weight for height as a measure of good nutrition. However, weight for height in cerebral palsy patients may underestimate their degree of malnutrition.[41] Stallings and Spender and their colleagues have found that linear growth in children with quadriplegic, hemiplegic, and diplegic cerebral palsy can be assessed by the measurement of upper arm and lower leg lengths.[42,45] Growth curves are available for these parameters.[45] In children with quadriplegic cerebral palsy, upper arm length and lower leg length were found to correlate with TSF and MAC.[42] Samson-Fang and Stevenson have recommended the use of TSF for the nutritional screening of children with cerebral palsy.[41] A TSF less than the 10th percentile indicates the need to more fully assess a child's nutritional status, growth, and overall health.

Table 52-3 lists suggested energy requirements in developmentally delayed children based on calorie per centimeter of height because experience has shown that estimating needs by Recommended Dietary Allowance (RDA) and weight often leads to excessive energy intake in this population. The role of malnutrition in infancy in contributing to the development of the central nervous system is addressed in Chapter 21, "Nutrition and Brain Development."

Children born with congenital anomalies are also at nutritional risk. For example, infants born with cleft lips and/or palates may have significant oral-motor dysfunction requiring special nipples and feeding instructions. Some of these infants may require feedings by nasogastric tube or gastrostomy. The occurrence of some congenital anomalies may represent part of a genetic syndrome of which intrauterine growth retardation, poor growth, or short stature is a component. If available, syndrome-specific growth curves should be used. As with the developmentally delayed child, weight for height is a useful anthropometric assessment of nutritional status in these patients. TSF and MAC may also be helpful in these children.

Lead intoxication is a medical risk for poor growth.[46] High blood lead levels probably correlate with poor nutrition based on the fact that a high-fat, low-iron diet promotes lead absorption from the intestine. What is less clear is to what extent the anorexia and other behavioral problems seen with iron deficiency and/or lead poisoning are contributing factors to malnutrition.

PSYCHOSOCIAL RISK FACTORS

Many factors that predispose to poor growth in the United States are not attributable solely to medical characteristics of the child but may be social or behavioral in origin. Feeding-related behavioral disorders are not uncommon in children with poor growth.[47–51] These behavioral difficulties may extend beyond mealtimes.[50] These children are perceived as having more difficult temperamental characteristics and are rated by their parents as being more negative, irregular, dependent, and unstoppable.[49] There may be a temperamental mismatch between the child and mother.[48] Chatoor and colleagues described the diagnostic criteria of the infantile anorexic, a severe eating disorder that arises in the toddler years.[49] Some behaviors may have a medical basis or have had roots in prior medical problems suffered by the child leading to food aversion[47,48,52] or the perception that the child is vulnerable or fragile.[50] Maternal developmental delay, learning disorders, anxiety, psychiatric disease, substance abuse, and difficulties with maternal attachment all may impact the feeding and nurturing of a child as well.[48,49,51] Indeed, an extensive literature has

TABLE 52-3 Estimated Energy Needs for Developmentally Delayed Children

Condition	*Daily Caloric Recommendation*
Ambulatory, ages 5 to 12 yr	13.9 kcal/cm height
Nonambulatory, ages 5 to 12 yr	11.1 kcal/cm height
Cerebral palsy with decreased levels of activity	10 kcal/cm height
Cerebral palsy with normal or increased levels of activity	15 kcal/cm height
Athetoid cerebral palsy, adolescence	Up to 6,000 kcal
Down syndrome, boys ages 5 to 12	16.1 kcal/cm height
Down syndrome, girls ages 5 to 12	14.3 kcal/cm height
Myelomeningocele	Approximately 50% of RDA for age after infancy; may need as little as 7 kcal/cm height

RDA = Recommended Dietary Allowance.

arisen around the transactional model of failure to thrive,[16] which emphasizes the interrelationships between medical, behavioral, and developmental characteristics of the infant on the one hand and the familial, psychosocial, and economic environment of the child's caretakers on the other. Such a multifactorial approach to the problem of poor growth has direct implications for treatment modalities, as discussed below.

Of all of the social risk factors, poverty is the most pervasive among children seen for growth failure.[53] Frank and Zeisel stated that 13% of their patients are homeless and noted that inadequate medical care can exacerbate the tendency of acute illnesses to lead to poor growth.[24] The degree to which federal food aid to poor families in the United States helps improve the nutritional status of this population is controversial.[54]

Other psychosocial risk factors for failure to thrive include the health and nutrition beliefs and concerns of the family, including a fear of obesity or cardiovascular disease.[55] Such concerns can lead to suboptimal caloric intake or a diet low in fat, resulting in poor growth. Also in this category are infants who are exclusively breast-fed for longer than is recommended because breast milk as the sole source of nutrition is inadequate for optimal growth after 6 to 8 months.[56] It should be noted that although growth failure in the neonatal period owing to breast milk insufficiency can be serious, failure to thrive in the older breast-fed infant is more likely attributable to underlying medical problems.[57,58] There have also been reports of severe malnutrition caused by the inappropriate use of health food beverages. Carvalho and colleagues reported two cases of children who developed severe nutritional deficiencies caused by the consumption of health food beverages.[59] One received a soy-based beverage and was placed on a strict vegan diet as a result of the dietary practices of the parents. Another was reported who received a rice beverage because of perceived milk intolerance. Concern about food allergies is widespread, with one-quarter of American households altering their dietary intake based on the perception that one or more household members suffer from food allergies.[60,61] These concerns can lead to the unnecessary restriction of a child's diet.[61]

Another dietary practice that can lead to poor nutrition, especially in toddlers, is excessive intake of fruit juices. In addition to the role some juices can play in the etiology of chronic diarrhea, it appears that juices can displace more calorically dense items from the diet.[62,63] Reduction of juice intake was recently shown to be associated with improved weight gain in a series of eight children who were referred for evaluation of growth failure.[64]

Parenting skills (especially feeding skills), life stresses, and social isolation are also factors that can contribute to growth failure. Most studies examining the role of stress and other social factors in pediatric malnutrition have been retrospective and therefore unable to say whether stress preceded or was caused by the infant's nutritional status. Altemeier and colleagues performed a prospective, case-control study among mothers at risk for having children with poor growth by performing prenatal interviews and monitoring subsequent growth.[65] They found that a combined measure of life stress of the parents correlated significantly with subsequent failure to thrive, as did maternal characteristics such as frequent separations, arguments, and reconciliations with the child's father. Self-reported drug and alcohol use, self-image, and attitude toward pregnancy were not correlated with infant growth. Of note, mothers whose children grew poorly reported unhappy childhoods and being subjected to physical abuse more often than did mothers whose children grew normally. In one series, 66% of mothers of infants with growth failure reported having been abused as children themselves compared with 26% of controls from a similar socioeconomic group.[66] The children of immigrants and international adoptees may experience unique stressors, including those related to relocating to a new country, language barriers, having spent extended periods in orphanages, or having witnessed war and other atrocities.[28–30]

Unfortunately, the theme of abuse and violence runs throughout much of the lives of children who grow poorly. Indeed, frank childhood neglect (or the maternal deprivation syndrome) was first hypothesized to be the etiology of many cases of growth failure, as implied by past uses of the term failure to thrive.[67] Food withholding has also been reported to occur in some cases of growth failure.[68] A case series of children diagnosed with Munchausen syndrome by proxy indicated that 29% had been diagnosed with failure to thrive, and 17% of their siblings had had either nonaccidental injury, neglect, inappropriate medication administration, or failure to thrive.[69] These reports all underscore the fact that infants with growth failure may represent a flag for serious social and psychological problems in the family.

APPROACH TO THE PATIENT WITH FAILURE TO THRIVE

Evaluation of a child with growth failure should begin (and often end) with a thorough history and physical examination because the diagnostic benefits of additional laboratory tests are minimal.[21,70] Because so-called nonorganic growth failure is by far the most prevalent type seen by US primary care physicians, simple but noninvasive efforts should be made to screen for possible underlying medical problems. The identification of psychosocial issues that may be afflicting the family should be done concurrently. Because many children with poor growth suffer from behavioral and developmental problems as well as social and economic disadvantages, a multidisciplinary approach has been advocated as an effective method of diagnosis and therapy.[71–73] The use of home visits in conjunction with a multidisciplinary growth and nutrition clinic may provide further benefit.[74] Evaluation by a social worker, behavioral specialist, and/or psychologist will obviously supplement the primary medical and nutritional evaluation. Translators are often essential to allow for adequate communication with immigrant families.

In the medical assessment, important historical points to consider (Table 52-4) include maternal history (espe-

cially use of drugs, possible congenital infections, maternal nutrition, and health during pregnancy), labor, delivery, and neonatal events. Altemeier and colleagues showed that although postpartum complications of the mother did not predict subsequent failure to thrive, unresolved health questions at nursery discharge (eg, bilirubin levels) and difficulty feeding in the neonatal period were associated with later growth problems.[65]

The child's general medical history should also be explored, especially with regard to intercurrent illnesses, medication use, and immunization history. Acute infections can embarrass nutritional status by the increased metabolic demands of fever and stress response, as well as by reducing caloric intake through anorexia. At the same time, a history of recurrent or unusual infections should increase the clinician's suspicion for the presence of an immunodeficiency, including acquired immune deficiency syndrome (AIDS). A developmental history should be obtained. Any suggestion of oromotor or feeding difficulties should also be sought. Assessment by an interdisciplinary feeding team may be helpful and effective.[52]

The growth history should be reviewed by careful plotting of past growth points on the CDC curves. Specific growth curves exist for a number of syndromes, and these should be used in those instances once the diagnosis has been established (see Appendix).[75–77] Dietary history should include a qualitative assessment of feeding behavior and organization of the household at mealtimes, as well as a quantitative measure of caloric intake. Intake data are most easily obtained by 24-hour food recall, but a more reliable and valid assessment is a record of food consumed over 3 to 5 days.[78] Calculation of intake with respect to the US RDAs for age can then be performed and the need for dietary supplementation of micro- and/or macronutrients determined. The child's activity level, feeding history, juice and soda intake, perceived food allergies, and presence of dietary restrictions should be assessed. Culturally based food preferences and feeding practices should also be ascertained.

Family history should include the growth parameters of siblings as well as the stature and growth patterns of parents. The average of maternal and paternal heights can be calculated to derive a midparental height using the following formula:

$$\frac{\text{maternal + paternal heights}}{2} \quad \begin{array}{l} +\ 5\text{ cm if a boy} \\ -\ 5\text{ cm if a girl} \end{array}$$

Comparison with published values can then be done to predict adult stature.[79]

A social history that documents the caretaker's economic status is crucial to help guide diagnostic and therapeutic efforts. Elicitation of the social risk factors outlined above should be performed, as well as the parent's perception of the child's nutritional status. The family's ability to afford, store, and prepare food should also be determined.

A home visit performed by an appropriately trained professional may be helpful. The child and family can be evaluated in a more natural setting, aiding the assessment of the child's environment and mealtimes and allowing for the modeling of behaviors. These visits can even be extended to the child's other significant caregivers (eg, other family members, day care, or preschool). Another method that may be helpful is to ask the child's primary caretaker to videotape the child eating a meal. This tape can then be reviewed with the family, with specific advice offered according to the feeding and caretaker behaviors noted on the tape.

Screening for organic disease should also include a thorough review of systems. Questions regarding gastrointestinal function (dysphagia, vomiting, abdominal pain, bloating,

Vomiting or gastroesophageal reflux
Recurrent fevers
Dysuria, urinary frequency
Activity level, ability to keep up with peers

AFDC = Aid to Families and Dependent Children; WIC = Special Supplemental Nutrition Program for Women, Infants and Children.

diarrhea, etc) are especially important. The presence of fevers or other metabolic stresses should be assessed.

The physical examination of a child with malnutrition should be comprehensive, and findings therein can implicate both organic and socioeconomic causes of growth failure. The importance of accurate anthropometric measurements has already been stressed. Indeed, the pattern of growth failure itself is often indicative of whether genetic or environmental factors are to blame; genetically small children often maintain normal weight for height; have proportionately low weights, lengths, and head circumferences; and can grow parallel to but lower than the 5th percentile curve. Alternatively, children with caloric deprivation or malabsorption fall off their weight curves first, followed by length, followed by head circumference. They will therefore acutely show a deficit of weight for length and then more chronically a deficit of height for age. Figure 52-3 illustrates characteristic linear growth curves for children with intrinsic shortness, constitutional growth delay, and attenuated growth (as might be seen with caloric deprivation or gastrointestinal disease).

A critical aspect of the physical examination is an assessment of caregiver–child interaction, such as physical proximity, verbalization toward each other, and eye contact. Evidence of child neglect should be sought by paying attention to general hygiene, oral health, and the presence of diaper dermatitis. The possibility of organic disease can be evaluated by examination of all major organ systems. Table 52-5 gives a summary of possible findings on physical examination in children with growth failure, which should prompt further evaluation for underlying medical problems.

Unfortunately, the extensive differential diagnosis that can be engendered by the consideration of a child with poor growth (which Tunnessen compared to the index of any pediatric textbook[80]) can lead to excessive diagnostic testing. Sills's landmark study in 1978 succinctly showed the lack of utility of many laboratory tests in children with poor growth, especially given the psychosocial etiology of most cases.[70] In 185 children less than 3 years old admitted for evaluation of failure to thrive, only 36 of 2,607 laboratory tests performed (1.4%) were helpful in making a diagnosis, and all of these 36 positive results were suspected on clinical grounds. Berwick and colleagues also demonstrated the importance of a thorough history and examination over extensive testing.[21] Thus, a good history and physical examination are effective screening tools for the presence of organic disease, and laboratory testing should be minimized. Some basic screening tests may include complete blood count, blood urea nitrogen, albumin, erythrocyte sedimentation rate, lead concentration, and urinalysis. By no means is it necessary for all patients undergoing evaluation to be so tested. However, the diagnostic yield of screening tests of immigrant children and international adoptees with undernutrition is higher.[28–30,81,82] Current recommendations for the health care and screening of immigrant children and international adoptees are covered elsewhere.[28,29]

Another diagnostic tool often employed has been admission to hospital and evaluation of growth under supervision.[83] It is hoped that the combination of the provision of adequate calories and extraction from an unfavorable environment may lead to a rapid weight gain in patients with so-called nonorganic failure to thrive, whereas children with medical reasons for their poor nutritional status will be correctly identified. Unfortunately, once a child is hospitalized, the tendency to perform diagnostic tests often increases, which may, in turn, interfere with feeding the child (multiple consultants, tests requiring nil by mouth status, etc). As noted before, the average acute care hospital can also be described as a poor environment for adequate nutrition. Berwick and colleagues pointed out that weight gain or loss in the hospital did not distinguish between organic and psychosocial causes of poor growth, and it is unclear whether children with poor growth owing to social or environmental reasons will actually grow better when admitted than those with organic disease.[21]

TREATMENT OF GROWTH FAILURE

The treatment of malnutrition in children is obviously determined by the etiology of any underlying pathology, be it biologic, psychiatric, or economic. Rarely, simple dietary advice regarding correct formula preparation may be all that is needed to ensure adequate caloric intake. Much more likely is the need for a long-term treatment and follow-up plan, involving nutritional advice, behavioral modification, and social work intervention. As noted above, the multidisciplinary team approach to management has advantages and may even result in better nutritional outcomes for patients.[70,72–74]

Obviously, if a heretofore unsuspected medical illness is diagnosed, treatment of this underlying problem should proceed. However, nutritional aspects of the medical illness should not be ignored, given the well-recognized propensity of poorly nourished individuals to suffer more complications and higher mortality rates with many disease processes.[84] The relationships between nutritional status and specific disease states are explored in Section IV of this text.

Alternatively, if medical and nutritional assessments indicate that inadequacy of caloric intake is the etiology of the poor growth, primary nutritional therapy should be the treatment of choice. The pace and aggressiveness of nutritional repletion should be dictated by the degree of malnutrition, with mild cases most suitable for outpatient management.[85]

It has been recommended that to achieve adequate catch-up growth, calories be increased in proportion to the weight deficit. A general guideline for caloric requirements for infants with poor growth is

$$\text{kcal per kg required} = \text{RDA for age (kcal/kg)} \times \frac{\text{ideal weight for height}}{\text{actual weight}}$$

where ideal weight for height is the median weight for the patient's height (as read from the NCHS weight for height curves).

For example, a 3-month-old boy with a weight of 3.6 kg and length of 57 cm has the following anthropometric measures: weight-for-age z-score, –2.50; height-for-age z-score,

–1.55; and weight-for-height z-score, –2.11. In addition, assessment via the Waterlow classification shows that he is suffering from moderate acute malnutrition (weight for height = 74% of the median) and mild chronic malnutrition (height for age = 93% of the median). Because his RDA for calories is 108 kcal/kg/day and his ideal weight for length is 4.8 kg, his estimated caloric requirement for catch-up growth is (108 × 4.8)/3.6 = 144 cal/kg/d. Similarly, because his RDA for protein is 2.2 g/kg/day, his protein requirement for catch-up growth is closer to (2.2 × 4.8)/3.6 = 2.9 g/kg/day.

In mild malnutrition, therapy should center on ways to increase oral caloric intake in an outpatient setting. Com-

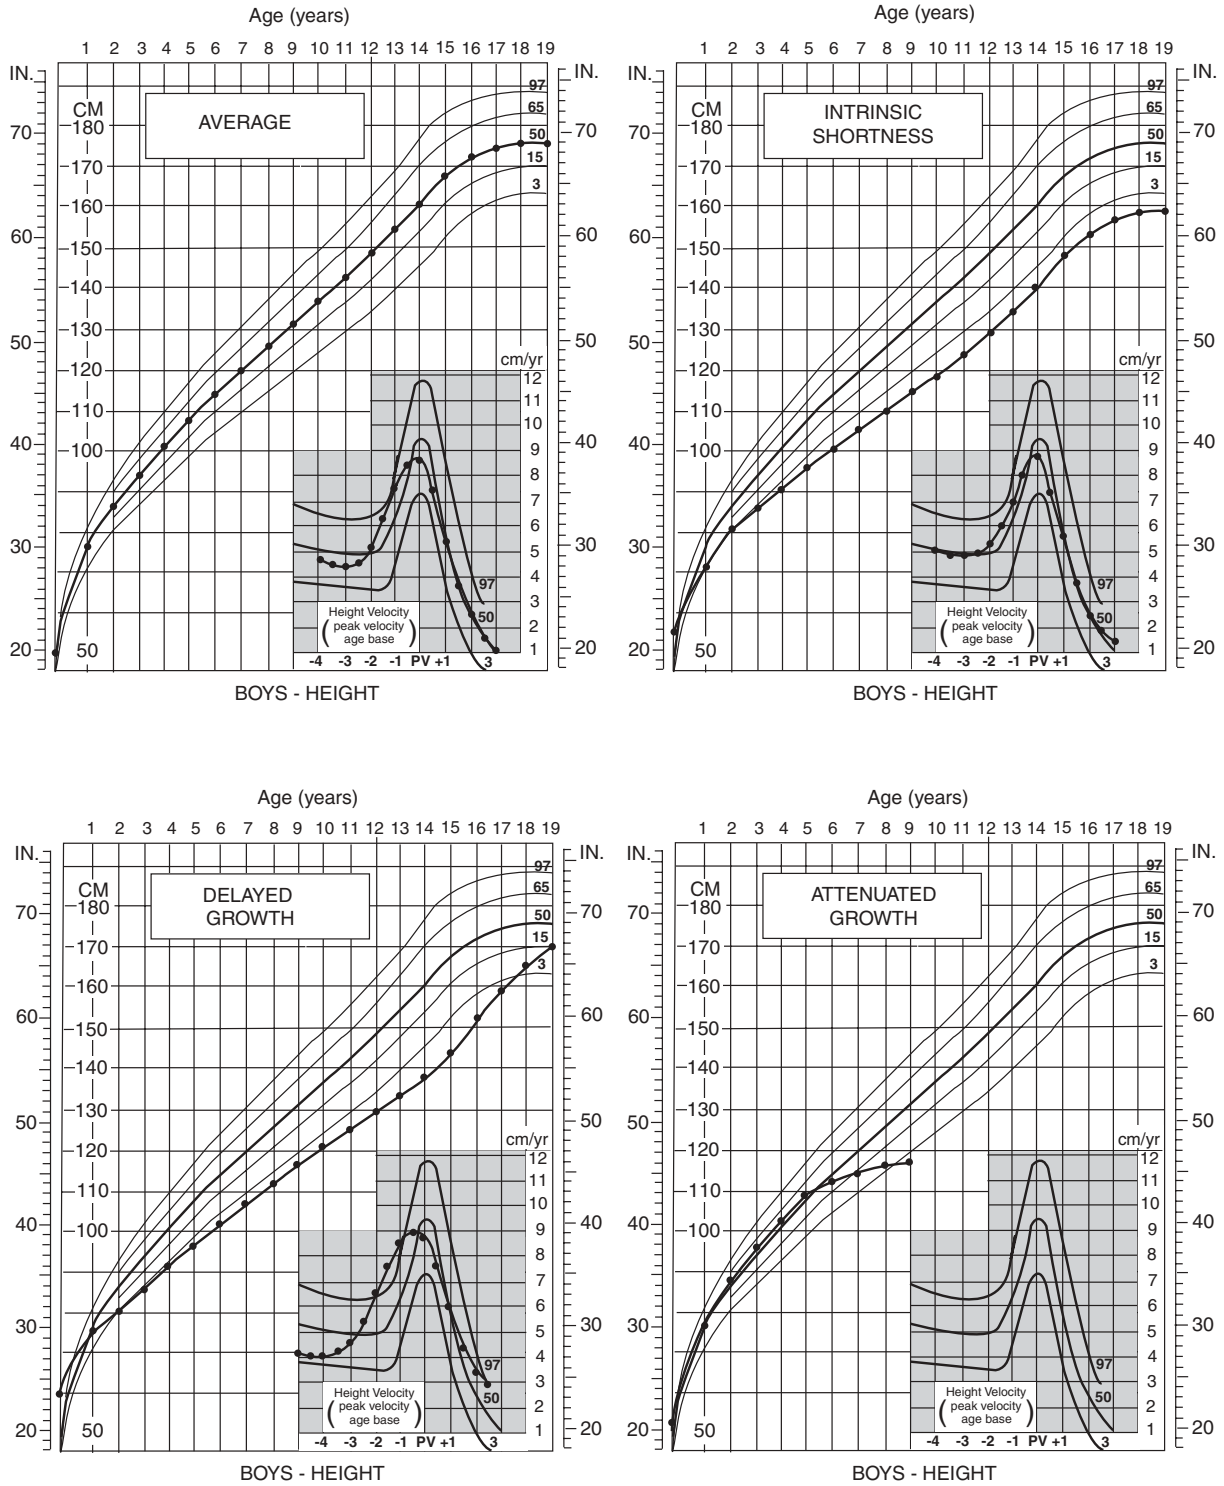

FIGURE 52-3 Linear growth curves (and height velocity curves, *insets*) of four different patterns of growth: average, intrinsic shortness, delayed growth, and attenuated growth. The last pattern is more characteristic of malnutrition. Adapted from Schaff-Blass E, Burstein S, Rosenfield RL. Advances in diagnosis and treatment of short stature, with special reference to the role of growth hormone. J Pediatr 1984;104:801–13.

TABLE 52-5 Physical Examination of Infants and Children with Growth Failure

	Abnormality	*Considerations*
Vital signs	Hypotension	Adrenal or thyroid insufficiency
	Hypertension	Renal disease
	Tachypnea/tachycardia	Increased metabolic demands
Skin	Pallor	Anemia
	Poor hygiene	Neglect
	Eccyhmoses	Abuse
	Candidiasis	Immunodeficiency
	Eczema	Allergic disease
	Erythema nodusom	Ulcerative colitis, vasculitis
HEENT	Hair loss	Stress
	Chronic otitis media	Immunodeficiency, structural orofacial defect
	Cataracts	Congenital infections, galactosemia
	Papilledema	Increased intracranial pressure
	Uveitis	Vasculitis
	Aphthous stomatitis	Crohn's disease
	Delayed tooth eruption	Delayed bone age
	Milk bottle caries	Neglect
	Thyroid enlargement	Thyroid disease
Chest	Wheezes	Cystic fibrosis, asthma
Cardiovascular	Murmur	Congenital malformations
Abdomen	Distention, hyperactive bowel sounds	Malabsorption
	Hepatosplenomegaly	Liver disease, glycogen storage, tumor
Genitourinary	Anomalies	Associated endocrinopathies
	Diaper rashes	Diarrhea, neglect
Rectum	Fistulae	Crohn's disease
	Empty ampulla	Hirschprung's disease
Extremities	Edema	Hypoalbuminemia
	Loss of muscle mass	Chronic malnutrition
	Clubbing	Chronic lung disease
Nervous system	Abnormal deep tendon reflexes	Cerebral palsy
	Developmental delay	Altered caloric intake or requirements
	Cranial nerve palsy	Dysphagia
Behavior and temperament	Uncooperative	Difficult to feed

monly, dietary supplementation with high-calorie foods and food additives is recommended to increase macronutrient intake. Infants may respond well to increasing the caloric density of their formula. For toddlers and children, the use of oils, sour cream, heavy cream, butter, peanut butter, and cheese as dietary additives is helpful. It may be necessary to work within the framework of the traditional food preferences and feeding practices of immigrant families and adoptees. For micronutrients, routine supplementation with a zinc- and iron-containing multivitamin is probably prudent, with the need for further iron therapy determined by laboratory values.

For some children, inpatient evaluation and treatment should be considered. Indications for hospital admission include (1) anthropometric evidence of acute or severe malnutrition, (2) evidence of child abuse or neglect, (3) significant dehydration, (4) significant mental illness in or substance abuse by the caretaker, (5) failure of outpatient management to achieve weight gain, and (6) a medical disorder requiring inpatient treatment or surgery.

A common error among hospitalized patients with growth failure is to underestimate their caloric requirements for growth because these can be quite high. Children recovering from severe malnutrition may gain weight safely on caloric intakes as high as 170 kcal/kg/day and protein intakes of 4 to 5 g/kg/day.[86] It should be noted that such extremes in caloric requirements are unusual in the average patient admitted for growth failure in the United States. It is also important to note that any calculations used to judge caloric requirements are merely estimates and that the sufficiency of any diet is proven by the occurrence of subsequent weight and, eventually, height gain. These parameters should be measured and charted graphically to allow assessment of the dietary intervention.

In addition to nutritional therapy, social evaluation to assess family dynamics and economic situation (eg, eligibility for state and federal assistance) should be performed. As mentioned above, visits to the home or other settings where the child receives care by a nurse or other appropriate personnel can also be enlightening in this regard. Regular outpatient and/or home visits should occur to document adequate weight gain and compliance with dietary management and to address any ongoing behavioral issues.

Behavioral modification should center on improving feeding techniques, removing conflict or struggles from mealtimes, reducing between-meal snacking or "grazing," and eliminating television and other distractions during mealtimes. Caregivers are encouraged to establish an eating routine with specific times, as well as a consistent setting and place for meals. It is also recommended that the duration of meals be limited to 30 minutes. Table 52-6 recounts a helpful schema in which three developmental stages of feeding disorders are described, with typical features of affected infants and caretakers. As noted, the approach to therapy will largely be determined by the type of feeding disorder and age of the patient.

PROGNOSIS

The ultimate growth potential of a child with growth failure is determined by a variety of factors, including genetic potential, the timing of malnutrition (intrauterine versus neonatal versus later infancy), and the severity of malnutrition (weight alone affected versus weight, height, and head circumference). The presence of underlying medical problems and their ability to be successfully managed are also important variables. Some premature infants fail to catch up

TABLE 52-6 Classification of Feeding Disorders in Infants and Children with Growth Failure

Disorder Type	*Age of Onset*	*Associated Medical Conditions*	*Features of Infants*	*Features of Caretakers*	*Treatment*
Homeostasis	0–2 mo	Limited experience with oral feeds (eg, respiratory distress)	Excitable; irritable; passive	Anxious; depressed; over- or under-stimulates infant	Pacifier during nasogastric feeds; occupational therapy re: suck and swallow
Attachment	2–6 mo	Prolonged hospitalization or separation from mother; developmental delay	Sad; hypervigilant; arches or resists when picked up	Detached; depressed; holds infant loosely	Emotional nurturance; developmental stimulation; education of caretaker re: needs of infant
Individuation or separation	6 mo–3 yr	Any condition that limits or restricts food intake (eg, diabetes, celiac)	Refuses food; defiant; plays with food	Frustrated; doesn't allow infant to self-feed	Regularly scheduled mealtimes; separate mealtimes from playtimes; encourage self-feeding

Adapted from Chatoor I, Dickson L, Schaefer S, Egan J. A developmental classification of feeding disorders associated with failure to thrive: diagnosis and treatment. In: Drotar D, editor. New directions in failure to thrive: implications for research and practice. New York: Plenum Press; 1985. p. 235–58.

normally. For instance, Kitchen and colleagues showed that in a cohort of children whose birth weights had been less than 1,500 g and who had weights or heights less than the 10th percentile at age 2 years, half were still less than the 10th percentile at age 8 years.[87] Casey and colleagues have shown that low birth weight premature infants demonstrated little catch-up growth in the first 3 years of life.[34,35] However, more recent studies have demonstrated that these children may demonstrate catch-up growth through childhood and even into adolescence, ultimately achieving predicted genetic height.[88,89] Another recent study compared adolescents born with an extremely low birth weight (ELBW, < 1,000 g) without significant neurodevelopmental disability with a matched group who had a normal birth weight.[90] It was found that those who were ELBW attained growth parameters within 2 SD of the mean, although they had smaller heights, weights, and head circumferences than their normal birth weight peers. The effect was most marked for those who were ELBW and small for gestational age. There were no significant differences in sexual maturation.

Long-term data on the growth of full-term children with a history of growth failure have been limited. In one cohort of 40 children who had been admitted for malnutrition, 17 (42.5%) had weights or heights below the 3rd percentile on follow-up after a mean of 3.4 years.[91] In another series of 30 children diagnosed before age 2 years, mean weights were 15% lower and mean heights were 5% lower than a control group in years 3 through 6 of life.[26] The interpretation of these types of studies is made difficult by biases introduced by patient selection and follow-up rate because patients requiring admission obviously represent a more severely affected spectrum of disease. Thus, not all children referred for growth failure are expected to suffer long-term growth problems.

The relationship between malnutrition in early infancy and subsequent intellectual and behavioral performance should also be commented on. As alluded to above and as further developed in Chapter 21, the human neurologic system continues to develop and grow postnatally, making environmental influences early in life crucial in any effort to achieve genetic potential. Studies from developing countries have clearly shown that children who were admitted early in life with protein-energy malnutrition had subsequently lower intellectual performance on standardized tests. Many of these studies, however, have been confounded by social and economic factors, which may also bear on ultimate intellectual function.

To help clarify the role of malnutrition per se in the genesis of developmental and intellectual delay, a classic study assessed the intellectual, motor, and social functioning of 41 patients who had suffered malnutrition in infancy.[92] Many of these patients had a history of cystic fibrosis, and none of the families had socioeconomic deprivation. Although controls scored higher than their previously malnourished siblings on intelligence testing at 2 to 5 years, this difference was not seen at later ages. Tests of motor development and social maturity were also similar between the two groups. Other more recent studies have supported the concept that appropriate psychosocial stimulation is important for cognitive development both early and later in the child's life.[93,94] How the generally milder degree of malnutrition seen in US children with growth failure impacts on subsequent cognitive, behavior, and emotional development is less clear.

PREVENTION

Because, in the United States, most causes of poor growth stem from or are complicated by social and economic adversity, amelioration of these conditions is the ultimate path to improved nutritional status of children. In the meantime, clinicians caring for these children should have an increased awareness of the medical and psychosocial factors that may predispose to growth failure, should classify such patients along the anthropometric guidelines mentioned above, and should recognize the benefits of multidisciplinary approach to difficult management situations.

CHAPTER 53

PROTEIN-ENERGY MALNUTRITION IN THE HOSPITALIZED PATIENT

Susan Baker, MD, PhD

Growth depends on a constant supply of essential nutrients in sufficient amounts and proportions. Failure to thrive occurs when growth fails as a result of inadequate nutrition. Inadequate nutrition can be caused by inadequate intake, increased losses, or increased requirements. Often a complex relationship exists between the nutrient needs of a child and the ability of the environment in which the child lives to provide the needed nutrients, whether or not in increased amounts relative to normal. Nowhere is this interaction more dramatic than in the hospital setting. In the hospital, children are physically sick and are in a stressful environment where fear, loneliness, a sense of abandonment, loss of control, and pain contribute to the physical factors that increase the demand for nutrients. Yet many diseases are associated with anorexia. Nutritional status has an impact on general health, healing after trauma or surgical procedures, risk of developing infections, clearing infections, and the pharmacokinetics of drugs. These are important factors in treating patients, especially children, who require hospitalization.

Whether it is possible or even desirable for critically ill children to grow may be debated. Although many of the nuances of nutrition support remain to be clearly demonstrated, starvation is undesirable and leads to malnutrition, with associated comorbidities. It seems reasonable that careful attention to nutritional status, disease state, and the nutritional requirements of hospitalized children could improve outcomes during a hospital stay.

Table 53-1 summarizes the many factors that affect nutritional status and hence whether children thrive or fail to thrive when hospitalized.

NUTRITIONAL STATUS ON ADMISSION

The nutritional status on admission to the hospital is an important factor in whether a child thrives in the hospital. Children whose nutritional status is poor or places them at nutritional risk may have deficits that must be repleted before growth can commence.[1–5] These deficits may be long-standing and profound, such as osteopenia caused by malabsorption, and their repletion may not be feasable during a single hospitalization. Or the deficits may be of short duration and easily reversed, such as acute weight loss associated with infectious diarrhea in an otherwise healthy child. The nutritional status on admission to hospital is an important aspect of the patient assessment and sets the baseline for nutrition planning. Recognizing this, the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) requires a focus on the provision of appropriate nutrition care in a timely manner.[6] JCAHO defines nutrition care for the hospitalized patient as consisting of the following process: (1) screening, assessing, and reassessing nutrition needs; (2) developing a plan for nutrition therapy; (3) prescribing or ordering food and other nutrients; (4) preparing and distributing or administering food and other nutrients; and (5) monitoring patient response to nutrition care.

The nutrition screen is generally conducted within 48 hours of hospitalization and determines the patient's need for a comprehensive nutrition assessment. Table 53-2 is an example of a nutrition screen. A nurse or diet technician can administer the nutrition screen. For patients who are determined to be at risk, that is, the probability exists that malnutrition is present or will develop, a full assessment and prescription for nutrition therapy are done by a

dietitian. For the screening tool identified in Table 53-2, a dietitian evaluates all children who have a BISON (Buffalo Integrated Scoring of Nutritional Status) score greater than 3, inappropriate growth velocity, presence of one of the chronic diseases listed in the table, or a serum albumin of 3.0 g/dL or less. Many children who enter the hospital enter in a poor nutritional state, often with a concurrent chronic disease. For example, between January 1, 2002, and June 30, 2002, 24% (range 15–32%) of the children admitted to the Children's Hospital of Buffalo were determined to be at risk by the nutritional screen. A dietitian then evaluates the at-risk children, a nutrition care plan is developed, and this plan is reassessed on a periodic basis during the hospitalization. The reassessment considers the appropriateness of the nutrition plan in light of disease progression or resolution, treatments, and diagnostic studies. This requirement by JCAHO appears to be a step forward in preventing the development or worsening of malnutrition during hospitalization. To date, however, no assessments of the nutritional status of children in the hospital have been performed and compared with data obtained prior to the implementation of the nutrition screen.

MALNUTRITION IN HOSPITALIZED PATIENTS

Surveys of hospitalized pediatric patients document that the prevalence of malnutrition ranges from 20 to 40%. Using anthropometric measurements, serum albumin levels, and lymphocyte counts when available, Merritt and Suskind demonstrated that one-third of all children older than 3 months in a large referral center exhibited evidence of acute malnutrition by Waterlow's criteria.[7–9] Half of these had second- or third-degree malnutrition; 55% exhibited chronic malnutrition. In addition, 9% of the patients had lymphocyte counts of less than 1.5×10^9/L and 6% less than 1.0×10^9/L. Of the 15 recorded serum albumins, 8% of the surveyed patients, 5 showed results of less than 3.5 g/dL. On a single day in 1992, Hendricks and colleagues resurveyed the Boston Children's Hospital patients, recording weight, height, serum albumin, and total lymphocyte counts.[10] They found the prevalence of acute malnutrition based on weight for height to be 24.5%, with 1.3% of the children demonstrating severe, 5.8% moderate, and 17.4% mild malnutrition. The prevalence of chronic malnutrition based on height for age was 27.2%, with 5.1% of the children demonstrating severe, 7.7% moderate, and 14.5% mild malnutrition. Fifty-four percent of the children had a serum albumin level recorded, and of those, 24% had a serum albumin level less than 3.0 g/dL. Sixty-six percent of the surveyed children had a lymphocyte count recorded, and of those children, 34.8% had a total lymphocyte count less than 1.5×10^9/L. The observations between 1979 and 1992 at the same institution show improved monitoring; 50% of the children had a serum albumin recorded in 1992 compared with 8% in 1979, and the prevalence of acute and chronic malnutrition was statistically less in 1992. For clinical purposes, however, the incidence of acute and chronic malnutrition remains high in children hospitalized at the same medical center.

In another large referral center, Cooper and colleagues studied 198 children with an age range of 0 to 22 years.[11] Anthropometric assessments were performed, and the degree of malnutrition was defined using McLaren and Read's criteria.[12,13] The overall prevalence of acute malnutrition was 54%, with 40% moderately to severely malnourished. If all infants less than 3 months of age were selected, the prevalence of acute malnutrition was 63%. Among infants requiring acute intensive care, 100% of all premature infants were malnourished, whereas 62% of term infants were malnourished. Among infants requiring chronic intensive care, 92% of premature infants and 43% of term infants were malnourished. Even infants requiring routine care were malnourished. Among the surgical population, 31% of children admitted for burns or trauma suffered from acute malnutrition, 39% of those admitted for elective procedures were acutely malnourished, and 64% of those admitted for acute but complex operative procedures were acutely malnourished. Data from two additional studies obtained on children on admission to the hospital show that the prevalence of malnutrition ranged from 15 to 32% and represented the nutritional status of children before hospitalization.[14,15] No attempt was made to correlate the presence of a chronic disease with nutritional status. Parsons and colleagues' study reassessed children after 14 days of hospitalization.[14] Only 12 of the patients who were initially studied remained in the hospital. Those patients, however, showed a significant decrease in triceps skinfold thickness, indicating that adequate nutrition was not being supplied. Biochemical values were also quantitated in this group of patients. Measurements of significance were low serum phosphorus and serum calcium concentrations in children more than 2 years old and low erythrocyte folate levels.

There is no information about hospitalized children and the effect that malnutrition has on the type and frequency of complications, length of hospital stay, or other adverse outcomes. But the serious consequences of malnutrition on adult hospitalized patients, beginning in 1935 with Studley's landmark study, are well documented.[16] Most recently, Naber and colleagues showed that patients who were malnourished on admission developed more complications during their hospital stay.[17] Patients who were more severely malnourished were more at risk than were less malnourished patients. Of interest, this study showed that confounding factors such as age, underlying disease, or severity of disease had an effect on the risk of complications developing in malnourished patients, and when these confounding factors were taken into consideration, the risk of complications decreased, although it remained high relative to nonmalnourished patients.

It is well established that primary malnutrition, that is, malnutrition caused by inadequate food intake and not associated with a disease process or surgical procedure, is associated with an increased mortality.[18–22] When coupled with an infectious process, which frequently occurs in malnourished children,[24] the risk of dying is increased further. Thus, it is likely that malnutrition has an adverse effect on children who are sick and malnourished.

AIDS = acquired immune deficiency syndrome; BISON = Buffalo Integrated Scoring of Nutritional Status; HC = head circumference; HIV = human immunodeficiency virus.

The costs that can be directly or indirectly ascribed to malnutrition in hospitalized children are unknown. Studies on adult hospitalized patients, as summarized by Tucker and Miguel and Smith and Smith,[25,26] show an increased length of stay and increased hospital charges for patients who are malnourished or at risk of becoming malnourished. These costs can be significant and when applied to the Children's Hospital at the Medical University of South Carolina amounted to $1.5 million annually in 1995 dollars.

DISEASES

A child who has a chronic disease that requires increased nutrient intake or is associated with decreased intake or increased losses on a long-term basis can enter the hospital with nutritional deficits that will likely require repletion before growth can occur. In addition to the repletion of deficits, any ongoing increased requirement will need to be met and ongoing losses replaced. It may be difficult or impossible to accomplish this during a hospitalization, especially because most hospitalizations are necessarily short. Children who are healthy but have experienced acute trauma, an elective procedure, or an acute illness present a less serious, but still important, requirement for attention to nutrition.

The actual ingestion of foods can be a problem for children with facial, oral, pharyngeal, or esophageal problems.[27–31] Central control of ingestion, mastication, and swallowing can interfere with the ability to take in enough nutrients, as can generalized muscular weakness or spasticity. Delays in the normal progression of feeding skills can occur, especially in children who have manifestations of delays in other skills.[32,33] Children who have been sick and required invasive procedures around their mouth, such as suctioning, nasogastric tubes, or endotracheal tubes, may become intolerant of oral stimulation and find feeding to be an aversive situation. Some children who have heart disease with a high oxygen requirement may simply tire before completing a feed or may have a limited ability to suck owing to anoxia or breathlessness.[34,35]

Vomiting, associated with reflux,[36] increased intracranial pressure, chemotherapy,[37] super mesenteric artery syndrome,[38,39] or volitional vomiting in older children, contributes to nutritional deficits. Disease of the gastrointestinal tract such as undiagnosed gluten-sensitive enteropathy, food allergy, inflammatory bowel disease, pseudo-obstruction, and even partial bowel obstruction can be chronic and result in inadequate nutrient retention. Loss of nutrients can also occur with rumination and cyclic vomiting. Acute causes of vomiting, such as obstruction or infections, are usually resolved in a short time and do not lead to chronic nutrient losses.

Nutrient losses also occur with diarrhea, malabsorption,[40] or protein-losing enteropathy.[41] The causes of malabsorption are many and generally involve one or more of three organs: the small bowel, the pancreas, and the liver. Any interference with the optimum functions of these organs can result in maldigestion and inadequate nutrient absorption. Problems of digestion and absorption are intrinsic to the organ itself, such as pancreatic insufficiency, cholestasis, or enteropathy. They are often long-standing and can have a severe impact on nutritional status.

Anorexia is a common occurrence in illness. Acute infections and injury are associated with the proliferation and release of inflammatory mediators such as cytokines, tumor necrosis factor, interleukins, and glucocorticoids.[42–47] These mediators are associated with anorexia, net protein breakdown, and liver anabolism. At the time of the initial infection or injury, muscle proteolysis may serve a beneficial function as a rapid source of amino acids for gluconeogenesis and liver synthesis of acute-phase reactants. Chang and Bistrian recently reviewed current understanding of the metabolic effects of individual mediators.[48] Cachexia and wasting syndromes occur in patients with a variety of serious illnesses. It is postulated that endogenous mediators of inflammation play a pivotal role in cachexia. Although the mechanisms of mediator action, interaction among mediators, and the interaction of mediators with tissues such as skeletal muscle, nervous tissue, and liver are unknown, it is likely that the endogenous mediators cause anorexia and ultimately the weight loss, low albumin, anorexia, and poor wound healing associated with severe chronic illness. Specific mediators proposed as agents in this process include tissue necrosis factor-α, interleukin-1 and -6, and interferon-γ. Currently, there are no anti-inflammatory treatments such as inhibitors, antibodies, competitive receptor binding proteins, or antisense molecules that have been shown to overcome the cachexia of chronic illness.[49] It is likely that nutrition support that is appropriately applied to critically ill patients can be beneficial in reversing protein loss and preventing the development of malnutrition. Cachexia caused by inflammation of chronic disease, however, has not been so readily reversed.

HOSPITAL-CENTERED PRACTICES THAT LEAD TO FAILURE TO THRIVE

General hospital practices, despite the best intentions, can hinder the provision of nutrition to ill children. For example, during times of financial crisis or nursing shortages, limited nursing staff may be available, the staff may be required to rotate among wards frequently, or temporary help who are not oriented to children may be employed. Knowledge of how long a child has been nil per os for diagnostic tests or treatments may be lost among the staff. Also, late food trays, incorrect formulas, child refusal to eat, and catering to specific child likes and dislikes may not be noted unless a calorie count is maintained.

DIAGNOSTIC TESTS

To understand disease and design effective treatments, diagnostic tests are required. For many of these tests, a child must not consume food for several hours prior to the test. Often scheduled tests are delayed, cancelled, or repeated, so the time a child cannot eat may be longer than anticipated. Diagnostic tests may be of considerable dura-

tion, during which time the child cannot eat. If a child requires several diagnostic tests over several days, the cumulative food intake can be very low.

TREATMENTS

Some diseases, such as a gastrointestinal obstruction, require that a child not consume food. When disease, surgery, or trauma makes it impossible to provide nutrition via the gastrointestinal tract, parenteral nutrition is an option. The use of parenteral nutrition, however, has declined over the past generation as the importance of the modulation of nutrients by the gastrointestinal tract became better understood, techniques to deliver nutrients were refined, and formulas were developed and improved to provide nutrients for different metabolic conditions. Other diseases, such as infectious diarrhea, do not routinely require food restriction, but it is not uncommon for "bowel rest," clear liquids, or other food restrictions to be inappropriately prescribed. For example, children with diarrhea are often made nil per os, given clear liquids, and then progress to a BRAT diet,[50–53] despite practice guidelines[54] and literature[55–59] that demonstrate the importance of emphasizing continued nutrition over the number or consistency of stools.

Children who have experienced significant trauma, have undergone surgery, or require care in an intensive care unit have specific nutrition needs that are best managed by a nutrition support service where dedicated nutrition professionals can frequently assess the nutritional status of the child and respond to the child's needs. Most often enteral or parenteral support is required. See Chapter 56, "Enteral Nutrition," and Chapter 57, "Parenteral Nutrition."

MEDICATIONS

A complicated interaction exists between medications and nutritional status. The relevance of this interaction to hospitalized children may be minimal or significant. The liver, gastrointestinal tract, and kidney are the organs primarily involved in drug metabolism.

Drug pharmacokinetics can be influenced by the route of drug administration; the absorptive anatomy and function of the gastrointestinal tract; the quantity of transport molecules; the ability of the liver to oxidize, reduce, and conjugate drugs; renal function; and the length of time the drugs are required. Drugs can alter nutritional status by inducing anorexia, changing the anatomy or absorptive physiology of the gastrointestinal tract, or altering liver and renal function. Specific nutrient deficiencies as well as general malnourished states can have differential effects on drug metabolism.

Drug metabolism in mildly to moderately malnourished children is not well studied. If drug metabolism is altered in mild or moderate malnutrition, the significance of the alteration is unknown. Although it is likely that mild to moderate malnutrition has important effects on some drugs, the effects may not be a serious concern for drugs that have a wide margin of safety. For drugs with a narrow therapeutic index, such as antineoplastic drugs, mild to moderate malnutrition may have important effects on their toxicity. Similarly, drugs that may be used repeatedly and for extended periods of time, such as acetaminophen, may present a cumulative risk for toxicity at a lower level than in well-nourished children.

Drugs affect the nutritional status of children. Many drugs, especially antineoplastic drugs, can cause anorexia, nausea, vomiting, and painful gastrointestinal disorders such as mucositis, diarrhea, and abdominal pain. Children receiving these drugs necessarily eat less and potentially have increased nutrient losses. These drug effects can contribute to the development or worsening of poor nutritional states and can be a cause of failure to thrive in themselves. Also, drugs can alter the absorptive capacity of the gastrointestinal tract by inducing achlorhydria, reducing pancreatic function, causing cholestasis, and damaging the absorptive surface of the small bowel. Through binding to transport proteins and direct effects on liver and renal function, drugs can alter nutritional status. Conversely, nutritional status can affect drug metabolism. Any nutrition-caused alteration in the gastrointestinal tract, such as vomiting, bacterial overgrowth, decreased motility, or altered absorptive surface area, can adversely affect drug absorption.[60] Transport proteins, such as albumin, may be low in malnourished states. For drugs that have a large fraction bound to proteins, an increase in plasma-free drug fraction may cause variation in response or toxicity.[61]

The hepatic CYP450 superfamily of enzymes oxidizes drugs. The expression of enzymes in this superfamily varies among individuals and is affected by nutritional status. Markers of hepatic oxidative metabolism, such as antipyrine and acetanilide,[62–64] show increased half-life and decreased clearance of the marker, suggesting that malnutrition decreases hepatic oxidative metabolism. Similarly, using such markers as chloramphenicol,[65] acetaminophen,[65] isoniazid,[66] and sulfadiazine,[65] conjugation of drugs was shown to be decreased in malnourished states. The impairment can result in decreased clearance and increased elimination half-life of some drugs. This altered

TABLE 54-3 Nutritional Status and Drug Metabolism

metabolism could lead to greater drug exposure and may influence drug toxicity or efficacy. See Chapter 14, "Drug Therapy and the Role of Nutrition," for further discussion.

CHILD-CENTERED FACTORS

Even if there are no impediments to a child receiving good nutrition during a hospitalization, there are many reasons why a child may not consume enough food. The child may be frightened and anxious, may need to exert control, or may exhibit oppositional behavior. Age-related eating behaviors or strong food dislikes, needing a special chair or plate, or disruption of the child's feeding schedule may contribute to inadequate intake. Careful attention to child-centered needs, such as provided by a child life program, pediatric trained nurses and physicians, and, when necessary, child psychologists, can help children overcome these issues.

SUMMARY

Many factors conspire to make the provision of adequate nutrition to hospitalized children difficult. These factors include the child's environment, the child's state of health, diagnostic and treatment requirements, and the child's developmental stage and mind-set. The importance of nutrition to hospitalized children is recognized, and efforts to overcome the many difficulties inherent in providing nutrition to sick children are ongoing.

CHAPTER 54

EVALUATION AND MANAGEMENT OF OBESITY

Carine M. Lenders, MD, MS, Alison G. Hoppin, MD

Worldwide, nutrition-related problems are increasing at an alarming rate. Trends in morbidity and mortality are shifting away from infectious diseases to nutrition-related diseases. By the end of the twentieth century, the cycle of poverty and undernutrition has worsened in some countries, whereas that of overnutrition has reached epidemic levels.[1,2] The notion of "nutrition transition" has been developed to describe the unique dietary and nutritional changes that accompany economic and sociodemographic changes in the world.[3,4] Currently, the prevalence of overnutrition and related complications is such that it is considered the most important nutritional problem globally.

DEFINITION

Any definition of obesity is useful only if it predicts medical disability or complications. Because most medical complications of obesity are associated with body fat and not muscle mass, measures of obesity represent an attempt to estimate the adipose compartment. Furthermore, most definitions of obesity represent an attempt to identify those individuals who are at risk for developing medical problems because of excess body fat.

At present, there is no precise clinically practical method to measure body fat in children and adolescents. Methods used to define obesity generally measure under- or overweight, not lean or fat. Therefore, an athlete with increased muscle mass may be classified as overweight but may not have excess body fat. Conversely, a child with an endocrine disorder that results in muscle wasting and excessive body fat may be classified as not overweight but may have an unhealthy proportion of fat tissue. Thus, measures that rely on body weight are imperfect, but they are inexpensive and practical for use in the clinical setting and in epidemiologic studies.

A variety of methods have been developed for measuring the adipose compartment directly. They include underwater weight measurements, dual-energy x-ray absorptiometry, magnetic resonance imaging, computed tomography, and stable isotope methods. These methods have recently been reviewed elsewhere[5,6] and are important for studies requiring accurate measures of adiposity but are generally too cumbersome or expensive for routine clinical use. Skinfold thickness measurements can be performed easily in a clinical setting but are imprecise. Bioelectric impedance analysis may be a reasonable compromise as it is considerably less expensive than the other direct measures of adiposity mentioned above but provides a measure of body fat with a level of accuracy that is generally acceptable for clinical and public health purposes as long as appropriate standards are available.[5,7]

Traditionally, in the United States, obesity has been defined as weight for height above the 90th percentile on the National Center for Health Statistics (NCHS) growth charts or excess weight above 120% of the median for weight given the child's age, height, and gender. More recently, body mass index (BMI), defined as the weight of the child in kilograms divided by the height in meters squared (kg/m^2), has been established as a useful standard measure of adiposity. Although BMI does not directly measure body fat, it is typically used to evaluate adiposity in adults and has been recognized as a useful predictor of adiposity in children and adolescents, which, in turn, also predicts risks for present or future medical complications of obesity.[8] BMI in children is not only correlated with other predictors of body fat but also with blood pressure,[9,10] lipid levels,[11,12] and insulin levels.[13]

Typically, BMI is not constant during childhood and adolescence and differs by gender (see BMI charts in the Appendix). Therefore, researchers who study changes in BMI should account for age and gender or for standard deviations of BMI (BMI z-scores). As reviewed elsewhere, BMI also depends on pubertal stage, reflecting disproportionate gains in fat-free compared with fat mass.[14] In addition, there is some evidence that BMI varies with ethnicity.[15] Therefore, in addition to age and gender, pubertal stage and ethnicity should be taken into account in studies involving BMI.

In 2000, the Centers for Disease Control and Prevention (CDC) established new growth charts using data from the NCHS in collaboration with the National Center for Chronic Disease Prevention and Health Promotion. These growth charts do not include data from the past decade because of the sharp rise in BMI during that period. Recognizing that the BMI of children and adolescents tends to predict obesity and related complications in adulthood, the CDC has also suggested specific nomenclature for the pediatric age group: subjects above the 85th percentile are

considered "at risk for overweight" and those above the 95th percentile are considered "overweight." Use of the term "overweight" rather than "obese" reflects the fact that the weight status of the adolescent may still improve before he or she reaches adulthood; thus, the overweight adolescent may not face the medical risks conferred by the term "obesity" in adulthood.

Most industrialized countries and countries in economic transition are experiencing a trend toward increasing obesity but at different rates, so creating definitions appropriate for international use is challenging but important. Following suggestions from the European Childhood Obesity Group and the practices of the NCHS, an International Obesity Task Force (IOTF) agreed on standard cutoff points to identify degrees of overweight among children and adolescents in both developed and developing countries. The IOTF has compiled data from six large data sets in various countries, allowing for more relevant international comparisons.[16] These data provide age- and gender-specific cutoff points for children aged 2 to 18 years. The 85th percentile on the IOTF standard charts, defining children and adolescents "at risk for overweight," also corresponds to a BMI of 25 kg/m^2 by age 18, the adult definition of "overweight." The 95th percentile on the standard chart, defining children and adolescents as "overweight," corresponds to about 30 kg/m^2 by age 18 years, the standard adult definition of "obesity."

EPIDEMIOLOGY

Relevance and Significance

Presently, one in five children in the United States is at risk for overweight, and 14% of children and adolescents in the United States are overweight (above the 85th and 95th percentiles for age and gender, respectively, based on the new CDC standards). Since the 1960s, the prevalence of obesity has tripled. Similar but more gradual trends are seen worldwide. Determining the specific causes of this rapid increase in rates of obesity is clearly essential, yet remarkably complex. Both genetic and environmental factors have been shown to contribute significantly to this problem. In general, genetic factors explain a large part of the variation of body weight within a given population in a common environment, whereas environmental factors tend to explain changes in obesity over time in that population. The study of Pima Indians provides an important example of the interaction between environmental and genetic factors.[17] The Pima Indians who live in the Southwestern United States are predisposed to obesity and diabetes, and these traits assort in patterns, indicating genetic inheritance. The genetically similar Pima living as subsistence farmers in Mexico are substantially less obese. Genetic factors clearly explain a large part of the obesity among Pima Indians in this country, whereas environmental factors explain the dramatic difference in rates of obesity between the two Pima populations.

Epidemiologists have used cohort studies and case-control designs to determine which environmental factors may contribute to obesity. Such studies have pointed to dietary trends, sedentary lifestyle, decreases in structured physical activity, psychosocial stressors, and cultural trends as likely contributors to the obesity epidemic.[3] A number of dietary factors have been proposed to play important roles. These include the easy availability, high caloric content, and strong marketing techniques of the fast-food industry, as well as general trends toward consumption of foods that are highly processed and contain high carbohydrates and/or total calories (including sugary beverages) and decreased consumption of fiber and low-density foods. Other factors include decreases in structured physical activity, particularly for children, as well as decreasing lifestyle activity (occupations and transportation require less movement than in the past) and increasing sedentary activities (particularly television viewing and computer use). However, it is important to note that, to date, no single factor among these has been shown to play a pivotal role in the increasing prevalence of obesity.

Obesity and Related Complications

A large body of evidence supports an association between obesity and important risk factors for cardiac disease and type 2 diabetes. Hyperinsulinemia, dyslipidemia, obesity, and hypertension often cluster together and are termed the "metabolic syndrome," "syndrome X," or "insulin resistance syndrome."[18,19] More recently, these findings have also been shown to be closely associated with nonalcoholic fatty liver disease, such that fatty infiltration of the liver is now often considered part of the metabolic syndrome.

The mechanisms underlying the association between these endocrine abnormalities and disease affecting diverse organ systems are the subject of ongoing research. There is support for the concept that an increased ratio of visceral to subcutaneous adipose tissue, perhaps acting through adipocyte-derived hormones such as resistin and leptin and through substrates such as circulating fats, leads to insulin resistance and high circulating levels of insulin.[20,21] Many adults with obesity display all of the elements of the metabolic syndrome, but there are some striking exceptions, even among those with severe obesity. For example, a multicenter study using clamp techniques in a group of obese adults showed that 26% of participants aged 18 to 85 years with a BMI > 25 kg/m^2 and 60% of those with a BMI > 35 kg/m^2 were insulin resistant. The frequency of hyperinsulinemia was 41% in participants with a BMI > 25 kg/m^2 and 77% in participants with a BMI > 35 kg/m^2.[22]

Similar clustering patterns have been found in children. Studies in children have shown a relationship among fasting insulin and lipids,[23–25] blood pressure,[25–28] weight,[29] and BMI.[30–32] As in adults, body fat distribution is also correlated with cardiovascular risk factors.[33,34] Berenson and colleagues showed that blood pressure, lipid levels, and BMI were positively correlated with aortic and coronary atherosclerosis at autopsy in both children and adults (2–34 years), suggesting that the metabolic syndrome starts before adulthood.[35] Using data from the Bogalusa study of cardiovascular risk factors,[36,37] Tershakovec and colleagues showed that the expression of the hypercholesterolemia in children precedes the expression of increased

body fat and that insulin and blood pressure subsequently rise as the children grow older and body fat increases.

Although there are many similarities between the findings of the metabolic syndrome in children and adults, it is important to recognize that children have a different hormonal milieu than adults, especially during puberty. All children become more insulin resistant at the time of puberty compared with either before or after puberty.[38] Increased body fat and BMI correlate strongly with fasting insulin levels and insulin resistance and have been proposed as potential mediators of the pubertal changes in insulin resistance.[39–42] However, insulin resistance can also occur during puberty in the absence of changes in BMI, coinciding with a period of rapid growth during puberty.[40] Interestingly, insulin resistance appears to oppose further weight gain in adults but may not have the same effect in children. Adults with lower insulin levels are more likely to gain weight, whereas higher insulin levels in children may predict weight gain, at least in studies either adjusted for obesity[42] or in populations in which obesity is rare.[43] However, in one study of obese children, childhood insulin resistance decreased the risk of obesity in adulthood,[44] suggesting that the difference in findings may depend on the weight class of the population studied.

In addition to hyperinsulinemia associated with the metabolic syndrome, frank type 2 diabetes is becoming increasingly common in children. The Third National Health and Nutrition Examination Survey (NHANES III) estimated a prevalence rate of 0.13% for type 2 diabetes and 1.76% for impaired glucose tolerance among a representative sample of US adolescents. Obesity increases the risk for diabetes substantially: in a study of obese adolescents, 4% had silent type 2 diabetes and 25% had impaired glucose tolerance.[45] The prevalence of type 2 diabetes is particularly high in children in people of non-European origins.[46] It has been estimated to be 3.6% among adolescent North American Indians[47] and 5.9% among Pima Indian adolescents.[48] In Ohio, type 2 diabetes accounted for 33% of all cases of diabetes among black and white adolescents, representing a 10-fold increase in the incidence of type 2 diabetes this past decade in Cincinnati.[49] Risk factors for type 2 diabetes include obesity, family history of diabetes, female gender, acanthosis nigricans, and nonwhite ethnicity.

Other consequences of obesity seen in childhood are sleep apnea, nonalcoholic steatohepatitis, cholelithiasis, pseudotumor cerebri, gastroesophageal reflux disease, polycystic ovary disease, and orthopedic problems, including Blount disease and slipped capital femoral epiphysis (Table 54-1). In addition to these complications, obesity in adults is associated with debilitating or life-threatening degenerative problems (axial arthritis and cardiovascular and cerebrovascular disease),[50,51] as well as with increased risk of certain neoplasias (breast, ovarian, prostate, and colon cancers).[52]

Tracking

"Tracking" describes the risk for a disease state persisting over time. In the case of obesity, there is a moderate risk of childhood obesity persisting into adulthood, and that risk increases if the child stays overweight as he/she grows older (Figure 54-1). Moreover, the child's risk for having obesity in adulthood also depends on the weight status of the parents. Whitaker and colleagues showed that the rate of obesity in adulthood ranged from 8% for children aged 1 and 2 years old without obese parents to 79% for adolescents aged 10 to 14 years old with at least one obese parent.[53] Before 3 years of age, the primary predictor of obesity in adulthood was the parents' obesity status, and the child's obesity status was not an important indicator of the risk of adult obesity. By contrast, after 7 years of age, the child's own obesity status became the more important predictor of his/her risk for adult obesity.

Obesity in childhood thus confers a higher risk of obesity in adulthood. Moreover, adults who were obese in childhood have a greater risk of morbidity and mortality, independent of their BMI in adulthood, family history of cardiovascular diseases or cancer, and smoking.[54,55] In the Harvard Growth Study, overweight adolescents were shown to have an increased risk for developing obesity-related medical problems in adulthood, including cardiovascular disease and diabetes, compared with adults with more recent onset of obesity. Furthermore, overweight boys had an increased risk of coronary heart disease, atherosclerotic cerebrovascular disease, colorectal cancer, and death from all causes.[54] Likewise, Sinaiko and colleagues showed that weight gain during childhood and adolescence predicts cardiovascular risk in young adults.[26]

Heritable Factors

Studies of twins and adoptees provide useful estimates of the role of heritable factors in determining an individual's body weight (see Bouchard's 1997 summary of relevant papers on heritability).[56] Adoption studies tend to generate the lowest heritability estimates (30%), whereas twin studies provide the highest heritability estimates (70%). The variability in these estimates of heritability depends in part on definitions of obesity: more severe obesity tends to have a greater heritability factor than lesser variations in BMI.[57] Such analyses are consistent with the "thrifty genotype hypothesis,"[58] in which genes predisposing to energy conservation were preserved as a survival characteristic in former times of famine but become a liability in environments with plentiful food and low required physical activity.[57] Possible mechanisms through which genetic polymorphisms can translate to differences in body weight regulation are discussed below.

Imprinting

Several decades ago, Hales and Barker showed that poor fetal and infant growth is associated with an increased risk for type 2 diabetes and other elements of the metabolic syndrome and proposed that poor nutrition early in life imprints permanent changes in glucose and insulin metabolism.[59] This concept of "fetal programming," also known as the "Barker hypothesis," has now been supported by numerous studies in other populations. It has also been extended to include the possibility that postgestational

TABLE 54-1 Prevalence of Diseases Associated with Obesity in Children

Disease	*Prevalence*	*Study Population*
Endocrine		
Type 2 diabetes	0.13%	Community, 10–19 years old; *n* = 2,867[175]
Fasting blood sugar > 110 mg/dL	1.76%	
Impaired glucose tolerance	21–25%	Obesity clinic, 4–18 years old; *n* = 167[45]
Polycystic ovaries	45% of oligomenorrheic girls, 9% of girls with regular menses	Community, all ninth grade girls (*n* = 2,249)[176]
Gastrointestinal		
Gallstones	0.6%	Pediatric inpatients[150]
Fatty liver (elevated aminotransferases)	10%	Community, obese, 12–18 yr (*n* = 332)[177]
Fatty liver (elevated aminotransferases)	20%	Obesity clinic, 2–18 yr (*n* = 72)[178]
Gastroesophageal reflux disease	22%	Community, 14–17 yr (*n* = 449)[179]
Constipation	25%	Obesity clinic, 2–18 yr (*n* = 80)[180]
Encopresis	15%	
Orthopedic		
Slipped central femoral epiphysis	0.01% (50–60% of patients are obese)	Community[181]
Blount disease	Prevalence not well established	
Respiratory		
Sleep apnea	1.6% (4.5-fold higher risk if obese)	Community; children[182]
Sleep apnea	5%	Obesity clinic[183]
Asthma	8.9% nonobese, 14.9% obese	Community[184]

influences can participate to create a "thrifty phenotype."[60] For example, a study of adults in Finland showed that the development of type 2 diabetes mellitus was associated with low birth weight followed by accelerated gain in height and weight during childhood and with high maternal BMI.[61] Similarly, a study of adults in England showed that accelerated weight gain in early childhood added to the effect of low birth weight on the risk of high blood pressure in adulthood.[62] Indeed, populations in transition from conditions of low to high nutrition may be at the greatest risk for such obesity-related complications because of the combination of fetal undernutrition and childhood overnutrition.[63]

Other studies show that the effect of birth weight on future risk is directly related to the intrauterine environment rather than to genetics, distinguishing the concept of a "thrifty *phenotype*" from that of the "thrifty *genotype*." In a study of the effects of wartime famine in Holland, infants exposed to famine in utero had higher rates of obesity and diabetes in adulthood compared with a genetically similar cohort not exposed to famine, and this effect was largely independent of birth weight.[64] Furthermore, the timing of the famine exposure during gestation appeared to have important effects as fetuses exposed to famine during the first trimester of gestation were more severely affected than those exposed later in gestation. The mechanisms underlying the observed associations, including the contributions of maternal hyperglycemia, insulinemia, and postnatal growth to the development of later complications, are an important subject for future studies.

BIOLOGY

Regulation of Body Weight

Both animals and humans have a strong tendency to maintain a stable body weight over time, owing to a close but sometimes imperfect matching of energy intake with energy expenditure. Animal studies in which energy

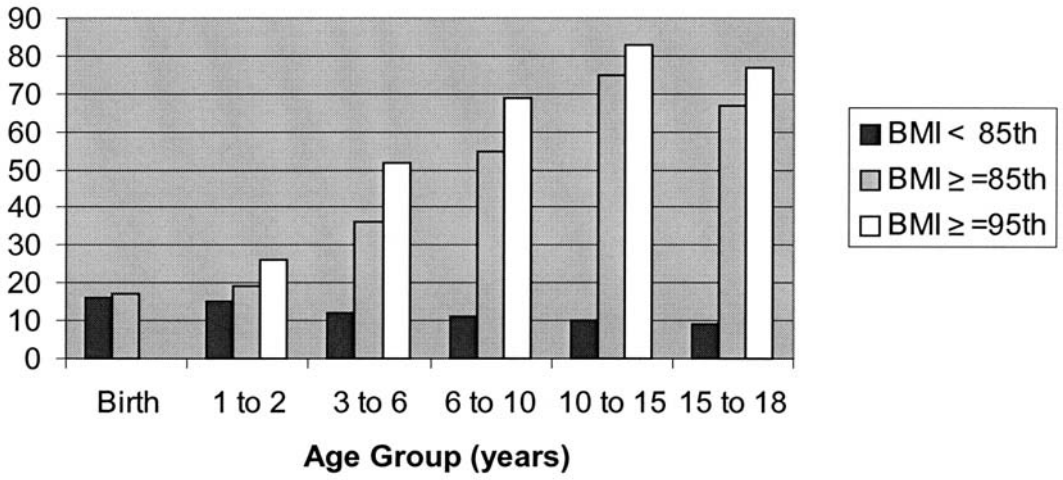

FIGURE 54-1 Percentage of children who will become obese adults. Adapted from Whitaker WC et al.[53] BMI = body mass index.

intake is manipulated reveal powerful influences from homeostatic mechanisms defending body weight. Similarly, the poor long-term results of weight reduction therapies in humans (about 95% of adults regain all weight after dieting) suggest that there are mechanisms that defend a highly individualized "set point" for body weight. When an individual has a heritable or acquired susceptibility to positive energy balance, superimposed on these native homeostatic mechanisms, he or she has a tendency to become obese.

Animal models of obesity have been invaluable in establishing an understanding of the complex mechanisms regulating body weight. Our growing understanding of these pathways is likely to lead to better-targeted interventions, both pharmacologic and behavioral. This is an area of vigorous ongoing research; the major elements of the pathways as we currently understand them are outlined below.

Afferent Pathways Circulating insulin, which reflects recent nutrient intake and metabolic demands, is an important regulator of nutrient partitioning in peripheral tissues and also communicates to centers regulating appetite in the brain. Peptides (such as cholecystokinin) secreted by the gastrointestinal tract in response to intraluminal nutrients and plasma concentrations of the macronutrients themselves also provide independent signals to the central nervous system, affecting short-term appetite and satiety.[65] For a discussion of the role of these nutrients as molecular signaling agents, see Chapter 23, "Energy and Substrate Regulation of Obesity."

Ghrelin is a peptide secreted by the stomach that is an important short-term mediator of appetite. Its name is derived from its ability to stimulate growth hormone release from the pituitary, but it also stimulates appetite through specific receptors in the ventromedial hypothalamus. Ghrelin is released from the stomach during periods of fasting and is suppressed by nutrient administration.[66] The specific stimulants of ghrelin release are not clear, but volumetric stretching of the stomach wall has no effect. A recent report shows that ghrelin is suppressed in humans who lose weight after gastric bypass surgery but not in the setting of weight loss through caloric restriction.[67] These findings suggest that ghrelin may be the mechanism for the appetite-suppressing effect and high success rates of gastric weight loss surgery.

Leptin is an important regulator of body fat, first identified in 1994 through studies of the leptin-deficient obese mouse.[68] It is produced primarily in adipose tissue and provides feedback to specific receptors in the ventromedial hypothalamus, an important center for regulation of appetite and energy expenditure. The leptin signal decreases appetite, increases both voluntary and resting energy expenditure, permits fertility,[69] and even activates central "reward" pathways that may, in turn, affect appetitive behavior.[70] The leptin-deficient animal or human therefore has hyperphagia and decreased thermogenesis and physical activity, all of which are reversible by leptin administration.

The central mechanisms through which leptin exerts these diverse effects have been partly elucidated through studies in other animal models. Animals with defects in the leptin receptor (the diabetes mouse and Zucker rat) predictably have phenotypes indistinguishable from leptin deficiency itself.

Central Nervous System The leptin signal activates a network of regulatory neuropeptides in the central nervous system. The anatomy of this network is the subject of ongoing research, but many important elements have been described. Some of the neuropeptides are orexigenic (favoring energy intake); others are anorexigenic (inhibiting energy intake). In general, leptin-generated signals tend to inhibit the orexigenic peptides and to stimulate the anorexigenic peptides, thus decreasing appetite. The network also participates in leptin's effects on the reproductive system and energy expenditure (Figure 54-2).

The melanocortin pathway is among the most important links downstream of leptin. Leptin appears to directly increase expression of pro-opiomelanocortin (POMC), which is cleaved by prohormone convertase to α-melanocyte-stimulating hormone (α-MSH),[71] as well as β-endorphin. α-MSH, in turn, stimulates the melanocortin-4 receptor (MC4-R),[72] a potent inhibitory influence on the lateral hypothalamus. Meanwhile, leptin also directly inhibits the expression of agouti-related protein, which opposes α-MSH action at the melanocortin receptors. The melanocortin pathway appears to be a particularly important regulator of body weight homeostasis because it exhibits less redundancy than other leptin-related pathways (eg, neuropeptide Y); an interruption in the melanocortin pathway can produce severe obesity, as seen in the agouti mouse.

Leptin also decreases appetite through melanocortin-independent pathways. It inhibits the expression of the orexigenic agent neuropeptide Y while increasing expression of cocaine- and amphetamine-related transcript (CART). In addition to decreasing appetite, CART has actions on the paraventricular nucleus of the hypothalamus and spinal sympathetic preganglionic neurons, where it affects energy expenditure via the autonomic nervous system (see Figure 54-2).[73]

Efferent Pathways This leptin-responsive network of neuropeptides in the hypothalamus acts on effector pathways in the cerebral cortex, pituitary-adrenal axis, and autonomic nervous system. Most signals regulating appetite and satiety meet in the nucleus tractus solitarius in the medulla, where they are further modulated by afferent signals from the autonomic nervous system. The pituitary-adrenal axis mediates leptin's effects on fertility and likely also affects energy expenditure. Indeed, adrenalectomy prevents the development of obesity in most animal models.[74]

Efferent signals to regulate energy expenditure are integrated in the locus ceruleus, from which the sympathetic nervous system stimulates lipolysis in white adipose tissue and mediates processes that facilitate voluntary energy expenditure and heat generation. Genetically engineered

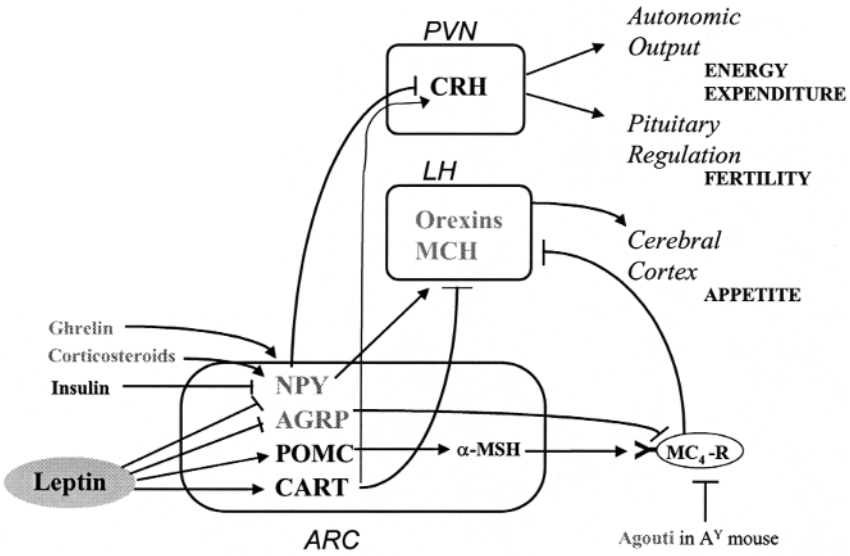

FIGURE 54-2 Central nervous system pathways regulating appetite and energy metabolism. Leptin positively regulates proopiomelanocortin (POMC) while negatively regulating agouti-related protein (AGRP)-releasing neurons in the arcuate nucleus (ARC) of the hypothalamus. POMC is a precursor of α-melanocyte-stimulating hormone (α-MSH), which is an antagonist at the MC4 receptor (MC4-R). AGRP and agouti protein are antagonists at MC4-R. The MC4-R pathway negatively regulates appetite, perhaps acting through appetite-stimulating neuropeptides in the lateral hypothalamus (LH), including melanin-concentrating hormone (MCH) and the orexins. Meanwhile, leptin has some actions that are independent of the POMC pathway, including negatively regulating neuropeptide Y (NPY), itself a potent appetite stimulant. Ghrelin also appears to act to stimulate appetite through the NPY pathway.[185] NPY also influences autonomic and pituitary output through the paraventricular nuclues (PVN), acting in part through corticotropin-releasing hormone (CRH).

animal models have clarified some elements of these effector pathways. Animals in which uncoupling protein in brown adipose tissue is knocked out have increased body fat and decreased thermogenic response to food.[75] A knockout of the β-3 adrenergic receptor has a similar phenotype, suggesting that these elements of the sympathetic nervous system are involved in increasing energy expenditure to match energy intake.[76] Parasympathetic efferent signals through the vagus nerve increase insulin secretion in the pancreatic beta cells and may be a mechanism for the hyperinsulinemia in some groups of obese people.[20]

In addition to these autonomic processes, energy expenditure has a "voluntary" component (5 to 50% of total energy expenditure, depending on the level of exercise)[77] and a component of "fidgeting," or nonexercise activity thermogenesis (NEAT). NEAT has been proposed as a genetically determined system of protection from obesity and may also be mediated by the sympathetic nervous system.[78]

Genetics of Obesity

Exploration of the genetic determinants of body weight can be done in several ways, each offering different insight and limitations. Candidate gene approaches focus on specific genes and pathways that prior studies have shown are likely to be important in producing a phenotype. Each of the neurohormones described above, as well as their receptors and the enzymes responsible for processing, can be considered a candidate gene with potential importance in the regulation of body weight. Association studies use a case-control design to assess the association between variations in genotype and obesity phenotype. This technique lends itself to testing of several polymorphisms in candidate genes within a population; however, it is also prone to substantial false-positive and false-negative results, depending on sample size. Such studies therefore are most reliable if similar gene associations can be demonstrated in several different populations. Linkage studies rely on genome-wide scans of large populations to assess the strength of the association between variations in a genomic locus and the phenotype. This technique does not rely on a priori assumptions about the biologic significance of a particular gene and is therefore important in identifying new areas for inquiry. However, it also has relatively low sensitivity and can easily overlook linkages that are common contributors to less extreme phenotypes (eg, common genes predisposing to moderate degrees of obesity). A complete list of published linkages to obesity phenotypes is summarized yearly.[79]

Any of the genes encoding a component of the mechanism for regulating body weight homeostasis, including those mentioned above, could be considered a "candidate gene" for a predisposition or resistance to obesity. Specific mutations in a few of these genes have been shown to cause obesity in rare kindreds. Mutations with strong effects were found in the leptin gene,[80] the leptin receptor gene,[81] the *POMC* gene,[82] the prohormone convertase gene (*PCSK1*),[83] and the MC4-R.[84] The latter is the most common gene in which specific mutations cause obesity, but it is still very rare (27 mutations in 68 individuals published by 2001).[85]

Association studies have analyzed many other candidate genes from the afferent and efferent pathways mentioned above in genetically similar populations (siblings, twins, or kindreds). By 2001, polymorphisms linked to

58 candidate genes had been shown to have some association with obesity phenotypes,[85] including ghrelin,[86] peroxisome proliferation–activated receptor gamma,[87] uncoupling proteins,[88] and the β-3 adrenoreceptor genes.[89]

Linkage studies in large populations have identified many chromosomal loci with associations to a variety of obesity-related phenotypes, including BMI, leptin levels, fat distribution, and hyperlipidemia. Thirty-three such loci have been identified as of the 2001 gene map update,[85] some of which appear to represent the chromosomal regions of previously identified candidate genes such as the leptin or MC4-Rs. For many other regions or quantitative trait loci, the biologic mechanisms for the apparent linkage with obesity phenotypes remain unclear.

A number of human genetic syndromes displaying mendelian patterns of transmission and whose phenotype includes obesity have been identified and catalogued in the Online Mendelian Inheritance in Man (OMIM) database.[90] Twenty-five of these syndromes have been mapped to one or more chromosomal locations. The most common syndrome with severe obesity is Prader-Willi syndrome (short stature, hyperphagia, hypogonadotropic hypogonadism, cognitive defecits), mapped to chromosome 15q 11-13, a region containing several candidate genes for which a mechanistic explanation for the Prader-Willi phenotype is being sought.[85] The Bardet-Biedl syndrome requires a mutation at one of six loci plus an additional mutation in a second locus[91] and includes polydactyly and retinopathy. Alström syndrome (obesity, retinopathy and deafness, no cognitive deficits)[92] and Cohen syndrome (hypotonia, retinopathy, and cognitive deficits)[93] have been mapped to one location each, but no obvious candidate genes have been identified.[85] Each of these syndromes has characteristic findings, as outlined in Table 54-2 and in the OMIM database,[90] and can usually be distinguished from common obesity by a careful medical history and physical examination.

EVALUATION

Medical Assessment

The initial step for the assessment of the overweight child is to exclude potential associated syndromes or endocrinopathies and to diagnose possible associated complications, as summarized in Table 54-1. Several syndromes associated with obesity should be considered, including the mendelian syndromes mentioned above. Obesity may also accompany the more common, easily recognizable syndromes of trisomy 21 and Turner. In most cases, these syndromes can be distinguished on the basis of their unique features (listed in Table 54-2 and in some excellent recent reviews,[94–96]) and specific laboratory testing is valuable for confirmation but not for screening. The assessment of medical conditions related to overweight (see Table 54-1) has also been summarized elsewhere.[97]

The value of screening laboratory testing has been debated[98] but can be useful to establish whether there is dyslipidemia, steatohepatitis, or evidence of glucose intolerance, particularly as specific treatments for some of these disorders are increasingly considered.[99,100] Blood testing should be done in a fasting state if practicable. Thyroid-stimulating hormone, hemoglobin A_{1C}, total cholesterol, very-low-density lipoprotein, low-density lipoprotein, high-density lipoprotein, aspartate aminotransferase, and alanine aminotransferase (ALT) have been recommended to screen for possible hypothyroidism, diabetes, dyslipidemia, and steatohepatitis, respectively. Fasting glucose and insulin levels will provide information on carbohydrate metabolism and insulin resistance and may predict a

TABLE 54-2 Characteristics of the Major Syndromes Associated with Obesity

Syndrome	*Cognitive Deficit*	*Obesity*	*Features*
Albright's[96]	Mild	Variable (general), early onset	Neuroendocrine anomalies, normal or short, skin hyperpigmentation/vitiligo, polydactyly, bone fibrous dysplasia, precocious puberty
Alström[186]	None	Moderate (central), onset age 2–5 yr	Retinitis pigmentosa, deafness, neuroendocrine anomalies, normal or short stature, normal or hypogonadism
Bardet-Biedl[95]	Moderate	Moderate (central), onset age 1–2 yr	Normal or short stature, hypotonia, compulsive behavior, retinitis, heart anomalies, polydactyly, renal dysfunction, hypogonadism
Carpenter[187]	Mild	Central	Acrocephaly, polydactyly, syndactyly, short stature, flat nasal bridge, high arched palate, heart anomalies, hypogonadism
Cohen[94]	Mild	Variable (central), midchildhood	Short or tall stature, hypotonia, microcephaly, retinochoroidal dystrophy, short philtrum, low hairline, heart anomalies, normal or hypogonadism
POMC mutation[82] (autosomal dominant)	None	Early onset	Red hair, ACTH deficiency, hyperphagia
Prader-Willi[188]	Mild to moderate	Moderate to severe (generalized), onset 1–3 yr	Short stature, hypotonia, almond-shaped eyes, V-shaped mouth, neuroendocrine anomalies, compulsive behavior, high arched palate, hypogonadism

ACTH = adrenocorticotropic hormone; POMC = pro-opiomelanocortin.

risk for diabetes. Specific guidelines to screen for type 2 diabetes in overweight children have been developed (Table 54-3) but are also controversial because of the large number of adolescents fitting the screening criteria (currently about 2.5 million in the United States) and the relatively low yield of the suggested screening tests.[101] Serum levels of vitamin E have been shown to be low in about 30% of obese children but return to the normal range with multivitamin supplements, so empiric treatment, rather than specific blood testing, is probably appropriate.

Further laboratory testing may be useful in selected cases but can be expensive, and some tests are not readily available. Sleep studies can and should be performed if there are strong clinical symptoms of sleep apnea, and radiographic evaluation is necessary when slipped capital femoral epiphysis or Blount disease is suspected. Indirect calorimetry can be used to predict the energy deficit necessary for weight loss.[102] This might be especially useful when poor compliance or an eating disorder is suspected and at times may be useful to provide concrete caloric goals to support dietary changes. Bone age may be helpful in supporting the diagnosis of an endocrinopathy. Consultations with specialists in sleep disorders, neurology, otorhinolaryngology, pulmonology/allergy, endocrinology, genetics, ophthalmology, and surgery may be necessary to manage specific complications. Involvement of specialists in nutrition, physical therapy, behavior therapy or psychology, psychiatry, and social work can be valuable in forming specific treatment plans.

The medical history should include assessment of concomitant medical diseases for their potential to contribute to weight gain (such as a history of significant head trauma or hypothalamic dysfunction) and to identify barriers to treatment (factors limiting mobility or ability to be physically active). A variety of drugs used for the treatment of psychiatric disease, epilepsy, diabetes, and migraines are associated with weight gain. Identifying these as a likely trigger of weight gain may prompt consideration of alternate drugs (Table 54-4).

TABLE 54-3 American Diabetes Association Guidelines for the Assessment of Type 2 Diabetes in Children with Overweight or Obesity

Children and adolescents should undergo specific testing for diabetes if they are:

Overweight, as defined by
- BMI > 85th percentile for age and sex, or
- Weight for height > 85th percentile, or
- Weight > 120% of ideal (50th percentile) for height, and

Have at least two of the following risk factors:
- A family history of type 2 diabetes in first- and second-degree relatives
- Belong to one of the following specific race/ethnic group
  - American Indians
  - African Americans
  - Hispanic Americans
  - Asians/South Pacific Islanders
- One or more of the following signs of insulin resistance or conditions associated with insulin resistance
  - Acanthosis nigricans
  - Hypertension
  - Dyslipidemia
  - Polycystic ovary syndrome
- Testing should consist of either
  - Fasting plasma glucose (8-hour fast), or
  - Oral glucose tolerance test (blood glucose level 2 hr post challenge)
- Further study is called for to determine the predictive value of Hgb A_{1C} and fasting insulin levels in determining risks for type 2 diabetes in children.

Adapted from American Diabetes Association.[49]

Nutritional Assessment

Nutritional evaluation should include, at a minimum, anthropometric measurements and a history of the onset of obesity, as well as of weight loss attempts. Periods of adiposity rebound and potential triggers for excess weight gain should be identified. Family history of obesity and related medical problems should be evaluated to help establish the genetic factors underlying the weight disorder and of the potential future medical risks. Assessing dietary intake by recalled food frequency helps to identify diet composition but, in most cases, does not provide a good estimate of energy intake as under-reporting of food intake by obese subjects is well described.[103] In particular, estimating the proportion of each macronutrient and fiber in the diet may help identify targets for dietary change if the diet is particularly skewed toward fat- or energy-dense foods. In addition, the diet recall may be useful to assess the diet for deficiencies in micronutrients, particularly calcium and vitamins A and E, betacarotene, folic acid, and other B vitamins; excessive energy intake does not always mean adequate intake of micronutrients.

To establish possible areas for intervention, the amount and type of dairy products, fruits, vegetables, and legumes should be evaluated, and particular attention should be given to the consumption of sugary beverages, including juices and soda. Excessive consumption of sugary beverages has been associated with excess weight gain and increased rate of obesity[104] and is an early target for dietary change. Similarly, the frequency of use of fast-food restaurants and other restaurant meals should be examined as these meals often contain excessive caloric content. The diet history should also determine usual meal patterns, with attention to whether there is regular skipping of meals, binge pattern of eating, and the social context of meals, particularly if there are routine family dinners.

Finally, the potential role of exercise and sedentary behaviors should be evaluated, with particular attention to determining the frequency of television and computer use. Several studies have suggested specific causal effects of television viewing on obesity,[105] and the American Academy of Pediatrics recommends limiting television viewing to 1 or 2 hours per day.[106] Assessment of lifestyle exercise, in the form of outdoor play or regular walking (eg, walking to school), is as important as assessing structured exercise, such as participation in sports programs.

Behavioral Assessment

The psychosocial complications of obesity are often subjective and difficult to measure in a standard fashion but undoubtedly represent one of the greatest burdens of obe-

TABLE 54-4 Selected Drugs Associated with Weight Gain

Drugs with Weight Gain Potential	*Alternatives with Less Potential for Weight Gain*
Atypical antipsychotics[189,190]	
Clozapine ++++ (gain 4–12 kg)	Quetiapine
Olanzapine ++++	Ziprasidone
Risperidone ++	
Mood stabilizers[191,192]	
Divalproex sodium +++	Lamotrigine (weight neutral)
Lithium +++ (10 kg over 6–10 yr)	Adjunctive topiramate (6% of weight lost at 1 yr)
Tricyclic antidepressants[191,193]	
Amitriptyline ++	
Imipramine ++	Desipramine
Nortriptyline	
Monoamine oxidase inhibitors[191,194]	
Phenelzine > isocarboxazid	Tranylcypromine
Selective serotonin reuptake inhibitors[195]	
Paroxetine ++ (3.6% gain at 6 mo; 25% of patients gained more than 7% of body weight)	
Sertraline +	Fluoxetine
Atypical antidepressants[196]	Buproprion (weight loss)
Anticonvulsants[197]	
Valproate +++ 10–60% of patients gain weight; average gain 8–20 kg[198]	Zonisamide Topiramate (weight loss)[199] 50% lose > 5 lb
Carbamazepine ++ 15 kg /3 mo	
Gabapentin ++ (23% gained > 10% of weight)	
Antidiabetic agents	
Insulin +++ (average 4 kg over 10 yr)[200]	Metformin (2–3 kg weight loss over 6 mo)[201]
Thiazolidinediones ++ (2–5 kg gain)[201]	

sity in children and adolescents. In many cases, psychosocial issues are best understood as consequences of the disease, brought on by feelings of discouragement and criticism by family, peers, or self. In other instances, the psychological issues precede or exacerbate the obesity. Regardless of the causality, it is important to acknowledge and assess these behavioral and psychological issues in each individual to best target treatment.

Depressive symptoms,[107,108] anxiety,[109,110] binge-eating disorder,[111–114] decreased self-esteem[115–117] and problems with social interactions[118,119] have generally been found more frequently in obese children and adolescents than in their lean peers. Negative psychosocial outcomes also persist into early adulthood, when obesity is associated with lower educational attainment and household income and lower rates of marriage, independent of baseline education and aptitude.[120,121] Many of these consequences can be attributed to the widespread and culturally entrenched bias against obese individuals in our current society.[121,122]

Optimal assessment of the psychosocial issues contributing to and stemming from obesity in a particular patient has not been established and varies greatly between centers and providers. Whether or not standardized instruments are used, some effort should be made to assess mood, motivation, school and social performance, self-image, and eating attitudes and behaviors. It is also important to assess these issues in parents or close caretakers of the patient as factors such as motivation, mood disorders, and eating disorders in a parent will have a substantial impact on the child's attitudes, behaviors, and ability to respond to treatment.[119] The family's financial resources and level of cognitive stimulation in the household also predict the development of obesity[123] and may also affect the family's ability to respond to treatment. A "stages of change" model may be helpful in establishing the readiness of the patient and family for making lifestyle changes (Table 54-5). If the patient or family is in an early stage of change (precontemplation or contemplation), efforts should be focused on helping them forward into the next stage, perhaps using motivational interviewing techniques.

TREATMENT

Nutritional Therapy

Long-term studies of nutrition and exercise interventions for prevention of pediatric obesity are sparse and generally inconclusive. However, studies with short and moderate lengths of follow-up have shown benefits from a variety of "lifestyle" interventions, including nutritional education (in 3- to 9-year-old school children),[124] exercise, and measures to decrease sedentary activity.[125] All of these interventions have some effects in specific settings, although similar interventions in different settings failed to show an effect.[126–128] These studies are the subject of several recent reviews.[6,129,130] Most such studies target a school-based population and do not include the family in the intervention. The interpretation of such studies is hampered by high attrition rates, lack of standardization in definitions of obesity and treatment techniques, and limited generalizability.

There is better information available about treatment interventions for preadolescents and adolescents with established obesity, but the majority of studies still do not provide long-term data, and many issues, such as optimal macronutrient composition of diets and strategies to change food preference, have not been adequately studied. A few studies have suggested that structured exercise increases weight loss compared to diet alone,[131,132] and treatments focusing on increasing lifestyle exercise and reducing sedentary behaviors have also shown beneficial effects.[133–135] In general, regimens that combine hypocaloric diets with exercise and behavior modification have been particularly effective.[134–136] Epstein and colleagues have shown a medically significant long-term effect of an 8-month family-based behavioral intervention for families with children 6 to 11 years old. The improvement persisted 10 years after the intervention was completed.[137] The design of this study supports the conclusion that the behavioral intervention was a critical component of the success.

Typically, dietary recommendations for adults and children with obesity have consisted of reduction in dietary fat and energy intake as a balanced, hypocaloric diet. Recommendations have been developed by the American Academy of Nutrition as summarized in the *Pediatric Nutrition*

TABLE 54-5 Stages of Change

Precontemplation
Unaware of, denies, or minimizes the problem
Needs: encouragement to re-evaluate current behavior; encouragement of self-exploration, NOT action; provide information, personalizing the risks
Contemplation
Aware of the problem, ambivalent about change
Needs: gentle confrontation, information and rationale for change, clarification of any misinformation
Preparation
Has decided to make change, plans to do so within the next month or is gathering information
Needs: assistance in identifying and overcoming obstacles; assistance to identify social supports; encouragement to take small initial steps
Action
Plan is in progress; attitudinal and behavioral changes have begun
Needs: tools and techniques to implement goals, positive reinforcement; support to deal with obstacles and losses, focusing on long-term benefits
Maintenance/relapse
Action maintained over 6 months (maintenance) or return to old habits (relapse)

handbook[138] and are similar to those supported by other governmental agencies, as described in a recent review by Ikeda and Mitchell.[139] The goal of the intervention is to reach a healthy weight without affecting linear growth. Specific recommendations include limiting beverages and foods with high caloric density and low nutritional value, including sugary beverages, full-fat or low-fat baked goods and candies, and encouraging whole grains, fruits, and vegetables. Simple behavioral measures such as meal planning and label reading during grocery shopping are also generally encouraged to support the implementation of these nutritional guidelines.

The "traffic light diet" provides a structured, balanced, hypocaloric diet in a simple format and has been used effectively for preadolescent[132,137] and preschool children.[140] It uses a simple color-coding scheme to categorize foods into categories for free consumption (low-density foods, green), moderate consumption (moderate-density and protein-containing foods, yellow), and very limited consumption (foods with high caloric density and/or with high sugar or fat content, red). The prescribed caloric content of the diet is generally between 900 and 1,300 kcal daily.

The protein-sparing modified fast diet (PSMF) provides high-quality lean protein while strictly limiting total calories. It has been used to treat severe obesity in a variety of settings, including hospitalized patients and school-based interventions. This diet has been effectively used in settings where short-term weight loss is medically necessary, but there are no data to suggest that it reliably improves obesity in the long term. The principles of this diet are described in Table 54-6 and have been reviewed elsewhere, with sample menus.[141,142] Typically, patients start with a hypocaloric diet for 2 weeks before the PSMF diet is started (1,200 kcal/day); the PSMF diet continues for about 12 weeks (600–800 kcal/day) and is followed by a maintenance diet (balanced, 1,200 kcal/day). Of note, Figueroa-Colon and colleagues reported an 11.2 kg weight loss after 10 weeks of a PSMF diet, substantially more than that achieved by less restrictive measures, but by 15 months follow-up, the weight loss achieved by the two groups was similar.[143]

Although the caloric content of a diet has been shown to relate to treatment success at 1 year,[144] to date, there is little evidence to suggest that alterations in specific macronutrients yield long-term weight reduction. A variety of popular diets have arisen around alterations of specific macronutrients, with or without limitations on total caloric intake. Many of these show good short-term weight loss, but whether these diets achieve long-term effects on obesity is unclear as no adequate long-term studies (with 5 or more years of follow-up) of these diets in representative adult or pediatric populations have been published. Freedman and colleagues reviewed the available evidence of benefits and risk associated with popular diets in adults.[145] Diets that specifically limit fat intake, popularized by Dean Ornish, were the subject of a recent review of studies with 6 to 18 months of follow-up.[146] The authors of that review conclude that fat-restricted diets are no better than calorie-restricted diets in achieving long-term weight loss in overweight or obese people.

Several dietary approaches have focused on limiting carbohydrates, with (as in the "Zone" diet) or without (as in the Atkins diet) restrictions on fat intake. Careful analysis reveals that in the short term, low-carbohydrate diets cause a greater loss of body water than body fat. If the diet is maintained in the long term, it results in the loss of body fat. There are few long-term data regarding the overall efficacy of these low-carbohydrate diets. High-fat, low-carbohydrate diets such as the Atkins diet are nutritionally inadequate and require supplementation of calcium and water-soluble vitamins.[145]

Caution should be used when considering the results of studies such as these that focus on adult populations because there is compelling evidence that at least some "lifestyle" approaches to obesity are substantially more effective in children than they are in adults.[147] Some dietary

TABLE 54-6 Protein-Sparing Modified Fast Diet

High-protein, hypocaloric diet for 12 weeks:
600–800 kcal
Protein 2 g/kg/d (maximum 100 g/d; approximately 50% of calories)
13–20 oz/d lean meat or substitute
Fat approximately 30–40% of calories
Carbohydrate 10–20% calories
As low-starch vegetables, may include one fruit
Ad libitum: tea, bouillion, pickles, spices, mustard
2 L of water per day
Supplements
Multivitamin with minerals
Elemental calcium supplement to meet Recommended Daily Intake
Monitor serum potassium and supplement as needed
Maintenance diet (36 wk)
Balanced macronutrients
1,200 kcals/d

Adapted from Suskind RM et al.[141]

approaches might prove to have long-term results in children even if none can be demonstrated for adults. Diets that include a low glycemic index/load approach or higher consumption of calcium are currently under investigation[104,148] and will require long-term study before any useful conclusions can be drawn. A trial of increasing the fiber content of a hypocaloric diet in children yielded no better short-term results than a hypocaloric diet alone.[149] Medical guidance is important as there are ongoing concerns about medical complications, including dyslipidemias arising from the use of some popular diets and from the use of dietary supplements for weight loss, including in children. As many as 80% of children using unsupervised diets from popular magazines had medical problems resulting from these diets.[139]

As the rates of obesity rise, obese children represent an increasing proportion of hospital inpatients.[150] Whether or not the child is hospitalized for an obesity-related condition such as gallstones, diabetes, sleep apnea, or orthopedic problems, their nutritional needs must be considered. It is particularly important to recognize that the obesity is a chronic problem and will not resolve by attempting weight loss acutely during the inpatient stay. Moreover, acute severe caloric restriction is inappropriate and can lead to metabolic problems, including refeeding syndrome, despite the child's adequate energy stores. Guidelines for nutritional care of the obese adult inpatients have been developed,[151] but this issue has not been examined in children. It may be appropriate to prescribe a modest reduction in caloric intake, guided by indirect calorimetry or by calculations based on adjusted body weights and using a stress factor that is appropriate to the child's condition (see Appendix). The inpatient stay may also present an opportunity for nutritional education and for engaging the patient and family in a therapeutic plan to address the obesity beyond the hospital stay.

Behavior Therapy

As discussed above, some interventions in childhood have demonstrated long-term improvement of obesity with 5[152] or 10 years[137] of follow-up; thus, children appear to have a more consistent and durable response to therapy than adults in the same family[147] or adult populations in general. The importance of including behavior therapy in the treatment of obesity in children has been demonstrated, at least in a family-based setting.[153] Although many interventions use combinations of dietary, exercise, and behavioral interventions, it is notable that the few studies with long-term results have had a rigorous and structured behavioral component.[136]

Commonly used techniques include self-monitoring of food intake and weight, modeling, positive reinforcement (praise), contingency management (certain behaviors are paired with predictable, reinforcing responses), and stimulus control (learning to avoid situations that are cues to overeat). Some studies have tested specific elements of these behavioral techniques. These have shown superiority of family-based over patient-focused treatment,[137] of gradual behavioral treatment (eight sessions over 15 weeks) over rapid behavioral treatment (eight sessions over 4 weeks),[154] of positive reinforcement over restrictive or critical approaches,[135] and of frequent (daily) over less frequent (weekly) positive reinforcement.[155] The value of problem-solving techniques has not been consistently shown.[156,157] Thus, there is ample evidence to support the use of behavioral modification techniques in the treatment and possibly the prevention of obesity in children. Behavior therapy should be thought of as a tool to achieve long-term changes in diet and exercise. By contrast, there are few data to support the use of behavior "micromanaging" techniques such as rate of eating and bite size.

Weight Loss Drugs

Many of the drugs used for the treatment of obesity in adults in the past are characterized by unproven claims, highly variable efficacy, or dangerous side effects. Nonetheless, the incomplete but growing understanding of the mechanisms underlying the homeostatic control of body weight and the increased rigor applied to clinical drug trials hold promise for the development and use of pharmacologic agents to treat this chronic disease. In the short term, drugs can be important for a patient whose medical condition requires acute weight loss. Drugs may also have a role in treating the chronic component of obesity. Modification of the environmental and societal pressures contributing to obesity should always be thought of as an important ultimate goal, but the use of drugs to promote weight loss may keep an individual patient engaged in the "lifestyle" component of treatment and might even change some of the consumer pressures that contribute to our obesity-promoting environment. Thus, pharmacotherapy for obesity is not at odds with lifestyle-changing approaches. As increasingly specific drugs are developed, efficacy and safety improve, and pharmacotherapy may ultimately be an essential tool to treat an otherwise refractory and devastating disease. Whether pharmacologic treatment is cost-effective depends in large part on whether it prevents the medical complications of obesity and associated costs of medical care.

Current options for the pharmacologic treatment of obesity are limited but may have some clinical utility in adults and adolescents. In general, the drugs demonstrate only modest efficacy but minimal side effects. Sibutramine (Meridia) is an appetite suppressant that has been the subject of extensive clinical trials and was approved by the US Food and Drug Administration (FDA) for use in adults with obesity in conjunction with a dietary regimen. It is an inhibitor of both norepinephrine and serotonin reuptake and also weakly inhibits dopamine reuptake. At doses of 10 or 15 mg daily, combined with a reduced calorie diet, modest weight loss is achieved in most patients (loss of 5 to 8% of baseline weight compared with 1 to 4% of weight on placebo),[158–160] but the range of weight loss varies greatly. Weight loss is sustained for most patients as long as the drug is continued (up to 3 years observation periods reported)[161] but generally is regained after the drug is discontinued. Side effects include modest increases in blood pressure (2 mm Hg average) and heart rate, dry mouth, constipation, and insomnia. Most side effects are

transient and lead to discontinuation of the drug in about 5% of patients.[160] Importantly, no evidence of valvular heart disease such as that associated with fenfluramine treatment has been found in rigorous studies. Metabolic abnormalities associated with obesity, including hyperlipidemia and insulin resistance, tend to improve commensurate with weight loss.

Orlistat (Xenical) is the only FDA-approved drug that reduces nutrient absorption. It acts by inhibiting gastrointestinal lipases, reducing fat digestion and absorption. Predictably, its side effects are related to fat malabsorption, consisting of steatorrhea when high-fat meals are taken and decreases in serum levels of fat-soluble vitamins, primarily vitamin D.[157] Daily administration of a multivitamin is therefore recommended. Modest weight loss (3.2% more than placebo)[162] is generally achieved, and sustained use partially prevents weight regain during a second year of treatment.[163] Orlistat and sibutramine are currently approved by the FDA for short-term use (up to 1 year). Long-term studies (up to 5 years) of these drugs in adults are in progress.

A few other drugs have been tested in preliminary phases in children and adolescents. Metformin improves insulin sensitivity and also promotes modest weight loss in adults.[164] By contrast to other antihyperglycemic agents, metformin does not increase insulin secretion but decreases hepatic glucose production and improves insulin sensitivity in both diabetic and nondiabetic adults.[165] Small open-label trials of metformin have suggested that it may be useful in ameliorating psychotropic drug-induced weight gain in children.[166] A small randomized trial of metformin in adolescents with hyperinsulinemia and a family history of diabetes showed improved glucose tolerance and a modest decrease in BMI.[167]

The safety and effectiveness of weight loss drugs in adolescents and children have not been established. Large multicenter randomized placebo-controlled trials of sibutramine and orlistat in adolescents are in progress, as are smaller randomized trials of metformin and ephedrine-caffeine. Careful review of these results will be necessary before pharmacotherapy outside clinical trials can be recommended in adolescents or children.

Based on current literature, the modest weight loss achieved by the use of current available drugs in conjunction with reduced-calorie diets is probably not adequate to treat individuals with severe life-threatening complications of obesity, but the drugs may be useful to boost weight loss, assist weight loss maintenance, and reinforce lifestyle change. Whether phenotypic or genotypic analysis can be used to select for patients who respond relatively well to these agents is a subject for future study.

Phentermine, diethylproprion, phendimetrazine, and benzphetamine are noradrenergic agents with appetite-suppressant effects but are studied and approved for short-term use only (generally 12 weeks or less).[157] The latter two drugs are considered to have some potential for abuse and are listed on Schedule III of the Drug Enforcement Agency. The use of any agent with only short-term goals for weight loss in children and adolescents, particularly one with any potential for abuse, is highly questionable.

Dietary "supplements" or herbal medicines are popular, and consumers spend more than 1 billion dollars on these products annually in the United States. However, they are unregulated and relatively untested. The commonly used herbal supplements are listed in Table 54-7. Supplements that could be used with caution in adults include conjugated linoliec acid, ginseng, chromium, hydroxy citric acid, dehydroepiandrosterone (DHEA), hydroxymethyl butyrate, chitosan, and St. John's wort, but there is little evidence of the effectiveness for these drugs. Substances that have questionable safety and should be discouraged include Ephedra (or ma huang), horsetail, herbal laxatives, and some forms of caffeine and fiber.[168,169] To our knowledge, there are no studies of dietary supplements and weight loss in children, and no supplements for weight loss can be recommended or even considered with caution.

Weight Loss Surgery

Over the past 15 years, surgically induced weight loss has emerged as an important option for adults with severe obesity. In contrast to poor long-term success rates for nonsurgical treatments of obesity, surgical approaches generally produce durable and substantial weight loss. Over 80% of patients lose at least half of their excess body weight during the first year. Weight generally stabilizes 12 to 24 months after surgery, and 10 to 20% of patients regain a significant portion of the lost weight. If a patient maintains weight loss for 5 years, there is an excellent likelihood that the weight loss will persist for at least 14 years.[170] Studies have shown improvement or resolution of many of the medical complications of obesity, including diabetes mellitus, hypercholesterolemia, and obstructive sleep apnea.[171]

The jejunoileal bypass was an early surgical procedure for weight loss and caused global malabsorption. It caused frequent and unacceptable side effects, including intractable diarrhea, nutrient deficiencies, kidney stones, and hepatic failure. The two most common operations performed today are the Roux-en-Y gastric bypass and vertical banded gastroplasty (Figure 54-3), both of which reduce the gastric capacity to restrict caloric intake. In contrast to the jejunoileal bypass, these operations do not cause significant malabsorption, and their safety profile is substantially better. The mechanism through which these operations cause weight loss is not fully understood, although recent studies suggest that it may suppress gastric production of ghrelin, thereby reducing appetite.[67] About 10% of patients have important complications of these procedures, which include anastomotic strictures, incisional hernias, and gallstone formation requiring cholecystectomy. Anastomotic leaks, staple line disruptions, and dumping syndrome can occur but have been reduced to 1 to 2% each by modifications in surgical technique.[172] Although protein-calorie malabsorption is rare, malabsorption of selected micronutrients, particularly iron and vitamin B_{12}, is common and requires postoperative monitoring and treatment.

Gastric restrictive procedures for weight loss are thus an appropriate treatment option for adults with medically significant obesity, but there is still significant uncertainty regarding optimal patient selection. To date, no psycholog-

TABLE 54-7 Dietary Supplements for Weight Loss[167,168,203]

Dietary Supplement	*Other Names*	*Mechanism*	*Effectiveness*	*Safety*
Ephedra alkaloids	Ma huang, norepinephrine	Thermogenic	Yes, only in combination with caffeine	Unsafe (hypertension, palpitation, tachycardia, stroke, seizures, death)
Caffeine	Guarana *(Paullinia cupana)*, Yerba maté *(Ilex paraguayansis)*	Thermogenic	No, when used alone	High doses or combinations may be unsafe (hypertension, tachycardia, nausea, dizziness)
Chromium	Chromium picolinate	≠ Insulin sensitivity	Uncertain	Uncertain
Ginseng	Korean ginseng *(Panax ginseng)*, American ginseng (*Panax quinquefolux*), Siberian ginseng *(Eleutherococcus senticosus)*	≠ Insulin sensitivity, Thermogenic, ≠ Lipolysis	Uncertain	Uncertain; may interfere with anticoagulant effect of warfarin
Fiber	Guar gum, psyllium, flaxseed, glucomannan	Malabsorption ≠ Insulin sensitivity	Unlikely	Generally safe, but some forms may have risk of gastrointestinal obstruction
Hydroxycitric acid	Malabar tamarind *(Garcinia cambogia)*	Ø De novo fatty acid synthesis	Unlikely	Uncertain
Dehydroepiandrosterone (DHEA)	Adrenal steroid hormone	Ø Fat synthesis	Uncertain	Uncertain, metabolites may stimulate breast and prostate tissue
Chitosan	Chitin (crustacean shells)	Blocks dietary fat absorption	Uncertain	Uncertain
Horsetail	*Equisetum* sp	Diuretic	Uncertain	Unsafe (may be K+ wasting)
Senna cascara	*Cassia* sp *Rhamnus pushiana*	Laxatives	Uncertain	Unsafe for treatment of obesity
St. John's wort	"Herbal phen-fen" *Hypericum perforatum*	Antidepressant	Unlikely	Uncertain, phototoxicity; drug interactions with many psychoactive drugs

ical or physiologic factors have been defined that will determine which patients are most likely to suffer weight regain after surgery (approximately 20%) or to suffer medical or psychological complications of surgery. Similarly, there are limited data on the outcomes of weight loss surgery in adolescent patients, but a few series have been published,[173,174] and these suggest that short- and long-term outcomes and complications in adolescents are similar to those seen in adults. Weight loss surgery may therefore be appropriate in selected severely obese adolescents. Given the limited data available on outcomes in this age group, these procedures should probably be limited to patients who have exhausted other management approaches and have significant medical complications of

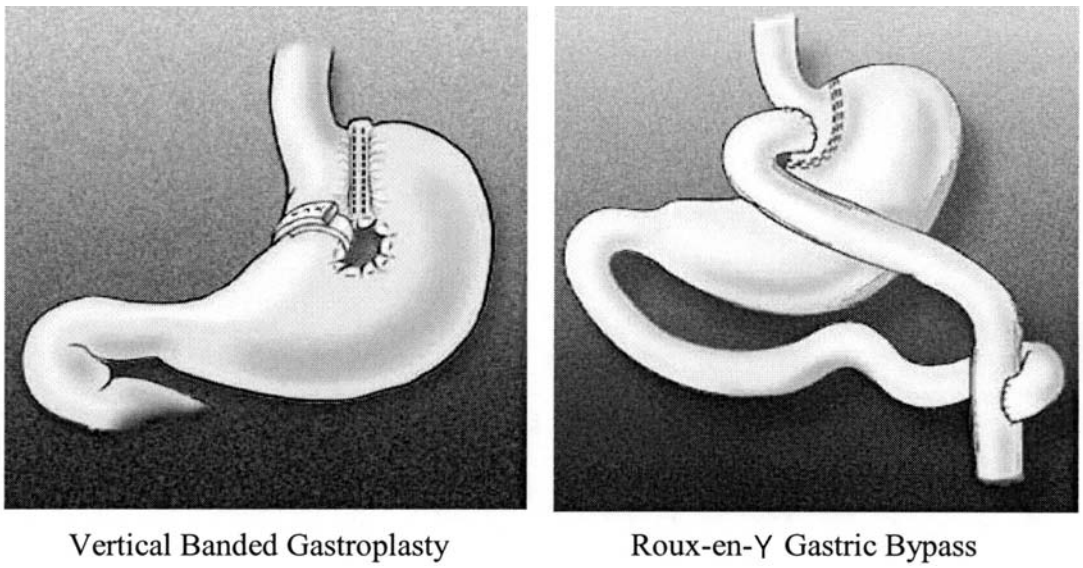

FIGURE 54-3 Gastric restrictive surgery for weight loss.

their obesity. To optimize long-term outcomes, any concomitant psychiatric disorders should be carefully assessed and under good control before surgery, and measures should be taken to ensure long-term follow-up for medical, surgical, and nutritional issues, ideally in the setting of a multidisciplinary obesity treatment center with substantial experience in surgical treatment of obesity.

Future Directions

With the exception of surgery, current treatments for established obesity have disappointing long-term outcomes. However, research is likely to lead to advances in several important arenas. Perhaps most importantly, public recognition of the obesity problem should lead to public education and public programs designed to prevent obesity during childhood. Such population-wide approaches are more likely to be effective than treatment approaches targeting individual patients with resource-intensive and weakly effective therapies. However, the identification of which preventive strategies will be most effective is important before they can be implemented widely. Second, improved understanding of the genetic determinants and neural pathways underling the homeostatic control of body weight is likely to lead to pharmacologic interventions that are more specific and therefore safer and more effective. Third, rigorously scientific and detailed analysis of specific environmental factors contributing to obesity, including issues of diet composition and meal patterns, may lead to more focused dietary and behavioral interventions to treat obesity. Finally, education of the public and health care community to recognize and reverse the commonly held bias against obese individuals should help to minimize the stigma and therefore much of the psychological burden associated with the disease.

CHAPTER 55

STANDARD AND SPECIALIZED ENTERAL FORMULAS

Tien-Lan Chang, MD, Ronald E. Kleinman, MD

As research and experience over the past century have advanced our knowledge of the nutrient requirements and digestive functions of infants and children in health and illness, enteral formulas have become more sophisticated and diversified to meet their nutritional and metabolic needs. These liquid meals, together with advances in enteral feeding techniques, have contributed to the increased survival and shorter hospitalizations of pediatric patients with severely compromised intestinal function. This chapter reviews the composition of the major groups of available formula feedings for infants and children and discusses their use in general. Breast- and formula feeding of infants and the enteral nutritional support of children with specific chronic illnesses are discussed in other chapters. The composition of these formulas is also listed in detail in Appendix 3, grouped by category and by use.

HISTORICAL BACKGROUND

Human milk was the principal source of nutrition for newborns and infants up to the mid-nineteenth century. Wet nurses provided an alternate source of milk when the mother's milk was not adequate or available. Milk from donkeys, horses, and cows was used as a substitute when human milk was not available. The mortality of bottle-fed infants was 4 to 10 times greater than that of breast-fed infants in the early part of the twentieth century, mainly because of unsanitary methods of preparation and storage of the milks. Innovations toward the end of the nineteenth and beginning of the twentieth century, such as evaporated cow's milk, the rubber nipple, pasteurization, and the introduction of refrigeration into most households in the industrialized world, led to a greater use of formula-feeding, and the practice of wet nursing was gradually replaced by feeding with cow's milk formula.[1,2]

The modification of cow's milk to make its nutrient composition more similar to that of human milk began in a scientific way with the German pediatrician Philip Biedert, who added cream, whey, and sugar to cow's milk to make it suitable for infants. Meigs' Mixture, formulated by the American physician John Meigs, was similar in composition to Biedert's mixture.[3] In addition to changing the quantity of cow's milk constituents, the quality of the protein, fat, and carbohydrate in cow's milk was also a subject of investigation and in some cases changed, as with the acid treatment of casein curds to render them smaller and softer.[4] These early formulas formed the basis for the modern formulas with a defined nutrient composition that are currently fed to human infants.

STANDARD INFANT FORMULAS

In spite of Abraham Jacobi's admonition that "Cow's milk cannot be changed into woman's milk.…The efficiency of all alleged improvements in artificial feeding is liable to be overestimated, and not always received with sound criticism,"[5] modern proprietary formulas intended for infants continue to attempt to simulate human milk. In doing this, however, the nutrient composition has also been adjusted to provide what are currently established as the nutrient requirements of growing infants. The levels of nutrients present in all infant formulas are determined by regulations established by the US Food and Drug Administration (FDA) (Table 55-1) (see Appendix 3).[6] For many nutrients, minimal and maximal amounts are specified. In addition, the Infant Formula Act of 1980 and the amendments of 1986 mandate the quality control standards under which all infant formulas are manufactured. Modifications in nutrient and non-nutrient content are generally based on recommendations from the

TABLE 55-1 Recommended Nutrient Levels for Infant Formulas*

Nutrient	*Minimum*	*Maximum*
Protein (g)	1.8	4.5
Fat (g)	3.3	6.0

‡Required only for non–milk-based infant formulas.

scientific and medical communities. These government regulations came about following an epidemic of hypochloremia and alkalosis in infants fed with a chloride-deficient soy formula.[7,8] The potential for error in preparation and contamination of infant formulas before and after marketing continues even in the twenty-first century. Recalls of batches of contaminated powdered infant formulas were made after one infant died of meningitis caused by *Enterobacter sakazakii* in Tennessee and another infant developed botulism from *Clostridium botulinum* type B toxin in the United Kingdom.[9,10]

Cow's Milk–Based Formulas

Standard cow's milk–based formulas are marketed in ready-to-use, concentrated liquid, and powdered forms. All are based on nonfat cow's milk, to which lactose and vegetable oils have been added. These formulas are low in cholesterol because the fat is derived from vegetable sources. In addition, emulsifiers (eg, lecithin) and thickeners (eg, carrageenan) have been added. Their mineral and vitamin content has also been adjusted to suit the needs of human infants.

Cow's milk has a relatively greater amount of casein than does human milk. Experience accumulated over the past 50 years has shown that casein-predominant milks support normal growth in both premature and full-term infants.[11] Casein has served as a standard reference protein by which to measure the biologic value of other proteins such as soybean or egg protein. The measure of the biologic value is the grams of weight that a reference animal gains for each gram of protein fed. Setting casein as 100%, FDA regulations require protein at a minimum level of 1.8 g per 100 kcal of formula. For proteins with a lower biologic value, the formula must contain proportionately more protein. No protein source can be used with a biologic value less than 70% that of casein.

Those formulas that are based on casein have an amino acid and mineral composition that more closely resembles that of cow's milk than human milk. The osmolality and renal solute loads of these standard formulas fall intermediately between human and cow's milk, although these values increase, as do those of the other constituent nutrients, if the formulas are prepared to be more highly concentrated.[12]

Infants who are fed a casein-predominant formula have a different profile of amino acids in their serum after feeding than do those taking human milk, and some have developed metabolic derangements on casein-predominant formulas.[13] For this reason and others, including attempts by manufacturers to simulate human milk, whey-predominant and whey-only formulas have achieved popularity for both premature and full-term infants. By increasing the amount of whey proteins, mainly α-lactalbumin and β-lactoglobulin, the amino acid composition of the formula is altered so that it resembles human milk more than cow's milk. This is particularly so for the sulfated amino acids, cystine, taurine, and methionine. Clinical studies have demonstrated the adequate growth of full-term infants taking these formulas. Serum amino acid profiles of infants fed whey-predominant formulas are different from those fed human or cow's milk, with a higher percentage of branched-chain amino acids and threonine in circulation. However, the significance of this finding is unclear.[14,15]

Just as other minerals and vitamins are present in the formula to prevent nutritional deficiencies, iron is added to the standard formulas to prevent iron deficiency in newborns in the first year of life. Iron supplementation is particularly important for premature or small-for-gestational-age infants, who have reduced iron stores. The amount of iron present in the fortified formulas ranges from approximately 4.7 to 14.5 mg/L in the United States and 4 to 7 mg/L in Europe.[16] The availability of low-iron formulas and parental misperception regarding iron as a cause of infantile constipation or hyperirritability are some of the reasons that could lead to discontinuation or avoidance of the iron-fortified formulas for some infants.[16]

Nucleotides are now being added to many of the standard cow's milk–based formulas based on the presence of nucleotides in human milk and a decreased incidence of diarrheal disease in a few studies of infants fed formulas supplemented with nucleotides.[17,18] Furthermore, nucleotide

supplementation in formula has also increased plasma lipoproteins and enhanced the growth of small-for-gestational-age infants.[19,20] In a study of full-term infants, cow's milk–based formula supplemented with nucleotides enhanced antibody responses to diphtheria and *Hemophilus influenzae* vaccinations, but the antibodies to poliomyelitis and tetanus were unaffected.[21] In preterm infants on formula supplemented with nucleotides, serum IgM and IgA were higher, whereas IgG and lymphocyte subsets were unaffected.[22]

The fatty acid composition of infant formulas is an area of intense investigation. Human milk contains relatively more monounsaturated fatty acids than regular infant formulas do, and also contains long-chain polyunsaturated fatty acids (LCPUFAs) such as arachidonic acid and docosahexaenoic acid (DHA). Arachidonic acid and DHA are important structural components of lipid membrane in the brain and retina. Studies have shown enhanced cognitive development and visual acuity in premature infants fed with formulas supplemented with arachidonic acid and DHA.[23,24] Studies in full-term infants, however, have shown mixed results.[25,26] LCPUFAs also influence the maturation of the immune system. The expression of CD45RO (mature phenotype) on CD4+ cells and interleukin-10 production were higher in preterm infants fed human milk and those fed formula supplemented with LCPUFAs compared with those in infants fed formula alone, although it is unclear whether this is a clinically important phenomenon.[27] The supplemented formulas appear to be safe as all studies have shown no significant difference in the growth parameters for infants on supplemented formulas with appropriate ratios of arachidonic acid and DHA.[24–26] Formulas with added arachidonic acid and DHA have been in use in Europe for a number of years and were formally approved for marketing in the United States in early 2002.

Cow's milk–based formulas with lactose are contraindicated for infants with galactosemia, cow's milk allergy, or lactose intolerance. However, a lactose-free cow's milk–based formula with corn syrup solids as the carbohydrate is an appropriate choice for infants with lactose intolerance. Lactose in cow's milk–based formulas was shown to enhance absorption of calcium in full-term infants between 8 and 12 weeks of age.[28] This apparent advantage of lactose-containing formulas over lactose-free formulas in enhancing calcium absorption was not clinically significant, however, at least for healthy full-term infants, because the amount of calcium absorbed in infants on the lactose-free formula was still adequate.

A cow's milk–based formula with added rice starch was specifically marketed for infants with uncomplicated gastroesophageal reflux. Rice cereal is frequently added to thicken the formula in the management of uncomplicated gastroesophageal reflux, although studies with esophageal pH probe have failed to demonstrate any significant decrease in the reflux time in infants fed with formulas thickened with cereal.[29,30] This practice increases the amount of carbohydrate relative to protein in the feeding and could potentially lead to intake of either excessive calories or inadequate protein by the infant. This formula addresses this concern by replacing part of the lactose with rice starch so that the protein-to-calorie ratio remains at 2.5 g per 100 kcal.

Milk feedings formulated specifically for premature and small-for-gestational-age infants are sold in a liquid ready-to-use form for use in hospitals and following discharge. These formulas differ from the standard formulas by attempting to meet the nutritional requirements of rapidly growing low birth weight infants within the limitations of intestinal and renal functions seen in these infants. These formulas have either 20, 22, or 24 kcal per ounce. When prepared at 20 kcal per ounce, they contain more protein than standard formulas do. Fat malabsorption is a common occurrence in the low birth weight infant. Therefore, a high percentage of the fat in most of these formulas is in the form of medium-chain triglycerides (MCTs), which have been shown to reduce steatorrhea, enhance calcium absorption, and improve nitrogen retention in low birth weight infants.[31,32] Carbohydrate is provided as a mixture of lactose, maltodextrins, and glucose polymers. Glucose polymers appear to be well tolerated by premature infants.[33] Finally, the concentration of both calcium and phosphorus in a 2:1 ratio is increased above levels found in standard formulas.

Soy-Based Formulas

The soy protein formulas were introduced for use in infants who are cow's milk intolerant. Although soy formulas are extensively used in cow's milk–allergic children, soy protein is also antigenic. Soybean protein, however, is readily available and is a high-quality protein. Soy protein isolate is supplemented with L-methionine and taurine to balance the amino acid ratio and improve its biologic value.[34] Soy formulas are also supplemented with carnitine, which is found only in animal proteins. Nucleotides are not added to the soy formulas as studies failed to show any obvious immunologic advantages, such as response to vaccines and lymphocyte maturation, in infants on nucleotide-supplemented soy formula.[35,36] The carbohydrates in soy formulas consist of sucrose, corn syrup solids, and/or maltodextrin. These formulas are therefore useful in patients with clinically significant lactose intolerance. Infants with acute diarrhea fed soy formula can have a shorter duration of diarrhea, although for most infants with acute infectious diarrhea, lactose intolerance is not clinically significant.[37,38]

Although earlier studies showed that bone mineralization was reduced in infants fed a soy-based formula compared with infants fed a cow's milk–based formula,[39] more recent studies on soy formulas with improved mineral suspension showed no difference in bone mineralization in full-term infants fed soy and cow's milk–based formulas.[40,41] Bioavailability of phosphorus, zinc, manganese, copper, and iron are reduced by phytic acid and polysaccharides present in the soy protein isolate.[42] Soy formulas are therefore supplemented with zinc and iron. Iron status appears to be equivalent in infants fed soy and cow's milk formulas.[43]

Aluminum has been found in soy formulas at concentrations of 600 to 1,300 ng/mL, compared with concentrations of 4 to 65 ng/mL found in human milk.[44,45] Alu-

minum is the most abundant metal in the earth's crust and is present in many plants. It is present in the formula as a contaminant of calcium salts and the soy protein isolate. Aluminum-induced encephalopathy has been reported in patients with renal disease and those taking aluminum salts as an antacid or as phosphate binders. Aluminum also competes with calcium for absorption and could contribute to the osteopenia seen in infants with compromised renal function.

Soy protein isolate also contains isoflavones with estrogenic activity. Plasma concentrations of the isoflavones in infants fed with soy formulas were two orders of magnitude higher than levels found in infants fed cow's milk formulas or human milk.[46] The high concentrations of isoflavones found in infants fed soy formulas have raised concern regarding the long-term health effects on infants exposed to soy. Although many studies have demonstrated adequate growth for infants fed with soy formulas, so far only one study has reported on the sexual development of infants fed soy-based formulas. It was a retrospective cohort study of young adults who had participated in studies on soy- and cow's milk–based formulas in their infancy. This study found no effect of soy formulas on either growth or sexual maturation of human infants.[47]

Specific indications for soy formulas, in addition to lactose intolerance, include galactosemia and a parental preference for avoiding feeding infants animal products (ie, vegans and those whose religious dietary laws preclude the use of animal-based milks). Patients with fructose intolerance should avoid soy formulas that contain sucrose. There is no benefit from the use of soy formulas to treat common problems in infancy such as gastroesophageal reflux, colic, or constipation unless these are symptoms of cow's milk intolerance. The majority of infants with cow's milk protein intolerance can tolerate soy formula. In two prospective studies, between 10 and 14% of those with cow's milk protein allergy were found to have concomitant soy allergy.[48,49] Infants who have allergic enterocolitis can have a higher risk of having both milk and soy allergy. In a retrospective analysis of 16 patients with food protein–induced enterocolitis syndrome, 7 (42%) were found to have reactions to both cow's milk and soy.[50] This finding remains to be confirmed by prospective studies involving a greater number of subjects.

Weight gain and bone mineralization in preterm infants fed soy formula were less than those in infants fed cow's milk–based formulas.[51,52] Because of this and a concern for aluminum toxicity associated with soy formulas, the American Academy of Pediatrics issued a policy statement that "soy protein–based formulas are not designed or recommended for premature infants who weigh < 1,800 g."[53] For the same obvious reason, soy formulas should also be avoided in patients with renal disease.

Other Non–Cow's Milk Infant Formulas

Goat's milk has frequently been used to feed infants sensitive to cow's milk, although studies show that it is as antigenic as cow's milk. Like almost all mammalian milks (the California sea lion is an exception), lactose is the carbohydrate in goat's milk. Goat's milk is high in essential fatty acids and has a higher percentage of MCTs than does cow's milk; it is low in folate. Because of more useful and effective commercial formula alternatives, its popularity has waned markedly in the United States. Goat's milk remains a significant source of nutrition for infants after weaning in other countries. Infants fed with home preparations of goat's milk are at risk for nutritional deficiencies and infections if the milk is contaminated.

Meat-based formula is yet another alternative for infant feeding free of lactose and cow's milk protein. Its nutritional adequacy for healthy infants has been demonstrated, but experience in infants requiring nutritional rehabilitation is too limited to recommend routine application.

PROTEIN HYDROLYSATE FORMULAS

Protein hydrolysate formulas are intended for patients with disorders associated with compromised enteric digestion, such as short-bowel syndrome, food allergy, autoimmune enteropathy, human immunodeficiency virus–associated enteropathy, cystic fibrosis, pancreatic insufficiency, and hepatobiliary disorders such as biliary atresia. The casein or whey in these formulas is modified by hydrolysis and the addition of free amino acids. The casein hydrolysates are supplemented with L-cystine, L-tyrosine, and L-tryptophan to increase their biologic value to the infant. The major portion of the nitrogen in the formulas is in the form of oligopeptides. Although the hydrolyzed protein peptides are less likely to induce an antigenic response than are whole protein molecules, they are not nonallergenic.[54–56]

A recent study suggests that peptides consisting of five, four, or even three amino acids can still activate T-cell clones in vitro.[57] There is evidence to support the considerably faster rate of intestinal amino acid uptake from solutions containing individual dipeptides, tripeptides, or partially hydrolyzed proteins than from solutions composed solely of free amino acids.[58] Formulas with oligopeptides produce a lower osmolality than a free amino acid–containing formula and therefore could have a theoretic advantage over the amino acid–containing formulas for infants and patients with short-bowel syndrome. With immaturity of the intestine or loss of absorptive surface area, either following bowel resection or as a result of inflammation, all of the disaccharidases, but most commonly lactase, can be diminished.[59] The use of sucrose or glucose polymers (partially hydrolyzed corn starch) would therefore be useful in circumventing the absence of lactase or both lactase and sucrase. Monosaccharides are not used exclusively in any of the prepared formulas because of their high osmolality, which can inhibit gastric emptying and further impair intestinal function.[60,61]

MCTs form a large percentage of the total fat content of these formulas. MCTs can be absorbed across the intestinal mucosa with minimal lipolysis to enter the portal circulation. Because of the enhanced solubility of medium-chain fatty acids in aqueous fluids, absorption of this form of fat can also take place in the absence of bile salts in the intestinal lumen and unstirred layer. None of these formulas con-

tain only MCTs because they would then be devoid of essential fatty acids. MCTs increase the osmolality of formula more than long-chain fatty acids do, and the excessive use of this form of fat can also contribute, in some patients, to excessive losses of stool water.

FREE AMINO ACID FORMULAS

The principal difference between free amino acid formulas and peptide-based formulas is in the protein composition. At present, only one of these formulas is specifically designed for infants under 1 year of age, with an osmolality of 360 mOsm. The lipid component is a mixture of safflower, coconut, and soy oils to provide essential and nonessential fatty acids. The carbohydrate is from corn syrup solids or maltodextrins, which are both derived from corn starch, differing only in the size of glucose polymers. Because free amino acids by themselves are nonimmunogenic, these formulas are most useful for children with multiple food allergies who do not tolerate even the peptide-based formulas.

Several studies have shown that most infants with cow's milk or multiple food allergies are able to grow adequately on amino acid–based formulas.[62,63] However, depending on the manufacturing and purification process, the soy oil can be contaminated by trace amounts of soy protein and could trigger an allergic response in susceptible individuals.[64] Children with severe enteropathy or short-bowel syndrome unable to tolerate protein hydrolysates might benefit from the amino acid–based formulas as an alternative and reduce their dependency on parenteral nutrition.[65]

FOLLOW-UP FORMULAS

Follow-up formulas are defined by the joint FAO/World Health Organization Codex Alimentarium Commission (1988) as "A food intended for use as a liquid part of the weaning diet for the infant from the 6th month on and for young children."[66] Currently, several formulas for this use are marketed in the United States. These formulas are either cow's milk– or soy-based, differing from infant formulas only slightly in nutrient concentrations. Even though follow-up formulas are nutritionally adequate, they have no advantage over a combination of solid foods and standard infant formulas or human milk and could interfere with the normal weaning process. Ideally, the weaning process should take place over a period of several months, effecting a transition to a solid-food diet comprising 30 to 50% of total calories. Solid foods should complement infant formula or breast milk in mineral and vitamin composition.[67] For the great majority of children who are able to make the transition to solid food, there is really no need for these follow-up formulas.

FORMULAS FOR CHILDREN 1 TO 10 YEARS OF AGE

Although the frequency of formula use decreases significantly after the first year of life, many children require continued nutritional support with a liquid formula for a variety of reasons, including inadequate intake, compromised digestion or absorption, or inherited disorders of metabolism. These formulas can be cow's milk–, soy-, peptide-, or amino acid–based. The carbohydrate is usually corn starch-derived glucose polymers and sucrose, and the fats a blend of vegetable oils, such as safflower, soy, canola, and coconut oil, to provide both medium- and long-chain triglycerides. These formulas are different from the infant formulas with higher caloric density and protein concentration. The mineral and vitamin concentrations are intended to support the daily requirements for this age group.

Children who are unable to chew and swallow adequately because of neurologic impairment but who have intact intestinal motility, digestion, and absorption exemplify those with a need for such a liquid enteral formula, often administered via a gastrostomy. Children in the intensive care unit who are unable to eat by mouth because of airway problems can use the enteral formulas in the short term via nasogastric or nasojejunal tube. Historically, both adult and infant formulas have been used with preschool and school-aged children because of a lack of pediatric formulations. If such formulas are "tailored" and use is monitored to meet individual patient needs, they can be used successfully in this age group. However, vitamin and mineral deficiencies or excesses, osmotic diarrhea, and an excess renal solute load are a few of the concerns with the use of adult products in young children. Products specifically manufactured for this age group have made it easier to monitor and to more appropriately recommend products based on individual requirements. Some of the formulas have added soy fiber. Studies in adult patients have shown fewer problems with diarrhea (and constipation) when fiber is added to enteral nutrition.[68,69]

Peptide- and amino acid–based formulas designed for older children are often used for patients with limited digestive and absorptive capacity, such as those with Crohn's disease, pancreatitis, and chemotherapy-induced enteropathy, in addition to those disorders mentioned above. In the case of Crohn's disease (see Chapter 37, "Inflammatory Bowel Disease"), peptide- and amino acid–based formulas have been used successfully to induce and maintain remission. Whereas a meta-analysis of several randomized, controlled trials indicated that enteral nutrition was less effective than steroids in induction of remission in adults with active Crohn's disease,[70] studies in children suggest the opposite.[71,72] Several studies have also demonstrated that enteral nutrition begun early in the course of acute pancreatitis was superior to parenteral nutrition, with fewer septic complications and lower cost.[73–75] Appendix 3 lists both standard and special enteral products for children and adolescents.

Children requiring long-term tube feeding support, without any oral supplementation, should be monitored for the development of macro- and micronutrient deficiencies, such as vitamin B_{12}, zinc, or selenium deficiency, especially in those with chronic disease processes and severe diarrhea. Children with severe developmental delay and mental retardation are also at risk for obesity and osteopenia because of a low resting energy expenditure and inactivity. Because vitamins and trace elements in these

formulas are present in proportion to the calories, provision of supplemental vitamins and minerals might be necessary if the number of calories provided is substantially less than the usual Recommended Dietary Allowance (RDA) for age.[76]

MODULAR FORMULAS

Modular formulas can be either complete or intended as supplements to the diet and can be used to satisfy a particular nutrient requirement or to augment an established feeding regimen (eg, caloric supplementation; see Appendix 3, Tables A-36 and A-37). For example, a carbohydrate-free product containing protein, fat, vitamins, and minerals can be mixed with another carbohydrate source in the treatment of conditions such as fructose intolerance or galactosemia. Carbohydrate-free formulas are also used in a ketogenic diet for infants and young children with intractable seizure disorders. Protein preparations of casein or whey are available separately without lactose or fat. Human milk fortifiers provide a mixture of protein (cow's milk), fat (MCTs), carbohydrate (corn syrup solids), vitamins, and minerals to provide additional nutrients to premature and full-term infants fed with breast milk. Problems can arise with their solubility in various commercial formulas, and they can also cause a significant increase in the osmolality of the new mixture.[77] Additionally, when modular formulas are prepared by supplementing a standard liquid diet with extra carbohydrate or fat, changes in the calorie-to-nitrogen ratio can occur that will not support optimal growth.

In spite of these limitations, when used appropriately, these formulas and additives provide a means of specifically tailoring formulas to meet the nutritional needs of infants and children for whom no standard prepared formula is available. Children with congenital heart disease, renal disease, liver disease, or bronchopulmonary dysplasia are representative of those requiring formulas of increased caloric density because they are often fluid restricted and have increased caloric requirements.

FORMULAS FOR METABOLIC DISORDERS

Liquid feedings are available to support patients with specific inborn errors of metabolism (see Appendix 3, Table A-38). These formulas generally use a mixture of amino acids as the protein source, minus the amino acid(s) that can cause toxicity owing to the particular enzyme deficiency in the disorder (eg, phenylalanine in phenylketonuria). These formulas are also available for different age groups. Some formulas can be used for more than one metabolic disorder. The formula for patients with maple syrup urine disease is free of the branched-chain amino acids leucine, isoleucine, and valine, and it can also be used for patients with hypervalinemia, methylacetoaceticaciduria, isovalericacidemia, hyperleucine-isoleucinemia, and leucine-induced hypoglycemia. Because the missing amino acid(s) are also essential for growth, a certain minimal amount of additional protein containing the missing amino acid(s) needs to be provided in the diet for these patients. For patients with metabolic disorders of fatty acids, such as long-chain and very-long-chain acyl-CoA dehydrogenase deficiencies, a formula with MCTs as the predominant fat source is used.

These patients' metabolic status can be easily deranged by an acute viral infection that affects their oral intake. The mainstay of a "sick-day plan" is provision of adequate calories using a glucose polymer to prevent starvation-induced gluconeogenesis and lipolysis and subsequent accumulation of toxic metabolites.[78] Patients must be monitored closely for clinical and laboratory indices of toxicity and deficiency. These formulas include vitamins and minerals age adjusted to meet the patients' needs. However, one study, based on 3-day diet records, indicated that children with maple syrup urine disease were getting only 21 to 66% of the RDA for selenium.[79] Until further studies have been completed, the long-term efficacy and safety of some of the metabolic formula products remain to be determined.

FORMULAS INTENDED FOR OLDER CHILDREN WITH CHRONIC ILLNESS

Enteral formulas intended for adults can generally be used for children with chronic illness older than 10 years. The osmolality of these formulas varies from 280 to more than 600 mOsm/L. Sucrose is often one of the carbohydrate ingredients, perhaps to make these formulas more palatable. The sources of protein, carbohydrate, and fat are similar to those used for younger children and infants but differ in their concentrations. Fiber is added to many of the formulas. In addition to standard formulas for those chronically dependent on feeding tubes, a number of disease-specific formulas are available (see Appendix 3).

Patients with severe pulmonary compromise can benefit from formulas that provide 40 to 55% of calories from fat, which has a lower respiratory quotient—that is, lower CO_2 production—than carbohydrates do.[80] In contrast, formulas with a high carbohydrate and low fat content are preferred for patients with burn injuries,[81] and patients with renal failure can benefit from formulas with low protein and salt concentrations. Some enteral formulas have increased concentrations of branched-chain amino acids that can be protein sparing or reduce ammonia production in patients with chronic liver failure. Although there are anecdotal reports of success, most studies have failed to show any significant long-term clinical advantages of these formulas compared with those with a conventional amino acid mixture or the use of lactulose in the treatment of acute or chronic hepatic encephalopathy.[82,83]

Formulas for Critically Ill Patients

A number of nutritional substrates can modulate the host response to critical illness, including major trauma. Included among these are zinc, glutamine, arginine, and omega-3 fatty acids. Animal, human, and epidemiologic data suggest that one or more of these nutrients can be beneficial in the treatment of diseases such as acquired immunodeficiency syndrome (AIDS),[84,85] ulcerative colitis,[86] systemic lupus erythematosus,[87] rheumatoid arthritis,[88] major burns,[89,90] and coronary heart disease.[91]

Possible effects include an improvement in nitrogen balance (arginine), normalization or reduction of platelet aggregation (arginine),[92] substrate availability for energy use in rapidly replicating cells such as enterocytes and lymphocytes (glutamine),[93,94] a decrease in the incidence of bacterial translocation (glutamine),[95] and alterations in eicosanoid and cytokine production (omega-3 fatty acids).[96,97] Several randomized, controlled, prospective studies have demonstrated decreased infection rates, improved nitrogen balance, a decrease in length of hospital stay, and decreased cost of care in adult patients on an enteral formula supplemented with glutamine or with added fish oil, arginine, and nucleotides.[98–102] However, none of the studies has shown any difference in mortality in patients as a result of these supplements, and their real benefit in clinical practice remains to be demonstrated both in adults and children.

In addition to the "conditionally essential" nutrients mentioned above, there is also research interest in the potential therapeutic role of cytokines and growth factors found in the whey fraction of cow's milk. Bovine colostrum is currently available as a dietary supplement and has been reported to protect against the nonsteroidal anti-inflammatory drug–induced increase in intestinal permeability.[103] Studies in vitro have demonstrated suppression of T- and B-lymphocyte proliferative responses to mitogens and protection of epithelial cells against chemotherapy drugs by a bovine whey protein concentrate.[104,105] Transforming growth factor β (TGF-β) is present in bovine whey, especially that of colostrum, but it can account for only some of the activities seen with the bovine whey extract or colostrum.[105,106] An enteral formula with bovine TGF-β is available for adult patients with inflammatory bowel disease. Further research will determine whether TGF-β or other factors in bovine whey are useful in the management of patients with severe enteropathies.

In all patients with critical illness on a defined diet, the potential for the development of serious metabolic complications, such as azotemia, hypocalcemia, or hypomagnesemia, is high. Thiamin deficiency has been reported in 10 of 80 critically ill children admitted to the intensive care unit for more than 2 weeks and in four of six patients on chemotherapy.[107] Thus, in spite of their label as "complete" enteral feedings, chemically defined diets can lack essential nutrients, especially trace nutrients. A regular system for monitoring nutritional adequacy, including anthropometric determinations, must be undertaken. Laboratory tests, such as complete blood count, total protein, albumin, ferritin, electrolytes, blood urea nitrogen, creatinine, calcium, magnesium, and phosphorus, require only small volumes of blood, and additional tests, such as zinc, copper, folate, and vitamins B_{12}, A, and E, might also be indicated, depending on the underlying medical condition.

CONCLUSION

Standard infant formulas have evolved significantly since the turn of the twentieth century and now provide some, but not all, of the advantages seen with breast-feeding. There has also been a significant advance in our ability to provide adequate and appropriate nutrition by the enteral route to infants and children who would otherwise have required extended parenteral nutrition support. In spite of the relative ease of enteral feeding, patients must be carefully observed to ensure that they are growing and developing appropriately and that nutritional deficiencies are not developing. Current research efforts will help define the role of nutrients and non-nutritive substances in the diet that will further promote the development and the health of these vulnerable infants and children.

CHAPTER 56

ENTERAL NUTRITION

M. Luisa Forchielli, MD, MPH, FACG, Julie Bines, MD, FRACP

The delivery of food via a tube directly into the gastrointestinal tract has been described since pre-Christian times. In ancient Egypt, and later in Greece, feeds were introduced into the rectum, and in the nineteenth century, rudimentary tubes were used to infuse basic foods such as broths, eggs, milk, and even alcohol into the esophagus and stomach.[1] Despite the increasing sophistication in other areas of medical care over the past century, treatment with enteral nutrition had been slow to develop. However, over the past two decades, enteral nutrition therapy has undergone a renaissance.[2–7] Many patients who previously received parenteral nutrition are now successfully managed with enteral nutrition alone or in combination with parenteral nutrition.[2,3,8,9] This has been made possible by the increasing range of options for gastrointestinal access, improved delivery systems, and advances in enteral nutrition formulas. Home enteral nutrition therapy is now an important adjunct to the management of infants and children with chronic disease or feeding problems.[6]

PRINCIPLES OF ENTERAL NUTRITION

Enteral nutrition therapy has a number of potential advantages over parenteral nutrition in the management of patients requiring nutritional support. The main advantages of enteral nutrition include preservation of gastrointestinal function, cost, manageability, and safety.

Preservation of Gastrointestinal Function

Apart from the oral phase of digestion, enteral nutrition activates the same gastrointestinal responses as the ingestion of normal meals. The presence of intraluminal nutrients stimulates (1) gastrointestinal neuroendocrine function, effecting motility and digestion through the secretion of digestive juices and gastrointestinal hormones, and (2) maintenance of gut mucosal mass, including gut-associated lymphoid tissue (GALT).

Intestinal functional and structural changes occur through local and systemic interaction of nutrients and neuroendocrine peptides, cytokines, and hormones.[10–15] The list of these mediators is constantly growing and includes gastrin; enteroglucagon; peptide YY; interleukin 3, 11, or 15; epidermal growth factor; growth hormone; insulin-like growth factors I and II; glutathione; fiber; short-chain fatty acids; glutamine; triglycerides; dietary nucleotides; and polyamines.[10–15] Monosaccharides and fatty acids can influence the secretion of enteroglucagon and peptide YY and via these mediators effect mucosal growth and decrease intestinal transit time.[16] Carbohydrate, protein, zinc, magnesium, potassium, or manganese deficiency can modify the effect of growth hormone and insulin-like growth factor II.[17–19]

GALT consists of the lamina propria, intraepithelial lymphocytes, immunoglobulin A (IgA), Peyer's patches, and mesenteric nodes and is responsible for processing intestinal antigens.[20] During periods of "bowel rest," such as occur with intravenous feeding and starvation, there is a reduction in gut mass and the functions of GALT are suppressed.[20] This has been associated with a reduction in IgA secretion and increased gut permeability and can result in increased bacterial adherence to the intestinal wall, cellular injury, and bacterial penetration with adverse systemic host responses.[20–22] In contrast to what has been found in animal studies, the correlation between parenteral nutrition and bacterial translocation has not yet been proven in humans.[23] During oral or enteral nutrition therapy, bacterial translocation does not seem to occur, except in association with disturbances in intestinal permeability related to the underlying disease process (eg, short-bowel syndrome) or the chemical composition of the enterally provided substance (eg, blue food dye).[20,24–26]

Cost

Enteral nutrition is estimated to be two- to fourfold less expensive than parenteral nutrition on an inpatient or outpatient basis.[2,3,27–29] In a recent study of home nutrition support, the annual cost per patient (based on US Medicare charges) was $55,193 ± $30,596 (US) for parenteral solutions versus $9,605 ± $9,327 (US) for enteral tube feeding.[4] In addition, the annual cost of hospitalization for a patient receiving parenteral nutrition (0.52 to 1.1 admissions/year/patient) ranged from zero to $140,220/patient, compared with zero to $39,204/patient for patients receiving enteral nutrition (0 to 0.5 admissions/year/patient).[4]

Manageability and Safety

As a result of advances in tube technology, delivery methods, technical skill of health professionals, and better education of parents and caregivers, the administration of enteral nutrition has been associated with improved clinical outcome and safety profiles.[30] Enteral nutrition therapy

is easier and safer to administer than is parenteral nutrition. Not only are the risks of intravenous access avoided, but there is also a wider margin for error for metabolic complications. As a result, enteral nutrition therapy is easier to administer in low-intensity hospitals and patient care settings, including the home.

INDICATIONS FOR ENTERAL NUTRITION

Enteral nutrition should be considered for any patient with a functional gastrointestinal tract who requires nutritional support. Indications for enteral nutrition in pediatric patients are listed in Table 56-1. With developments in options for gastrointestinal access, delivery systems, and enteral formulas, the list of absolute contraindications for enteral nutrition therapy has been reduced significantly. Contraindications include gastrointestinal ischemia, including necrotizing enterocolitis and toxic megacolon; intractable vomiting or diarrhea; paralytic ileus; diffuse peritonitis; and intestinal obstruction (either mechanical or functional).[7,31] Extreme care should be taken when administering enteral nutrition in patients in whom the gastrointestinal blood flow could be compromised, such as during treatment with hypothermia or infusions of specific drugs.

The goal of enteral nutrition therapy varies considerably among patients or within an individual patient at different phases of the disease process. In many patients, enteral nutrition will be aimed at providing their full macro- and micronutrient requirements. However, in some patients this might not be possible, and parenteral nutrition might be needed to supplement insufficient enteral intake. Conversely, a patient might require enteral nutrition to supplement an inadequate oral intake caused by increased disease requirements (eg, cystic fibrosis), malabsorption (eg, chronic liver disease), or voluntarily reduced intake (eg, anorexia nervosa).[7,31] Although enteral nutrition has mainly a therapeutic intent, it can also be used to prevent the development of malnutrition, such as can occur during cancer chemotherapy.[32] Advances in the understanding of the role of nutrients in the modification of inflammation and specific disease processes have led to the development of disease-specific formulas (eg, for Crohn's disease).[33] A more recent concept is that of minimal enteral feeding, in which enteral nutrition is provided at a very slow rate and volume with the aim of presenting nutrients to the intestinal mucosa without attempting to contribute significantly to total-body nutrition.[34]

TABLE 56-1 Indications for Pediatric Enteral Nutrition

1. **Inability to ingest adequate nutrition orally**
   - i. Disorders of sucking and swallowing
     - • Prematurity
     - • Neurologic impairment (eg, cerebral palsy, dysphagia)
   - ii. Congenital abnormalities of the upper gastrointestinal tract or airways
     - • Tracheoesophageal fistula
   - iii. Tumors
     - • Oral cancer
     - • Head and neck cancer
   - iv. Trauma
   - v. Critical illness
     - • Mechanical ventilation
   - vi. Severe gastroesophageal reflux
   - vii. Drug related
     - • Chemotherapy
   - vii. Severe food aversion
   - viii. Severe depression
2. **Disorders of digestion or absorption**
   - i. Cystic fibrosis
   - ii. Short-bowel syndrome
   - iii. Inflammatory bowel disease
   - iv. Congenital abnormalities of the gastrointestinal tract
     - • Microvillus inclusion disease
     - • Tufting enteropathy
   - v. Enteritis
   - vi. Intractable diarrhea of infancy
   - vii. Immunodeficiency
     - • AIDS
     - • Severe combined immunodeficiency
   - viii. Chronic liver disease
   - ix. Graft-versus-host disease
   - x. Intestinal fistulae
3. **Disorders of gastrointestinal motility**
   - i. Chronic pseudo-obstruction
   - ii. Ileocolonic Hirschsprung's disease
4. **Increased nutritional requirements**
   - i. Cystic fibrosis
   - ii. Chronic renal disease
   - iii. Congenital heart disease
   - iv. Chronic pulmonary disease
     - • Bronchopulmonary dysplasia
5. **Growth failure or chronic malnutrition** (in addition to above)
   - i. Anorexia nervosa
   - ii. Psychosocial causes
   - iii. Chronic liver disease
   - iv. Solid organ transplantation
6. **Metabolic diseases**
   - i. Inborn errors of metabolism
   - ii. Diabetes mellitus
7. **Acute or acute/chronic pancreatitis**

ROUTES OF ADMINISTRATION

During enteral nutrition therapy, nutrients are directly delivered via a tube into the stomach, duodenum, or jejunum. The tube is inserted either through the nose or mouth for short-term enteral nutrition (less than 3 weeks) or through a surgically or endoscopically created stoma for long-term enteral nutrition (more than 3 weeks). The choice of the location and the route of administration will depend on the patient's underlying medical or surgical condition, including gastrointestinal anatomy and function, the indication and duration of enteral nutrition therapy, and psychosocial factors. Additional factors, such as local technical expertise, tube availability, and cost, will also influence the route and type of device selected.

Noninvasive Access for Enteral Nutrition

Nonsurgical or nonendoscopic placement of a feeding tube through the mouth or nose is the most common method of establishing gastrointestinal access in infants and children. The tube is generally of small diameter (5 to 10 F) and is well suited to nutritional support of short or

intermediate duration. The nasal access is usually preferred, except in preterm infants or patients with nasopharyngeal abnormalities or obstructions, such as trauma or congenital malformations.

There is a wide range of enteric feeding tubes available for use in children. The original nasogastric tubes were made of polyethylene or polyvinyl chloride. However, because of their inherent stiffness, they require routine changing to reduce the risk of skin necrosis, gastric ulceration, and perforation. The current generation of feeding tubes is made of flexible silicone, polyurethane, or elastomer and usually may stylets to assist placement.

Despite their increased flexibility, these tubes have a longer life span and can have a number of specialized features. These include (1) aids for tube placement and to prevent dislodgment, including water-activated hydrophilic lubricant at the distal end and in the lumen, plastic-coated stylets to minimize the risk of tube perforation, marked reference points on the tubing to allow proper tube selection and positioning, and a rounded, nonweighted bullet-shaped tip to favor insertion; (2) a combination of distal-end and side exit ports to prevent blockage; and (3) a double port at the proximal end to allow for feeding and side injections. Accurate tube positioning is enhanced by radiopaque material within the tube wall. Tube sizes differ in length and port diameter, with the longer tubes suited for jejunal feeding (Table 56-2). Weighted tips are designed to allow gravity to assist with small-bowel placement and to prevent retrograde displacement. However, with the possible exception of intubated patients, the weighted tubes have not been shown to have significant benefit over nonweighted tubes.[35–37]

Nasogastric Tube Nasogastric tubes can be safely inserted by allied health staff, caregivers, family members, and even the patients themselves, with training. Prior to insertion, the desired length of tube is estimated by measuring the distance from the tip of the nose to the ear and down to the xiphisternum. A small amount of lubricant is applied to the nostril and along the length of the tube. The tube is then advanced through the nose past the nasopharynx into the stomach. Voluntary swallowing by the patient can aid the passage of the tube. Once the tube is in place, the stylet is removed and the proximal end of the tube is secured close to or behind the ear. Before commencing any infusion, tube location should be verified. Fluoroscopy or endoscopy can be used to assist difficult gastric tube placement.

Nasoduodenal or Nasojejunal Tube Advances in tube technology and the techniques for placement of nasoenteric tubes in children have provided an opportunity for postpyloric feeding in children in whom gastric feeding is difficult or contraindicated.[38] Nasoenteric tubes can be placed blindly or under fluoroscopic or endoscopic guidance.[39] The blind tube placement technique relies on the spontaneous passage of an enteric feeding tube from the stomach into the small intestine. This can occur after a period of hours or days and be facilitated by positioning the patient on the right side; the "corkscrew" technique, whereby a wire stylet is twisted when the tube is in the stomach; or the administration of prokinetic drugs, such as metoclopramide.[40,41] The use of erythromycin for postpyloric intubation is controversial, with both positive and negative effects observed in children.[42,43]

Postpyloric tube placement can also be attempted under fluoroscopic control.[44] Using this method, the passage of the tube is monitored with the aid of the radiopaque markings on the tube. Endoscopic placement of a nasoenteric tube has a number of advantages over the other methods of placement. The tube is placed under direct vision with a guidewire within the tube lumen using a drag and pull technique.[39,45,46] This method avoids exposure to ionizing radiation and can be performed in high-dependency patient care areas such as the intensive care unit.[38,39] Complications such as dislodgment, ampullary obstruction, and jaundice are reported with nasoenteric tubes.[47]

TABLE 56-2 Pediatric Enteric Tubes

	Tube French Size	*Tube Length (cm)*
Premature to neonate	4–5	38–41
Infants to young children	6–8	51–91
Older children to adolescents	8–14	91–114

Invasive Access for Enteral Nutrition

Placement of a feeding tube using surgical, radiologic, or endoscopic techniques is recommended for long-term enteral nutrition therapy or gastric decompression. There are a number of important advantages of these tubes over nasogastric or nasoenteric tubes in children. The gastrostomy or jejunostomy tube can be maintained in position for a longer period because it is fixed against the anterior abdominal wall, hidden under clothing. The tube does not interfere with breathing and avoids potential complications of chronic nasal discharge, sinusitis, and developmental abnormalities of the nose. In addition, for some children, repeated insertion of a nasogastric tube is associated with psychological trauma and feeding aversion. As these tubes are aimed at providing long-term home enteral nutrition therapy, once the decision has been made to place a gastrostomy or jejunostomy, education of the patient, parents, and caregivers should be initiated.

Gastrostomy Tube Gastrostomy tubes are usually large-bore tubes to deliver high feeding volumes and medications with minimal risk of occlusion. The original gastrostomy tubes were made of latex with a balloon retention device, such as the Foley catheter. Today, most gastrostomy tubes are made of a biocompatible material such as silicone and are anchored in place with either parallel bumpers or a mushroom or balloon at the gastric site and a retention disk at the skin. This allows the tube to be secured to the stomach wall without sutures. A wide range of gastrostomy tubes is available for use in children. The gastrostomy tube can extend through the stoma with at least two access ports for simultaneous administration of feed and medica-

tions. The low-profile gastrostomy tube devices allow the tube to be easily disguised under clothing, with the feeding tube connected only at the time of infusion. These tubes are particularly popular with older children and adolescents. Most tubes have an antireflux valve to prevent the reflux of gastric contents when the tube is accessed.

The introduction of the percutaneous endoscopic gastrostomy (PEG) technique has revolutionized the placement of enteric feeding tubes in children.[48] This relatively simple and fast procedure can be performed during esophagogastroduodenoscopy in an endoscopy suite with the use of conscious sedation and local anesthesia or general anesthesia. Although several techniques (Ponsky pull, Sachs-Vine push, Russel introducer) have been developed, all have in common the basic principle that the endoscope locates the site of tube placement from within the stomach while transillumination of the light from the endoscope through the abdominal wall identifies the site of skin incision. The ideal site is on the greater curvature of the stomach with the stoma sited on the anterior abdominal wall, below the costal margin with consideration of the axis of bending and of clothing.

With the Ponsky pull technique, the anterior abdominal wall is indented at the point of maximal transillumination of the endoscope light. This should be seen as a sharp indentation on the gastric wall by the endoscopist. A poorly defined indentation could indicate an overlying viscus (eg, transverse colon) and either an alternative site should be sought or the procedure converted to a surgical gastrostomy. After sterile preparation of the abdominal wall, local anesthetic is instilled and a small incision is made. The endoscopist distends the stomach with air and prepares the snare. A cannula is inserted perpendicular to the abdominal wall through the incision and punctures the gastric wall. The stylet is then removed; a thick suture is introduced along the cannula and is snared by the endoscopist. The endoscope and the suture are retrieved. The gastrostomy tube is tied to the suture and is slowly pulled back, by tension at the abdominal wall, through the mouth, along the esophagus, and into position on the gastric wall under direct vision by the endoscopist. Once the position has been verified by endoscopy, the external bolster can be opposed to the abdominal wall and the tube cut to the desired length. Postinsertion edema at the stoma site is common, and care should be taken not to pull the bolster too tight. To minimize infection at the stoma site, perioperative antibiotic prophylaxis is advocated.[49] The tube can be used within 12–24 hours in most patients.

Immediate complications of PEG placement include abdominal wall skin infection, necrosis of the skin or mucosa caused by a tight bolster, perforation of a viscus, and pharyngeal or esophageal trauma associated with the passage of the internal fixation device. Pneumoperitoneum is common following PEG placement and does not necessarily indicate a complication of insertion. Long-term complications include gastroesophageal reflux, granulation tissue formation, recurrent stoma-site infection, and dislodgment of the tube distally into the small bowel or proximally along the fistula track (ie, buried bumper syndrome).[50] Contraindications to the PEG technique include gastric varices, severe esophageal stricture, or abnormalities that might restrict the ability to oppose the stomach against the anterior abdominal wall, such as ascites, previous gastrointestinal surgery, or abnormalities in gastrointestinal rotation or position. Extreme care must be taken in patients with musculoskeletal deformities, hyperinflation of the lungs, organomegaly, immunodeficiency disease, cyanotic heart disease, or prior gastrointestinal surgery, including ventriculoperitoneal shunts.

Radiologic placement of gastrostomy tubes has been shown to be safe and relatively cost-effective in pediatric patients.[51,52] During this procedure, the stomach is distended with air instilled via a nasogastric tube. The stomach is then directly punctured under fluoroscopic control. A guidewire is inserted, followed by an introducer, a dilator, and then finally the feeding tube.

Because of the development of the PEG technique, surgical placement of a gastrostomy tube is generally restricted to patients who have a contraindication for PEG placement, have had a failed previous PEG placement, or require another surgical procedure in conjunction with tube placement, such as a fundoplication. Placement of the feeding tube can be performed using an open surgical approach or by laparoscopy. In the classic open gastrostomy technique (Stamm and Witzel techniques), the tube is inserted into the stomach along a serosa-lined tract, whereas in the revised version (Janeway technique), a small portion of the stomach is used to make a mucosa-lined tube attached to the skin as a modified fistula. The procedure for laparoscopic gastrostomy tube placement requires the creation of pneumoperitoneum and insertion of an umbilical catheter. The anterior stomach wall is fastened to the abdominal wall with temporary sutures. An opening (by a needle and a J-wire) is made in the stomach and progressively enlarged using dilators to finally allow the insertion of the feeding tube.[53] In experienced hands, laparoscopic gastrostomy is faster than the open procedure and is associated with reduced length of hospital stay and patient discomfort.[54]

Jejunostomy Tube The percutaneous endoscopic technique can be used to place an enteric tube using either a direct approach (direct percutaneous endoscopic jejunostomy; DPEJ) or by the creation of a PEG and placement of a specialized double-lumen tube (percutaneous endoscopic gastrostomy jejunostomy; PEJ).[55] The method for the DPEJ is similar to the PEG technique but with the endoscope placed in the jejunum. Transillumination of the bowel through the anterior abdominal wall and a sharp indentation easily seen within the small bowel by the endoscopist is necessary prior to the direct puncture of the duodenum or jejunum.[55] The suture is advanced along the cannula and is grasped by forceps rather than a snare. The PEGJ can be inserted as part of an initial PEG procedure or through an existing gastrostomy stoma. The specialized tube has a gastric lumen and port and another longer lumen and port for the small bowel. This enables gastric decompression during postpyloric feeding. Once the tube is inserted into the stomach, the intestinal lumen of the tube can then be advanced

into the duodenum or jejunum under direct endoscopic vision using a guidewire and grasping forceps.

Among the range of surgical techniques described for jejunostomy tube placement, the needle-catheter jejunostomy is the most common. Using this technique, a large-bore needle is tunneled through the seromuscular layers of the jejunum distal to the ligament of Treitz. The jejunum is then anchored to the anterior abdominal wall and the tube is secured to the skin. The tunneling procedure limits reflux of formula and heals quickly upon tube removal. In the presence of intestinal adhesions, severe intestinal disease, or high risk of infection or bleeding, straight insertion of a tube into the jejunum (Stamm technique) or direct jejunal stoma (Maydl technique) might be preferred. Laparoscopic placement of a jejunostomy tube requires two additional cannulae to bring the proximal jejunum into proximity of the abdominal wall and secure it there.[56]

Monitoring Tube Position

Before infusing any fluid through a gastric or enteric feeding tube, the position of the tube should be confirmed. Complications owing to incorrect placement or tube dislodgment can potentially be fatal. Plain or contrast radiography is a universally accepted method for assessing tube position. However, repeat radiologic studies are impractical and potentially unsafe in patients requiring long-term enteral nutrition therapy. As a result, bedside methods have been developed to screen for correct tube position. These include clinical observation, auscultation, and analysis of tube aspirate. If a nasogastric tube is incorrectly placed in the airways, cough, choking, and pulmonary distress can occur. However, these features can be minimal or absent if the tube is small or if tracheal reflexes are absent (eg, in coma or intubated patients). Although commonly used, auscultation does not reliably distinguish between either gastric and pulmonary placement or gastric and small-bowel placement.[57–59] Aspirates from either the feeding tube or the lungs can be assessed for color, appearance, pH level, and enzyme measurement (Table 56-3).[60–66] Aspirate pH value can be measured with a qualitative colorimetric test strip or a quantitative pH meter. Bilirubin can also be measured with spectrophotometer readings, using urine bilirubin test strips, or on the colorimetric visual bilirubin scale. Factors such as fasting for 4 or more hours, intermittent or continuous feeding, and use of acid inhibitors can modify these measurements.[60–66]

New approaches are being developed to confirm correct tube position. The measurement of myoelectric slow-wave frequencies has been proposed because these differ in the stomach (3 cycles/minute) and the duodenum (11 to 12 cycles/minute) and are not influenced by other gastrointestinal contractions.[67] The "bubbling under water" method relies on the exit of bubbles from the external end of the tube when placed under water if it has been misplaced in the lungs. However, misplacement of the tube into the bronchioles or pleura does not produce bubbles.[60] Other options under development include electromagnetic navigation devices, self-propelling tubes, fiberoptic tube tips, and ultrasonography-guided tube placement.[68–71]

DELIVERY OF ENTERAL NUTRITION

The method of delivery of enteral nutrition will depend on the route of administration (gastric, duodenal, or jejunal), characteristics of the feeding tube (small- versus large-bore catheter), the desired feeding pattern (bolus, intermittent, or continuous), and the cost and availability of equipment. Bolus tube infusion usually mimics the normal meal pattern based on age. Intermittent feedings are delivered at a specified rate over 1 or more hours, with up to 8 hours per day of gut rest. Continuous feeding delivers a constant-rate infusion, usually by a pump, over a prolonged period with less than 8 hours per day of gut rest.

Gastric feeding is preferred because it is considered more physiologic, allows bolus feeds through large-bore tubes, and is generally cheaper and easier to administer.[7] Many patients intolerant of bolus feeds can be successfully fed intragastrically using an intermittent or continuous feeding regimen. Jejunal feeding is an option for patients with disorders of gastric or esophageal anatomy or function and in the nutritional management of the critically ill.[2,3,8,9,38,39] Jejunal feedings are usually delivered as an intermittent or continuous infusion because rapid-rate infusion of nutrients is often limited by abdominal discomfort, diarrhea, or dumping syndrome.

There are specific physiologic and metabolic considerations associated with continuous-rate feeding. During continuous intragastric feeding, gastric emptying increases parallel to the rate of infusion if the infusion rate is maintained at less than 3 kcal/minute.[71] Because increased caloric density and osmolarity of the formula can delay gastric emptying, formulas with caloric densities greater than 1 kcal/mL should be avoided. In animals, the absorptive capacity of the proximal small intestine is unchanged during continuous enteral nutrition. However, the protein and DNA content of the distal small intestine and the enzymatic and functional capacity of the distal small intestine and colon are reduced.[72] The relative lack of nutrients

TABLE 56-3 Bedside Evaluation Tests for Tube Placement in Children[61,63–67]

Aspirate	*Color and Appearance*	*pH Value*	*Pepsin (μg/mL)*	*Trypsin (μg/mL)*	*Bilirubin (mg/dL)*
Gastric secretions	Yellow-gray or white-tan; cloudy	< 6	> 100 (> 20)*	< 30 (< 50)*	< 5
Intestinal secretions	Green	> 6	< 100 (< 20)*	> 30 (> 50)*	> 5
Respiratory secretions	Yellow-gray; mucoid	6–8	< 100 (< 20)*	< 30 (< 50)*	< 5

*Trypsin and pepsin ranges specific for children.

reaching the distal gut during jejunal feeding with an elemental or hydrolyzed formula could explain this observation. This might provide an opportunity for the treatment of gastrointestinal inflammatory diseases, such as Crohn's disease, by providing nutrients to the proximal intestine but reducing antigenic stimulation to the distal gut.[73]

Energy intake goals are more successfully achieved in critically ill patients receiving postpyloric feeds compared with those receiving intragastric feeds.[74] In addition, energy expenditure owing to the thermic effect of feeding is lower in patients receiving continuous enteral nutrition than in patients receiving the same quantity of nutrients delivered by bolus.[75] The continuous delivery of nutrients into the small intestine affects glycemic control by modifying the typical fluctuating pattern of insulin and glucagon production.[76,77] The reduction in steatosis during continuous enteral nutrition compared with parenteral nutrition with the same carbohydrate intake is also consistent with this observation.

ENTERAL FORMULAS

In the early days of enteral nutrition, a mixture of blenderized diets and milk products was administered. This approach was associated with the potential for nutritional imbalance, micronutrient deficiencies, feeding intolerance, and tube blockage. Today, there is a wide range of enteral nutrition products suitable for use in infants and children (see Chapter 55, "Standard and Specialized Enteral Formulas" and Appendix 3). Most formulas are designed to provide complete macro- and micronutrient requirements as the sole nutritional intake. Specific needs of different ages and stages of development are reflected in the composition of preterm infant, full-term infant, and pediatric enteral nutrition formulations. Modular formulas are specialized combinations of nutrients that provide a nutritional supplement or fulfill a specific nutrient requirement. A recent area of development has been the introduction of disease-specific enteral formulas. These formulas aim to modify the metabolic or gastrointestinal response to feeds by limiting some nutrients, supplementing others, or both (eg, branched-chain amino acid formula for hepatic failure and immune-enhancing formula for critical illness).[78–81]

The majority of patients with normal gastrointestinal tracts will tolerate the gastric administration of a polymeric formula. In polymeric formulas, intact protein or polypeptides are usually derived from cow's milk or soybeans. The nitrogen to non-nitrogen calorie ratio approximates 1 to 150. Carbohydrates are sourced from different starches, including corn and tapioca. Maltodextrin and hydrolyzed cornstarch, glucose-derived saccharides, and corn syrup are commonly used. Formulas can have different lactose contents. Fats are usually present as polyunsaturated fatty acids from corn, safflower, sunflower, or soybean oil or from animal fat. Some enteral nutrition formulas contain soluble fiber. The soluble fiber is added primarily to normalize gastrointestinal transit, but after it is converted to short-chain fatty acids it provides an additional source of calories and can exert trophic effects on the colonic mucosa. Electrolytes, vitamins, and trace elements are added to approximate the Recommended Dietary Allowance at the target volume. At standard dilution, the caloric content of infant formula is usually 0.67 kcal/mL, and of standard enteral formula, 1 kcal/mL. Concentrated enteral nutrition formulas are also available (2 kcal/mL). The osmolality can range widely depending on the nutrient composition and caloric density (~ 200 to 750 mOsm/L).

In patients with underlying gastrointestinal disease or those requiring jejunal feeding, an oligomeric formula might be indicated. The protein in oligomeric formulas is hydrolyzed to peptides or a combination of peptides and amino acids. The carbohydrate complexity varies among formulas, although many oligomeric formulas are lactose free. A proportion of medium-chain triglycerides is often provided to improve fat absorption. Elemental formulas contain completely digested macronutrients, such as monosaccharides, medium-chain triglycerides, and crystalline amino acids, with an essential to nonessential amino acid ratio reflecting high biologic protein values. Lactose and gluten are absent and residues are low. The unpalatability and high osmotic load of simple sugars and amino acids limit the use of elemental formulas to tube feeding when feeding intolerance occurs with other types of formula (eg, severe malabsorption or short-bowel syndrome).

Advances in the understanding of the role of specific nutrients and their effects on metabolism have led to modification of enteral nutrition formulas for treatment of specific diseases. The aim of the disease-specific formulas is to provide therapeutic benefits in addition to the maintenance of general nutritional status. Glutamine-enriched formula has been advocated for the prevention and treatment of intestinal mucosa injury associated with chemotherapy and critical illness.[78,80] Omega-3 fatty acids have been supplemented in infant formula to enhance neurologic development.[82] So-called immune-enhancing formulas supplemented with arginine, glutamine, ribonucleic acid nucleotides, medium-chain triglycerides, or omega-3 fatty acids have been used in the treatment of critically ill patients.[78–81] Evidence for improved clinical and economic outcomes of many of the disease-specific formulas, compared with standard formulas, is still required to justify recommendations of their routine use.[78,80]

COMPLICATIONS OF ENTERAL NUTRITION THERAPY

Despite the potential benefits of enteral nutrition, complications can occur (Table 56-4).[83–88] Fortunately, life-threatening events are rare. However, problems related to the tube, the method of delivery, or the composition of the formula can seriously interfere with achieving nutritional goals. To minimize complications, prior consideration should be given to the patient's medical and physical condition, including any metabolic or electrolyte abnormalities, previous diet, dietary tolerance, and the time that has elapsed since the last significant oral or enteral nutrition.

Gastrointestinal Complications

Intestinal discomfort, bloating, cramping, diarrhea, nausea, and vomiting can occur during enteral feeding. Whenever symptoms occur, the position and integrity of the tube should be confirmed. In some cases, these symptoms relate to the high osmolality of the formula or the rate of infusion; alterations to the formula composition or infusion rate will be sufficient to improve feeding tolerance. The assessment of a sample of stool from a patient with diarrhea can assist in directing further investigations as required (bacterial culture, guaiac test, absorptive status by pH, microscopy, and reducing substances). The use of concomitant medications should be reviewed for possible drug–nutrient interactions or gastrointestinal side effects. Bacterial contamination of the feed or the tubing can result in diarrhea or vomiting. The method of formula preparation and storage and the technique of hanging and administering should be reviewed.[83] Samples of the feed, the tubing, and the feeding reservoirs are necessary to confirm this diagnosis.

Patients with a primary gastrointestinal disorder could be at risk of bacterial overgrowth owing to disturbances in gut motility. Bacterial culture of an intestinal biopsy or a lactulose breath hydrogen test will assist in establishing the presence of bacterial overgrowth of the small intestine. Constipation associated with enteral nutrition is uncommon and when it occurs is usually associated with insufficient fluid or fiber intake, intestinal dysmotility or obstruction, or medications. Gastroesophageal reflux can be exacerbated by tube feeding. The nasogastric tube can split open the lower esophageal sphincter, and irritation owing to tube trauma can contribute to lower sphincter incompetence. Placement of a gastrostomy tube plicates the stomach against the anterior abdominal wall, distorting the normal gastric anatomy, with a potential impact on gastric function. Owing to the frequency of this complication in high-risk patients, such as those with cerebral palsy or cystic fibrosis, assessment for gastroesophageal reflux with a 24-hour pH probe and nuclear gastric emptying study is routine prior to gastrostomy tube placement may be considered.

If the gastrostomy or jejunostomy tube is no longer required, the tube can be removed after consideration of the original method of insertion. For tubes inserted using a PEG, DPEJ, or PEGJ technique, the tube can usually be withdrawn and the stoma edges opposed using a dressing or suture. In most cases, this will be sufficient to allow closure of the stoma and tract within days to weeks. This process can be assisted with the use of gastric acid suppression aimed at minimizing gastric secretion. If the gastro- or jejunocutaneous fistula does not close spontaneously, formal surgical closure might be required. Patients in whom the gastrostomy or jejunostomy tube has been inserted using the traditional surgical approach usually require surgical closure of the fistula.

Pulmonary Complications

Aspiration of gastric contents—and pneumonia owing to aspiration—incorrect tube placement, or tube dislodgment into the airway can be fatal. Children at high risk include those with chronic neurologic disease, depressed conscious state, intestinal dysmotility, or severe gastroesophageal reflux and those patients requiring mechanical ventilation. In addition to checking tube position, tracheal aspirates can be measured for glucose content or fat-laden macrophages.[84] The addition of blue dye to the formula to assess tube position and aspiration in intensive care patients should be avoided because it has been associated with fatalities.[26]

Infectious Complications

Irritation owing to the mechanical trauma of tubes or exposure to gastric or intestinal secretions render the skin and mucosa susceptible to infection. A well-fitting, well-maintained device specifically designed for enteral nutrition use will limit this complication. Contamination of the formula and the delivery set can occur as a result of preparation or administration of the feed.[83] Nasogastric tubes are also associated with chronic nasal discharge, otitis media, and sinusitis.

Mechanical Complications

Mechanical complications related to enteral tube feeding are common. However, these can generally be treated and do not involve the same risks as a central venous catheter in critically ill children.[85–88] Tube occlusion can occur as a result of problems related to the tube (length, caliber, characteristics), the infusion (formula, drugs), pumps and clamps, the method and rate of delivery, and the level of tube care (method, frequency). Infusions that contain a highly viscous formula or crushed or powdered drugs are often associated with tube occlusion.

If flushing the tube with warm water is unsuccessful in clearing the blockage, a number of other options are available. The instillation of pancreatic enzyme supplements is sometimes successful in clearing a blockage. The use of meat tenderizer is not recommended because of its high sodium content and the risk of tube breakage during infusion. Cytology brushes, guidewires, neonatal tubes inserted into larger tubes, and specially designed catheters have been developed to treat tube occlusion. A biliary catheter for endoscopic retrograde cholangiopancreatography was recently described for the treatment of an occlusion in a nasojejunal tube.[89] The key to the prevention of tube occlusion is careful monitoring and repeated flushing of the tube. Mixing of drugs and formula should be avoided.

Irritation can occur anywhere along the interface between the tube and the skin or mucosa, resulting in inflammation, ulceration, or even perforation. Granulation tissue formation at the stoma site can occur as a result of chronic irritation. The migration of tubes with an internal balloon or retention device distally along the gastrointestinal tract can cause bowel obstruction. Migration of a gastrostomy tube along the fistula tract can cause pain and inflammation around the site or buried bumper syndrome.[50]

Metabolic Complications

Compared with what is seen with parenteral nutrition, metabolic complications associated with enteral nutrition are uncommon. Patients with chronic malnutrition or cardiac, hepatic, or renal impairment require careful monitoring of fluid and electrolyte status to prevent imbalance.[90] Patients

TABLE 56-4 Complications Associated with Enteral Tube Feeding

Complication	*Possible Cause*	*Prevention and Treatment*
Tube occlusion	Failure to flush tube regularly, inappropriate feed or medications placed down tube, inadequately dissolved feed, high-energy feed	Flush tube regularly with water; use prescribed feeds and medications only
Tube dislodgment	Inadequate securing of tube, inadequate monitoring of tube position	Check tube placement every 8 hours during continuous feeds and before every bolus or intermittent feed
Accidental tube removal	Inadequate securing mechanism, deterioration of tube (balloon rupture)	Review method of securing tube; consider specific dressings or clothing to prevent access to tube; regularly review tube function and integrity; ensure availability of replacement or "emergency" tube to prevent stoma closing prior to reinsertion
Diarrhea	Gastroenteritis, medications (antibiotics, sorbitol-containing drugs), rapid administration or bolus feeds, malabsorption, formula intolerance (lactose, hyperosmolar)	Review for possible causative factors including medications, formula, and gastrointestinal absorptive function; consider changing rate of delivery or formula as indicated (reduced osmolality, fiber enriched, lactose free)
Bloating, abdominal cramps	Gastrointestinal dysmotility, bowel obstruction, intolerance to formula (lactose intolerance), bacterial overgrowth	Reduce or cease feeds according to severity until cause is defined; consider investigations to address possible causes
Constipation	Inadequate fluid intake or large fluid losses, gastrointestinal dysmotility, medications, immobilization, underlying medical condition	Correct fluid losses and provide adequate ongoing fluid requirements; review medications; consider stool softeners or fiber supplementation
Dumping syndrome	Rapid infusion of high-volume or hypertonic feeds into duodenum or jejunum, postgastric surgery or vagotomy, gastrostomy sited in distal gastric antrum	Administer continuous feeds, reduced volume or osmolality of formula; use uncooked cornstarch
Nosocomial infection (bacteremia, pneumonia)	Enteral feed or equipment contamination, aspiration, increased risk with gastric acid suppression in paralyzed or ventilated patients	Change sets every 24 hours; limit feed hang time; use sterile system and sterile water to reconstitute feeds; culture feeds and equipment if contamination suspected; review for "silent" reflux or aspiration or tube dislodgment
Metabolic complications (increased or decreased glucose, phosphate, potassium or magnesium)	Complication of the primary disease (renal failure) or treatment (amphotericin), refeeding syndrome	Correct any significant electrolyte abnormalities prior to initiating enteral nutrition; undertake regular biochemical monitoring particularly in malnourished patients; gradually increase feed volume and concentration if at risk of refeeding syndrome
Malabsorption	Underlying gastrointestinal disease (cystic fibrosis), inappropriate formula selection or rate of administration	Assess absorptive status and alter formula and rate of delivery as appropriate
Perforation	Tube malposition, wrong type of tube, disorders of mucosal integrity	Ensure appropriate tube selection and placement technique; regularly check tube position; surgical treatment might be required
Gastric Tube Feeding (General)		
Vomiting, nausea	Gastroenteritis, intolerance to formula, rate of infusion too rapid, medications, bacterial contamination of feed, delayed gastric emptying	Review feeding regime and medications; culture feeds and equipment if contamination is suspected; consider intermittent or continuous infusion, postpyloric administration, or prokinetic agents
Gastroesophageal reflux	Underlying abnormality of esophagus or stomach associated with reflux or medical illness (eg, neurologic, pulmonary diseases), mechanical aspects related to tube	Assess for underlying reflux; consider antireflux therapies or postpyloric feeding
Large-volume gastric aspirates	Delayed gastric emptying related to underlying medical condition (eg, neurologic disease, critical illness, diabetes, intestinal pseudo-obstruction) or medications	Review medications; consider continuous or postpyloric feeds or prokinetic agents
Pulmonary aspiration	Incorrect tube placement, tube dislodgment, gastroesophageal reflux, gastric stasis, or vomiting (neurologic disorders, coma)	Cease feeds and check tube position; consider postpyloric feeding
Gastrointestinal bleeding	Tube-related irritation, ulceration, or perforation; vitamin K deficiency	Review tube position and gastrointestinal status; assess for alternative tube placement sites; try gastric acid suppression; supplement with vitamin K when indicated
Cellulitis	Postplacement contamination of wound, inadequate cleaning of stoma site, bolster too tight, chronic leakage through stoma	Perioperative antibiotics during tube placement, regular skin care, antibiotic therapy as appropriate; check tube and stoma site for areas of mechanical irritation and poor fit
Stoma leakage	Site infection; incorrect tube size, type, or position; perished tube; gastric stasis (eg, diabetes, pseudo-obstruction); medications	Examine site; assess tube integrity, suitability, and position; check balloon volume; replace with larger or different type of tube if appropriate; treat stoma site infection
Nasogastric Tube Feeding		
Nasal airway obstruction	Inappropriate tube size, nasopharynx disorders	Insert smaller-bore tube
Chronic nasal discharge or ulceration Epistaxis Sinusitis or otitis media	Inappropriate tube size or composition, immunodeficiency, disorder of mucosal or skin integrity	Re-evaluate tube size and type; regularly change tube; assess for alternative sites for tube placement
Feeding aversion	Repeated tube replacement in infants and young children, development implications of tube feeding	Consider alternatives to nasogastric route in infants requiring long-term enteral nutrition; involve speech therapist early
Esophageal perforation	Incorrect tube placement, ulceration related to tube position, underlying disorders of mucosal integrity (eg, epidermolysis bullosa)	Use appropriate tube placement technique; regularly check tube position
Pulmonary intubation	Incorrect tube placement or tube dislodgment	Use appropriate tube placement technique; take particular care in children with neurologic disorders or disturbances of conscious state

Continues

TABLE 56-4 Complications Associated with Enteral Tube Feeding (*Continued*)

Complication	*Possible Cause*	*Prevention and Treatment*
Gastrostomy Tube Feeding		
Granulation tissue formation	Chronic inflammation at stoma site, leakage, tube moving too freely along tract	Check tube size, type, and position; specialized dressings, corticosteroid cream, or cautery might be required
Site swelling or tenderness	Site infection, migration of tube along tract, tube shaft too short or bolster too tight	Examine site; tube removal and replacement might be required
Fasciitis	Incorrect tube or bolster position	Remove tube; obtain surgical opinion; administer intravenous antibiotics
Buried bumper syndrome	Retaining device and bolster secured too tight	Remove tube; administer antibiotics
Gastritis, gastric ulceration, or perforation	Trauma caused by tube, often of wall opposite insertion site, wrong tube type (composition or design)	Consider change in tube design to minimize trauma and gastric acid suppression
Duodenal or Jejunal Tube Feeding		
Reflux into stomach	Tube placed in proximal small intestine, dysmotility	Consider more distal placement
Bowel obstruction	Tube too large, tube malposition, disorder of gastrointestinal anatomy	Review tube size and position
Volvulus	Tube providing an abnormal fixation point	Remove tube; obtain surgical review

commencing enteral nutrition who have had a period of prolonged fasting or inadequate nutritional intake or significant weight loss (> 10% body weight) should be monitored for the metabolic features of refeeding syndrome. Daily monitoring of fluid status, serum sodium, potassium, phosphate, and magnesium levels is required until stability has been achieved with feeding advancement. Serum glucose levels, which are usually stable during continuous enteral nutrition therapy, can increase with overfeeding or as part of a stress response during critical illness. Hypoglycemia during intermittent feeding can be prevented with a progressive slowing of the rate of infusion in the period prior to disconnection. Dumping syndrome is reported in patients during enteral feeding in response to the presence of nutrients within the proximal intestine.[91] This is often associated with a rapid infusion of a formula with a high nutrient density and can be treated with modifications to the formula (such as adding uncooked cornsatch) or rate of delivery.[91]

HOME ENTERAL NUTRITION

Over the past two decades, advances in tube design, methods of delivery, and formulas have made enteral nutrition therapy safer, cheaper, and easier to administer for a wide range of disorders in childhood.[5,92–94] With attention to appropriate patient selection, education, and providing adequate technical support, enteral nutrition therapy can be safely and effectively provided in the home.[92–94] In 1992, data from Medicare and insurance companies estimated that there were about 152,000 patients of all ages receiving home enteral nutrition in the United States.[5] The rapid growth of home enteral nutrition therapy observed in the United States in 1987 had reached a plateau in 1992.[5]

In contrast, in Britain, home enteral nutrition therapy has been increasing rapidly—at a rate of up to 20% per year—and is about 10 times more common than home parenteral nutrition therapy.[94] Of patients receiving home enteral nutrition therapy in Britain, 40% are children, compared with 5 to 20% in three US cohorts.[95]

Best-practice guidelines for the administration of safe and effective home enteral nutrition therapy have been developed by national nutrition support organizations.[7,94] These guidelines take into consideration patient selection, assessment, monitoring, and the development of the enteral nutrition plan, including methods of implementation, documentation, and protocols for termination of therapy. Education about and management of home enteral nutrition therapy is ideally performed by a multidisciplinary team, including the gastroenterologist or surgeon, dietitian, stomal therapist, or nurse specialist.[9,94] An essential component of a successful home enteral nutrition service is availability of health professionals to provide support to the patient or caregivers at home to address concerns and direct appropriate intervention when necessary. A mechanism should be established to manage after-hours tube malfunction. To facilitate this process, all patients should carry a card with the type and size of tube and the date of last insertion clearly listed. Written documentation of routine tube care, as well as the recommended steps to take in the event of tube malfunction, is invaluable to the patient and caregiver at home.

Regular review by the multidisciplinary home enteral nutrition team should be a part of the routine management of patients using this therapy. At these appointments, all aspects of the administration of enteral nutrition are assessed. The tube is examined for size, function, and integrity and can be changed if necessary. The stoma site is examined. The method of delivery is reviewed, along with protocols for formula preparation. The intake of formula is assessed with reference to the nutritional goals. The patient is examined for growth, weight gain, and nutritional status; changes to the feeding regimen can be made where appropriate. Laboratory markers of nutritional status can be obtained as indicated. Complications of the tube or feeding protocol can be addressed.

INTERACTIONS BETWEEN DRUGS AND ENTERAL FEEDING

Administration of medications through an enteral feeding tube, either in combination with formula or alone, is problematic because only a few drugs have been tested and

approved for tube delivery. Characteristics of the tube's composition can influence the binding of drug to the tube wall (eg, carbamazepine reacts with polyvinyl chloride feeding tubes).[7,96] Interactions between a drug and a nutrient can result in an undesired side effect of the drug or feeding intolerance. Drug–nutrient interactions can result in changes in medication bioavailability, distribution, metabolism, or excretion.[97] Drug–nutrient interactions are described with substances containing calcium, zinc, and iron or when acidic and neutral liquid medications are combined with casein or soy protein. Impaired absorption of phenytoin is well documented in the literature and occurs as a result of pharmacokinetic incompatibility.[7] Long-chain fatty acids can enhance the absorption of lipid-soluble drugs but hasten the degradation of other medications (eg, carbamazepine).

Liquid preparations of medications are preferred by children and for enteral administration. However, liquid drug preparations tend to have a high osmolality, which can cause gastrointestinal intolerance if infused into the jejunum. The majority of oral liquid medications have an osmolality of between 1,000 and 11,000 mOsm/kg.[98] The osmotic properties of these liquids are usually attributable to the presence of sorbitol, propylene glycol, or polyethylene glycol. Although included among the inactive ingredients in labels, they are not quantified. Osmotic diarrhea and delayed gastric emptying can occur if the cumulative dose is more than 20 g (range, 7.5 to 30 g). The resolution of diarrhea after cessation of a liquid medication containing sorbitol in tube-fed patients is suggestive of a cause–effect relationship.[99]

CONCLUSION

Advances in tube placement techniques, tube design, delivery systems, and enteral formulas have enabled the safe and effective provision of enteral nutrition therapy for a broad range of disease indications in children. Successful enteral nutrition therapy has enabled the limitation of parenteral nutrition therapy, resulting in important benefits in terms of safety, manageability, and cost. The management of nutritional problems in patients with chronic diseases, such as neurologic disorders and cystic fibrosis, can be enhanced by home enteral nutrition therapy. The development of disease-specific formulas provides new therapeutic options. Further improvements in technology enabling light, simple, feeding pumps and modifications to tube design will continue to assist in the administration of enteral nutrition to children.

CHAPTER 57

PARENTERAL NUTRITION

John A. Kerner Jr, MD

Intravenous nutritional care was introduced more than 50 years ago when protein hydrolysates first became available. In the late 1930s, Shohl and colleagues demonstrated positive nitrogen balance with infusion of glucose plus protein hydrolysates in pediatric patients.[1] In 1944, Helfrick and Abelson infused 50% glucose, 10% casein hydrolysate, and a homogenized emulsion of olive oil and lecithin in an alternating manner into a 5-month-old marasmic infant for 5 days via a peripheral vein.[2] During the next 20 years, parenteral nutrition (PN) in infants and children was unsuccessful, largely because of the inability of peripheral veins to tolerate the hyperosmolar infusates. Significant side effects, including allergic reactions and marked elevations of body temperature, further complicated attempts at PN. Often, there was inadequate provision of calories to allow the nitrogen to be used efficiently. Intravenous fat preparations also were used, but they were removed from general use because of toxic side effects, such as thrombosis, embolism, fever, vomiting, rash, eosinophilia, and thrombocytopenia.[3,4]

In the late 1960s, a group of surgeons at the University of Pennsylvania demonstrated, first in beagle puppies and later in an infant, that the continuous intravenous infusion of hypertonic dextrose and amino acids through deep central venous catheters (CVCs) could provide adequate caloric intake safely and allow normal growth and development.[5–7] The development of a safe intravenous fat preparation, Intralipid (Kabivitrum, Alameda, CA), was another major advance in clinical PN. Fat emulsions offered the dual advantage of high caloric density and isotonicity, thereby meeting caloric requirements with less damage to peripheral veins. In the mid-1970s, protein hydrolysates were replaced by crystalline amino acid solutions. Their composition was more controlled than that of the hydrolysates, reducing the risk of allergic reactions. In the 1980s, crystalline amino acid solutions specifically designed for newborn infants became available. Finally, appreciation of the vitamin and trace element requirements of neonates and older children led to the development of the infusible vitamin and mineral solutions designed to meet these needs.

INDICATIONS

PN is indicated for most patients who are unable to tolerate enteral feedings for a significant period of time.[8] Four or 5 days without adequate oral nutrient intake is an indication for instituting some form of PN. Even 2 to 3 days without adequate nutritional intake for very low birth weight infants or infants with preexisting nutritional depletion is likely to result in significant depletion of their limited endogenous stores. PN is not indicated in patients with adequate intestinal function, in whom nutrition can be maintained by oral or tube feedings. Relative contraindications to PN include intended use for fewer than 5 days and the probability that a patient will die imminently because of underlying disease. Although PN is a potentially life-saving therapy and is now an accepted practice, experience has demonstrated metabolic, mechanical, and infectious complications. Therefore, candidates for PN should be selected carefully (Table 57-1).

PN is supportive therapy for some illnesses and primary therapy for others. It is supportive for burn patients, patients with protracted diarrhea and malnutrition, and patients with congenital gastrointestinal anomalies. Studies have documented its value as primary therapy for patients with gastrointestinal fistulas, short-bowel syndrome, renal failure, and Crohn's disease. In addition, PN is suggested for use in malnourished oncology patients, patients with hepatic failure, malnourished patients before major surgery, patients with cardiac cachexia, and those requiring prolonged respiratory support. Nutritional repletion in these patients seems to reduce the incidence of sepsis and encourage proper wound healing and a return of normal skin test reactivity. Although PN is used to replenish the malnourished child, it can be started prophylactically in clinical situations in which prolonged starvation is expected (eg, after extensive intestinal surgery in the newborn infant and after bone marrow transplantation in the older child). Other indications for PN include a recent loss of more than 10% of body weight with a concomitant inability to ingest sufficient nutrients to reverse this state, and marginal nutritional reserves in a patient who is unable to ingest sufficient calories to prevent further negative nitrogen balance.

Infants receiving central venous PN retain nitrogen and grow as well as normal infants fed human milk or standard formulas. PN has been directly credited with improving the survival of infants with certain conditions. The mortality rate of patients with gastroschisis and intractable diarrhea has decreased to approximately 10%

TABLE 57-1 Indications for Parenteral Nutrition in Pediatric Patients

Condition	*Examples*
Surgical gastrointestinal disorders	Gastroschisis, omphalocele, tracheoesophageal fistula, multiple intestinal atresias, meconium ileus and peritonitis, malrotation and volvulus, Hirschsprung's disease with enterocolitis, diaphragmatic hernia
Intractable diarrhea of infancy	
Inflammatory bowel disease	Crohn's disease, ulcerative colitis
Short-bowel syndrome	
Serious acute alimentary diseases	Pancreatitis, pseudomembranous colitis, necrotizing enterocolitis
Severe malabsorption	Idiopathic villous atrophy
Chronic idiopathic intestinal pseudo-obstruction syndrome	
Gastrointestinal fistulas	Fistulas in Crohn's disease
Hypermetabolic states	Severe burns and trauma
Renal failure	
Low birth weight infants	Asphyxiated infants, very low birth weight infants, respiratory distress syndrome
Malignancies	Especially those receiving abdominal irradiation (causing radiation enteritis) or chemotherapy, which leads to severe nausea and intestinal dysfunction
Marrow and organ transplantation	
Special circumstances	Anorexia nervosa, cystic fibrosis, cardiac cachexia, hepatic failure, sepsis
Rare disorders	Congenital microvillous inclusion disease, chylothorax and chylous ascites, *Cryptosporidium*-induced secretory diarrhea

from the 75 to 90% rate before the development of PN.[8] This drop in mortality seems to be attributable to the prevention of starvation.[8]

Low birth weight infants constitute the largest group of pediatric patients who receive parenteral nutrients.[9] Premature infants, especially those who have respiratory distress syndrome and are incapable of full oral feedings, often receive PN because of their extremely limited substrate reserve, very rapid growth rate, and possible susceptibility to irreversible brain damage secondary to malnutrition. A classic study that remains a model for nutritional support in the very low birth weight infant was performed by Cashore and colleagues.[10] They described 23 infants who weighed less than 1,500 g at birth in whom peripheral PN was begun on day 2 of life to supplement enteral feedings; these infants regained their birth weight by the age of 8 to 12 days and achieved growth rates that approximated intrauterine growth.

Most centers do not feed an asphyxiated infant enterally for the first 5 to 14 days after the insult. This practice is extrapolated from animal data on gut cellular proliferation and migration. The intestinal mucosa of newborn and suckling rats has a very slow rate of cellular proliferation and migration compared with that of adult animals.[11–13] This same slower rate of turnover of intestinal epithelia could exist in the newborn human.[14] Asphyxia, which in itself can cause significant injury to the gastrointestinal tract, can predispose the premature infant to necrotizing enterocolitis (NEC). Because enteral feedings impose additional risks in this fragile situation, they should be withheld and PN given instead. There is evidence that enteral feeding could be the critical element that triggers postnatal gut maturation through release of gut peptide hormones.[15] Intestinal development is arrested when animals receive PN with no enteral nutrients, but maturation resumes on reintroduction of intraluminal nutrients.

PARENTERAL NUTRIENT REQUIREMENTS

Calories (Energy)

There are many different recommendations and methods to calculate the caloric needs of children. The World Health Organization (WHO) recommendations are based on evaluations of several thousand children and have proven to be relatively accurate for children more than 1 year of age.[16] The WHO recommendations provide an estimated resting energy expenditure (REE), which can then be multiplied by a factor to adjust for catch-up growth, activity, and medical status, to provide an estimate of total daily caloric needs. In obese patients (weighing more than 120% ideal body weight), the Schofield height/weight equation more accurately predicts energy needs.[17] Tables A-23 to A-26 show energy expenditures for infants and children, along with activity and stress adjustment factors, and Tables 57-2 and 57-3 show protein and caloric needs. Predictive equations often do not accurately reflect patients' needs.[18] Indirect calorimetry (measurement of oxygen consumption and carbon dioxide production) provides a precise and practical measurement of REE.[19] This measurement should be used when possible, especially for patients with increased needs and for those not responding to nutritional therapy. Indirect calorimetry technology in the nonintubated patient not receiving supplemental oxygen is well standardized, but measurements in the newborn baby and the intubated patient receiving supplemental oxygen are fraught with technical difficulties.

Adequate protein intake must be provided with adequate caloric intake for optimal caloric use and growth (see Tables 57-2 and 57-3). In a controlled trial of 14 premature appropriate-for-gestational-age infants, two isocaloric (60 kcal/kg/day) intravenous feeding regimens were compared, one with glucose alone and the other with glucose plus 2.5 g/kg/day of crystalline amino acids.[20] Infants on the glucose-only regimen had a nega-

TABLE 57-2 Protein and Energy Requirements for Infants

	Full Term		
	Preterm	*0–6 mo*	*6–12 mo*
Energy (kcal/kg/d)	100–120	90–110	80–100
Protein (g/kg/d)	2.5–3.5	2.5–3.0	2.0–2.5

tive mean nitrogen balance, whereas those fed glucose plus amino acids had a positive balance. There was no significant weight gain in either group. Additionally, intravenous intakes of 70 to 90 kcal/kg/day have resulted in weight gain in premature infants, and energy intakes providing more than 70 kcal/kg/day (including intakes of 2.7 to 3.5 g/kg/day of protein) resulted in nitrogen accretion and growth rates similar to in utero values.[21] Earlier studies of adults suggested that additional stresses, such as sepsis, increase caloric requirements by as much as 40%. These conclusions have been questioned[22]: severe stress in children probably does not increase requirements by any more than 15%. The impact of stress on caloric requirements in preterm infants has not been critically studied, but decreased physical activity could reduce demands and balance the increased needs owing to the stress associated with the underlying disorders. Adult studies suggest that energy requirements of patients with disease are similar to or less than those of healthy subjects for the same reasons.

Early aggressive nutritional support is being recommended by many neonatologists to improve premature infants' nutritional status.[23] One key component is protein intake. In most nurseries around the world, preterm infants start at only 0.5 g/kg/day. When given parenteral glucose alone, an infant will lose 1% of body protein stores per day (approximately 1 g/kg/day). Parenteral protein is usually started on day 1 or 2 of life, or as soon as serum electrolytes are stable. A number of studies over the past 12 years indicate that most preterm infants will tolerate 1.5 to 2 g/kg/day of parenteral amino acids in the first day of life and that these infants are not catabolic. Several studies have shown that the parenteral intake required to avoid catabolism in extremely low birth weight infants could be as low as 1.1 to 1.5 g/kg/day when administered with 30 kcal/kg/day of energy. To achieve intrauterine rates of protein deposition, the upper limit of protein intake is 3 g/kg/day for full-term infants and up to 4 g/kg/day for most preterm infants.[24]

Fluid restrictions mandated by severe respiratory, cardiac, or renal disease can prevent the delivery of adequate calories—even when the calories are given as central PN. Peripheral PN seems best suited for minimally stressed patients undergoing a limited course of PN for whom full growth and development are not the therapeutic goals. Central PN is indicated either for nutritional repletion of a seriously malnourished patient or when full growth and development are essential. Concentrations of glucose of up to 30 to 35% might be necessary to provide sufficient carbohydrate calories. PN solutions should be balanced, especially when there is a risk of PN-induced liver disease. Regimens high in carbohydrate increase the respiratory quotient, resulting in excessive carbon dioxide retention, which leads to increased difficulty in weaning from the ventilator.

TABLE 57-3 Protein Requirements: Children and Adolescents

Age (yr)	*Protein (g/kg/d)*
1–6	1–2
7–10	1–2
11–14	1–2
15–18 (boys)	0.9–2
15–18 (girls)	0.8–2

Fluids

Fluid requirements depend on hydration status, size, age, environmental factors (eg, radiant warmers, phototherapy), and underlying disease. Daily maintenance fluid requirements for children are outlined in Table 57-4. Premature babies have unique requirements. Factors that increase fluid requirements include radiant warmers, conventional single-walled incubators, and phototherapy; those that decrease fluid requirements include heat shields, thermal blankets, and double-walled incubators. Furthermore, excess fluid intake (more than 150 mL/kg/day) in low birth weight infants can be associated with patent ductus arteriosus, bronchopulmonary dysplasia, NEC, and intraventricular hemorrhage.[25]

During PN, it might be necessary to give fluids in excess of maintenance amounts to provide adequate calories, especially if using a peripheral vein, but one must be careful to avoid fluid overload. Highly concentrated glucose solutions and 20% fat emulsion are used to decrease total fluid volume. It is important not to use PN for replacing ongoing losses because the fluid contains not just electrolytes but protein, vitamins, and minerals. We recommend the provision of PN to meet maintenance fluid needs and the use of specifically designed replacement solutions for ongoing losses.

Carbohydrate

The major source of nonprotein calories in PN is D-glucose, which is provided in the monohydrate form for intravenous use, reducing its caloric yield to 3.4 kcal/g rather than the 4 kcal/g of enteral glucose or other carbohydrates. Glucose provides most of the osmolality in the PN solution; peripheral PN concentrations with more than 10% glucose increase the risk of phlebitis and, thus, decrease the life span of peripheral venous lines. The carbohydrate load is initiated in a stepwise fashion to allow an appropriate response of endogenous insulin and thus prevent glucosuria (and subsequent osmotic diuresis). Solutions containing excessive glucose can contribute to hepatic steatosis. Using glucose as the sole calorie source leads to greater water retention than when it is combined with lipids.[26] As mentioned previously, a balanced PN solution, including carbohydrate and fat (as non-nitrogen calories) can avoid fatty infiltration of the liver, water retention, and worsening respiratory compromise in acutely ill ventilator-dependent patients. Carbon dioxide production is higher with glucose as the only source of nonprotein

TABLE 57-4 Fluid Recommendations for Parenteral Nutrition

Initial volume for patients free of cardiovascular or renal disease
< 10 kg = 100 mL/kg/d
10–30 kg = 2,000 mL/m^2/d
30–50 kg = 100 mL/hour (2.4 L/d)
> 50 kg = 124 mL/hour (3 L/d)
Volume can be increased by
10 mL/kg/d in infants until the desired caloric intake is achieved (maximum of 200 mL/kg/d, if tolerated)
> 10 kg: by 10% of initial volume per day until desired caloric intake is achieved (maximum of 4,000 mL/m^2/d, if tolerated)

calories than it is when fat emulsion provides some of the total caloric content.[27]

Small, premature infants have poor glucose tolerance in the first days of life, and hyperglycemia (more than 125 mg/dL of sugar) occurs frequently. The infusion, along with glucose, of alternative carbohydrate sources, such as galactose and fructose, has enabled investigators to increase the total number of carbohydrate calories infused into the very premature infant, while avoiding the development of hyperglycemia. The potential side effects of these regimens, however, argue against their routine use. Glucose infusions are well tolerated by the newborn infant if the initial rate of administration does not exceed the hepatic rate of glucose production (6 to 8 mg/kg/minute). The premature infant can develop hyperglycemia even at lower rates of infusion. Glucose infusion rates between 5 and 12 mg/kg/minute are recommended in neonates and 2 and 5 mg/kg/minute in older children and adolescents. Serum glucose measurements should be monitored when PN solutions are abruptly stopped.[28]

The response of premature infants to insulin is highly variable; some develop profound hypoglycemia with minuscule insulin doses, and others have no response. There have been numerous studies in very low and extremely low birth weight infants (weighing less than 1,000 g) documenting improved weight gain, increased tolerance of intravenous glucose, normalization of serum glucose levels, and increased caloric intake with the use of continuous insulin infusions.[29,30] There are still serious concerns about the use of insulin in the neonate because (1) suppression of muscle proteolysis might not be desirable (the glutamine released is an important substrate for intestinal epithelial cells and the immune system), (2) there is a lack of understanding of the composition of the weight gain (especially protein accretion) in these infants, and (3) it is not known whether increased glucose use deprives the brain of this important substrate or whether increased glucose can be efficiently oxidized. Otherwise, it might be converted to fat. In older children and adolescents, insulin might be required to improve caloric intake in the face of hyperglycemia. Adding insulin to the PN bag is not recommended; rather, deliver the insulin as a separate infusion that can be titrated according to serum glucose.

Protein

The problems of hyperammonemia and poor use of nitrogen often seen with protein hydrolysates have been alleviated by the use of purer, crystalline amino acid formulations. Hyperammonemia, seen with earlier solutions, rarely occurs with the increased amounts of arginine and decreased glycine in the newer formulations. Hyperchloremic metabolic acidosis, a problem noticed with earlier crystalline amino acid solutions, has been ameliorated by the substitution of acetate for chloride in the salts of lysine and the use of basic salts of histidine. In addition to decreased toxicity, crystalline amino acids promote greater rates of nitrogen retention than do protein hydrolysates. All amino acid formulations currently marketed consist of crystalline amino acids; most were designed according to the requirements of normal, orally fed adult subjects and not for growing infants and children. These solutions produced weight gain and positive nitrogen balance in the stable neonate or infant when adequate nonprotein calories were also provided. However, use of these solutions leads to high plasma concentrations of such amino acids as methionine, glycine, and phenylalanine (a cause for safety concerns) and to low plasma concentrations of such amino acids as the branched-chain amino acids (BCAAs), tyrosine and cysteine.

Heird and Malloy found that free amino acid patterns, total weight, and protein content of brains in beagle puppies that received PN were grossly abnormal compared with those of suckled puppies.[31] The abnormal free amino acid patterns of the brains of the PN-fed puppies reflected plasma amino acid levels. Extensive research led to the production of a parenteral formula, TrophAmine (B. Braun, Irvine, CA), that normalizes plasma amino acid levels to within the range recommended by Wu and colleagues (normal 2-hour postprandial levels in healthy 30-day-old breast-fed full-term infants[32]). TrophAmine is unique in that it provides the essential amino acids (including taurine, tyrosine, and histidine) in adequate amounts, as judged by the normalized plasma amino acid profile, plus aspartic acid, glutamic acid, and the dicarboxylic acids at appropriate levels. Studies of this product have been conducted in preterm and full-term infants and in older children.

Helms and colleagues compared TrophAmine with a standard amino acid formula (Freamine III; B. Braun) in neonates[33] and found that the TrophAmine group had significantly greater weight gain and nitrogen retention and had plasma amino acid concentrations within the postprandial neonatal target range.[32] Levels of methionine, glycine, and phenylalanine were above and levels of tyrosine were below the target range when Freamine III was used. L-Cysteine was supplemented in both groups.

An uncontrolled, nonblinded multicenter study of the clinical, nutritional, and biochemical effects of intravenous administration of TrophAmine with a cysteine additive was conducted in infants and children (2.0 to 12.6 kg in weight) receiving only PN for 5 to 21 days, 2.5 g/kg/day of TrophAmine, 1.0 mmol/kg/day of cysteine hydrochloride, and approximately 110 kcal/kg/day of nonprotein calories.[34] The subjects gained approximately 11 g/kg/day and all were in positive nitrogen balance and had normalization of the plasma amino acid profile without adverse effects. Serial γ-glutamyl transpeptidase values actually

declined during the course of the study. Only 1 of the 31 subjects who received PN for more than 10 days had an increase in direct bilirubin, despite a predicted incidence of cholestasis of 30 to 50%. TrophAmine has been shown to be equally efficacious in preterm infants.[35] This distinct decrease in cholestatic tendency with TrophAmine could be because of the solution's taurine content, which results in "normal" plasma levels of taurine. Taurine deficiency has been proposed as a possible cause of cholestasis in patients receiving PN for prolonged periods.[36] Overall imbalance of amino acids or toxicity of one or more amino acids elevated in plasma could also be responsible for hepatic dysfunction and cholestasis.

Of the standard amino acid solutions, Aminosyn (Abbott Laboratories, North Chicago, IL), with its low pH value, allows the addition of greater amounts of calcium and phosphate for growing preterm infants.[37] TrophAmine has a lower pH level than Aminosyn does and allows even larger amounts of calcium and phosphorus to be added to the PN solution without precipitation.[38]

TrophAmine contains 60% and Aminosyn-PF (Abbott Laboratories), a comparable product, contains 50% essential amino acids. A large multicenter study comparing TrophAmine and Aminosyn-PF in low birth weight infants described similar nitrogen balance and weight gain in both groups.[39] However, one center (from the multicenter study) reported improved nitrogen balance and better levels of methionine and tyrosine in the TrophAmine group. Both formulas contain supplemental taurine, based on data showing a potentially deleterious effect of taurine deficiency on the developing brain and retina[40] and the concern that taurine deficiency might be a cause of cholestasis. Adult formulations lack taurine, which is essential because it conjugates bile acids. Taurine has also been shown to promote bile flow and bile acid secretion. Both Aminosyn-PF and TrophAmine appear to better meet the metabolic needs of the preterm infant than do standard amino acid solutions.

Cysteine is considered an indispensable amino acid for infants because hepatic cystathionase activity is absent or low until some time after full-term birth (cystathionase converts methionine to cysteine). In addition, removal of cysteine from an otherwise adequate diet inhibits the rate of weight gain and nitrogen retention. Enterally fed infants do not have a major problem because both human milk and infant formulas contain cysteine. Because cysteine is unstable and is only sparingly soluble in aqueous solution, parenteral amino acid solutions previously did not contain cysteine. Infants receiving PN have low plasma cysteine levels; furthermore, nitrogen retention is usually lower than in infants receiving the same nitrogen enterally. Cysteine hydrochloride (HCl) can be added to PN solutions, but within 24 hours, approximately 50% of it forms a complex with glucose, making D-glucocysteine. Previous studies of this method of cysteine supplementation of PN failed to show improvement in growth or nitrogen retention. This might have been because the regimens used were also deficient in tyrosine. Kashyap and colleagues showed that supplementation of PN with cysteine HCl (where the amino acid solution contained tyrosine), by either admixture or piggyback, resulted in cysteine retention, higher plasma cysteine concentrations, possible improved nitrogen retention, and increased acidosis (which required increased acetate to offset it).[41]

Helms and colleagues reported positive nitrogen balance (greater than 200 mg/kg/day) and weight gain (more than 10 g/kg/day) with low doses of TrophAmine (2 g/kg/day) and calories (50 kcal/kg/day) in preterm infants receiving PN.[42] In the past, these results were achievable only with higher-calorie and standard protein intakes.

Glutamine

Clinical experience with glutamine added to PN solutions is expanding, despite glutamine's short shelf-life in solution. Glutamine, a primary fuel source for enterocytes, colonocytes, lymphocytes, and macrophages, is a precursor for nucleotide synthesis and for glutathione, an important antioxidant that could be protective in a variety of circumstances. A nonessential amino acid by definition, cellular uptake of glutamine can exceed synthesis and release from skeletal muscle during catabolic illness, making glutamine essential under these conditions.[43] Supplemental glutamine seems to

- Increase protein synthesis
- Decrease protein breakdown
- Improve nitrogen balance
- Enhance intestinal adaptation after massive small-bowel resection
- Attenuate intestinal and pancreatic atrophy associated with PN or elemental enteral feeding
- Reduce bacterial translocation after radiation therapy
- Reduce bacteremia and mortality after chemotherapy[43]

In critically ill humans, glutamine supplementation can enhance D-xylose absorption, reflecting increased small-bowel absorptive capacity, and in stable patients, it can attenuate the villous atrophy and increased intestinal permeability associated with PN.[43] Variable results have been found in studies of glutamine-supplemented PN in bone marrow transplant recipients.[44] In a child with short-bowel syndrome, clinical improvement (weight gain, improved intestinal absorption, improvement of histology of an intestinal biopsy) occurred at least coincidentally with the addition of 5 g/day of parenteral glutamine administered separately from the PN solution (the patient weighed 12.6 kg at the onset of treatment; dosage was 0.4 g/kg/day).[45] The patient tolerated the infusion well with no obvious side effects.

Preliminary studies in very low birth weight (VLBW) infants have shown benefit of glutamine-supplemented PN. Lacey and colleagues performed a randomized trial in VLBW infants of glutamine-supplemented PN (15 to 20% of administered amino acids as L-glutamine); the infusion was safe and was associated with improved plasma glutamine levels without elevation of ammonia or glutamate.[46] In addition, of the 44 randomized infants, in the group with birth weights of less than 800 g, the glutamine-

supplemented group required fewer days (13 versus 21) on total parenteral nutrition (TPN), had a shorter length of time to reach full feedings (8 versus 14 days), and needed less time on the ventilator (38 versus 47 days). Wilmore and colleagues successfully used supplemental glutamine (0.56 g/kg/day) by the intravenous or oral route, parenteral growth hormone (0.14 mg/kg/day), and a modified enteral diet (about 60% of calories from carbohydrate, 20% from fat, and 20% from protein) in long-term PN patients with short-bowel syndrome.[47] Treatment resulted in improved protein absorption, decreased stool output, and reduction in dependence on PN as a source of nutrition. The findings suggested a significant potential role for glutamine in promoting intestinal adaptation in short-bowel syndrome. Alternative methods of administration (eg, enteral administration or the addition of the stable dipeptide alanyl glutamine to PN,[48] or providing intravenous α-ketoglutarate to PN, which is converted to glutamine) might need to be explored to facilitate long-term therapy.

Other researchers have attemped to reproduce the positive results from intravenous or oral glutamine supplementation. Scolapio and colleagues studied eight patients with short-bowel syndrome (two with colon) with a mean residual small-bowel length of 71 cm who had required home TPN for 13 years.[49] Treatment included growth hormone (0.14 mg/kg/day), glutamine (oral, 0.63 mg/kg/day), and a complex carbohydrate diet. No benefit of this treatment could be demonstrated; small intestinal morphology did not change, with no improvement in D-xylose absorption, and the "treatment" group had obvious fluid retention and peripheral edema.

Powell-Tuck and colleagues performed a randomized, double-blind, controlled trial in 168 heterogeneous patients needing PN; the treatment group received 20 g of free glutamine.[50] Overall, there was no difference between the two groups in infectious complications or length of hospital stay. Glutamine was associated with a significant ($p < .03$) reduction in length of stay in the subset of surgical patients (45 versus 30 days).

The National Institute of Child Health and Development (NICHD) Neonatal Research Network performed a randomized trial of parenteral glutamine supplementation for extremely low birth weight infants.[51] Fifteen centers randomized infants with birth weights between 401 and 1,000 g to TrophAmine or an isonitrogenous amino acid solution with 20% glutamine. A total of 1,430 patients were studied. There were no differences between the two groups for late-onset sepsis, NEC, days to full enteral feedings, days to regain birth weight, length of hospital stay, or survival, even though glutamine concentrations in plasma significantly increased in the treatment group.

In contrast, in a study of severely burned patients, glutamine administration reduced gram-negative bacteremia in a prospective, randomized, double-blind trial versus isonitrogenous control.[52] A study of pediatric patients with burns supported the notion that exogenous glutamine supplementation in pediatric patients with severe injuries might be needed.[53]

Guidelines: Amino Acids

Guidelines for protein requirements in PN are shown in Tables 57-2 and 57-3. Preterm neonates given 2.5 to 3.5 g/kg/day of amino acids and approximately 80 kcal/kg/day achieve nitrogen retention at levels that approximate intrauterine nitrogen retention; intakes for older children and adolescents vary from 1.0 to 2.0 g/kg/day. In neonates, we start at 1.5 to 2.5 g/kg of amino acids per day and increase to the desired goal. In older infants and children, we start at the goal dose, except in cases in which there is hepatic or renal insufficiency or disorders of protein metabolism. Special amino acid solutions are available for use in patients with maple syrup urine disease. Daily quantitative serum amino acid estimation in these patients allows for advancement and adjustment of the protein dose. Solutions high in BCAAs have been used in patients with liver failure and encephalopathy. These solutions are expensive, and the data justifying their use are not well substantiated. We often use TrophAmine (with its higher percentage of BCAAs) in patients less than 6 months old and those with cholestasis. In an attempt to decrease cholestasis and hepatic dysfunction, we consider the use of TrophAmine for all of our long-term PN patients (eg, children with short-bowel syndrome or intestinal pseudo-obstruction).

We have described two siblings (16 and 11 years old) with microvillus inclusion disease who have received TrophAmine as their amino acid source since infancy.[54] Even though they have a disease that usually has a short life expectancy and significant morbidity from lifelong dependence on TPN, these two boys continue to thrive and lead normal lives. The older boy was free of significant morbidity until he was 14 years old, when he was found to have a large liver mass and eight additional hepatic nodules, leading to a right hepatic lobectomy. Final pathology confirmed the diagnosis of adenoma, with the remainder of the liver biopsy showing no evidence of TPN-related liver disease. The younger child has no evidence of TPN-induced liver disease; he has not developed cholestasis and is free of hepatic nodules on ultrasonography.

Calorie-to-Nitrogen Ratio

To promote efficient net protein use and not use the protein as an energy source, it is often recommended to provide approximately 150 to 200 nonprotein calories per gram of nitrogen, as follows: nitrogen content (g) equals protein (g)/6.25; 1 g protein contains 0.16 g nitrogen; therefore, 24 to 32 non-nitrogen calories must be supplied per gram of protein infused to yield a desirable ratio of 150 to 200:1:

- Non-nitrogen calories/N (g) = 24/0.16 = 150/1; 32/0.16 = 200/1
- If 2 g/kg/day of protein as amino acids is supplied, then 48 to 64 kcal/kg/day of non-nitrogen calories must be supplied to ensure adequate protein use.
- If 2.5 g/kg/day of protein is supplied, then 60 to 70 kcal/kg/day of non-nitrogen calories must be supplied.

Albumin

Albumin at a concentration of 0.5 to 1.0 g/kg/day can be administered to PN patients who are hypoalbuminemic from non-nutritional causes. Such infusions are for oncotic, not nutritive, benefits. Albumin has a long half-life when synthesized endogenously, in contrast to its short intravascular half-life when given exogenously. Albumin should be infused separately via a "Y" connector and not placed in the PN solution because (1) albumin is a blood product and should not be hung for more than 8 hours, (2) recent concerns exist about flocculation of albumin in PN solutions, and (3) albumin in PN solutions increases the risk of sepsis.[55]

Fat

Intravenous fat is an integral part of the PN regimen. It provides a concentrated isotonic source of calories (20% solution supplies 2.0 kcal/mL) and prevents or reverses essential fatty acid deficiency. Patients who cannot tolerate large glucose or fluid loads can receive sufficient calories if intravenous fat is added to the glucose-amino acid regimen.[10] In addition, continuous administration of intravenous fat with the PN regimen prolongs the viability of peripheral intravenous lines in infants who might have limited venous access.[56] The intravenous fat must be infused separately from the PN solution because these solutions can "crack" (disturb) the fat emulsion. It is given using a "Y" connector near the infusion site and beyond the micropore filter.

The rate of elimination and metabolic fate of intravenous fat particles are the same as those of naturally occurring chylomicrons, so plasma clearance is dependent on the activity of lipoprotein lipase in the capillary endothelial cells, primarily in muscle and adipose tissue. The intravenous fat should be infused over 24 hours whenever possible. Continuous intravenous fat infusions (24 hours/day) are better tolerated than are intermittent infusions (8 to 18 hours/day),[57,58] with less fluctuation and lower concentrations of plasma lipids, especially at higher rates of infusion. Early studies argued against exceeding a rate of 0.15 g/kg/hour (3.6 g/kg/day). Slower infusion rates are required for small-for-gestational-age infants. Infusion rates of 0.12 g/kg/hour or less resulted in less elevation of plasma lipid levels than did rates of 0.17 g/kg/hour or more.[58]

Biochemical evidence of essential fatty acid deficiency has been observed in the serum of fasted newborn infants as early as 2 days after initiating fat-free PN.[59] Biochemical evidence precedes clinical signs of deficiency: reduced growth rate, flaky dry skin, poor hair growth, thrombocytopenia, increased susceptibility to infections, and impaired wound healing.[59] An essential fatty acid deficiency can be assessed by determination of the ratio of 5,8-11-eicosatetraenoic to arachidonic acid (triene-to-tetraene ratio). An elevated ratio is an indicator of essential fatty acid deficiency. An initial report that topically applied sunflower seed oil reversed biochemical and clinical essential fatty acid deficiency in two newborn babies on fat-free PN could not be duplicated in subsequent studies.[60] Interestingly, 15 mL twice a day of corn oil, sunflower oil, or safflower oil enterally provides as much linoleic acid as 150 mL of 10% intravenous fat at less than 5% of the cost.

Many PN patients not on complete bowel rest tolerate such a regimen. An essential fatty acid deficiency can be prevented by providing 2 to 4% of total calories as intravenous fat (1 to 2% linoleic acid)—an intravenous fat dose of 0.5 to 1.0 g/kg/day. Linoleic and linolenic acids are essential fatty acids. There is the possibility that too much linolenic acid inhibits the conversion of linoleic acid to arachidonic acid. These concerns led to the development of Liposyn II (Abbott Laboratories), a blend of safflower oil (0.1% linolenic acid) and soybean oil (8.0% linolenic acid). Currently used intravenous fat products are shown in Table 57-5. One study demonstrated that hypertriglyceridemia is more common in preterm infants who receive

safflower oil–based as opposed to soybean oil–based intravenous fat.[61] However, studies in newborn babies comparing Liposyn II and Intralipid found no difference in the incidence of hypertriglyceridemia between the two products, with comparable plasma fatty acid profiles.

Carnitine is necessary for optimal oxidation of fatty acids. Solutions currently used for intravenous alimentation contain no carnitine, but they do contain all of the precursors for its endogenous production. Infants and newborns maintained on PN solutions have decreased total plasma and tissue carnitine levels. Normalization of serum carnitine levels occurs in infants receiving long-term PN and supplemental oral L-carnitine (50 μmol/kg/day = 8.1 mg/kg/day)[62] or intravenous L-carnitine.[63] The latter study also led to lower peak triglyceride levels after delivery of a fat bolus (suggesting an enhanced ability to use fat for energy) and modest increases in growth and nitrogen accretion. The very low birth weight infants requiring PN developed low carnitine levels and impaired ketogenesis that appeared to improve with parenteral carnitine. In very low birth weight infants on PN supplemented with L-carnitine (50 μmol/kg/day), increased carnitine levels and improved tolerance to intravenous fat were noted (only in the infants in the 1,001 to 1,500 g and not the 750 to 1,000 g birth weight range).

Other studies of carnitine supplementation have failed to demonstrate significant improvement in clinical outcome.[64,65] Some experts recommend 10 mg/kg/day intravenous L-carnitine for very low birth weight infants. Higher doses of carnitine seem to have pharmacologic effects, leading to increased protein and fat oxidation with associated energy loss. Supplementation with 48 mg/kg/day of L-carnitine (about 300 μmol/kg/day) increased the metabolic rate, decreased fat and protein accretion, and prolonged the time to regain birth weight in preterm infants receiving PN with lipids.[66] We do not routinely supplement PN solutions with carnitine. Cholestatic infants and children without enteral intake on long-term PN are supplemented when serum carnitine levels are low.

Structured lipids are being considered as an alternative energy source.[67] They contain medium- and long-chain fatty acids esterified to the same glycerol molecule. They are different from physical mixtures of medium-chain triglycerides (MCTs) and long-chain triglycerides (LCTs). Fat emulsions containing MCTs have been released in Europe; their advantage is that they are not stored in the liver or adipose tissue, and they undergo hydrolysis and rapid beta-oxidation independent of the carnitine enzyme system. Although early laboratory and clinical studies demonstrated intravenous MCTs to be a safe, carnitine-independent energy substrate, subsequent studies have shown increased mortality in previously starved animals and central nervous system toxicity in dogs.[68] The potential advantage in pediatric patients would be for cases in which endogenous lipoprotein lipase levels are low, as in infants of less than 28 weeks gestation or those with sepsis or trauma.

Some reports suggest a benefit of adding MCTs to intravenous preparations compared with using LCTs alone. Fifty-one newborn infants received Lipofundin MCT/LCT (50% MCT, 50% LCT; B. Braun Medical, Germany) or conventional intravenous fat over 20 hours. Triglyceride and fatty acid levels were not significantly different in the two groups. After 6 days of intravenous fat, mean plasma cholesterol was 100% higher in the group receiving conventional intravenous fat.[69] A second study of neonates showed elevation of triglycerides and free fatty acids in the MCT/LCT group.[70] Further studies are needed to evaluate the MCT/LCT regimen for pediatric patients. Finally, Canadian investigators were concerned that preterm infants lacked transplacental accretion for eicosapentaenoic (EPA) and docosahexaenoic acid (DHA), so they designed a soy emulsion enriched with EPA and DHA and found no toxicity or biochemical abnormalities in piglets that received it. These fatty acids are essential for brain development but are not available in any current intravenous fat products.

Fat can frequently contribute 30 to 40% of total nonnitrogen calories, but, generally, it should not exceed 60%. Four grams per kilogram per day of 20% intravenous fat caused less increase of plasma lipids than did 2 g/kg/day of 10% intravenous fat. Hyperlipidemia occurs with PN with 10% intravenous fat but not 20% intravenous fat and is caused by an increase in lipoprotein X. The phospholipid-to-triglyceride ratio is 0.12 in 10% intravenous fat and 0.06 in 20% intravenous fat (see Table 57-5).[71,72] Phospholipid is believed to inhibit lipoprotein lipase, which is the main enzyme responsible for intravenous fat clearance, probably explaining why 20% intravenous fat is cleared more rapidly than 10% intravenous fat. Twenty percent intravenous fat is currently used exclusively in our institution. The dose should not exceed 0.15 g/kg/hour. Thirty percent intravenous fat has been shown to be safe and has metabolic effects similar to those of 20% intravenous fat. It is administered as a three-in-one solution and cannot be given alone via a peripheral intravenous line.[73] Suggested dosing for intravenous fat is shown in Table 57-6.

Electrolytes

The ranges of recommended daily intakes of electrolytes and minerals for PN solutions in pediatrics are shown in Table 57-7. Calcium and phosphorus requirements change with age and are much greater in preterm infants than in full-term infants, older children, and adults (Table 57-8).[74]

TABLE 57-6 Dosing for Intravenous Fat*

Age	*Starting Dose*	*Daily Dose Increase*	*Maximum Dose*
Preterm	0.5–1.0	1.0	3.5
Full-term (0 to 6 mo)	1.0–1.5	1.0–1.5	3.5
Older infants (6 to 12 mo)	1.0–1.5	1.0–1.5	3.0
Children (1 to 10 yr)	1.0	1.0–1.5	3.0
Adolescents (11–18 yr)	1.0	1.0	2.0–3.0

*In grams per kilogram per day.

TABLE 57-7 Parenteral Provision of Electrolytes and Minerals

Electrolytes and Minerals	*Daily Amount*
Phosphate	0.5–2.0 mM/kg
Sodium	2.0–4.0 mEq/kg
Potassium	2.0–3.0 mEq/kg
Chloride	2.0–3.0 mEq/kg
Acetate	1.0–4.0 mEq/kg
Magnesium	0.25–0.5 mEq/kg
Calcium gluconate*	50–500 mg/kg

*Gluconate is the recommended calcium salt for use in parenteral nutrition solutions. Calcium chloride dissociates more readily than calcium gluconate solutions and can lead to precipitation problems with phosphate.

During the last 6 to 8 weeks of gestation, calcium and phosphorus are incorporated into the bone matrix. Thus, premature infants are at risk for developing rickets and handling fractures. Any radiograph taken should be checked for the early bone changes of rickets. Serum calcium, phosphorus, and alkaline phosphatase levels should be monitored. The serum calcium level will be maintained at the expense of bone (demineralization), so normal serum calcium does not necessarily mean that adequate amounts of calcium are being delivered. The serum phosphorus level does not fluctuate as rapidly and is a better indicator of total body stores. Kovar and colleagues suggest screening for rickets in preterm infants with plasma alkaline phosphatase: levels six times the upper limit of the normal adult reference range should prompt a radiograph to exclude rickets.[75]

Calcium and phosphorus requirements for some patients might exceed the solubility of these two elements in PN solutions, particularly when patients are fluid restricted or have several other intravenous fluid lines in place. The maximum amounts of calcium and phosphorus that can be admixed in PN solutions are determined primarily by the pH of the solution,[37] which, in turn, is determined primarily by the amino acid product and concentration. Currently, TrophAmine and Aminosyn-PF have low enough pH values to allow adequate amounts of calcium and phosphorus for growth. Of the other amino acid solutions designed for use in adults, Aminosyn has the lowest pH level and is probably the next best choice for use in children with active bone growth. Continuous infusion of calcium in the PN solution is preferable to bolus administration. With bolus administration, large amounts of calcium are lost in the urine.[76] Also, the potential tissue damage from line infiltration is much greater with concentrated calcium given as a bolus than with dilute calcium as a continuous infusion.

Infusions of solutions containing both calcium and phosphorus result in stable calcium and phosphorus concentrations. Calcium concentrations of 50 mEq/L and phosphate concentrations of 20 mmol/L are compatible in solutions containing 2% TrophAmine, 10% glucose, and 0.08% L-cysteine.[38] Calcium-phosphorus solubility is less in Aminosyn-PF than in TrophAmine.[77] Previously, experts recommended a calcium-to-phosphorus ratio of 1.3:1 by weight or a 1:1 molar ratio. Recently, a higher, more physiologic ratio of 1.7:1 by weight (1.3:1 by molar ratio, similar to the fetal mineral accretion ratio) allowed for a higher absolute retention of both minerals and came closest to in utero accretion of calcium and phosphorus.[78,79] This successful ratio provided 76 mg/kg/day of calcium and 45 mg/kg/day of phosphorus, using Aminosyn-PF as the amino acid source. There could be an advantage to using calcium glycerophosphate versus conventional calcium gluconate because the former is more soluble.[80,81] Dunham and colleagues have generated calcium and phosphorus precipitation curves for neonatal PN, using TrophAmine, to guide pharmacists and clinicians to help avoid compounding PN solutions that will precipitate.[82]

Calcium phosphate is more soluble at cooler temperatures than at room or body temperature. Thus, serious concerns have been raised about the recent advocacy of three-in-one infusates[83] that contain glucose, amino acids, and lipid emulsion in the same bottle or bag with electrolytes, minerals, and vitamins. Because these infusates must be administered without an in-line filter, the presence of lipid in the infusate obscures any visual detection of precipitation that can occur either on removal from refrigeration and warming before administration or during the time of infusion. Their use in low birth weight infants seems unwise, especially when efforts are being made to maximize calcium and phosphate intakes. One retrospective review of the use of three-in-one solutions in infants found their use safe, efficacious, and cost-effective for infants younger than 1 year of age.[84] The amino acid solutions compatible in three-in-one solutions are not those with the lowest pH values. In the review of Rollins and colleagues, Travenol was the amino acid solution used[84]: it does not have the lowest pH level of the adult standard solutions. Thus, maximal calcium and phosphorus levels cannot be achieved with three-in-one solutions, and they should not be used routinely in the neonate.

In April 1994, the US Food and Drug Administration (FDA) issued a safety alert regarding three-in-one solutions after a report was received from one institution of two deaths and at least two cases of respiratory distress that developed during peripheral infusion of a three-in-one (amino acids, carbohydrate, and lipids) PN admixture. The admixture contained 10% Freamine III, dextrose, calcium gluconate, potassium phosphate, other minerals, and a lipid emulsion, which were combined using an automated compounder. The solution might have contained a precipitate of calcium phosphate. Autopsies revealed diffuse microvascular pulmonary emboli containing calcium phosphate. The presence of a lipid emulsion in the PN admixture would have obscured the presence of any precipitate. The American Society for Parenteral and Enteral

TABLE 57-8 Recommended Amounts of Calcium and Phosphorus

	Calcium Gluconate	*Phosphate*
Premature infants	300–500 mg/kg/d	1–1.5 mM/kg/d
Full-term infants	300–400 mg/kg/d	1–1.5 mM/kg/d
Older infants and children	100–200 mg/kg/d	1.0 mM/kg/d
Adolescents	50–100 mg/kg/d	0.5–1.0 mM/kg/d

Nutrition's safe practice guidelines state clearly that given the limited amount of published stability information available, the use of two-in-one formulation with a separate administration of intravenous fat is recommended for neonatal and infant patients.[85]

VITAMINS

In 1975, the Nutrition Advisory Group of the Department of Food and Nutrition, American Medical Association (AMA), proposed adult and pediatric guidelines for parenteral multivitamins.[86] In the United States, the FDA accepted the AMA adult formulation MVI-12 (Armour Pharmaceutical, Blue Bell, PA) in 1979. The pediatric formulation MVI-Pediatric (Armour Pharmaceutical), which was not approved until 1981, has been tested primarily in medically stable infants and children receiving PN. The specific recommendation from a 1988 review is to use one vial of MVI-Pediatric per day for term infants and children and 40% of a vial per kilogram per day for preterm infants.[87] Patients receiving oral multivitamin supplements might need adjustments in parenteral multivitamin dose. For several years, there was a shortage of MVI-Pediatric, resulting in clinical deficiency states, especially thiamin deficiency.[88] Alternative ways to provide multivitamins, if there is an MVI-Pediatric shortage in the future, are supplied by the American Society for Parenteral and Enteral Nutrition, both in their newsletters and on the Internet (<http://www.clinnutr.org>). Recommended intakes of parenteral vitamins are shown in Table 57-9.

Lipid-Soluble Vitamins Lipid-soluble vitamins must be dispersed in an aqueous solution if they are to be provided in a single vitamin mixture. To "solubilize" these lipid-soluble molecules for intravenous use, synthetic detergents, such as polysorbate, have been used. There are concerns about the safety of these detergents given intravenously to preterm infants.[89,90] In Europe, Vitalipid (KabiVitrum, Stockholm) is a preparation containing vitamins A, D, E, and K dissolved in fractionated soybean oil and emulsified with fractionated egg phospholipids in the same manner in which Intralipid is prepared. Infants requiring PN receive water-soluble vitamins in the glucose amino acid solution and the lipid-soluble vitamins with intravenous fat (devoid of synthetic emulsifiers). Such use has proven successful for years.

Intravenous vitamins, including vitamin A, can be lost through adsorption to plastic PN bags and tubing or biodegradation in the presence of light. Using radiolabeled vitamins, researchers found that only 31% of vitamin A, 68% of vitamin D, and 64% of vitamin E were actually delivered to the patient over a 24-hour period.[91] Retinol depletion during PN is much more severe in very low birth weight infants because of the higher light intensity in nurseries and lower infusion rates of PN, which result in longer exposure time.[87]

Armour Pharmaceutical originally recommended MVI-Pediatric doses of 5 mL/day for all patients weighing more than 3 kg and 3.25 mL/day for infants weighing less than 3 kg. Unfortunately, at the 3.25 mL dose, infants weighing less than 1,000 g displayed elevated vitamin E levels (greater than 3.5 mg/dL).[92] Such elevations have been associated with an increased incidence of NEC and sepsis. The manufacturers subsequently modified their recommendations, suggesting that infants weighing less than 1,000 g receive 1.5 mL/day of MVI-Pediatric. At this lower dosage, vitamin E levels were less than 1 mg/dL in 44% of infants weighing less than 1,000 g,[93] which is lower than the safe and effective levels (1 to 2 mg/dL) suggested by the American Academy of Pediatrics.[94] The recommended dose of 40% of a vial (2 mL = 2.8 mg α-tocopherol) per kilogram per day results in normal serum vitamin E levels within the range of 1.0 to 2.5 mg/dL, even in infants with birth weights between 450 and 1,360 g.[95] However, this dose might be inadequate for some infants weighing 1,000 g or less because 15% of neonates receiving 50% of a vial of MVI-Pediatric (a larger dose than recommended) had vitamin E levels of less than 1 mg/dL. Vitamin D requirements of infants receiving PN are met with the recommended doses of MVI-Pediatric.

Greene and colleagues have shown that very low birth weight infants who receive PN for 1 month show a progressive decline in serum retinol levels,[96] a significant finding in light of two reports correlating a higher incidence of bronchopulmonary dysplasia (BPD) with low plasma retinol levels.[97,98] Shenai and colleagues, in a blinded, randomized trial, found that vitamin A treatment increased plasma retinol levels and reduced the incidence of BPD.[99] Pearson and colleagues were unable to duplicate these results,[100] but Robbins and Fletcher found similar results with early vitamin A supplementation.[101] Vitamin A should be administered early to small premature infants who are at risk for BPD.

Given the previous data on vitamin E and the above data on vitamin A, serum levels of vitamins A and E should be monitored in high-risk neonates so that adjustments in their PN regimen can be made, if needed. The benefits of adding fat-soluble vitamins to intravenous fat solutions (to prevent loss of vitamin A into the plastic tubing) was further demonstrated by increased plasma retinol levels in premature infants.[95] The authors concluded, however, that 280 μg/kg/day was insufficient to raise the blood levels in all infants into the normal range. Meta-analyses suggest that vitamin A supplementation could reduce chronic lung disease and sepsis in extremely low birth weight (ELBW) infants. A 14-center randomized trial of vitamin A supplementation was recently performed in such infants, using a higher dose of vitamin A than that used in most neonatal trials (based on a pilot study)—5,000 IU vitamin A given intramuscularly three times per week for 3 weeks.[102] This vitamin A supplementation reduced biochemical evidence of vitamin A deficiency and reduced the incidence of BPD at 36 weeks postconceptional age from 62 to 55% ($p < .03$). The investigators concluded that vitamin A supplementation is safe and reduces the incidence of BPD.

MVI-Pediatric contains 200 μg per vial of phytonadione, a lipid-soluble vitamin K preparation. No deficiency state or toxicity has been reported with this dose. Patients more than 10 years of age who receive one vial of MVI-12 (designed for patients older than 11 years) will need sup-

TABLE 57-9 Suggested Intakes of Parenteral Vitamins in Infants and Children

Vitamin	*Full-Term Infants and Children (dose per day)**	*Preterm Infants (dose/kg body wt; maximum not to exceed full-term infant dose)*

Adapted from Greene HL et al.[87]

*These guidelines for full-term infants and children are identical to those of the American Medical Association (Nutrition Advisory Group) published in 1979.[86] MVI-Pediatric (Armour; currently produced by Astra) meets these guidelines. Recent data indicate that 40 IU/kg/day vitamin D (maximum 400 IU/day) is adequate for full-term and preterm infants. The higher dose of 160 IU/kg/day has not been associated with complications and maintains blood levels within the reference range for fed orally full-term infants. This dosage therefore appears acceptable until further studies using the lower-dose formulations indicate their superiority.

†These represent a practical guide (40% of the currently available single-dose vial MVI-Pediatric formulation per kilogram of body weight), which will provide adequate levels of vitamins E, D, and K but low levels of retinal and excess levels of most of the B vitamins. The maximum daily dose is one single-dose vial for any infant.

‡Because of elevated levels of water-soluble vitamins, the current proposal is to reduce intake of water-soluble vitamins and increase retinal as described in the committee's report.[87]

§700 μg retinal equivalents = 2,300 IU; 7 mg α-tocopherol = 7 IU; 10 μg vitamin D = 400 IU.

plemental vitamin K intravenously daily instead of a weekly intramuscular injection. The regular addition of vitamin K (1 mg/day intravenously in the PN solution or 10 mg intramuscularly weekly) to PN regimens decreased the incidence of elevated prothrombin time.

Water-Soluble Vitamins Deficiency of thiamin results in acute or chronic beriberi. A possible case of Shoshin (cardiac) beriberi, determined by erythrocyte transketolase assay during PN, was reported in a 12-year-old girl who received PN with inadequate amounts of thiamin.[103] As much as one-third of riboflavin in PN solutions is inactivated by light, especially phototherapy lights; riboflavin deficiency causes abnormalities of epithelia (hyperemia and edema of the pharyngeal and oral mucous membranes, cheilosis, stomatitis, glossitis, and seborrheic dermatitis) and normocytic anemia.[87] Such deficiency has not been described in children maintained on PN. Findings of riboflavin-induced photohemolysis with excess riboflavin indicate the importance of maintaining normal blood levels of this vitamin. The recommended parenteral dose of pyridoxine in full-term infants (1 mg/day) might be more than necessary, but it has not resulted in toxicity or deficiency. For preterm infants receiving 40% of a MVI-Pediatric dose (0.4 mg/kg/day), pyridoxine levels increased more than 10-fold over cord blood and maternal levels; a lower dose of 0.18 mg/kg/day resulted in only twofold increases.[104]

Another study by the same group also argued that the current dosage of pyridoxine for very low birth weight infants is excessive and recommended a newer formulation with a lower dose. Pyridoxine also is destroyed by exposure to direct sunlight. The clinical syndrome resulting from omission of biotin from PN is characterized by scaly dermatitis, alopecia, pallor, irritability, and lethargy.[105] Biotin is currently included in MVI-Pediatric in doses that are not toxic but are adequate to prevent deficiency. Two studies support the continued use of the 1975 AMA Nutrition Advisory Group guidelines for water-soluble vitamin doses for full-term infants and children.[106,107]

Trace Elements

Guidelines for intravenous administration of trace elements to pediatric patients are summarized in Table 57-10.[87,108] Moukarzel and colleagues evaluated the chromium status of children on long-term PN receiving the standard recommendations.[109] Elevated serum chromium levels and lower glomerular filtration rates (GFRs) were noted. The GFRs were significantly inversely correlated with serum chromium concentration. After 1 year of PN without supplemental chromium, the mean serum chromium levels had fallen but were still higher than in controls. No change occurred in the GFRs. Unplanned chromium contamination of the PN solutions still provided 0.05 μg/kg of chromium, which is one-fourth of the amount currently recommended. Since 1990, the University of California, Los Angeles (UCLA) group has discontinued chromium supplementation in all long-term PN patients.[109]

Persistent diarrhea or other excessive gastrointestinal fluid losses from ostomy sites can grossly increase zinc losses. In adult balance studies, the following additional zinc replacement is required: (1) 17.1 mg of zinc per kilo-

TABLE 57-10 Recommended Intravenous Intakes of Trace Elements*

Element	Infants		Children (μg/kg/d)	Maximum (μg/d)
	Preterm† (μg/kg/d)	Full Term (μg/kg/d)		
Zinc	400.00	250 < 3 mo	50.00	5,000
	—	100 > 3 mo	—	—
Copper‡	20.00	20.00	20.00	300

*When TPN is only supplemental or limited to less than 4 weeks, only zinc (Zn) need be added. Thereafter, addition of the remaining elements is advisable.

†Available concentrations of molybdenum (Mo) and manganese (Mn) are such that dilution of the manufacturer's product might be necessary. Neotrace (Lyphomed, Rosemont, IL) contains a higher ratio of Mn to Zn than suggested here (ie, Zn = 1.5 mg and Mn = 25 μg/mL).

‡Omit in patients with obstructive jaundice. (Manganese and copper are excreted primarily in bile.)

§Omit in patients with renal dysfunction.

gram of stool or ileostomy output and (2) 12.2 mg of zinc per kilogram of small-bowel fluid lost via fistula or stoma. Monitoring of serum zinc levels in patients with persistent losses is recommended.

Selenium deficiency causes Keshan disease, an often fatal cardiomyopathy affecting children and young women in a large geographic area of China.[110] Deficiency states associated with long-term PN have been seen in adults and children[111] with intermittent leg muscle pain and tenderness; white fingernails; increases in serum alanine aminotransferase, aspartate aminotransferase, and creatine kinase; and cardiomyopathy. Low selenium levels were also found in children receiving long-term PN[112] with similar findings and, additionally, profound muscle weakness. Long-term intravenous supplementation with 2 μg/kg/day of selenium resulted in improved clinical and laboratory findings. Similarly, regression of walking skills and a tender myopathy were seen in a 27-month-old child on long-term PN with low plasma selenium levels.[113] Intravenous repletion with sodium selenite resulted in complete disappearance of muscle pain and tenderness within 1 week; crawling and walking skills were regained within 6 weeks. Suggested selenium requirements are 1.5 μg/kg/day for maintenance and 3.0 μg/kg/day for replacement,[113,114] on the basis of an extrapolation from selenium intake in breast-fed infants, assuming 80% absorption.[87] There is no good evidence that selenium is required for short-term PN.

Molybdenum deficiency symptoms (tachycardia, tachypnea, vomiting, and central scotomas, with rapid progression to coma) have been reported in an adult on long-term PN.[115] The patient had an excellent clinical and biochemical response to 2.5 μg/kg/day of molybdenum.

Iron

Intravenous iron in PN regimens remains controversial owing to concerns about the risks of adverse effects. Excess iron is thought to enhance the risk of gram-negative septicemia. Iron has powerful oxidant properties and can enhance the demand for antioxidants, especially vitamin E; particular caution is needed in giving iron to the preterm infant.[87] Iron dextran (Imferon, Fisons Corp., Bedford, MA) has been added to PN infusates at a daily dose of 0.5 mg (1 mL)[116] and 2 mg of iron[117] with no adverse physiochemical or clinical effects. Porter and colleagues agree that malnourished patients with low transferrin could be at risk of receiving a substantial infusion of iron in the free form,[117] which can lead to stimulation of bacterial or fungal growth. In an otherwise stable patient who cannot take oral iron, starting at low doses (0.5 mg) of iron (as dilute Imferon) daily appears to be safe.

Serum iron, total iron-binding capacity, percent saturation, and ferritin should be assayed to assess repletion of iron stores. There is danger of adverse reactions, including death, when iron dextran is given intramuscularly or as a large infusion. We use iron dextran in maintenance doses in PN in all infants and children age 2 months or more, who are receiving long term PN, except those receiving chronic blood transfusions (for bone marrow transplantation and oncology treatment and in certain selected hematology patients).

Aluminum

Current PN solutions are contaminated with aluminum, which can accumulate in bone after only 3 weeks of PN in infants. Aluminum impairment of bone matrix formation and mineralization can be mediated by its direct effect on bone cells or indirectly by its effect on parathyroid hormone and calcium metabolism. Toxic effects are proportional to tissue aluminum load.[118] Intravenous calcium, phosphorus, and albumin solutions have high aluminum levels (greater than 500 μg/L), whereas crystalline amino acids, sterile water, and dextrose have low levels (less than 50 μg/L).[118] Calcium gluconate can contribute up to 80% of the total aluminum load from PN.

The FDA has proposed labeling requirements concerning aluminum content on PN additives, establishing an upper limit permitted in additives, and has suggested that manufacturers develop validated assay methods.[119] Bishop and colleagues demonstrated developmental delay in premature infants on PN solutions who were receiving 45 μg/kg aluminum per day.[120] Aluminum intake should be determined in children at high risk for toxicity; these include preterm infants, infants or children with impaired renal function, and patients on prolonged PN.[87]

Heparin

Heparin (1 U/mL) is added prophylactically to PN solutions to prevent thrombosis. It reduces the formation of a fibrin sheath around the catheter and possibly reduces phlebitis with peripheral PN solutions. No controlled studies have conclusively demonstrated heparin's benefits in PN. One controlled trial has shown that it reduces catheter-related sepsis[121] and that it stimulates lipoprotein lipase release, thereby enhancing clearance of intravenous fat. Heparin decreased total lipid levels and turbidity when given as a single injection of 50 to 100 U/kg to small-for-gestational-age infants.[122,123] One unit of heparin per milliliter of PN solution seems safe for full-term infants on up to adults. In premature babies, no definitive guidelines are available. We routinely give 0.5 units heparin per milliliter of PN solution to neonates.

ROUTE OF ADMINISTRATION

Caloric need is the primary determining factor for selecting the intravenous route for nutritional support. Solutions given in a peripheral vein are less calorically dense than are solutions given in a central vein; therefore, centrally alimented patients can receive more calories and gain more weight on a daily basis. Furthermore, if infiltration of the intravenous catheter occurs, the number of calories actually infused can often be lower than was ordered. Because peripheral venous PN regimens maintain existing body composition, this route is a reasonable choice for a normally nourished infant or child who is expected to need PN for less than 2 weeks. Central venous PN is a more reasonable choice for infants and older children, regardless of initial nutritional status, who will be intolerant of enteral feedings for more than 2 weeks. It is difficult to maintain peripheral venous PN for longer than 2 weeks.

Ziegler and colleagues compared the complication rates of PN using central and peripheral veins.[124] Although infectious complications occurred in approximately 10% of the central vein group and in none of the peripheral vein group, morbidity related to the administration of solution (primarily in the form of soft tissue sloughs) was more prevalent in the peripheral vein group. Complications such as pleural effusions and thrombosis occurred in the central-vein group. The overall complication rate was higher in the central vein group (20% versus 9% in the peripheral vein group). However, the complication rates per day in the two groups were not different. Heird has pointed out that pediatric patients who receive peripheral venous PN are not as likely to develop the characteristic cushingoid appearance as those on central venous PN.[9] In addition, the rate of weight loss immediately after cessation of peripheral venous PN is not excessive; the composition of the weight gain might not be hyperhydrated like that observed with central venous PN regimens.

Intradialytic PN given with hemodialysis or peritoneal dialysis can be an additional route of nutrient delivery in patients with chronic renal failure and end-stage renal disease.[125] Patients receiving PN while on extracorporeal membrane oxygenation (ECMO) life support can have a glucose–amino acid solution administered through the ECMO circuit.[126] Some centers administer intravenous fat through a peripheral intravenous line because of concerns that the fat could occlude the ECMO filter; however, other centers have not had this experience and infuse fat into the ECMO circuit directly.

Central Venous Catheters

To achieve a high caloric intake, a hyperosmolar infusate should be delivered through a central, large-bore vein with high-volume blood flow to minimize the risk of venous thrombosis and phlebitis. The definition of a CVC at Lucile Packard Children's Hospital/Stanford University Medical Center is as follows: The optimal location for the tip of the CVC is at the junction of the superior vena cava and right atrium. Venous catheters will be defined as "central" if the catheter tip is positioned in the distal superior vena cava (SVC), SVC/right atrial junction, or in the inferior vena cava (IVC) at or above the level of the diaphragm. Catheter tips positioned in locations other than these will be defined as peripheral catheters. The distal SVC and IVC at or above the level of the diaphragm are the largest veins with the highest flow rate in the venous system. Infusion of cytotoxic, hypertonic, hypotonic, acid, or alkaline solutions or drug admixtures in CVC locations minimizes the risk of venous thrombosis, postinsertion malposition, and vessel perforation.

At Children's Hospital, Boston, the definition of "central" venous access includes lines whose tips reside in the SVC (including the brachiocephalic-SVC junction), right atrium, or IVC; all other tip locations are considered "noncentral." Otherwise, their definition of "central" venous catheter is similar to the one used at our center. Like the policy at Stanford, Boston Children's Hospital's recommendation is that PN solutions infused in a noncentral catheter be limited in osmolarity to 900 mOsm/L or less (eg, 10% dextrose, 2% amino acids with standard additives). Silastic catheters, which have been used effectively in pediatric central venous PN for many years, are preferred to polyvinyl or polyethylene catheters because of their high degree of flexibility. They do not become rigid when in place for only a short time, unlike polyvinyl catheters, which are associated with an increased likelihood of perforation of a vessel.

Two specially designed catheters for long-term PN are the Hickman and Broviac catheters (Davol Evermed, Kirkland, WA), which can be placed by either a cut-down incision or a percutaneous method into the SVC. Improved catheter stability and decreased risk of infection are achieved by subcutaneously tunneling the catheter to a distant exit site. The Hickman and Broviac catheters differ from the traditional Silastic catheter in the following ways:

- The portions of the catheter extending from the patient and the catheter neck are reinforced with Teflon to reduce the risk of cracking and breakage.

- The distal end of the catheter has a Luer-Lok connector to enable snug insertion of intravenous tubing and to allow secure screw-capping of the catheter when not in use.
- A Dacron cuff attached to the midportion of the catheter is placed subcutaneously at the catheter exit site; this stimulates the formation of dense fibrous adhesions that anchor the catheter securely and create a barrier for ascending bacteria. This process takes approximately 2 weeks, at which time the cutaneous sutures at the exit site can be removed.
- Placement of the central venous PN catheters is by either a percutaneous approach (internal jugular, subclavian, or femoral vein) or a cut-down technique (scalp, common facial, external jugular, brachial, cephalic, or inferior epigastric vein).

Chung and Ziegler have reviewed central venous access.[127a] After the insertion of any type of CVC, chest films are mandatory to confirm proper line placement and to rule out mechanical complications secondary to catheter placement. Infusion of hypertonic PN solutions or fat emulsions should not be initiated until the film has been interpreted and line placement documented.

Umbilical Artery Catheters

In some newborn nurseries, umbilical arterial catheters are used for infusing PN. Yu and colleagues found no difference in mortality in 34 infants with birth weights of less than 1,200 g who received PN via umbilical arterial catheters or enteral feedings.[127b] No data on catheter-related complications were noted. Higgs and colleagues had similar results in a trial of PN versus formula feeding by continuous nasogastric drip in 86 infants (birth weight 500 to l,500 g).[128] Four of the 43 PN babies had "catheter problems," described in the text only as blockage of the catheter. Hall and Rhodes compared the administration of PN by umbilical arterial lines (80 infants), umbilical venous catheters (9 infants), and tunneled jugular catheters (23 infants) in high-risk infants unable to tolerate enteral feedings.[129] They found that morbidity, mortality, and common complications, such as infection and thrombosis, were similar in both groups (umbilical lines versus jugular catheters). Careful analysis of the data reveals that six deaths might have been catheter related. Five of those deaths occurred in the umbilical arterial catheter group (thrombosis of the aorta in one patient; candidal, streptococcal, or enterococcal sepsis in four patients). One death occurred in the jugular catheter group, with right atrial thrombosis, SVC syndrome, and *Staphylococcus epidermidis* on blood culture.

A retrospective review compared PN via umbilical arterial catheters with PN via CVC in 48 neonates (birth weight 1,700 ± 600 g).[130] There was no difference in the infection rate between the two groups when adjustment was made for the number of days of catheter life. Transient hypertension occurred in two patients (4%) in the umbilical arterial catheter group and in one (4%) in the CVC group. There was one aortic thrombus noted on autopsy in the umbilical arterial catheter group and one incident of vegetation on the tricuspid valve in the CVC group. The use of umbilical arterial catheters for PN is not recommended[131] because this practice is associated with a high incidence of arterial thrombosis. There is also a concern about long-term complications, such as inappropriate growth of one limb. Although the first three studies described above claimed no short-term complications, they did not address the important issue of long-term complications.

INITIATING THERAPY WITH PARENTERAL NUTRITION

Before initiating PN, a complete nutritional assessment, including anthropometric measurements, should be carried out to determine the potential need for nutritional repletion and to estimate caloric requirements. The PN solutions can be ordered using two formats: customized or standardized. Customized solutions are formulated specifically to meet the daily nutritional requirements of the individual patient and nutrients are dosed on a per-kilogram basis. Standardized solutions are designed to provide a formulation that meets most of the nutritional needs of patients with stable biochemical and metabolic parameters. We feel that a customized PN regimen is best suited for pediatric patients.

Preprinted PN order sheets (Figure 57-1) save time for physicians and pharmacy personnel. In addition, the order sheet helps to avoid errors of omission, ensuring that all necessary nutrients are ordered. The order sheet provides the necessary input for specific PN computer programs. Required data for some of these programs include the patient's weight in kilograms, total fluid intake (mL/kg/day), the amount of fat emulsion (g/kg/day), fluid volumes contributed by other parenteral solutions or enteral feedings, desired protein intake via amino acids (g/kg/day), and the percentage concentration of dextrose. The doses of trace elements, vitamins, and electrolytes are ordered in amounts per day or amounts per kilogram per day. The computer performs all necessary calculations. Protocol recommendations are provided in the right-hand column of the order sheet for reference. For teenage patients, it may be acceptable to use a standard adult solution. Depending on the patient's electrolyte and nutritional status, calorie, fluid, and electrolyte requirements are determined and the solution ordered appropriately. As mentioned earlier, doses of carbohydrate, fat, and protein are gradually advanced to avoid overtaxing the metabolic capacities of the patient. Our recommended advancing guidelines are shown in Table 57-11. Clinical pathways have been developed for the administration of PN.[132]

CYCLIC PARENTERAL NUTRITION

The administration of PN over a period of less than 24 hours a day is termed cyclic PN. It allows more physical activity, less stress, and more flexible PN scheduling for these patients.[133] Conditions necessary for instituting cyclic PN include stable metabolic status and electrolyte and fluid requirements, and steady weight gain for at least 2 to 4 days on continuous PN. Patients should be able to

Advance*	5–10%	1.0	1.0

*Rate of advancement might be limited by metabolic tolerance, eg, hyperglycemia, hypertriglyceridemia, or azotemia.

handle maintenance fluids over a short period and have well-positioned CVCs. Safe administration of cyclic PN has been described in all ages, including infants with weights as low as 5 kg.[134] Cyclic PN in the hospital has become standard for patients on stable regimens. If the glucose concentration exceeds 10% or if the glucose infusion rate is high, then tapering the rate over the last hour by 50% is recommended. Almost all home PN patients receive cyclic PN for ease of care.

TRANSITION FROM PARENTERAL TO ENTERAL NUTRITION

There is an approximately 50% decline in enteric mucosal mass in normal animals maintained on intravenous nutrition in positive nitrogen balance without enteric stimulation.[135] Pancreatic atrophy and impairment of function also occur.[136] All segments of the small intestine demonstrate a decrease in the rate of proliferation and migration of the epithelial cells in parenterally fed versus enterally fed animals. Numerous animal studies have demonstrated the positive impact that luminal nutrients have on maintaining the structural and functional integrity of the gastrointestinal tract. These trophic effects on the intestinal mucosa can be direct or can be mediated by gastrointestinal hormones. Although human data are limited, it seems prudent to maintain a small oral nutritional intake during PN whenever possible.

In infants with intractable diarrhea, Greene and colleagues have demonstrated more rapid recovery of intestinal disaccharidases with the combination of PN and elemental enteral feedings than with PN alone.[137] Intestinal development is arrested when animals receive PN with no enteral nutrients; resumption of intestinal maturation occurs on reintroduction of intraluminal nutrients. Unlike that of the intestine and pancreas, the digestive function of the stomach is not impaired during PN in the very preterm infant. PN without gastric feedings decreases acid and pepsin in human infants, but when these infants are placed on constant-rate enteral infusion, these secretions return to normal.[138]

The transition from parenteral to enteral feeding should be gradual because the sudden cessation of PN can result in severe rebound hypoglycemia (secondary to high levels of insulin produced from high glucose intake). Small-volume oral feedings are begun and then increased to full feedings. The volume of the PN is proportionally decreased. After prolonged PN, many infants and children are reluctant to feed orally for reasons that are not clear.[139] Early involvement of oromotor therapists with these patients (before starting oral feedings) could prove extremely helpful.

COMPLICATIONS

Patients receiving PN are at risk of technical, infectious, and metabolic complications. These complications can be avoided or minimized only by regular monitoring, strict aseptic technique, and a multidisciplinary nutrition support team. Possible complications are listed in Table 57-12.

Technical Complications

Possible complications at the time of catheter insertion include pneumothorax, hemothorax, hydromediastinum, arterial injury, hematoma formation, arterial laceration, arteriovenous fistula and air embolism, catheter embolism, malposition, cardiac perforation, and tamponade. Complications related to ongoing use of the catheter include venous thrombosis, catheter dislodgment, and perforation of the pericardium, pleura, and mediastinum with leakage of the PN solution.

Forty-two newborns who had Broviac catheter placement were followed prospectively with echocardiograms.[140] Six infants (14%) had thrombus formation after the catheter had been in place for a median of 7 weeks. Those with thrombus formation had significantly lower birth weights and gestational ages than those without

thrombus, but there was no correlation of thrombosis with duration of catheter placement. Many nurseries employ percutaneous central venous catheterization. In a study of 481 catheters placed percutaneously in a neonatal intensive care unit over a 3-year period, 50% were placed in infants weighing 1,000 g or less.[141] Mean catheter life was 13 days; almost half were removed nonelectively for leaking, clotting, or suspicion of sepsis (6%). Catheter sepsis was confirmed in 1.3%. For catheter-related sepsis, three factors were important: prolonged catheter placement (3 to 5 weeks), infection by *S. epidermidis*, and infant weight of 1,000 g or less.[141]

These percutaneous lines result in lower complication rates than those reported with surgically placed venous catheters. Complications with this method include leakage or perforation of the catheter. Placement of the catheter in the atrium can stimulate cardiac arrhythmias or cause the catheter to incorporate itself into the endocardium. Cardiac tamponade can result from atrial perforation by the CVC.[142–144] Regular and meticulous care of the CVC, particularly the catheter exit site, is essential for prolonged, safe, complication-free use. Use of the catheter for purposes other than delivery of PN, particularly for blood transfusions and blood sampling, should be avoided. PN teams using strict aseptic techniques have reduced sepsis rates to 2%.[145]

For long-term venous access, the Broviac catheter continues to demonstrate a lower complication rate than the traditional Silastic catheter.[146] Long-term venous access can be safely accomplished even in infants weighing less than 1,000 g.[147] Broviac catheter–associated infections occur more often in very low birth weight infants (69%) than in infants weighing more than 1,500 g (20%).[148] Of these infections, 78% (14 of 18) were successfully treated with antibiotics without catheter removal. The rate of thrombosis was also higher in very low birth weight infants. Triple-lumen catheters are becoming available for pediatric use.[149]

Catheter-Associated Infection

The major catheter-related complication is infection, usually the result of improper care of the catheter. Most of these infections can be treated with the catheter in situ.[150] *S. epidermidis* is the most frequent organism encountered, so vancomycin and gentamicin can be used successfully as initial therapy,[151] pending final culture report and sensitivities. Lack of defervescence and continued positive blood cultures for 2 to 4 days despite antibiotic use are indications for catheter removal.[152] Otherwise, antibiotics should be continued for 10 to 21 days.[152] The complete cure of catheter sepsis in patients treated with antibiotics through the infected lumen has occurred in 75 to 86% of patients.[151,152]

When continued use of a Broviac or Hickman catheter is desired, a trial of antibiotic therapy should be attempted before catheter removal.[151] The gastrointestinal tract could be a source of microbial seeding of the bloodstream via the catheter. There is considerable interest in therapies that maintain or improve the integrity of the gut.[153] For example, the role of glutamine in preventing gut atrophy in parenterally fed, enterally fasted patients needs to be further explored[154] because gut atrophy can foster increased intestinal permeability of bacterial pathogens.

Catheter Occlusion

Estimates suggest that 25% of CVCs become occluded, with thrombosis as the most common etiology. Nonthrombotic causes include deposition of intravenous lipids, calcium-phosphorus precipitates, heparin-induced occlusion, and intraluminal drug precipitates (eg, antibiotics).

Before 1999, the only approved pharmacologic agent for the medical treatment of thrombosed CVCs was urokinase (Abbokinase–Open Cath; Abbott Laboratories, Abbott Park, IL) derived from human neonatal kidney cells. In January 1999, the FDA suspended the distribution of urokinase because of the theoretic concern for the transmission of infectious agents.

Recombinant tissue plasminogen activator (alteplase) has subsequently been shown to be very effective in the restoration of function of CVCs occluded by a thrombus.[155] In September 2001, CathFlo Activase (alteplase; Genentech Inc., San Francisco, CA) was approved by the FDA for occlusions caused by thrombus. Published pediatric data on alteplase to date have demonstrated both safety and efficacy, and many pediatric centers are using alteplase to treat CVCs believed to be obstructed by a thrombus, but the FDA has requested additional safety data in pediatric patients. Therefore, a multicenter, phase IV, open-label, single-arm study of the safety and efficacy of CathFlo Activase in pediatric subjects is under way.

Should a thrombolytic agent fail to clear an occlusion, alternative causes should be considered. Mechanical catheter occlusion can be caused by external clamps, kinking of the catheter, occluded port needles, and constricting sutures. Six pediatric patients with occlusion of CVCs by calcium phosphate crystals were successfully treated by irrigating their catheters with a dilute hydrochloric acid solution.[156] Temporary febrile reactions occurred in three of these cases, but no serious complications were encountered. In the meantime, clinicians can minimize such precipitation by closely watching that concentrations of calcium and phosphorus fall well within standard solubility curves. Catheter occlusion caused by lipid material associated with PN treatment has been successfully cleared with ethanol after urokinase failed to clear these occlusions.[157,158] A recent review provides specific guidelines for clearance of catheter occlusions.[158]

Metabolic Complications

Use of Intravenous Fat The incidence of complications associated with the use of intravenous fat is low. If the intravenous fat infusion exceeds its maximal clearance rate, hyperlipidemia occurs, which can cause impairment of pulmonary function, displacement of albumin-bound bilirubin by plasma free fatty acids (which can lead to kernicterus), and fat overload syndrome (hypertriglyceridemia, fever, lethargy, liver damage, and coagulopathy). Thus, careful monitoring of the use of intravenous fat emulsions is essen-

tial; regularly check serum triglyceride levels. Cyclosporine use has been associated with elevated serum cholesterol and triglycerides in patients undergoing bone marrow or renal transplantation.[159] Allergic or hypersensitivity reactions to intravenous fat are extremely rare.[160,161]

After boluses of intravenous fat are infused into newborn infants, several investigators have demonstrated significant drops of arterial oxygen tension (PaO_2) without alteration of other pulmonary function test results.[162] Two hypotheses exist to explain the fall in arterial oxygen saturation: (1) lipid microemboli block pulmonary capillaries and alter perfusion ventilation ratios, and (2) fat metabolism leads to increased production of certain prostaglandins, which leads to pulmonary hypertension. The use of intravenous fat in patients with pulmonary compromise has yielded conflicting results. Although fat emboli were found on postmortem examination of pulmonary capillaries in neonates and infants who received Intralipid,[163–166] other reports have found no consistent association.[167] Fat deposition in the pulmonary microcirculation also has been documented in babies who never received intravenous fat.[164]

McKeen and colleagues found that administering intravenous fat doses of 0.25 g/kg/hour to sheep caused an increase in pulmonary artery pressure, a decrease in arterial PaO_2, and an increase in pulmonary lymphatic flow.[168] Identical findings have been described with doses of only 0.125 g/kg/hour. Heparin treatment did clear the serum of triglycerides but did not change the other parameters; therefore, the pulmonary hypertension and hypoxia were not caused by hyperlipemia. Treatment with indomethacin, a potent prostaglandin inhibitor, blocked the rise in pulmonary artery pressure, the increase in lymphatic flow, and the fall in arterial PaO_2. In rabbits there were no blood gas or prostaglandin changes in lipid-infused normal animals.[169] However, when the rabbits' lungs were damaged with oleic acid and then infused with intravenous fat, significant deterioration in gas exchange occurred. Furthermore, these changes were blocked by indomethacin (implying prostaglandin-mediated effects of intravenous fat). Brans and colleagues found that oxygen diffusion in the lungs of premature infants was not affected by the infusion of up to 4 g/Kg/d of Intralipid over 24 hours.[170]

Studies evaluating the effect of early infusion of intravenous fat in low birth weight infants on the development of chronic lung disease are conflicting. Forty-two neonates (birth weights less than 1,750 g) were given PN with and without intravenous fat for 5 days in the first week of life.[171] Chronic lung disease was increased in duration and tended to be more severe after lipid administration. A study of small doses (approximately 1 g/kg/day) of lipids on the first day of life, compared with administration starting later in the first week, also resulted in an increase in chronic lung disease.[172] In two subsequent studies (one starting intravenous fat on the first day of life[173] and one starting on day 4[174]), the above findings were not seen. Gilbertson and colleagues concluded that when it is given at rates not exceeding 0.15 g/hour, sick very low birth weight infants can tolerate intravenous fat with stepwise dose increases from the first day of life, without increased incidence of adverse effects.[173] In the study by Adamkin and colleagues, intravenous fat doses were similar to those in the study by Gilbertson and colleagues (0.5 to 3.0 g/day); the mean free fatty acid albumin molar ratio was less than 1.0 at all doses (maximum ratio, 3.0). Interestingly, in the Adamkin study, 5% of the patients had triglyceride levels higher than 200 mg/dL.[174]

Cooke studied 195 infants of less than 30 weeks gestation between 1983 and 1989 who were ventilated 4 or more days and survived to at least 28 days; 87 developed chronic lung disease.[175] There was a *sevenfold increase* in the annual incidence of chronic lung disease (most of that increase occurred in 1988 and 1989). The observed increase was associated with earlier use of parenteral fat (up to 4 g/kg/day of 20% intravenous fat). Intravenous fat was started between day 0 and 9 of life in 1 patient in 1983, none in 1984, 1 in 1985, 1 in 1986, 5 in 1987, 19 in 1988, and 26 in 1989.

To assess the impact of early initiation of intravenous fat on the incidence and severity of chronic lung disease, 133 infants weighing 600 to 1,000 g were randomized to either receive intravenous fat at less than 12 hours of age[176] (at 0.5 g/kg/day, increased to a maximum of 1.5 g/kg/day on day 7) or to not receive intravenous fat in the first week of life. There was no difference between the two groups in the incidence of chronic lung disease. There was no difference in mortality in the total population studied, but the mortality rate significantly increased in the 600 to 800 g group receiving intravenous fat. In that group there was also more pulmonary hemorrhage. Both intravenous fat groups (600 to 800 g; 801 to 1,000 g) had larger numbers requiring supplemental oxygen at day 7 compared with controls. A meta-analysis of six randomized controlled trials (N = 522 patients) of early (day 1 to 5) versus late (day 5 to 14) introduction of intravenous lipids in preterm, low birth weight infants found no significant trend or effect on the incidence of death or chronic lung disease, either at 28 days or at 36 weeks of age.[177]

Unsaturated fatty acids are highly susceptible to peroxidation, and the products (hydroperoxides) can interfere with arachidonic acid metabolism or react to form organic free radicals, which can initiate peroxidative injury in tissues.

Helbock and colleagues demonstrated significant levels of lipid hydroperoxides in Intralipid.[178] These toxic hydroperoxides could represent a significant risk to premature infants, particularly those with preexisting lung disease. Neuzil and colleagues demonstrated oxidation of intravenous fat by ambient and phototherapy lights in a neonatal intensive care unit.[179] Minimizing exposure of lipids to ambient and phototherapy light decreases the hydroperoxide levels. At Primary Children's Hospital in Utah, staff cover the fat emulsion bottle or syringe (they do not cover the tubing).

Inositol is a component of membrane phospholipids. A deficiency of this nutrient can be secondary to a deficiency in the diet, intracellular uptake, endogenous synthesis, or an increase in elimination rate. Its administration to immature animals increases levels of pulmonary surfactant. Breast milk, especially colostrum, has a high inositol con-

centration; intravenous feedings lack it altogether (colostrum contains 1.5 to 2.5 mmol/L; mature breast milk, 1 to 2 mmol/L; infant formula, 0.2 to 0.8 mmol/L; PN, 0.1 mmol/L). In a double-blind, controlled, randomized clinical trial, preterm neonates with respiratory distress syndrome who were given intravenous inositol had better survival rates and a lower incidence of BPD and retinopathy of prematurity.[180]

A study by Park and colleagues confirms previous observations that septic infants can develop significant elevations in triglyceride levels.[181] A sudden rise in triglycerides not associated with an increase in intravenous fat dose should make caregivers suspicious of sepsis. Dahlstrom and colleagues also argue that the dose of intravenous fat should be lowered during acute illness.[182] In a 1-year prospective study of 15 children on home PN, they noted that acutely sick children had higher serum triglyceride levels and prothrombin and partial thromboplastin values than when they were well. Their monocyte activation and complement factors remained normal even with acute illness.[182] A study in neonates receiving intravenous fat for 2 weeks or more (N = 162) demonstrated that liver dysfunction and fetal growth retardation were associated with lipid intolerance (elevated triglycerides), perhaps secondary to reduced hepatic lipase activity and, hence, impaired triglyceride clearance. Infection was not independently associated with hypertriglyceridemia.[183]

There is a reluctance to use intravenous fat in patients with low platelet counts, on the basis of reports of varying degrees of thrombocytopenia with earlier intravenous fat preparations and on the basis of one case report with Intralipid. Many anecdotal reports of thrombocytopenia could be secondary to an underlying condition (eg, sepsis) rather than to intravenous fat use. Cohen and colleagues could not implicate intravenous fat as a cause of thrombocytopenia in any of the 128 patients they studied.[184] In addition, 10 patients with thrombocytopenia secondary to sepsis or chemotherapy had rises in platelet counts, concomitant with the improvement of the septicemic state or with marrow recovery after cessation of chemotherapy. Actually, PN without intravenous fat can lead to essential fatty acid deficiency, which, in turn, can cause thrombocytopenia and platelet dysfunction. A study in ill neonates also failed to document any association between intravenous fat and thrombocytopenia. Goulet and colleagues have the only documented association of intravenous fat with thrombocytopenia.[185]

We recommend that intravenous fat be started at 0.5 to 1.0 g/kg/day (preterm) and 1.0 to 1.5 g/kg/day (full term) in the first week of life and that the dose be increased depending on the triglyceride level and clinical status of the baby. In infants of less than 30 weeks gestation, we hold the dose at 1.0 to 1.5 g/kg/day until the second week of life.

Use of Carbohydrate Hyperglycemia and hypoglycemia can occur with inappropriate dosing of carbohydrate. Hyperglycemia can result in glucosuria. If urine glucose by Keto-Diastix (Ames Co., Elkhart, IN) strip is 0.25% (250 mg/dL) or greater, it should be monitored with Dextrostix strips. If the Dextrostix result is elevated, it should be confirmed with a blood glucose evaluation. The glucose content of the PN solution might need to be decreased to prevent osmotic diuresis. A systematic review of all possible etiologies for glucosuria should consider medications, including corticosteroids; dietary indiscretions; error in the PN delivery rate; and sepsis. Excessive carbohydrate intake can result in an increased respiratory quotient and carbon dioxide retention and so affect weaning from the ventilator.

Use of Protein Excessive amino acid infusions can result in increased blood urea nitrogen (BUN), increased ammonia production, and metabolic acidosis in at-risk patients with liver or kidney disease and in low birth weight infants who have limited tolerance.[186] Thus, frequent monitoring of serum electrolytes, blood pH level, BUN, and even ammonia could be indicated in these patients. In patients with ongoing protein losses and hypoproteinemia despite good protein intake, a 24-hour urine collection to test for urine urea nitrogen (UUN) might be necessary to determine nitrogen balance. The UUN is measured in milligrams per 100 mL:

$$N_2 \text{ balance} = \text{grams of protein (intake)}/6.25 - (\text{UUN} + 3)$$

The protein intake should include protein provided by oral or enteral feedings plus that provided by intravenous amino acids. Dividing by 6.25 converts the grams of protein intake into grams of nitrogen. The UUN in this equation is expressed in grams. For example, if UUN equals 500 mg/100 mL or 5,000 mg/L and the patient's 24-hour urine is 2 liters, UUN equals 10,000 mg or 10 g/24 hours. The constant of 3 in the equation corrects for non–urea nitrogen losses (approximately 2 g/day); fecal losses (approximately 1 g/day); and skin, hair, and nail losses (approximately 0.2 g/day). This constant has been established in adult balance studies. It is not clear that the same constant can be used in premature infants or young children.

Osteopenia of Prematurity

Premature infants are susceptible to a unique condition, osteopenia of prematurity or rickets of prematurity, a common but poorly defined metabolic bone disease causing decreased mineralization. In most cases, decreased bone mineralization is subclinical; this condition is diagnosed only after the development of bone fractures or overt rickets.[187] Experts believe that a deficiency of calcium and phosphorus is more likely than a defect in vitamin D metabolism as the cause of osteopenia in preterm infants.[188]

Hepatobiliary Dysfunction

Hepatic dysfunction, one of the most common and most serious complications of PN, has been reviewed extensively.[189–191] Cholestasis is especially prevalent in very premature infants and in infants on PN for more than 2 weeks. Hepatomegaly with mild elevation of serum transaminases in the absence of cholestasis can result from hepatic accumulation of lipid or glycogen secondary to either excess carbohydrate calories or an inap-

TABLE 57-13 Monitoring of Parenteral Nutrition

Short-Term Monitoring
1. Anthropometrics: daily weight check
2. Laboratory studies (baseline): complete blood count, serum electrolytes, triglycerides, cholesterol, calcium, magnesium, phosphorus, alkaline phosphatase, total protein, albumin, BUN, creatinine, ALT, GGTP, bilirubin (total and conjugated), iron studies, prealbumin
3. Daily laboratory studies (initial): serum electrolytes, BUN, creatinine, triglycerides, calcium, phosphorus, magnesium
4. Weekly laboratory studies (the above daily laboratory studies plus): ALT, alkaline, phosphatase, GGTP, bilirubin (total and conjugated), cholesterol, total protein, albumin, prealbumin

Long-Term Monitoring
1. Anthropometrics: < 2 years of age: Weight, length, head circumference, arm anthropometrics (every 2–4 weeks)
   > 2 years of age: Weight, height, arm anthropometrics (monthly)
2. Every 3 months: Iron studies (serum iron, TIBC, % saturation, ferritin)
3. Every 6 months:
   a) Vitamin A, E, 25-OH vitamin D, PT/PTT
   b) Serum selenium, zinc, copper,* chromium, whole blood manganese
2. Yearly:
   a) Abdominal ultrasonography
   b) Bone mineral density study
   c) Renal clearance

ALT = alanine aminotransferase; BUN = blood urea nitrogen; GGTP = γ-glutamyl transpeptidase; PT = prothrombin time; PTT = partial thromboplastin time; TIBC = total iron-binding capacity.
*Obtain monthly if copper has been removed from total parental nutrition secondary to cholestasis.

propriate non-nitrogen calorie-to-nitrogen ratio. Fatty infiltration of the liver as a result of excessive caloric intake is readily reversible in nearly all instances by reduction of total calories administered. Abnormal liver function test results are not uncommon in patients on PN for long periods of time. Those with chronic intestinal conditions complicated by infection and bacterial overgrowth are particularly susceptible to hepatic complications. In most of these patients, elevated liver enzymes improve with the initiation of partial enteral alimentation.

The earliest abnormality noted (at 2 weeks) is an elevated serum γ-glutamyl transpeptidase or bile acid level. A small percentage of infants and children go on to develop chronic liver disease associated with poor growth[192] and even cirrhosis and hepatic failure.[193] A follow-up study of patients on long-term PN documented a wide variety of complications, but all of them (except liver dysfunction) proved to be temporary.[194] In this study, 58% of the children showed liver dysfunction during PN; some showed long-term abnormalities after its cessation. If PN-associated liver disease is suspected, then excessive caloric or protein intake should be avoided, trophic feedings should be started if possible, PN solution should be cycled, and the percentage of calories from carbohydrates should be kept between 50 and 55%.

Long-term administration of PN increases the risk of gallstones in patients of all ages,[195–198] and children with ileal disease or resection are at particularly high risk.[197] The gallbladder disease appears to be secondary to bile stasis. Clinically, gallbladder disease can be detected by the demonstration of "sludge" or a stone (or stones) in a patient with liver function test results consistent with cholestasis. Messing and colleague demonstrated sludge in 6% of cases in the first 3 weeks of PN; the incidence increased to 50% between the fourth and sixth weeks and reached 100% after 6 weeks.[196] Roslyn and colleagues recommend periodic ultrasonography in children on prolonged PN, especially if they have an ileal resection or underlying ileal disease.[197] They advise clinicians to suspect cholecystitis in any child on PN who complains of abdominal pain. A review of 246 infants and children receiving PN for more than 4 weeks revealed significant biliary disease.[199]

Refeeding Syndrome

Refeeding syndrome is the term used to describe the metabolic disturbances that occur when malnourished patients are refed rapidly. Drops in serum phosphorus, potassium, and magnesium; changes in glucose metabolism; vitamin deficiency; and need for fluid resuscitation can occur.[200,201] The most important preventive measure is to identify the at-risk patient and then start caloric intake at 75% of the REE, followed by a cautious increase of caloric intake by 10 to 15% per day, provided that the electrolyte, calcium, phosphorus, and magnesium levels are within normal limits. See Chapter 53, "Protein-Energy Malnutrition," for additional discussion of refeeding syndrome.

MONITORING PARENTERAL NUTRITION

The suggested schedule for chemical and anthropometric monitoring of patients receiving PN is shown in Table 57-13. Such monitoring should allow detection of metabolic complications in sufficient time to permit alteration of the PN infusate, with resultant correction of any abnormality. Detailed guides for monitoring are readily available.[202a]

HOME PARENTERAL NUTRITION

For patients who require long-term chronic PN administration and who would need hospitalization solely for the provision of PN, techniques have been developed to provide PN at home. Since the first patients being managed on home parenteral nutrition (HPN) were described by

Scribner and others in 1970,[202b] the technique has been successfully adapted to children. Over the past two decades, the use of HPN has been greatly expanded, and it has come to be accepted as a useful supportive and therapeutic technique for various gastrointestinal diseases and other conditions as well.[203–207]

Indications

The clinical conditions requiring HPN are the same as those for PN in the hospital, except that the patient no longer requires acute hospital care. Discharge on HPN, although expensive, can save health care dollars. The most common indications for HPN[206] are as follows:

- Short-bowel syndrome, with and without the potential for bowel adaptation (eg, from NEC or Crohn's disease)
- Motility disorders (eg, pseudo-obstruction syndrome)
- Intractable diarrhea (eg, intestinal lymphangiectasia, Crohn's disease, microvillus inclusion disease)
- Acquired immune deficiency syndrome (AIDS)
- Cancer-related conditions (eg, after bone marrow transplantation, graft-versus-host disease)

Contraindications for HPN include a functional gastrointestinal tract and lack of vascular access. Patients with anorexia nervosa are generally not candidates for HPN. HPN also should not be used when no family member is dedicated to and capable of learning and performing the daily techniques required for a successful program.[203] Moukarzel and colleages believe that a child should require HPN for a minimum of 30 days to justify the time and expense involved in training family members and establishing the program.[203] However, discharging a patient on HPN might afford overall cost savings to all parties, even if the patient might be able to take adequate oral nutrition in fewer than 30 days after discharge (eg, a patient who has undergone bone marrow transplantation).

All HPN patients are encouraged to take some oral nutrients as soon as possible to ensure maximal stimulation of the gastrointestinal tract for its adaptation and to diminish bacterial translocation. Such oral intake applies even to infants who have minimal chance of surviving without PN. Failure to initiate oral feedings in infants can result later in sucking or swallowing problems.[203] Oral intake also stimulates bile flow and decreases the likelihood of the development of sludge or gallstone formation.

Implementation

Preparing a patient for HPN requires a multidisciplinary team approach, including medical specialists, nursing staff, pharmacists, dietitians, social workers, and psychologists or psychiatrists. Social workers need to assess the family's ability to perform HPN and then provide emotional support at home. Before discharge, parents must master the necessary technical skills for providing HPN on a continuous or cyclic basis. Such skills include using aseptic technique, adding medications to the HPN solution, administering HPN through a central venous line, operating the infusion pump, heparin-locking the line, and performing dressing changes. Once the child is home, the family is faced with integrating these procedures into their life, while coping with the child's illness and the demands of normal child development.[208]

General information outlining benefits and risks are the first aspects of HPN discussed with the family. Potential complications, including catheter infection, sepsis, thrombosis, bleeding from inadvertent tubing disconnection, hyperglycemia, hypoglycemia, and myriad other potential metabolic derangements, need to be discussed. These discussions with caregivers should also include the expected outcome of PN therapy and the predicted degree of bowel adaptation.[203] Ninety percent of children with short-bowel syndrome who have at least 25 cm of small intestine and an ileocecal valve eventually are able to discontinue PN support.[209] Children who have an intact ileocecal valve and 15 to 20 cm of small bowel ultimately might adapt completely or only partially.[203,209] The anticipated impact of HPN on the lifestyle of the patient and family also must be discussed openly.

For long-term PN, cuffed silicone elastomer (Silastic) tunneled CVCs, such as the Hickman and Broviac catheters, have been commonly used. Totally implantable venous access systems, for example, Infuse-A-Port (Intermedics Infusaid Corp., Norwood, MA) and Port-A-Cath (Pharmacia Laboratories, Piscataway, NJ), have been used in children for administering blood products, drugs, and PN. Instead of exiting from the skin, the end of the catheter is attached to a small chamber that is placed in a subcutaneous pocket, usually on the anterior chest wall. Venous access is achieved by passing a Huber needle through the skin into the chamber via a Silastic gel window. The port can remain accessed for as long as a week or can be accessed as needed just before an infusion. The catheter system has the advantage of requiring minimal care and allowing complete freedom of activity because there is no external portion. However, it is more expensive and must be accessed with a needle each time it is to be used, which some patients find unacceptable. In adults, the subcutaneous port has lower clotting and occlusion rates compared with a traditional CVC, but no comparable studies exist in pediatric patients. The choice of vascular access device should be based on patient needs, capability, lifestyle, preference, and the HPN team's experience and knowledge of the available products. Patients can be freed from multiple intravenous poles, bottles, and tubing with the advent of lightweight portable pumps carried in ambulatory vests or backpacks.

Home nutritional requirements and fluid needs are assessed as stated previously. Generally, patients are stabilized before discharge from hospital. Virtually all patients can receive a cyclic PN schedule. The duration of infusion time can vary from 8 to 17 hours, depending on the age, nutritional requirements, medications, and enteral intake of the patient.

Complications

Complications of HPN are fewer when an experienced team is involved. The three types of complications that can

occur are infectious, technical, and metabolic. In the series of De Potter and colleagues, the mean duration of HPN was 615 days (range, 30 to 3,532 days).[206] Twenty-nine patients died, but only three deaths were HPN related, one because of cirrhosis and two because of catheter-related sepsis. Catheter-related complications included sepsis (n = 105), occlusion (n = 10), and dislodgment (n = 9).

The most common HPN-related complication requiring hospital readmission is catheter sepsis,[203] but these infections are less common in HPN than in hospitalized PN patients.[203] The lower incidence of catheter infection at home reflects the positive impact of one dedicated caregiver, well trained in meticulous catheter care. The incidence of HPN catheter infections is higher in children than in adults.[210] Catheter infections usually are caused by some known or unsuspected break in standard technique for HPN. Fever can occur in children because of catheter infection but also from usual childhood illnesses. With each fever, HPN patients should be seen for a careful physical examination and history. If there is no recognizable source of infection, the most likely possibility is a catheter infection or an intercurrent viral infection. The patient should have central and peripheral venous blood cultures done for aerobes, anaerobes, and fungi; a complete blood cell count; urinalysis; and chest radiograpy; other tests depend on clinical findings. If infection is found, the patient should be treated with intravenous antibiotics because most HPN patients cannot absorb oral antibiotics. If no source of infection is found, antibiotic coverage might be started anyway.

The UCLA group treats catheter infections in HPN patients for 4 weeks "through the line."[211] In general, not removing a line is important because of the long-term need for vascular access. Catheter removal is required for the following reasons: fungal infection (almost always), septic shock, endocarditis, embolism, persistent fever with positive blood culture growth, or disseminated intravascular coagulation. Tunnel tract infections usually require catheter removal.[210] After a catheter is removed, antimicrobial therapy is continued for 5 to 7 days and a new catheter is inserted after the patient is afebrile for 72 hours and blood cultures no longer contain the infectious organism.[211] In a large series, 87% of gram-positive and 53% of gram-negative infections were treated successfully without catheter removal. Of exit-site infections, 50% were successfully treated without catheter removal. There was also a longer life span with the second catheter, as well as a higher incidence of catheter-related complications of HPN in the first 2 years versus later years.[211]

The major technical problem with HPN is catheter occlusion. Warfarin has been used to prevent catheter-related thrombosis.[212] Of a group of 12 children on HPN,[213] bilateral upper limb venography showed extensive deep vein thrombosis (DVT) in 8. Warfarin treatment lengthened the average life span of their catheters, and no catheter-related DVT had occurred on follow-up. The authors advocated venography as the reference test for the diagnosis of central venous line–related DVT. Magnetic resonance imaging (MRI) has been used to diagnose DVT in adults, but there are no comparable studies in children. Lineograms, consisting of injection of contrast media into the central venous line, were found to be insensitive. Sola and colleagues described their 6-year experience with 22 Infuse-A-Ports in 15 cystic fibrosis patients. The overall complication rate was low—1 in 1,483 catheter days—but the incidence of major thrombotic events in 3 of 22 catheters (14%) led to a policy of administering low-dose acetylsalicylic acid therapy (80 mg/day) in all patients who did not have liver disease or other risks of bleeding.[214]

Metabolic complications of HPN are similar to those previously described. In a 1-year prospective study of 15 children receiving HPN, Dahlstrom and colleagues observed that acutely sick children had significantly increased triglyceride levels and prolonged prothrombin and partial thromboplastin time compared with when they were well.[182] There is a report in the literature of thrombocytopenia in seven children on long-term HPN, all of whom were receiving only 1 to 2 g/day of fat emulsion.[185] Recurrent thrombocytopenia (platelets less than 100,000) occurred in all seven. Platelet life span measured with indium 111 was reduced. These data contrast with an 18-year HPN experience at UCLA, where no patient receiving long-term daily parenteral fat emulsion has developed significant thrombocytopenia.

Since the guidelines for intakes of trace elements and vitamins have been developed,[87] deficiency states previously described (copper, zinc, manganese, chromium, selenium, biotin) rarely occur on long-term HPN. As stated previously, extra serum zinc supplementation is required in patients who have massive diarrhea and malabsorption. Ament's group feels that standard recommendations for chromium in PN (0.2 μg/kg/d)[87] could lead to elevated chromium levels, so they no longer supplement PN with chromium.[109] Similarly, this group does not supplement PN with iodide because iodide is in the water used in PN and is also a natural contaminant of a number of the PN salts. If iodide antiseptic solutions are used in central venous line care, this iodide is absorbed through the skin and contributes to normal iodide levels.[203] Intravenous iron must be provided in patients who are unable to absorb it enterally. When patients receiving PN develop cholestasis (conjugated bilirubin of 2 mg/dL or more), it is routine to remove copper and manganese from the TPN solution because both are hepatotoxic and are cleared by the liver. Because many centers use a standard solution of four trace elements (zinc, copper, manganese, and chromium), the trace element solution is held and zinc is added back separately. Recently, severe copper deficiency has been reported in cholestatic patients, associated with symptoms such as pancytopenia, depigmentation of the hair, and pseudoscurvy. In these patients, it is wise to monitor serum copper at least monthly and replace it if values are low.

Recently, there have been reports of manganese toxicity in long-term TPN patients. Symptoms have included disturbances in thought processes and gait, hallucinations, and parkinsonian symptoms. MRI can detect accumulation of manganese in the brain, and T_1-weighted MRIs have shown high intensity in the basal ganglia, especially in the globus pallidus, in patients receiving TPN. Whole-blood

manganese is the best screen for excessive levels. In adults, the dose of 1 μmol/day in TPN keeps those blood levels normal.[215] Cholestatic patients should definitely have manganese held in their TPN.

Carnitine deficiency can be associated with abnormal oxidation of long-chain fatty acids and progressive hepatic dysfunction. In a longitudinal study of nine children on carnitine-free PN, plasma total and free carnitine were 50% lower than in healthy control subjects, but they did not decrease further during the 3-year prospective follow-up.[216] Mean alanine aminotransferase, aspartate aminotransferase, and alkaline phosphatase were slightly increased at the onset of the study but remained unchanged 3 years later. Low plasma carnitine concentrations appeared to be without clinical consequences after 10 years of carnitine-free HPN.[216]

In the past, patients receiving long-term HPN were seen with bone pain, hypercalciuria with normocalcemia, normal phosphatemia, and normal 1,25-dihydroxyvitamin D, 25-hydroxyvitamin D, and parathyroid hormone levels. The pathogenesis of this syndrome was secondary to aluminum toxicity because casein hydrolysates (used as the protein source in PN at some centers) were heavily contaminated with aluminum. This symptomatic bone disease has not been seen since all children have been receiving crystalline amino acid solutions. Osteopenia is a characteristic of patients who receive long-term PN. Such patients have been demonstrated to have a mean loss of 25% of the calcium in their trabecular bone.[217] This osteopenia could be multifactorial. Deficiencies of manganese, fluoride, boron, and silicon have all been suggested as causative factors. Additionally, adequate amounts and proportions of calcium and phosphorus are sometimes difficult to achieve in PN solutions. In a recent study, Moukarzel and colleagues found that serum silicon levels in children receiving HPN were 50% lower than those in non-HPN controls.[218] Furthermore, a significant correlation between silicon intake and mineralization suggests an involvement of silicon in the pathogenesis of the bone disease.[218]

Buchman and colleagues reported that long-term PN is associated with a marked decrease in both GFR and tubular function.[219] The observed decline could not be entirely explained on the basis of nutritional status, age, duration of PN, protein load, exposure to nephrotoxic drugs, or frequency of infectious episodes. A previous study of renal function in children on long-term PN showed that GFR might be reduced in these patients.[220] No nephrocalcinosis or tubular dysfunction was identified in this group of patients.

Long-term effects of PN on the liver and biliary tree were discussed earlier. A comprehensive review concluded that excessive caloric provision,[221] especially in the form of carbohydrate, plays an important role in the pathogenesis of steatosis; loss of enteric stimulation rather than PN per se could be the critical determinant in the development of cholestasis, biliary sludge, and gallstones. In the extensive experience of Ament's group at UCLA, life-threatening liver disease occurred in five children over a 20-year period.[203] In recent years, there has been a dramatic reduction in PN-induced liver disease associated with two key differences in management practices: initiation of enteral feedings (even as little as 1 to 5 mL per feeding in the preterm neonate) and availability of balanced amino acid solutions (such as TrophAmine and Aminosyn-PF) specifically designed for infants, reducing the toxicity occurring with adult formulations.

In addition, choline deficiency plays a role in hepatocyte damage. In animal models, choline-deficient diets are associated with fatty infiltration of the liver, a process that is reversible by adding choline to the diet. Buchman and colleagues reported low free-plasma choline in HPN patients.[222] They found that there was a significant correlation ($p < .02$) between low free-plasma choline and elevations in serum aminotransferases. The same group reported the reversal of PN-associated hepatic steatosis in four long-term HPN patients using an intravenous choline supplement added to the PN, 1 to 4 g/day for 6 weeks.[223] Fifteen of their HPN patients who had low free-plasma choline levels were randomly assigned to receive oral lecithin at 40 g/day or placebo for 6 weeks.[224] Lecithin supplementation resulted in increased free-plasma choline and a significant and progressive reduction in hepatic fat as assessed by computed tomography.

A recent placebo-controlled trial demonstrated proof of a human choline requirement for long-term home TPN patients.[225] All 15 study patients had hepatic steatosis confirmed by computed tomography. Those randomized to choline received 2 g choline chloride per night, rather than placebo, and experienced resolution of hepatic steatosis, along with decreases in serum aspartate transaminase and alanine transaminase.

Long-Term Growth and Nutritional Problems

Children receiving only HPN can achieve normal height, weight, midarm circumference, midarm muscle circumference, and triceps skinfold thickness. HPN patients receiving 30 to 70% of their total nutrients orally or enterally do gain weight and grow, but not as well as those on exclusive TPN.[226] In this latter group, there could be a propensity to underestimate the amount of PN needed by patients who ingest some nutrients.[203] Enteral calories can be malabsorbed to various degrees, depending on the underlying disease. Periodically, one should assess the amount of nutrients these patients can absorb enterally. Frequently, long-term HPN patients have growth retardation in the face of an apparently adequate caloric support. Causes for such failure of growth might include essential fatty acid deficiency, trace element deficiency, various endocrine disorders, or α-ketoglutarate deficiency.[227] Six prepubertal children on HPN who were well below their expected 50th percentile for height were studied over two successive 5-month periods. A dose of 15 g of ornithine α-ketoglutarate was added to the HPN solution in the first 5 months but not in the second 5 months. During supplementation, height velocity significantly increased, two patients entered puberty, and insulin-like growth factor I levels increased.[227]

In general, the patients on HPN who have been assessed with standard developmental tests have had normal or near-normal intelligence and motor function.[228] Parents tend to be overprotective of children on HPN, with particular fear of harm to the CVC. Some children have poor muscle development of unknown cause.[203] Most children receiving long-term HPN have deficits in perceptual-motor performance, especially the older children,[228] but their overall ability to sustain normal age-related activity is judged to be partial or complete in more than 95% of cases.[207] In the large series of De Potter and colleagues (156 children on HPN), 86% of subjects achieved normal growth, 89% were regularly attending school, 91% took part in physical activities, and 50% were able to go on family vacations.[206]

Visual function might be altered in children receiving long-term HPN.[203] It has been noted that despite normal visual acuity, half of the children had at least one and usually two abnormalities on their electroretinograms.[229]

Monitoring

Standards of practice for home nutrition support have been developed[230] and recently updated.[204] As discussed previously, a multidisciplinary team responsible for ongoing nutritional assessments is the optimal way to manage HPN patients. Theoretically, HPN should be feasible and effective for an entire life span.

SUMMARY

PN remains an evolving therapy. New technology to help better assess caloric needs has been designed, and standards for nutritional support in hospitalized pediatric patients[231] and HPN patients have been recently updated.[204]

CHAPTER 58

DIETARY SUPPLEMENTS (NUTRACEUTICALS)

Steven H. Zeisel, MD, PhD, Karen E. Erickson, MPH

We constantly search for new substances that can improve biologic function or make us fitter and healthier. Recently, Western society has turned to foods as sources of these enhancing molecules. These products are called, variously, vitamins, dietary supplements, functional foods, "nutraceuticals," phytochemicals, biochemopreventatives, and designer foods. These terms vary in meaning from country to country, as does regulation of these agents. Dietary supplements are ingredients extracted from foods, herbs, and plants that are taken without further modification outside of foods for their presumed health-enhancing benefits. The term dietary supplements was formally defined for US government offices in 1994 as a product (other than tobacco) intended to supplement the diet to enhance health that bears or contains one or more of a vitamin, mineral, amino acid, herb, or other botanical or is a dietary substance for use to supplement the diet by increasing the total dietary intake and is intended for ingestion in the form of a capsule, powder, softgel, or gelcap and not represented as a conventional food or as a sole item of a meal or the diet (Dietary Supplement Health and Education Act [DHEA]).[1] The dose to be administered is not included as part of the definition. Although not legally defined, we suggest that the term nutraceuticals should apply to those dietary supplements that deliver a concentrated form of a presumed bioactive agent from a food, presented in a nonfood matrix, and used to enhance health in doses that exceed those that could be obtained from normal foods. (A good example is genistein purified from soybeans and delivered in a pill in doses greater than could be consumed in soy.) "Functional foods" are similar in appearance to conventional foods and are consumed as part of a normal diet. They deliver one or more active ingredients (that have physiologic effects and perhaps enhance health) within the matrix of a food (eg, a bread or breakfast cereal with added high-dose folic acid). Diet supplements, nutraceuticals, and functional foods are designed to supplement the human diet by increasing the intake of bioactive agents that are thought to enhance health and fitness. For the purposes of this chapter, diet supplements, nutraceuticals, and functional foods will be combined under the term dietary supplements.

Use of dietary supplements has increased rapidly since the 1960s. Although consumption dates back to early Greek and Chinese cultures, their popularity in the United States and Europe has only recently experienced rapid growth. A 1997 follow-up to a 1990 US survey on the prevalence and frequency of use of alternative therapies among adults showed that 12.1% of respondents used herbal medicines and 5.5% used megavitamins, representing considerable increases between 1990 and 1997 (130% and 380%, respectively). Of the 44% of respondents who reported regular prescription medicine use, 18.4% had concurrent use of herbal products, high-dose vitamins, or both.[2] The 1999 HealthFocus Trends Report estimated that 54% of Americans used vitamin and mineral supplements at least once a week and 35% used herbal supplements.[3] Use of dietary supplements by children is not well documented; however, children whose parents use dietary supplements are more likely to use them.[4] It is estimated that approximately 50% of US children receive some form of vitamin and mineral supplements.[5,6] Supplement use in children also has been studied in disease states such as inflammatory bowel diseases,[7] cancer,[8,9] attention-deficit/hyperactivity disorder (ADHD),[10] and autism.[11,12] The growth of the industry and the lack of product regulation raise serious concerns for the health and safety of children.

Medicine and the pharmaceutical industry have already developed an approach to introducing new drugs that depends on safety evaluations and controlled clinical trials. This is not always true for dietary supplements. To distinguish between useful, worthless, and potentially harmful dietary supplements, it is important that health professionals carefully define the effect that they are trying to obtain using the supplement, review efficacy data that are available, review safety data, and then establish the balance between benefit and risk before recommending the treatment (see Chapter 13, "Food Safety," for further details).

GROWTH OF THE DIETARY SUPPLEMENT INDUSTRY

A growing industry exists to commercialize dietary supplements. From 1996 to 2000, US consumers tripled to $16.8 billion.[13,14] The American Pharmaceutical Associa-

tion estimates that 80% of pharmacies in the United States sell these products.[15] Until a few years ago, most companies in this field were relatively small, but now multibillion-dollar companies (such as Roche, Central Soya, Archer Daniels Midland, Bristol-Myers Squibb, Lipton, Johnson & Johnson, DuPont, Procter & Gamble, and Novartis) commit major resources to discover health-enhancing activities within the foods we eat and to change traditional foods so that they contain more of these active ingredients. The National Institutes of Health (NIH), acting on directives from the US Congress, set up the Office of Dietary Supplements (ODS) within the Office of the Director of the NIH in 1995 to accelerate basic research to identify effective dietary supplements.

DRUGS IN OUR FOODS?

It is often difficult to distinguish among nutrients, food additives, and drugs. Independent of the matrix (food or pill) in which it is delivered, a dietary supplement can sometimes be food-like and other times drug-like. Nutrients are defined as having nutritive value (they participate in metabolism or are used to build the structures of our cells) and are presumed to be safe. Food additives enhance the aroma, color, structure, or taste of foods but are not nutritive. Under present conceptualizations, the boundary at which a food ingredient becomes a drug is not well defined; often the health claims made for the substance are used to make the determination.[16] Should a nutrient used as part of a treatment for a defined disease be considered a drug, whereas the same nutrient used to enhance health (reduce the risk of disease) is considered a functional food or dietary supplement? This approach could result in classifying a naturally occurring cholesterol-lowering agent as a drug when it is used to reverse atherosclerosis and as a dietary supplement when it is used to prevent atherosclerosis.

One way to differentiate between foods and drugs is to examine how people are exposed to them. Drugs can sometimes be found naturally in foods, and they can participate in metabolism. However, they are substances that humans are not normally exposed to at the doses at which they exert their beneficial effects. In contrast, a nutrient exerts its effects at doses that correspond to reasonably expected exposures for a given population. Some supplements are drug-like when ingested in amounts that could never be achieved in the diet, even though they are essential nutrients when ingested in smaller amounts. At low doses, tryptophan is a necessary amino acid required for metabolism and incorporation into proteins. At high doses, it (or the currently used 5-hydroxy-L-tryptophan) increases brain serotonin synthesis and thus acts as a drug that treats insomnia.[17,18] In this case, a substance normally part of most foods was administered in doses that exceeded dietary requirements to obtain a pharmacologic response and so was drug-like in this circumstance. Another case is a substance that is not usually consumed by humans. Some plant constituents (eg, ephedra and digitalis glycosides) are biologically active at even small concentrations and have toxicity relative to this activity at higher concentrations.[19,20] Even small doses of these constituents are beyond common human experience. Foods are presumed to be safe because we can extrapolate from a known history of exposure to them, whereas a drug that has no such widespread exposure history cannot be presumed to be safe. Thus, we must weigh the risk-to-benefit ratio before large populations of humans are encouraged to ingest drugs.

REGULATION

In 1994, the US Congress passed the DSHEA,[1] which established a new framework for regulation of dietary supplements by the US Food and Drug Administration (FDA). Legislators recognized that people believed that dietary supplements offer significant health benefits. The US Congress wanted to facilitate access to these so-called "natural" medicines so that the public could be empowered to take some measure of control of their own health care. The DSHEA gave manufacturers of dietary supplements freedom to sell these supplements and to provide information about product benefits on labels, with significantly reduced requirements (compared with those for drugs and food additives) for premarket review by the FDA. Dietary supplements on the market before October 1994, when the DSHEA was passed, were exempted (ie, presumed to be safe). For these supplements, the FDA must show they are unsafe before it can restrict marketing of the products. For new ingredients in dietary supplements, the manufacturers (not the FDA) are responsible for determining that the products they market are safe. The FDA must be notified of a new ingredient in a supplement, and this notice must provide information that supports the manufacturer's conclusion that the ingredient is safe. This is a less rigorous process than is required for review of food additives (used to enhance the aroma, color, structure, or taste of a food) or drugs, for which there is a formal process for evaluation of safety. A manufacturer wishing to use a new food additive or a drug must conduct safety studies in a manner defined by the FDA and must submit the results to the FDA for review and approval before the ingredient or drug can be used in marketed products. This is not the case for dietary supplements in the United States because they are legally in a class by themselves; they can be marketed without the manufacturer's satisfying the FDA that they are safe. For more information, see <http://www.fda.gov/>.

The DSHEA ensures rapid access to products that are taken by half of all Americans. This legislation makes it easy for a relatively small enterprise to create and market a product without investing the time and money typically needed to prove safety and efficacy. However, the DSHEA modifies the regulatory environment so that it becomes possible, even likely, that products will be marketed that inadvertently harm people. To date, the FDA has asked for the voluntary recall of a product containing the herbal ingredient plantain contaminated with *Digitalis lanata* after an individual consuming the product suffered a complete heart block. The FDA proposed a regulation to limit the amount of ephedrine alkaloids in dietary supplements (ephedra, ma huang) after serious side effects, including

death, were observed.[21,22] The FDA asked for the voluntary recall of supplements containing γ-butyrolactone because this agent was associated with serious side effects, including coma and death.[23] Because of concerns over severe liver toxicity, the FDA issued a consumer advisory regarding the use of kava (*Piper methysticum)*, a product used for relaxation, sleeplessness, and menopausal symptoms.[24]

Many believe that dietary supplements are natural and therefore must be safe; however, this concept is fallacious. A presumption of safety derives from a history of exposure to the agent as part of a normal diet (or as part of long-term practice); when the dose is in excess of historical exposure, there can be no presumption of safety. Normal metabolism of nutrients includes many physiologic regulatory protective mechanisms (eg, activation of hepatic enzymes that metabolize or store excess nutrient) that make adjustments for modest changes in intake of the nutrient. When a nutrient or chemical is eaten in amounts that greatly exceed normal exposures, these safeguards can be overwhelmed. Similar considerations apply to substances derived from plants. As long as supplements do not appreciably increase exposure to plant-derived substances, it is reasonable to think of these as food ingredients. When dosage of food components, botanicals, or their extracts exceeds levels achievable in normal diets, their bioactivity can be drug-like. Although the determination of normal dietary exposure for an individual is complex, it may be possible to implement policy based on the highest common dietary intake for a human population (eg, use the Japanese population's intake of soy products to set the upper bounds for soy components such as genistein).

It would be advisable to create the category of nutraceuticals for dietary supplements administered in large doses to obtain pharmacologic effects. The benefits and risks of nutraceuticals should be considered much more carefully than those for foods. For the smaller health effects usually seen after administration of nutraceuticals (compared with drug effects such as those of penicillin, which completely eliminate a disease pathogen), the cost of demonstrating efficacy (required of all drugs) may be prohibitive. Thus, it may be inappropriate to classify all nutraceuticals as drugs, but, clearly, we should require more rigorous safety evaluation than we do for foods. The FDA should be empowered to ask for this evidence before—and not after—humans are exposed to potential risk. Perhaps the FDA could regulate nutraceuticals by requiring safety data similar to those required for over-the-counter medications (such as cold remedies).

At any dose, there is further reason to regulate the preparation of dietary supplements, nutraceuticals, and functional foods. Some plants contain a wide variety of toxic chemicals that help them to survive in their environmental niche and defend against bacteria, insects, and herbivores. Manufacturers may inadvertently add toxic constituents during the manufacturing process; the recent experience with eosinophilia myalgia syndrome and impurities in tryptophan preparations is an example.[25] Natural ingredients stored improperly can be substrates for molds that make highly dangerous mycotoxins; mold on peanuts forms the potent carcinogen aflatoxin.[26] There is as much reason for oversight of natural supplements as there is for oversight of synthetic drugs and foods. The dietary supplement industry has adopted a voluntary code of good manufacturing practices (GMPs).[14] The FDA proposed reasonable rules for current GMPs for dietary supplement ingredients in 1997[27] and a public meeting was held in July 1999,[28] but, at this time, there is no mandatory code established by the FDA. These rules are an essential first step toward a rational oversight of dietary supplements.

In response to growing concerns about the quality of dietary supplements on the market, the US Pharmacopoeia (USP) established the Dietary Supplement Verification Program (DVSP) in 2000.[29] Through compliance testing and document review, adherence to GMPs, and postmarketing surveillance, the DSVP is designed to help ensure that dietary supplement products contain the declared ingredients in the declared quantities. Participation in the program is voluntary. A supplement that carries the USP DVSP symbol is certified to contain the ingredients stated on the label in the declared amount and strength, meet specified standards for product purity by meeting requirements for known contaminants, and has been manufactured properly by complying with USP and proposed FDA standards for GMPs.[29]

The increased review and regulation of dietary supplements could decrease the access of the public to some beneficial products. For supplements administered at doses that can be found in foods, the adoption of GMPs should not significantly alter availability. For nutraceuticals that expose humans to ingredients at doses to which they would normally not be exposed, demonstration of safety should be mandated. This may mean that it will take years rather than weeks to introduce a new product, and some products may never be introduced. This seems a reasonable cost to protect the public health. The proposed schema for regulation also is in the interest of supplement manufacturers. In a manner similar to the experience of the pharmaceutical industry after the thalidomide debacle,[30,31] a dietary supplement harming a large number of individuals, with ensuing publicity, could result in public reaction that would damage the marketplace for all dietary supplements. In addition, with no requirement to show efficacy or safety, corporate investments in research and development of better nutraceuticals are unlikely because competitors can jump in without having to amortize the costs of such research. Although the DSHEA has fostered a situation that encourages continued market growth, it has not fully protected the public or fostered an atmosphere conducive to continuous quality improvement through an investment in research.

Table 58-1 summarizes recommendations for monitoring the supplement industry.

MARKETING TO CHILDREN

Children have become a critical niche for dietary supplement manufacturers. The *Nutrition Business Journal*, which tracks the industry, reported 1999 sales of $120 million in herbal and nutritional supplements for

TABLE 58-1 Recommendations for Monitoring the Supplement Industry

Create the category of "nutraceuticals" for dietary supplements administered in large doses to obtain pharmacologic effects
Require safety data similar to those required for over-the-counter medications
Regulate the preparation of dietary supplements, nutraceuticals, and functional foods
Adopt a mandatory code of good manufacturing practices for dietary supplements
Require participation in the US Pharmacopoeia Dietary Supplement Verification Program

children.[32] In 1999, a study conducted by National Public Radio, the Kaiser Foundation, and the Kennedy School of Government found that 18% of parents were giving their children dietary supplements that were not vitamins or minerals.[32] In Germany, where dietary supplement use in children is lower than in US children, over 100 supplements are marketed directly or indirectly for use by children with products containing anywhere from 1 to 26 constituents per product.[33] There are myriad reasons for supplement use by children. Parents give dietary supplements to their children to enhance health, as a substitute for good nutrition, to be a good parent, because of personal positive experiences, or at the recommendation of alternative medicine specialists.[34] Teens often use supplements that are touted as appearance, energy, and athletic performance enhancers.

SPECIAL CONSIDERATIONS IN PEDIATRICS

The use of dietary supplements in children most likely falls into the following categories: optimization of growth, development, and performance; addressing dietary inadequacies; and prevention and treatment of childhood and adult diseases. When assessing the safety and efficacy of a dietary supplement for a child, several considerations must be made. Nutrients can compete for absorption and use in the body, making high-dose supplementation with single nutrients potentially dangerous. For example, supplemental zinc competes with iron absorption and can lead to iron deficiency.[35,36] Also, dietary supplements can interact with pharmaceuticals and either attenuate or dampen treatment effects of drugs and/or cause adverse side effects. For example, St. John's wort activates cytochrome P-450 and affects the metabolism of antiretroviral protease inhibitors.[37]

Although dosages may be recommended on dietary supplement labels, actual dosages necessary to achieve the desired effects can vary. Bioavailability of the active compound is affected by maturation of the gastrointestinal tract, growth, character of the child's diet, and nutritional status.[37] In addition, the chemical form of the nutrient, food, or supplement matrix in which the nutrient is consumed and other foods in the diet affect bioavailability.[38] Although vitamin and mineral supplements may deliver the dosage listed on the label, numerous reports on herbal supplements have shown that the amount of active substance is not necessarily consistent with what is reported on the label.[39,40] Consequently, a child may take a prescribed dosage and actually get much less or much more of the actual ingredients. Data on the bioavailability and toxicity of micronutrients were used in establishing the Dietary Reference Intake (DRI) values and should be used as guidance for recommendations of acceptable limits for nutrient consumption in children.[41] Supplementation of individual and multiple megadose preparations of vitamins and minerals often provides amounts far in excess of the recommendations. Supplement users assessed in the National Health Interview Survey consumed two times the Recommended Dietary Allowance (RDA) for vitamin A, 7 times the RDA for riboflavin, and 17 times the RDA for vitamin C.[42] The message that excess administration of vitamin/mineral supplements at levels far exceeding the recommendations can result in adverse health effects must be communicated to children and their caregivers.

FOLATE: A SUPPLEMENTATION SUCCESS STORY

One of the true success stories in supplementation is folate. Folate affects embryogenesis of the brain. Individuals with diminished folate status are much more likely to have babies with neural tube defects (anencephaly and meningomyelocele),[43] and pregnant mice with folate deficiency had increased rates of exencephaly.[44] Currently, it is recommended that all women be folate supplemented during the periconception period because this reduces the risk for these serious defects in brain development.[45–47] Folic acid administered to women who had previously had a child with a neural tube defect lowered the risk of recurrence by 72%.[48] Folate effects on brain function may have greater significance because genetic polymorphisms of folate metabolism are relatively common and increase dietary requirements for folate. A thermolabile variant of 5,10-methylenetetrahydrofolate reductase (MTHFR 677 C->T) occurs in as many as 8 to 15% of the European and Japanese populations and in 28% of individuals with premature vascular disease.[49,50] Heterozygotes and homozygotes have high homocysteine levels in tissues, which are lowered by dietary supplementation with folate.[49]

COMMONLY USED DIETARY SUPPLEMENTS

Vitamin and Mineral Supplements

A daily multivitamin and mineral supplement is often used to make up for inadequacies in a child's diet. American children generally fall short of achieving recommendations for dietary adequacy. Although the American Dietetic Association maintains that eating a balanced diet that adheres to the Food Guide Pyramid is the best way to meet nutrient needs, they recommend a daily supplement of 100% of the RDA for selected vitamins and minerals for certain individuals unable to meet needs.[51] The American Academy of Pediatrics sees no evidence for supplementing the diets of healthy children.[52] However, if the dietary intake of nutrients is chronically inadequate, the use of a multivitamin and mineral supplement may be advisable.

Herbal Supplements

The following descriptions are from the German Commission E monographs[52]:

Echinacea (*Echinacea purpurea*): Fresh or dried root of *E. purpurea* and its preparations. Contains caffeic acid derivatives, alkamides, polyacetylene derivatives, polysaccharides, glycoproteins, and essential oil. Approved by the Commission E for the treatment of symptoms of upper respiratory infections associated with colds.

Ephedra/ma huang (*Ephedra sinica)*: Dried, young branchlets, harvested in the fall, of *E. sinica* or equivalent *Ephedra* species; the herb contains alkaloids (eg, ephedrine, pseudoephedrine). In the United States, ephedra is regulated under the DSHEA in aqueous infusion, alcoholic tincture, and dry extract in capsules or tablets. The alkaloids of ephedra (ephedrine and pseudoephedrine) are approved as over-the-counter ingredients in remedies for the common cold, flu, and allergies by the FDA. Ephedra's use in products for weight loss, athletic performance enhancement, and nervous system stimulation has raised concern with questions about the safety of these products. The Commission E approved ephedra for internal use in the treatment of diseases of the respiratory tract with mild bronchospasms in adults and children over 6 years. The FDA has received reports of 80 deaths and 1,400 adverse effects associated with ephedra in dietary supplements, and ephedra has been linked to heart attack, stroke, seizures, and psychosis.[54]

St. John's wort (*Hypericum perforatum)*: Dried parts above ground, gathered during the flowering season, of the *H. perforatum* and their preparation in effective dosage. The Commission E approved the use of St. John's wort internally in the treatment of psychovegetative disturbances, depressive moods, anxiety, and nervous unrest. It is thought that the active ingredient for the treatment of depression is hyperforin; however, studies are still being conducted. Oily preparations are approved for external use in the treatment of acute and contused injuries, myalgia, and first-degree burns.

Ginkgo biloba *(Ginkgo biloba)*: Dry extract pharmaceutically prepared to a 35 to 67:1 ratio of dried leaves to final extract containing flavonone glycosides (quercetin and kaempferol), terpene lactones (eg, ginkgolides A, B, and C), and ginkgolic acids. Ginkgo biloba has been approved by the Commission E for symptomatic treatment of disturbed performance in organic brain syndrome within a therapeutic regimen, improvement in pain-free walking in peripheral arterial occlusive disease, vertigo, and tinnitus.

Garlic (*Allium sativum*): Fresh or dried compound bulbs of *A. sativum* with no less than 0.5% allicin. Active compounds include thiosulfinates (allicin). In clinical trials, garlic has been effective in lowering cholesterol in hyperlipidemia and in treating hypertension. Garlic has antibacterial, antimycotic, lipid-lowering, inhibiting of platelet aggregation, prolonging of bleeding and clotting time, tumor-inhibiting, and fibrinolytic activity–enhancing properties. Commission E approved the use of garlic as a support to dietary measures for lowering elevated levels of blood lipids and in age-dependent vascular change prevention. However, limited results in the use of garlic for pediatric patients with hyperlipidemia have been shown.

Saw palmetto berry (*Serenoa repens*): The berry is the ripe fruit of the *S. repens* tree and contains fatty oil with fatty acids, esters, phytosterols, and polysaccharides. Saw palmetto is native to North America and was used as a staple food and medicine of Native Americans. Considerable clinical studies support its safe and effective use in treating symptoms associated with benign prostatic hyperplasia. Commission E approved the internal use of saw palmetto berry for urination problems in benign prostatic hyperplasia stages I and II. It has also traditionally been used for chronic or subacute cystitis, catarrh of the genitourinary tract, testicular atrophy, and sex hormone disorders.

Chamomile (*Chamomilla recutita*): Fresh or dried flowerheads of *Matricaria recutita* and its preparations in effective dosage. It is a popular ingredient in herbal tea in the United States and is prepared for topical use in rinses, creams, ointments, and vapor baths. In German pediatrics, chamomile is widely used in caring for infants' and children's sensitive skin, particularly for inflammatory skin conditions. Commission E has approved chamomile for gastrointestinal spasms and inflammatory diseases of the gastrointestinal tract. It is also approved for external use for skin and mucus membrane inflammation and bacterial skin diseases.

Ginger (*Zingiber officinale*): Peeled, fresh, or dried rhizome of *Z. officinale* and its preparations in effective dosages. Ginger contains oleoresin, volatile oil, carbohydrates, lipids, vitamins niacin and A, minerals, and amino acids. Ginger is used alone and as a component in digestive, antinausea, and cold and flu dietary supplements in the United States. Commission E approved ginger for dyspepsia and prevention of motion sickness.

Valerian root (*Valeriana officinalis*): Fresh underground plant parts or carefully dried parts of *V. officinalis* and its preparations in effective dosages. Valerian roots contain essential oil with monoterpenes and sesquiterpenes. Commission E approved the product for restlessness and sleeping disorders based on nervous conditions. Clinical data support its action as a mild sedative and sleep-promoting agent. The USP does not support the use of valerian owing to inadequate clinical studies.

Performance Supplements

There is evidence that the use of performance-enhancing supplements is prevalent among young people (see Chapter 51.2, "The Adolescent Athlete: Performance-Enhancing Drugs and Dietary Supplements," for further details).[55,56] In particular, androstenedione, creatine, and ephedra are touted to boost athletic performance, although none of these supplements has been shown to significantly enhance performance, and their safety in children is questionable.

Androstenedione is a steroid hormone and a precursor to testosterone that is taken to promote muscle growth and athletic performance. Clinical trials of androstenedione show that it raises estradiol and testosterone levels in healthy men.[57] Long-term use has not been studied, but it is thought that effects similar to those seen in chronic steroid use could be seen. Although the use of androstene-

dione is banned in most sports, both in the United States and abroad, many young athletes report using it.

Creatine is a nonessential dietary element that is present in meat and fish and is endogenously synthesized in the liver. Skeletal muscle phosphorylates creatine to create phosphocreatine, a high-energy compound. During exercise, if aerobic energy production cannot meet adenosine triphosphate (ATP) demand, phosphocreatine conversion assists in the production of ATP. There is also no evidence that dietary phosphocreatine is necessary for muscle contraction or that creatine stimulates protein synthesis. The American College of Sports Medicine (ACSM) released a consensus statement in 2000 concluding that creatine has a potential impact on intense short exercise, such as short-distance sprints that last 6 seconds. They also noted that owing to the lack of research in the pediatric population, they do not recommend supplementation for children under 18 years.[58] One study of sixth to twelfth graders in the northeastern United States found that 8.8% of surveyed boys and 1.8% of girls used creatine. Among grade 12 athletes, use was at 44%.[59]

Probiotics

Although widely used in other parts of the world, probiotics are recently achieving popularity in the United States. Often in the form of a functional food such as yogurt, a probiotic is a preparation containing viable, defined microorganisms in sufficient numbers, which alter the microflora (by implantation or colonization) in a compartment of the host and by that exert beneficial health effects on the host.[60] They are marketed in single-bacteria and multiple-bacteria preparations, with some of the more common ones being *Lactobacillus casei, Lactobacillus acidophilus,* and *Bifidobacterium bifidum*. Although actual colonization by the live bacteria cannot be proven directly, it is inferred by bacterial shedding in the feces after the cessation of supplementation. In children, reports suggest that supplementation with *L. casei* shortens the duration of diarrhea[61] and helps eliminate recurrent *Clostridium difficile* colitis in children in whom antibiotics had failed.[62] Supplementation with a combination of *Bifidobacterium bifidum* and *Streptococcus thermophilus* shortened the duration of rotavirus shedding in hospitalized children.[63] Also, there is evidence that probiotics improve lactose tolerance when live cultures are present in fermented dairy products. They result in decreased cramping and gas as well as a decrease in the concentrations of exhaled hydrogen.[64] Probiotics have also been reviewed for their roles in immunomodulation, cholesterol levels, cancer prevention, *Helicobacter pylori* infection, allergy, inflammatory bowel disease, and mineral absorption.[65]

SUPPLEMENT INTERACTIONS AND POTENTIAL RISKS

In 2002, the National Toxicology Program, in partnership with the NIH ODS and FDA, reviewed the safety of a select number of dietary supplements including aloe vera gel, black walnut extract, comfrey, *E. purpurea* extract, gingko biloba extract, ginseng, goldenseal, grapeseed extract, pine bark extract, kava kava, milk thistle extract, pulegone, and thujone, focusing on characterization of potential adverse health effects.[66] The following are side effects and contraindications for popular herbs excerpted from the *Physician's Desk Reference for Herbal Medicines*[67] and medical literature:

- *Echinacea:* Because of a conceivable activiation of autoimmune and other overreactive immune responses, the drug should not be administered in the presence of multiple sclerosis, leukoses, ollagenoses, acquired immune deficiency syndrome (AIDS), or tuberculosis.[67]
- *Gingko biloba:* The ginkgolide B component has a potent inhibitory effect on platelet-activiting factor (PAF) by displacing PAF from receptor binding sites and thus may inhibit platelet activation.[67]
- *Kava:* May potentiate the effectiveness of substances that act on the central nervous system, such as alcohol, barbiturates, and psychopharmacologic agents.[67]
- *St. John's wort:* The most prominent adverse effect associated with this herb is photosensitivity attributed to its hypericin component.[67] It has also been shown to increase clearance of antiretroviral protease inhibitors.[37]
- *Ephedra:* Contraindications include death, states of anxiety and restlessness, high blood pressure, angle closure glaucoma, cerebral perfusions, prostate adenoma with residual urine volume, pheochromocytoma, and thyrotoxicosis.[67]
- *Eucalyptus:* Infants and young children should not have preparations containing the oil applied to their faces as this can lead to glottal spasm or bronchial spasms through asthma-like attacks or even death by asphyxiation.[67]

Table 58-2 outlines some potential pitfalls in the use of common dietary supplements.

PHYSICIANS' ROLE IN DIETARY SUPPLEMENT USE

The FDA maintains the MedWatch Program for reporting adverse events. Physicians should report adverse events experienced by their patients. The program can be accessed on-line at <http://www.accessdata.fda.gov/scripts/medwatch/>. Patients do not always discuss their use of dietary supplements with their physicians. In one survey of patients completing a survey during a routine physical, only 30% of dietary supplement users reported use.[68] Patients may think that the supplement use is not related to conditions for which care is being sought or may not feel supported by their physician.[34] It is extremely important to obtain a thorough history of supplement use in pediatric patients. Figure 58-1 provides a reasonable assessment tool for use by physicians. Often it is helpful to photocopy labels from supplement bottles brought in by patients.

ACCESSING INFORMATION ABOUT DIETARY SUPPLEMENTS

- The Institute of Medicine DRI publications provide extensive information on vitamin and mineral needs.[69–72]

Dietary Supplement Intake Form

DATE _____

PATIENT NAME _____ AGE _____

1) What kind of supplements does your child take? (check all that apply)
- ❑ none
- ❑ multivitamin/mineral supplement
- ❑ herbal or botanical supplement
- ❑ amino acid or protein supplement
- ❑ fiber supplement
- ❑ other (see question 19 checklist)

2) How long has your child taken this supplement(s)?
- ❑ 1 month or less
- ❑ 3 months
- ❑ 6 months
- ❑ 1 year
- ❑ more than 1 year (specify) _____

_____

3) How long do you plan to give your child this supplement(s)?
- ❑ indefinitely
- ❑ 1 year
- ❑ 6 months
- ❑ 3 months
- ❑ 1 month or less

4) What are your primary reason(s) for giving your child this supplement(s)?
- ❑ for its preventive effect against disease/medical condition
- ❑ to help treat a disease/medical condition
- ❑ general wellness
- ❑ energy
- ❑ weight loss
- ❑ other (specify) _____

_____

If used to *treat* specific medical condition:
What are the child's specific medical symptoms:_____
_____
_____
_____

5) How long has your child had these symptoms/medical conditions?
- ❑ 1 week or less
- ❑ 1 month
- ❑ 3 months
- ❑ 6 months
- ❑ 1 year
- ❑ more than 1 year (specify) _____

_____

6) Have symptoms improved since your child started taking this supplement?
- ❑ yes (explanation) _____

_____
_____
_____

7) Is your child currently taking or has your child recently taken any over-the-counter or prescription medications to treat these symptoms/medical condition?
- ❑ yes (explanation) _____

_____
_____
_____

8) Has your child experienced any adverse reactions after taking the supplement(s)?
- ❑ yes (explanation) _____

_____
_____
_____
_____
_____
_____
_____
_____
_____
_____
_____
_____

*Attach to this form copies of labels from dietary supplements taken by patient.

❑ Vitamin C			
❑ Vitamin D			
❑ Vitamin E			
❑ Other			

FIGURE 58-1 (continued)

Based on exhaustive research, expert analysis, and diverse input, the DRIs are reference values for intake and include three categories: Estimated Average Requirement (EAR), RDA, and Tolerable Upper Intake Level (UL). The EAR is the intake value that is estimated to meet the requirement defined by a specified indicator of adequacy in 50% of an age- and gender-specific group. At this level of intake, the remaining 50% of the specified group would not have its needs met. The RDA is the dietary intake level that is sufficient to meet the nutrient requirements of nearly all individuals in the group. The UL is the maximum level of daily nutrient intake that is unlikely to pose risks of adverse health effects to almost all of the individuals in the group for whom it is designed.[73] DRI documents are produced by the Food and Nutrition Board of the Institute of Medicine, National Academies. Full text is available on the Web site at <http://www4.nationalacademies.org/IOM/IOMHome.nsf/Pages/Food+and+Nutrition+Board>.

There are also several reputable sources for information on other dietary supplements:

- *The Physician's Desk Reference for Herbal Medicines*[67]
- The Cochrane Database of Systematic Reviews is an evidence-based analysis prepared by the Cochrane Collaboration, an international nonprofit organization and part of Britain's National Health Service. It "prepares, maintains, and promotes the accessibility of systematic, up-to-date reviews of health care interventions" (<http://www.update-software. com/cochrane/order.htm>).
- The National Center for Complementary and Alternative Medicine (NCCAM) is 1 of the 27 institutes and centers that make up the NIH. Its mission is to support rigorous research on complementary and alternative medicine (CAM), to train researchers in CAM, and to disseminate information to the public and professionals on which CAM modalities work, which do not, and why. The Web site offers health, research, training, and clinical trials information (<http://nccam.nih.gov/>).
- The NIHODS plans, organizes, and supports conferences, workshops, and symposia on scientific topics related to dietary supplements. The Web site features dietary supplement fact sheets and the Computer Access to Research on Dietary Supplements (CARDS) Database (<http://ods.od.nih.gov/index.asp>). The ODS produces the International Bibliographic Information on Dietary Supplements (IBIDS), a database of published, international, scientific literature on dietary supplements, including vitamins, minerals, and botanicals. IBIDS assists the public, health care providers, educators, and researchers in locating credible, scientific information on dietary supplements (<http://ods.od.nih.gov/databases/ibids.html>).

TABLE 58-2 Potential Pitfalls in Common Dietary Supplements

Category	*Description and Examples*
Toxicity	Androstenedione may increase testosterone and estrogen levels. Not recommended for anyone under 25. Creatine may lead to kidney dysfunction. Side effects include cramping, diarrhea, and dehydration. Not recommended for children or adolescents owing to lack of safety data. St. John's wort has been associated with photosensitivity (at high doses), allergic reaction, and stomach and intestinal problems. Comfrey is a source of pyrrolizidine alkaloids, which have been shown to be hepatotoxic. There is also evidence that pyrrolizidine alkaloids may be carcinogenic. Ephedra has been associated with seizure, stroke, heart attack, psychosis, and death.* High-dose vitamin B supplements were thought to be the cause of rosacea fulminans in a 17-year-old girl.†
Interference with the absorption of other nutrients	Zinc supplementation may interfere with the absorption of iron and copper. Chitosan may interfere with the absorption of fat-soluble vitamins A, D, E, and K as well as the mineral calcium.
Interference with other pharmaceuticals	Oral aloe vera can act as a laxative and may interfere with absorption of other oral medications taken concurrently. St. John's wort may increase the effect of antidepressants and barbiturates and alter the metabolism of reserpine, digoxin, theophylline, immunosuppressive drugs, and protease inhibitors.
Inconsistency in dosage listed on label and dosage found in product, or product contamination	Examples of contamination and excessive dosages in dietary supplements reported by Consumer Lab include lead in a nettle product; excessive vitamin A in diet bars; and quintazene and hexachlorobenzene at 20 times the allowed amount in ginseng supplements.‡ In the case of a man with vitamin D toxicity, the bottles of the product taken contained 26 to 430 times the amount of vitamin D as that listed by the manufacturer.§
Lack of research or established safe levels of intake for children	Few dietary supplements have been studied in children. Although limited adverse effects have been reported for the majority of dietary supplements, it is best to consult the *PDR for Herbs* as well as monographs from the US Pharmacopoiea for information on individual dietary supplements.

CHAPTER 59

SPECIAL DIETS

Sherri L. Utter, MS, RD, LD, CNSD, Sharon B. Collier, MEd, RD, LD

The role of nutrient requirements in disease and the importance of providing essential nutrients to prevent disease were recognized by some of the earliest physicians. The recognition of fruits and vegetables as antiscorbutics in 1671 and the discovery of scurvy as a deficiency disease in 1734 are two examples of the early appreciation of the importance of diet. Some of the first scientific research related to diet was published in 1843 by Pereira, who experimentally fed underprivileged individuals and the sick in metropolitan institutions. Florence Nightingale, the founder of dietetics and modern nursing, was devoted to feeding and nursing the sick and wounded during the Crimean War. The concept of diet as an adjunct mechanism to support health and to prevent and treat various disease states has a strong historical foundation.

The term "special diets" refers to diets that are modifications of the normal adequate diet pattern based on the Dietary Reference Intakes suggested by the Food and Nutrition Board of the Institute of Medicine. Modern medical nutrition therapy promotes the use of diet in the prevention and treatment of a variety of diseases.

The majority of healthy children never require special diets. Typically, children thrive on a varied diet with erratic bursts in growth, usually coupled with concomitant changes in appetite. However, many children with chronic diseases require special diets for optimal health, growth, and development. Depending on the condition, the required nutrient adjustments might be acute or chronic. For example, a surgical procedure might necessitate the use of a special diet for a short duration. Other diseases, however, such as insulin-dependent diabetes mellitus, phenylketonuria, or celiac disease, require lifelong modifications in nutrient consumption. It is important to recognize that disease is not the only indication for implementation of a special diet. Various situations, including the prevention of unwanted disease, personal religious beliefs, and individual lifestyle preferences, can influence an individual to choose a special diet. In these instances, it is important to evaluate the safety of the special diet for a child.

To implement a special diet, adequate education and supervision are keys to successful compliance. For children who require permanent alterations of their diet, regular follow-up, ongoing education, re-evaluation of the diet, and continual attempts to motivate the family and maintain the child's commitment to the diet are important elements of success. Most special diets can be planned to meet 100% of the Dietary Reference Intakes for nutrients. However, some diets could be deficient in particular nutrients and might require vitamin or mineral supplementation. In particular, chronic use of special diets in the pediatric population necessitates periodic monitoring of macro- and micronutrient status. With the proper use of special diets, optimal growth and development can be achieved.

This chapter describes commonly used special *diets* for selected pediatric disorders. Chapter 55, "Standard and Specialized Enteral Formulas," reviews the rationale and development of types of special *formulas*, and Appendix III provides a comprehensive list of commercially available enteral formulas. The conditions and diets described here do not comprise a comprehensive list but rather represent the most common ailments seen in pediatrics. Special diets for clinical conditions such as food allergy, gastrointestinal disease, growth failure, hyperlipidemia, inborn errors of metabolism, mineral deficiency, and weight control are found in this chapter. Included are descriptions, rationales for implementation, and lists of specific foods allowed and to be avoided. Checking food labels diligently is strongly advised because manufacturers often change product recipes.

FOOD ALLERGY

Food allergies can require major dietary changes, depending on the food antigen in question. Some of the most common allergens in infancy include cow's milk protein, soy protein, fish, eggs, and grains. In older pediatric patients, the list expands to include berries, nuts, peanuts, and chocolate. Cow's milk protein allergy, one of the most common allergies in infancy and early childhood, occurs with a frequency of between 0.5 and 7.0% in the general population. Up to 60% of pediatric patients with immediate hypersensitivity to cow's milk protein are allergic to soy protein as well.[1]

The gold standard for the diagnosis of a potential food allergy is the double-blind placebo-controlled study. Liquid preparations can be used for infants and toddlers, and tablets or capsules can be used for older children. Such studies should be conducted in a hospital or clinic setting to ensure patient safety, especially in cases of suspected immunoglobulin E (IgE) mediation. Although elimination diets remain popular, they are fraught with problems, including the correct identifica-

tion of the allergen in question, patient compliance, and other potential agents (dietary or otherwise) that could elicit a similar response.[2]

Nutritional management includes complete exclusion of the dietary antigen. Families are instructed to read product labels for terms indicative of the antigen, such as whey and sodium caseinate in the case of cow's milk protein allergy (see "Milk-Free Diet" below for a complete list). A hypoallergenic infant formula is recommended to replace the cow's milk–based formula.[3] Fortified soy or rice milk can be substituted for cow's milk in diets for toddlers. When food allergies are severe or multiple, amino acid–based formulas can be used. Children not receiving complete enteral supplement should be assessed for mineral and vitamin deficiencies. In families with a high risk for the development of one or more food allergies, it would be prudent to initially breast-feed infants, use a hypoallergenic formula, or both, in conjunction with the avoidance of the common food allergens mentioned.

Periodic patient education updates are necessary. This is especially important with a diagnosis made in infancy because of the introduction of solid foods and the increased possibility of multiple caregivers. Education for family and even extended family should stress the necessity of continued dietary compliance. Support groups, cookbooks, and the like can be beneficial to patients requiring long-term dietary restrictions.

Corn-Free Diet

The corn-free diet is for individuals with an allergy to corn and its derivatives. Elimination of the following ingredients is necessary for individuals adhering to a corn-free diet: corn, cornstarch, corn syrup, corn oil, corn meal, corn sweeteners, maize, and popcorn.

The following ingredients might contain corn: hydrolyzed plant protein, hydrolyzed vegetable protein, and starch (99% likelihood of cornstarch content).

Egg-Free Diet

The egg-free diet is for use in patients with a suspected or documented allergic reaction to egg-related products.

Elimination of the following ingredients is necessary: egg albumin (also called ovalbumin), eggs, egg white, egg yolk, dried egg, egg powder, egg solids, egg substitutes (which contain eggs), eggnog, globulin, livetin, lysozyme (used in Europe), mayonnaise, meringue, ovoglobulin, ovomucin, ovomucoid, vitellin, and Simplesse.

Noteworthy Points

- The egg white, or albumin, is the most allergenic part of the egg.
- Many baked products that have a yellow color or shiny glaze are made with eggs or egg whites.
- Egg whites are often used as a clarifying agent in broths or soups. Always check with the chef when eating out.
- The measles, mumps, and rubella (MMR) vaccine is a source of egg exposure for children.
- Influenza vaccines are grown on egg embryos and could contain trace amounts of egg protein.
- Simplesse is used as a fat substitute in ice cream and frozen desserts and is made from either egg or milk protein.

Tips for Egg-Free Cooking

- Egg substitutes can be used if they are free of egg whites.
- Mashed bananas and apricot puree add flavor and act as both a binder and a thickener in place of egg in quick breads, cakes, cookies, and other sweets.
- Use 2 tbsp pureed fruit for each egg in recipe.
- Two tablespoons of pureed vegetables can replace an egg in soups, sauces, and other dishes.
- To bind or thicken fruit desserts, use 1 tsp dry, unflavored gelatin mixed with 2 tbsp of liquid to replace one egg.
- Because baked goods without eggs crumble easily, use smaller pans. For example, make cupcakes instead of a cake or muffins instead of bread.
- Xantham gum is excellent for holding baked goods together. Use 1 tsp for each egg.
- To help leaven baked goods, add an extra half-teaspoon egg-free baking powder for each egg called for in a recipe, along with another egg substitute to bind or thicken.
- For thickening cream dishes and sauces, add extra flour, cornstarch, or xantham gum.
- To enhance the flavor of egg-free cookies or cakes, add extra ingredients such as raisins, nuts, coconut, seeds, or spices.
- Use any of the following as a binder to replace each egg in your egg-free baked goods:
  - 2 tbsp tahini (ground sesame seeds)
  - 2 tbsp any nut butter
  - 2 tbsp oat flour plus 1 tbsp water
  - 1 tsp baking powder, 1 tbsp liquid, and 1 tbsp vinegar
  - 1 tsp yeast dissolved in $^1/_4$ cup warm water
  - $1^1/_2$ tbsp water, $1^1/_2$ tbsp vegetable oil, and 1 tsp baking powder

Milk Protein–Free Diet

The milk-free diet is for use in patients with a documented, or in some cases suspected, allergy to cow's milk protein. It should not be confused with a lactose-free diet. If the patient is taking a fortified milk substitute, then additional supplements might not be necessary. If a fortified milk substitute is not consumed, the diet could be deficient in calcium, phosphorus, and vitamin D; therefore, supplementation might be needed.

Elimination of the following ingredients is necessary: artificial butter flavor, butter, butter fat, buttermilk, casein, caseinate (ammonium, calcium, magnesium, potassium, sodium), cheese, cottage cheese, curds, cream, custard, pudding, ghee, half and half cream, hydrolysates (casein, milk protein, protein, whey, whey protein), lactoglobulin, lactose, milk (derivative, protein, solids, malted, condensed, evaporated, dry, whole, low fat, nonfat, skim), nondairy creamer (check for casein), nougat, rennet, sour cream, sour cream solids, whey (delactosed, demineralized, protein concentrate), and yogurt. Ingredients that might indicate the presence of milk proteins are brown

sugar flavoring, caramel flavoring, chocolate, high-protein flour (protein source could be skim milk powder), margarine (might contain whey), natural flavoring, and Simplesse (could be made from eggs or milk protein).

Noteworthy Points

- Product that have KD or (U)D on their labels indicate the presence of milk in the product. The ingredient list does not always list the milk source. It could be present as the result of cross-contamination from a milk-containing product that is produced in the same facility. Some labels now state "K_{DE}," which indicates that the product is kosher but made on dairy equipment.
- Parve or Pareve on the label indicates that the product may be milk free; check all labels to confirm.
- Certain vitamin and mineral supplements, as well as some prescription and over-the-counter drugs, contain lactose as a filler. Consult a doctor or pharmacist for specific information.
- The brines that surround prepackaged deli meats often contain whey or casein. There could also be cross-contamination from other meat or cheese products when meats are sliced in a store's deli area.

Suggested Milk-Free Foods

Fats: Kosher margarine, unsalted Mazola margarine, unsalted Fleishmann's stick margarine, lard, vegetable oil, mayonnaise, cocoa butter, Better than Cream Cheese (Tofutti brand), Sour Supreme (Tofutti brand).

Fruits: All types.

Meat, fish, poultry, and eggs: Plain beef, poultry, fish, pork, lamb, bacon, kosher frankfurters, kosher cold cuts (eg, Morrison & Schiff or Hebrew National), tofu, peanut butter, eggs.

Cheese: Soy cheese (without sodium caseinate).

Potatoes, pasta, and rice: All except prepackaged (canned or frozen) products, in which casein is added to pasta to maintain shape.

Soups: Clear canned soups and commercial and homemade soups made with allowed ingredients. Be sure to check labels as even some clear soups might contain margarine, which will probably contain milk products.

Beverages: Milk-free infant formulas such as Isomil, ProSobee, and Alsoy; fruit juices; carbonated beverages; Kool-Aid; cocoa without added milk solids; Nut Quick (Ener-G Foods); Westbrae Rice Drink, Amazake Original, Rice Dream; soy milks such as EdenSoy Original, Vitasoy Original, Vitasoy Light Original, and WestSoy Lite Plain.

Bread and crackers: French, Italian, Vienna, or Syrian bread; bagels are traditionally milk free but check labels.

Cereals: Most do not contain milk products in the ingredient list but often have the (U)D symbol, which suggests that the product could contain some milk and should be avoided.

Sweets: Sugar, jams, jellies, syrups, honey, candies such as gum drops, baking chocolate, Marshmallow Fluff.

Desserts: Jello, fruit sorbet, Italian ice (gelato), milk-free Popsicles; baked products made with Crisco, Spry, or allowed margarine; Royal brand instant pudding mix made with appropriate milk substitute.

Vegetables: All types.

Miscellaneous: Mustard, relish, ketchup, salt, pepper, spices, soy sauce, cocoa powder, carob powder, potato chips, pretzels (check labels for (U)D), olives, peanut butter without added milk, plain popcorn, corn chips.

Peanut-Free Diet

The peanut-free diet is for individuals with a known peanut allergy. The peanut is a legume and not a member of the nut family. Legumes are edible seeds enclosed in pods; others include soybeans, lima beans, carob, and sweet clover. Peanut allergy can be fatal.

Elimination of the following ingredients is necessary: cold-pressed peanut oil, ground nuts, mixed nuts, peanuts, peanut butter, peanut flour, and nut meats. Foods that could contain peanuts or peanut products include African, Chinese, and Thai dishes; baked goods (eg, pastries, cookies); candy; chili and spaghetti sauce (which might be thickened with peanut butter); chocolate candies; hydrolyzed plant protein; hydrolyzed vegetable protein; and marzipan (which can be a mixture of nuts).

Noteworthy Points

- Peanut allergies are usually not outgrown.
- Skin tests for peanut allergy are positive throughout life.
- Peanut oil is usually not a problem as long as it is free of peanut protein. Only oil prepared by the hot-solvent extraction processes that are commonly used in the United States is known to be free of protein.[4]
- Check all candy labels; often they will list peanuts on the label if the product was made in the same facility as another peanut-containing candy. For example, plain M&Ms and Raisinettes both note on the label that they may contain peanuts, but peanuts are not necessarily in the ingredients list.
- Avoid mixed nuts, which often contain peanuts.
- Some cuisines use peanuts in a variety of foods, which makes cross-contamination in restaurants highly possible.
- Egg rolls are occasionally sealed with peanut butter.

Shellfish-Free Diet

The shellfish-free diet is for individuals with a documented allergy to shellfish. Individuals allergic to one type of shellfish could be allergic to others in the same family. Edible shellfish are usually divided into two categories: mollusks and crustaceans. Mollusks, such as clams and mussels, have two shells, but also include the abalone, which has a shell covering and a soft underpart. The crustaceans, such as the lobster, have segmented bodies that are covered with an armor-like section of thick and thin shells.

Elimination of the following ingredients is necessary: mollusks, such as abalone, clams, mussels, oysters, scallops, mollusk, cockle, periwinkle, and sea urchin, and crustaceans, such as crab, crawfish, crayfish, ecrevisse, lobster, shrimp, prawn, and crevette.

Soy-Free Diet

The soy-free diet is for patients with a documented, or in some cases suspected, soy protein allergy. Patients with a soy protein allergy rarely have difficulty meeting their macro- and micronutrient requirements. However, patients with both cow's milk and soy protein allergies should be monitored for caloric and protein (quality and quantity) intakes, as well as for calcium, phosphorus, and vitamin D intakes. If possible, supplementation with a fortified milk-free, soy-free formula will assist in meeting nutrient requirements for growth.

Elimination of the following ingredients is necessary: hydrolyzed soy protein, miso, shoyu sauce, soy flour, soy grits, soy nuts, soy milk, soy sprouts, soy protein concentrate, soy protein isolate, soy sauce, tempeh, textured vegetable protein, and tofu. The following ingredients might indicate the presence of soy protein: flavoring, hydrolyzed vegetable protein, hydrolyzed plant protein, natural flavoring, vegetable broth, vegetable gum, and vegetable starch.

Noteworthy Point Most people with soy allergies can safely eat soy lecithin and soy oil. Soy lecithin is a mixture of fatty substances, a by-product of soybean processing. Lecithin is often used as a stabilizer, emulsifier, or an antioxidant.

Suggested Soy-Free Foods

Beverages: Milk, fruit juices, carbonated beverages, Kool-Aid, cocoa, hot chocolate; infant formulas such as Enfamil, Similac, Nutramigen, Alimentum, and Pregestimil; rice beverages such as Rice Dream and Westbrae Rice Drink.

Bread and crackers: Syrian and French bread.

Cereals: Oatmeal, cream of rice, cream of wheat; any cold cereals with allowed ingredients; infant cereals without soy (check labels).

Fats: Butter, cream, bacon, soy-free mayonnaise, lard, pure vegetable oil (eg, coconut, corn, cottonseed, olive, peanut, safflower, sunflower).

Meat, fish, poultry, cheese, and eggs: All types when plain or prepared with allowed ingredients, such as water-packed tuna; kosher 100% beef hot dogs; eggs; all cheese except soy cheese and imitation cheeses containing soy.

Meat alternatives: Legumes (eg, baked beans), nuts, and seeds, except soybeans.

Potatoes, rice, and pasta: All, including spaghetti, macaroni, and plain noodles.

Vegetables: All except soybeans.

Fruits: All fruit and fruit juices.

Soups: Homemade and canned soups made with allowed ingredients.

Desserts: Fruit, gelatin, homemade puddings (cornstarch, tapioca, rice); ice cream, sherbet, and fruit ices; Popsicles, Fudgsicles; homemade cakes, cookies, and pies made with allowed ingredients; baking chocolate; yogurt.

Sweets: Sugar, jams, jellies, honey, molasses, syrups, marshmallows.

Miscellaneous: Salt, pepper, spices, mustard, relish, ketchup, pickles, olives, coconut; snack foods only if prepared without soy (potato chips, popcorn, dry roasted peanuts).

Wheat-Free Diet

The wheat-free diet is for patients with a documented, or in some cases suspected, wheat allergy. The following ingredients should be eliminated from the diet: bread crumbs, bran, cereal extract, cracker meal, enriched flour, farina, flour, gluten, graham flour, high-gluten flour, high-protein flour, malt vital gluten, wheat bran, wheat grain, wheat gluten, wheat starch, and whole-wheat flour. The following ingredients could have wheat present: gelatinized starch, hydrolyzed vegetable protein, modified food starch, natural flavoring, soy sauce, starch, vegetable gum, and vegetable starch.

Noteworthy Points

- $^1/_2$ cup oat flour and $^1/_2$ cup rice flour can be substituted for 1 cup wheat flour.
- Hispanic and Asian cooking uses rice as a staple. Check multicultural cookbooks at the library for wheat-free recipes.
- Spaghetti squash, corn, and rice pasta make great substitutions for regular pasta.
- Fresh, frozen, and canned vegetables are your best choice. Prepackaged vegetables in sauces often contain wheat as fillers.
- Gluten free also means wheat free.

Suggested Wheat-Free Foods

Beverages: Milk, fruit juices, carbonated beverages, Kool-Aid, cocoa, hot chocolate.

Breads and crackers: Only those made with 100% rye, oat, corn, or rice flour with no wheat added; corn tortillas.

Cereals: Any corn, oat, rice, or rye cereal that has no wheat flour added (eg, puffed rice, corn flakes, crispy rice).

Potatoes, rice, and pasta: All plain rice and wheat-free pastas.

Fats: Butter, margarine, vegetable oils, lard, bacon, cream, mayonnaise, homemade gravy thickened with cornstarch.

Meat, fish, poultry, eggs, cheese: All types when plain or prepared with allowed ingredients; all eggs; all cheeses. Be sure to read the labels of processed cheeses.

Meat alternatives: Legumes, nuts, seeds (eg, peanut butter, baked beans, tofu).

Vegetables: All types; avoid those prepared with sauces.

Soups: Homemade soups with allowed ingredients.

Desserts: Fruit, gelatin, junket, cornstarch and tapioca puddings.

Miscellaneous: Salt, pepper, spices, mustard, ketchup, pickles, relish, olives, coconut, baking chocolate, potato chips, corn chips, popcorn.

Allergy Organizations, Support Groups, and Resources

GASTROINTESTINAL DISEASES

A number of gastrointestinal diseases require dietary modification, both short and long term. Patients can have malabsorption, maldigestion, or both coupled with an inadequate intake, as seen in both celiac disease and Crohn's disease, for example. Patients often require individually tailored diets based on their degree of bowel integrity or function. Enteral formulas, both standard and special, are commonly used with several gastrointestinal disorders (see Appendix III). In addition, Chapter 55, "Standard and Specialized Enteral Formulas," reviews the rationale and development of many of these formulas. Below, we review the more common diets used in pediatric gastroenterology. Please refer to other chapters for a more detailed discussion of each disorder.

Fat Modification for Pancreatic Disease

A low-fat diet might be indicated in the treatment of chronic pancreatitis, as well as the later stages of acute pancreatitis. Acute pancreatitis usually warrants the discontinuation of oral feedings. As clinical parameters indicate improvement of the disease state, careful reintroduction of food might be allowed, with the eventual return to a normal diet.

Chronic pancreatitis with pancreatic enzyme insufficiency will necessitate enzyme replacement therapy; however, dietary modification is usually not necessary. Children with chronic pancreatitis and pancreatic enzyme sufficiency can consume a diet containing 20 to 30% of calories from fat, unless laboratory and clinical data suggest fat intolerance.

Low-fat diets are based on individual requirements and must be designed by using food tables, reading labels, and following the Food Guide Pyramid; they also must be evaluated for tolerance and acceptance. Caloric consumption should be carefully monitored whenever fat restriction is warranted. Fat restriction to less than 5% of total daily calories places the child at risk for the development of essential fatty acid deficiency.

For specific foods pertaining to the low-fat diet, see "Low Cholesterol and Low Saturated Fat Diet" below.

High-Fiber Diet

Dietary fiber is a food component that is neither digested nor absorbed by the body. This undigested material can itself absorb water, resulting in the formation of larger, softer stools, which are more easily moved through the intestines and then passed. A high-fiber diet can benefit the whole family. Diets high in fiber have been shown to control constipation, lower the risk of colon cancer, and reduce blood cholesterol levels. Children are more accepting of dietary changes when they are adopted by the entire family.

A general rule of thumb for recommended daily fiber intake is 5 plus the age (in years) of the child more than 2 years of age, to a maximum of 35 grams per day. For example, a 7 year old should receive 12 g per day (5 + 7 years).

Noteworthy Points To increase the fiber content in a child's diet, include fruits, vegetables, and whole grains (Table 59-1). During commercial processing the fiber content of these sources can be reduced. Therefore:

- Instead of white bread, use 100% whole-grain breads.
- Instead of processed cereals, use whole-grain cereals.
- Instead of canned fruits and juices, use fresh fruits.
- Maintain a well-balanced diet: choose a variety of foods from the Food Guide Pyramid (see Appendix).
- Increase fiber in the diet gradually. A sudden increase in dietary fiber intake can cause gas and bloating.
- If a child refuses high-fiber foods, remember that children often need to be introduced to foods several times before the foods become familiar and acceptable. Slow changes in a child's diet are often better accepted than rapid ones.
- Increase fluid intake with an increase in dietary fiber (Table 59-2). Inadequate fluid intake can also cause constipation.
- Give children choices as to what they would like to eat but provide appropriate choices.
- Add 2 to 4 tbsp of a high-fiber cereal to a favorite hot or cold cereal.
- Add unprocessed wheat bran to yogurt, applesauce, hot or cold cereal, soup, peanut butter, tuna salad, pancake batter, or spaghetti.

Gluten-Restricted Diet

The gluten-restricted diet is necessary for patients diagnosed with celiac disease. The diet is designed to provide adequate nourishment while eliminating foods containing the gliadin fraction of gluten, a protein found in many grains, which causes intestinal injury in susceptible people. Although many cereal grains contain gluten, only wheat, rye, barley, and oats contain the gliadin fraction. Gliadin from these grains is present in many everyday foods, including breads, rolls, crackers, cookies, and breakfast cereals, and might also be present as an incidental ingredient in food additives and derivatives (see the list below). For this reason, food labels must be read carefully. When all sources of gliadin are removed from the diet, the intestine will heal and function normally.

TABLE 59-1 Dietary Fiber Content of Foods

Food	*Little (< 0.5 g)*	*Low (1 g)*	*Moderate (2 g)*	*High (3 g)*	*Very High (> 4 g)*
Dairy	Milk, yogurt, pudding, ice cream, cheese	—	—	—	—
Protein	Eggs, beef, chicken, pork, turkey, fish	—	2 tbsp peanut butter	1/2 cup garbanzo beans, lima beans	1/2 cup lentils (5 g), northern beans (4 g), navy beans (5 g), pork and beans (6 g), kidney beans (6 g)
Fruit	Fruit juice, watermelon, cherries	1/2 cup canned pears, pineapple, fruit cocktail, peaches, fresh grapes	Fresh: 1 peach, 3 apricots, half a grapefruit; 1/2 cup applesauce, blueberries, strawberries	Fresh: 1 apple, orange, banana, 3 dates; 1/2 cup raspberries; dried: 1/4 cup raisins, peaches, apricots, apples	Fresh: 1 pear (5 g), half an avocado (4 g), 3 plums (4 g), 3 prunes (4 g)
Vegetables	—	1/2 cup tomato juice, lettuce, spinach, celery, cauliflower, cucumber, green beans	1/2 cup tomato, cabbage	1/2 cup sweet potato, broccoli, carrots, peas, potato salad, corn	1 baked potato with skin (4 g)
Breads	1 slice French, Italian, raisin, or white bread; 1 pancake or donut; half a bagel	1 slice cracked wheat, pumpernickel, or rye bread; 1 tortilla or whole-wheat pancake	1 slice 100% whole-wheat bread	1 slice Branola; 1 bran muffin	1 slice flourless bread (5 g)
Cereals	1/2 cup corn flakes, Frosted Flakes, Lucky Charms, Cheerios	1/2 cup oatmeal, Life, Nutrigrain, Wheaties, Total, Honey Nut Shredded Wheat	1/2 cup shredded wheat, granola, Crispy Wheats n' Raisins, Wheat Chex	1/2 cup Bran Flakes, Raisin Bran, Grape Nuts, wheat germ	1/2 cup 100% bran (9 g), All Bran, (9 g), Fiber 1 (12 g); 1/4 cup unprocessed wheat bran (7 g; 2 g/tbsp)
Pasta and rice	1/2 cup white pasta	1/2 cup egg noodles, white rice	1/2 cup brown rice	—	1/2 cup whole-wheat pasta
Crackers	Goldfish, saltines, Ritz	2 graham; 16 Wheat Thins, 1 granola bar	3 Harvest Wheats, 3 Triscuits	1 rye crisp	Metamucil wafers
Desserts	Chocolate chip cookies	Oatmeal cookies	Fig Newtons, Peak Freans, Bran Crunch (3 g)	—	—
Miscellaneous	Beverages, fats, sweets	1 cup popcorn	1/4 cup cashews, pecans	1/4 cup almonds, peanuts, walnuts	1/4 cup coconut

Modified from Hendricks KM et al. Manual of pediatric nutrition. 3rd ed. Hamilton (ON): B.C. Decker; 2000.

Noteworthy Points

- Despite the restrictions, the gluten-restricted diet should be well balanced based on the Food Guide Pyramid. Table 59-3 lists foods allowed and restricted while following a gluten-restricted diet. Table 59-4 provides sample menus for a gluten-restricted diet.
- Read food labels carefully to avoid gluten-containing grains and gluten derivatives such as
  - Flour and cereal products: avoid textured vegetable protein
  - Colorings: avoid hydrolyzed vegetable protein
  - Emulsifiers: avoid hydrolyzed plant protein
  - Flavorings: avoid starch
  - Malt or malt flavoring: avoid modified food starch
  - Preservatives: avoid vegetable gum
  - Vinegar: avoid distilled white or grain vinegar
  - Product ingredients can change from one batch to another. To check an ingredient, contact the Celiac Sprue Association/USA, the Gluten Intolerance Group of North America, or the manufacturer of the product. Foods of unknown composition should be omitted. Brand names of gluten-free products are available from the celiac sprue support groups. Table 59-5 provides a list of additives and ingredients to avoid while following a gluten-free diet; Table 59-6 lists those that are permitted.
- Many gluten-free foods can be purchased at grocery stores, Asian food markets, and health food stores.
- Eating in restaurants requires planning and a basic knowledge of foods and food preparation. Choose foods prepared simply, such as broiled or roasted meats, plain vegetables, plain salads, and foods without breading, gravies, or sauces.
- A lactose-restricted diet might be necessary in the early treatment of newly diagnosed celiac disease if symptoms of malabsorption are severe. Milk and

TABLE 59-3 Gluten-Restricted Diet

Type of Food	*Allowed*	*Avoid*
Grains and flours	Arrowroot starch, corn flour, cornstarch, cornmeal; maize and waxy maize; potato flour, potato starch flour; rice bran; rice flours: plain, sweet, brown, and rice polish; soy flour; tapioca starch	Low-gluten flours; all flours containing wheat, rye, barley, and oats; durham wheat, all purpose flour, white enriched flour, wheat germ, whole-wheat flour, wheat starch; wheat bran; oat bran; amaranth; buckwheat, buckwheat groats; bulgar; graham; kasha; matzo; millet; rusks, semolina, sorghum; triticale
Breads	*Specially prepared breads using only allowed flours* (100% potato, corn, rice, arrowroot, soybean); special commercial gluten-free baking mixes (Ener-G Foods, Dietary Specialties)	All breads, rolls, etc, made with wheat, rye, barley, or oats
Cereals	Hot or cold cereals made from corn meal, rice, hominy*	All containing wheat, rye, barley, oats, farina, bran (except rice bran), graham, wheat germ, kasha, bulgar, buckwheat, millet, triticale *Do not eat cereals that contain malt unless the source is known.*
Noodles and pasta	Gluten-free corn pasta; special gluten-free pasta (Aproten and other brands); oriental rice noodles or bean noodles	Regular noodles, spaghetti, macaroni, etc
Crackers and snacks	Pure cornmeal tortillas; rice wafers; rice cakes without added rye or millet*; popcorn; crackers made with allowed flours (100% potato, corn, rice, arrowroot, soybean); some potato chips*	All containing wheat, wheat snack foods, starch, rye, barley, oats, bran (except rice bran), graham, wheat germ, malt, kaska, bulgar, buckwheat, matzo, millet, durham wheat, sorghum, rusks, amaranth, triticale
Milk products	Fresh, dry, evaporated, or condensed milk; cream; sour cream†; whipping cream,† yogurt†	Malted milk; commercially prepared milkshakes; some nondairy cream*; some commercial chocolate drinks*
Meat and alternatives	Fresh meat, fish, poultry, and eggs; fish canned in oil, brine, or water; luncheon meats, frankfurters, and prepared meat products packaged without food starch or gluten derivatives; peanut	Any meat or meat products containing wheat, rye, barley, oats, or gluten derivatives; some canned tuna in vegetable broth,* some sausages,* frankfurters, luncheon meats, and sandwich spreads; canned chili and stews; bread-containing products such as Swiss steak, pot pies, croquettes; self-basting turkey with hydrolyzed vegetable protein (HPV) injected as part of the basting solution
Cheese	Aged cheese (100% cheddar, Swiss, parmesan, etc); cottage cheese,† cream cheese; processed cheese*	Cheese foods; cheese spreads or dips; imitation cheese products
Fruit and juices	Most fresh, frozen, dried, or canned fruit	Thickened or prepared fruits as in pie fillings*
Vegetables	Most plain, fresh, frozen, or canned vegetables; dried beans, peas, and lentils; tomato puree and paste; white and sweet potatoes; yams; hominy; rice	Vegetables in sauces*; commercially prepared vegetables; canned baked beans; most packaged rice mixes
Fats	Most margarines,* butter, vegetable oil, lard, shortening; nuts; pure mayonnaise made without distilled white vinegar*	Commercial salad dressings and dips,* unless product contents are known
Sweets and desserts	Special commercial gluten-free cakes, cookies, and baking mixes; homemade puddings with cornstarch, rice, or tapioca; some pudding mixes,* gelatin desserts, custards, and ices; sherbet and ice cream if they do not contain gluten stabilizers,* hard candy flavored with sugar, honey, molasses, marshmallow, coconut, or chocolate; most jams and jellies*; most nonbuttered syrups*; some candy*	Most commercially prepared cakes, cookies, and other baked goods; "instant" puddings and bread pudding; ice cream cones; frozen desserts containing gluten stabilizers; check contents of commercial candies
Beverages	Fruit juice; plain tea; brewed coffee; hot chocolate made with pure cocoa powder; carbonated drinks except most root beers; wine and brandy without dyes or preservatives; most rums; vodka distilled from potatoes	"Instant" drinks, such as tea, coffee, cocoa, and fruit punch, which are processed with additives, stabilizers, or emulsifiers*; ground coffee with added grain; some flavored coffees*; some herbal teas*; most root beers*; all beer and ale; all whisky (including corn whisky); bourbon; any liquor made from grain alcohol; vodka distilled from grain
Soups	Homemade broths and soups made with allowed ingredients; special gluten-free commercial soups (Ener-G Foods)	Most canned soups and soup mixes,* bouillon, bouillon cubes or powder
Miscellaneous	Cider, rice, or wine vinegar; salt; black or red pepper; herbs; spices; monosodium glutamate (MSG); bicarbonate of soda; pure cocoa; most yeast; baking powder; cream of tartar; flavoring if not made with alcohol (choose imitation)	Distilled white vinegar; most white pepper; some curry powder*; some dry seasoning mixes (such as chili seasoning mix)*; some gravy extracts and meat sauces*; yeast flakes*; extracts,* natural flavorings containing alcohol; ketchup,* prepared mustard, and horseradish

Commercially prepared condiments (pickles, ketchup, mustard, mayonnaise, steak sauce) are usually made with distilled white vinegar, which is made with grain. A very small amount of protein may be carried over into white vinegar during distillation. Moderate use of commercially prepared condiments is allowed by some physicians. However, individuals with newly diagnosed or extreme gluten sensitivity should avoid these condiments.

*Some products may be used if checked with the manufacturer and found to be gluten free.

†Check label for oat gum.

milk products are generally restricted for 6 weeks and gradually reintroduced into the diet.

Tips for Gluten-Restricted Cooking Gluten's elasticity is an important element in baked products. Special recipes to compensate for this are required when gluten-free flours are used for baking. Cookbooks specifically for the gluten-restricted diet are available. When gluten-free flour or starch is used as a substitute in baked goods, it is necessary to increase the amount of leavening (baking powder, baking soda, yeast, or eggs) and protein (eggs, milk or powdered milk, soy flour, tofu, or cottage cheese). A mixture of flours gives a better result in gluten-free baking.

The following grains can also be used in the quantities listed as a substitute for 1 cup of wheat flour:

- 5/8 cup potato starch flour (1/2 cup plus 2 tbsp)
- 7/8 cup white rice flour (3/4 cup plus 2 tbsp)
- 1/2 cup soy flour plus 1/2 cup potato starch flour
- 1 cup corn flour
- 1 cup fine cornmeal
- 3/4 cup coarse cornmeal

To substitute for 1 tbsp of wheat flour as a thickener in sauces, gravies, and puddings, use one of the following:

- 1 1/2 tsp cornstarch
- 1 1/2 tsp potato starch
- 1 1/2 tsp white rice flour
- 1 1/2 tsp arrowroot starch
- 2 tsp quick-cooking tapioca

TABLE 59-4 Sample Menus for a Gluten-Restricted Diet

Breakfast	*Lunch*	*Dinner*	*Snack*
Orange juice Scrambled egg Gluten-free muffin with margarine Milk	Corn pasta with tomato and meat sauce Fresh fruit Milk	Tossed salad with gluten-free dressing Grilled chicken Rice Ice cream (check label) Milk	Potato chips Fruit juice
Grape juice Gluten-free waffles with strawberries or gluten-free syrup Milk	Tacos (pure corn tortilla, beef, cheese, beans, lettuce, tomato) Mixed fruit cup Milk	Oven-fried whitefish (gluten-free cornflake crumbs) French fries Carrot coins Pudding (check label)	Milk Gluten-free pound cake
Apple juice Hot rice cereal Gluten-free toast Margarine, jelly Milk	Grilled cheese on gluten-free bread Fresh fruit Gelatin Milk	Baked pork chop Whipped potatoes Corn Applesauce Gluten-free cookies	Peanuts and raisins Milk

*Some products can be used if the manufacturer verifies that they are gluten free.

Celiac Disease Organizations, Support Groups, and Resources Support groups provide a network for people with celiac disease. Group services include information and referrals; publications, such as newsletters and gluten-free diet instructions; and annual conferences; and workshops provide up-to-date information about celiac disease and the gluten-free diet.

National groups include

- Celiac Sprue Association/United States of America, Inc. (CSA/USA), PO Box 31700, Omaha, NE 68131-0700; telephone: 402-558-0600; fax: 402-558-1347; www.csaceliacs.org
- Canadian Celiac Association National Office, 5170 Dixie Rd., Ste. 204, Mississauga, ON L4W IE3; telephone: 800-363-7296; fax: 905-507-4673; www.celiac.ca
- Gluten Intolerance Group of North America (GIG), 15110 10th Ave. SW, Ste. A, Seattle, WA 98116; telephone: 206-246-6652; www.gluten.net
- Celiac Disease Foundation, 13251 Ventura Blvd., Ste. 3, Studio City, CA 91604; telephone: 818-990-2354; fax: 818-990-2379; www.celiac.org
- Celiac Support Group; www.childrenshospital.org
- www.celiac.com

Organizations that can be of assistance in following the gluten-free diet include

- American Dietetic Association, National Center for Nutrition and Dietetics; telephone: 800-366-1655 (consumer hotline); www.eatright.org
- United States Department of Agriculture, Dr. Donald D. Kasarda, 800 Buchanan St., Albany, CA 94710; telephone: 415-559-5687 or 559-5650 (messages); fax: 415-559-5777; www.usda.gov

TABLE 59-6 Additives and Ingredients Allowed on Gluten-Free Diet

Adipic acid	Mannitol
Ascorbic acid	Microcrystalline cellulose
BHA	Monosodium glutamate (MSG)
BHT	Niacin
Betacarotene	Polyglycerol
Biotin	Polysorbate 60 and 80
Calcium phosphate	Potassium citrate
Calcium chloride	Potassium iodide
Calcium pantothenate	Propylene glycol monostearate
Carboxymethylcellulose	Propylgallate
Carrageenan	Pyridoxine hydrochloride
Citric acid	Riboflavin
Corn sweetener	Sodium acid pyrophosphate
Corn syrup solids	Sodium ascorbate (ascorbic acid)
Demineralized whey	Sodium benzoate
Dextrimaltose	Sodium caseinate
Dextrose (dextrins)	Sodium citrate
Dioctyl sodium sulfosuccinate	Sodium hexametaphosphate
Folic acid (folacin)	Sodium nitrate
Fructose	Sodium silaco aluminate
Fumaric acid	Sorbitol
Gums: acacia, arabic, carob bean, cellulose, guar, locust bean, tragacanth, xanthan	Sucrose
	Sulfosuccinate
	Tartaric acid
Invert sugar	Thiamine hydrochloride
Lactic acid	Tricalcium phosphate
Lactose	Vanillin
Lecithin	Vitamins and minerals
Magnesium hydroxide	Vitamin A (palmitate)
Malic acid

- US Food and Drug Administration, www.fda.gov

Lactose-Free Diet

The lactose-free diet is intended for the individual who must eliminate sources of lactose from the diet, such as patients with galactosemia (an inborn error of metabolism) or those who have difficulty digesting lactose.

Lactose is the primary carbohydrate of dairy products; therefore, foods containing milk or milk products are to be excluded from the diet. People with lactose intolerance might not produce enough intestinal lactase to break down the lactose in their diet. The undigested lactose can cause symptoms such as gas, abdominal pain, diarrhea, and poor weight gain. Table 59-7 outlines the foods that are permitted and those that are to be avoided while following the lactose-free diet.

Noteworthy Points This diet is not intended for those who are sensitive to cow's milk protein. Read labels carefully. Avoid any food containing milk, nonfat milk solids, skim milk, butter, cream, lactose, casein, caseinate, sodium caseinate, or whey.

Calcium Supplements If a nutritionally complete lactose-free infant formula, enteral product, or nutritional supplement is taken, this diet can be sufficient in all nutrients. If a lactose-free fortified milk substitute is not consumed, the diet could be deficient in calcium, phosphorus, and vitamin D. If a milk-free diet is followed for more than 4 to 6 weeks, calcium and other vitamin or mineral supplementation might be needed. Choose a supplement that is complete, well absorbed, and cost efficient. Calcium supplements are available in several acceptable forms: carbonate, gluconate, lactate, and citrate. Avoid dolomite or bonemeal supplements because they have been linked with lead poisoning.

Low-Lactose Diet Guidelines These guidelines are intended for individuals who can tolerate small amounts of lactose or those who are reintroducing lactose after following the lactose-free diet. Note that a lactose-containing diet is not appropriate for persons with galactosemia.

Some foods that contain lactose might be better tolerated than others owing to natural processing. Examples are naturally aged cheeses and yogurt with live cultures. After a period of lactose-free intake, the reintroduction of lactose into the diet should be gradual, based on individual tolerance. Better tolerance might be achieved by consuming lactose-containing foods in small amounts. There are products available that are designed to aid in the digestion of lactose. Lactase enzymes are commercially available as chewable tablets and drops. Refer to Table 59-7 for further information about lactose-containing foods.

GROWTH FAILURE

Growth failure and failure to thrive are terms that describe the condition of infants, children, and young adults whose physical growth deviates significantly from standards or falters from their individual growth pattern. Growth failure can be a result of a variety of factors, including medical, social, and psychological conditions. In most cases, these factors create an environment in which caloric intake is inadequate to meet requirements for normal growth and development. See Chapter 52, "Failure to Thrive: Malnutrition in the Pediatric Outpatient Setting," for more details.

Nutritional management is the cornerstone of therapy for individuals afflicted with growth failure. Therapy should aim to reverse nutrient deficits, achieve ideal body weight for height, and restore optimal body composition. Diets rich in calories and adequate in protein facilitate reversal of growth failure and failure to thrive. The following section provides guidelines for increasing the caloric content of the diet and outlines sample foods and meal plans designed to promote a high-calorie intake with adequate protein.

High-Calorie Diet

The high-calorie diet is indicated for promoting weight gain or preventing excessive weight loss during periods of increased nutritional needs (eg, infectious or postoperative states). A well-balanced diet based on the Food Guide Pyramid with an emphasis on foods that are high in protein and calories should be followed.

TABLE 59-7 Lactose-Free Diet

Foods Allowed	*Foods to Avoid*
Milk: none Soy protein infant formulas	All milk, milk drinks—including whole, skim, low-fat, dried, evaporated, and condensed milk, breast milk; yogurt (any type, cream or sour); infant formulas other than those permitted, frappes, ice cream sodas
Fortified soy or rice milk	An enzymatic preparation such as LactAid may be added to milk to convert lactose into digestible sugars; instructions are for conversion of 70 to 95% of the lactose to glucose and galactose; check with your nutritionist or physician before beginning use of LactAid
Eggs: As desired	Eggs prepared with milk—use specific formula; do not prepare with butter
Meats: Any except those to be avoided	Creamed or breaded meat, fish, or poultry; prepared meats that contain dried milk solids including bologna and cold cuts, frankfurt, salami, commercially prepared fish sticks, and some sausage; kosher products are milk free
Beverages: Powdered, fruit-flavored drinks, ginger ale, tonics	Any made with milk, such as frappes, eggnog, hot chocolate
Cheese: Soy or lactose-free cheeses	All types of cheeses and cheese dishes that are not listed as allowed
Breads: Breads made without milk, such as French bread, Italian bread, water bagels, or parve breads	Any baked products made with milk; muffins, biscuits, waffles, pancakes, donuts, sweet rolls, commercial mixes
Cereal: Any made without milk, cooked or ready to eat. Macaroni, spaghetti, pasta, rice—all prepared without milk	Any prepared cereal that contains dry milk solids
Vegetables and potatoes: All cooked, canned, frozen, or fresh	Any vegetable prepared with milk, butter, milk solids, bread, or bread crumbs; no cheese or cream sauces
Fruit: All	
Desserts: Any made without milk or milk products, such as gelatin desserts, fruit crisp, snow puddings, fruit and water sherbets, pie with fruit filling, angel food cake	All commercial cake and cookie mixes, ice cream, custard puddings, junket, ice milk or sherbets that contain milk; frosting made with milk or butter, dessert sauces, cheese cakes
Soup: Any prepared without milk or milk products; homemade or canned (eg, chicken rice)	All creamed soups, chowders; no cheese
Fats: Milk-free margarine or parve margarine; oils, nuts, peanut butter	Butter, margarine, some commercial salad dressings
Sugar and seasonings: Sugar, honey, molasses, maple syrup, corn syrup, jelly and jam, hard candy, gum drops, marshmallow, hard peppermints, fondant; salt, pepper, spices, herbs, condiments, vinegar, ketchup, relish, pickles, olives, tomato sauce, coconut, wheat germ; artificial flavoring or extracts	Any product made from milk, butter, cream, chocolate, toffee, cream mints, caramel candy, candy with cream centers
Miscellaneous	Medications that use lactose as filler or bulk agents; party dips, nonprescription vitamins; spice blends; Easter egg dyes; dietetic foods and foods advertised as high protein sometimes contain lactose or dry milk solids

Adatped from Hendricks KM, Walker WA, editors. Manual of pediatric nutrition. 2nd ed. Toronto: BC Decker Inc; 1990.

Suggestions for Increasing Calories and Nutrient Density

Milk and Milk Products

- Use high-calorie milk (recipe follows) or half and half cream as a beverage and as a substitute for milk or water in cooking whenever possible (pudding, cocoa, milkshakes, cream soup, custard, eggnog).
- Add powdered milk to yogurt, casseroles, bread, muffins, sauces, and gravies.
- Melt cheese on sandwiches, meats, potatoes, vegetables, rice, pasta, and cream sauces; add cheese to salads.
- Have cream cheese or cottage cheese on crackers or added to vegetables or pasta.
- Make Instant Breakfast with whole or high-calorie milk.
- Add whole-milk yogurt to fruit or desserts and use as a topping for cereal, pancakes, and waffles.

Protein Group

- Add small pieces of cooked meat, fish, poultry, or eggs to salads, casseroles, soups, vegetables, omelets, and noodles.
- Use peanut butter with all grain products, spread on fruit or vegetables, or blended in milk drinks, ice cream, or yogurt.
- Add nuts to desserts, salads, ice cream, vegetables, or fruits (nuts are not recommended for children under 3 years of age).
- Add textured vegetable protein or legumes to casseroles or soups.
- Offer simple fried foods such as chicken or fish.
- Serve meat with extra gravy or sauce when appropriate.

Fruits and Vegetables

- Add mashed fruit to milk, yogurt, shakes, ice cream, and pudding.
- Add dried fruits to muffins, cookies, cereal, and grains or combine with vegetables and nuts (children under

3 years of age can be at increased risk for choking with dried fruits and nuts).
- Serve vegetables raw with a dip, cooked cream style, or topped with melted cheese.
- Add butter, sour cream, or mayonnaise to vegetables.

Grains
- Make hot cereals with milk instead of water.
- Use high-protein noodles and grains in casseroles and soups.
- Coat meat with breading or flour before cooking.
- Top muffins, toast, crackers, and pancakes with margarine, cream cheese, syrup, jam, peanut butter, cheese, or honey (honey is not recommended for children under 1 year of age).
- Serve granola over ice cream, frozen yogurt, or fruit or mixed with nuts or dried fruit.

Tips for Increasing Caloric Intake
- Eat small, frequent meals throughout the day.
- Keep snacks handy for nibbling.
- Try eating a snack or drinking a high-calorie beverage before going to bed in addition to other meals.
- Instead of drinking water, select beverages that contain calories, such as high-calorie milk or frappes (see recipes).
- Notice the times of day that appetite is best and eat more at those times.

Sample Meal Plan The following daily food plan is one example of a high-calorie diet:

Breakfast
1/2 cup citrus juice
1 protein serving (eg, 1 egg, 1/4 cup cottage cheese, 2 tbsp peanut butter, 1 oz cheese, or 1 oz meat)
2 servings of whole-grain bread products or enriched cereal
margarine, butter, jam, jelly, sugar
1 cup high-calorie milk (recipe follows)

Morning Snack
Frappe

Lunch
3 to 4 oz of protein
1/2 cup vegetable
2 servings whole grain, potato, rice, or other starch
1 serving fruit or dessert
butter, margarine, jelly, sugar
1 cup high-calorie milk

Afternoon Snack
Frappe or high-calorie milk
Peanut butter or cheese with crackers or as a sandwich

Dinner
3 to 4 oz of protein
2 servings vegetable (one deep-green or yellow vegetable)
2 servings whole grain, potato, rice, or other starch
1 serving fruit or dessert
margarine, butter, jelly, sugar
1 cup high-calorie milk

Evening Snack
Frappe or high-calorie milk
Pizza, grilled cheese sandwich, or pudding

Recipes
The following recipes are revised from those developed by clinical nutrition staff at Children's Hospital, Boston.

Fortified Milk (180–210 calories)
Add 2–4 tbsp of powdered nonfat dry milk to 8 oz of whole milk

Vanilla Shake/Frappe (400 calories)
1 1/2 cups ice cream (3–4 scoops)
1/2 cup whole milk
3 tbsp nonfat milk powder
(Can also add 2 tbsp of strawberry, chocolate, or coffee syrup)
Mix in blender.

Strawberry Shake/Frappe (530 calories/8 oz)
2 cups whole milk
2/3 cup nonfat dry mild powder or 1 pkg of Carnation Instant Breakfast
2 1/2 cups strawberry ice cream
2 tbsp heavy cream
Mix in blender.

Creamsicle Shake/Frappe (560 calories)
1/2 cup whole milk
2 tbsp instant nonfat dry milk powder
1/2 cup orange juice
1 cup orange sherbet
1 pkg of vanilla Instant Breakfast
Mix in blender.

Peanut Butter Shake/Frappe (400 calories)
1 cup whole milk
3 tbsp smooth peanut butter
3 tbsp chocolate syrup
Mix in blender.

Banana Orange Shake/Frappe (690–790 calories)
1/2 cup milk
1/2 cup orange juice
1 cup vanilla ice cream
2 whole bananas
Mix in blender.

Super Pudding (326 calories)
1 cup fortified milk
1 cup heavy cream
1 pkg (4 1/2 oz) instant pudding
Make into 1/2 cup servings.

Super Grilled Cheese
Dip cheese sandwich into egg fortified milk mixture before grilling with lots of butter or margarine. This will be like French toast with cheese in the middle.

CONGENITAL HEART DISEASE AND HYPERLIPIDEMIA

Pediatric patients with congenital heart disease or hyperlipidemia require careful nutritional monitoring to ensure optimal growth and development. Growth failure in congenital heart disease is common and can be attributable to anorexia, hypermetabolism, frequent respiratory infections, decreased peripheral blood flow, malabsorption, or pulmonary hypertension, among other factors.[5,6] Patients requiring dietary fat restriction because of hyperlipidemia are placed at greater risk for caloric deficits, as well as deficits in calcium and iron. Nutrition education with frequent monitoring is necessary to prevent these deficiencies.

Fluid-restricted and sodium-restricted diets are often used in the management of congenital heart disease.

Fluid-Restricted Diet

The fluid-restricted diet is a modification of the normal diet in which all fluids are limited to a prescribed level. Individuals with renal, liver, or cardiac insufficiency might require it.

Noteworthy Points

- All foods contain water in varying amounts. All foods that are liquid at room temperature are considered to be fluids. These include water, tonic, coffee, tea, fruit and vegetable juices, milk, ice, ice cream, sherbet, Popsicles, fruit ices, gelatins, soups, gravies, sauces, cream, and alcohol.
- Fluid from solid foods is not routinely restricted in a fluid-restricted diet. Solid foods with the highest water content are fruits and vegetables. Excessive consumption of these foods should be avoided.
- Liquid medications and fluids consumed while ingesting medications must be accounted for in the fluid-restricted diet.
- The following measurements are useful in calculating daily fluid allowance:
  - 1 oz = 30 cc = 2 tbsp
  - 4 oz = 120 cc = $^1/_2$ cup
  - 8 oz = 240 cc = 1 cup
  - 32 oz = 960 cc = 4 cups = 1 quart
  - 1 liter = 1,000 cc = 1 kg

Sodium-Restricted Diet

The sodium-restricted diet is a modification of the normal diet in which the sodium content is limited to a prescribed level. Many people consume much more than the Recommended Dietary Intake of sodium. Conditions that might require sodium restriction include hypertension, congestive heart failure, liver disease, renal disease, and corticosteroid therapy. If a strict sodium restriction is necessary, see Table 59-8 for lists of foods allowed and to avoid. For children, a no added salt diet might be a sufficient restriction.

Suggestions for Limiting Sodium Intake

- Do not use salt in cooking and do not add salt to food at the table. Do not put the salt shaker on the table.
- Read labels carefully on all canned, frozen, and packaged foods. Avoid products with added sodium or salt. Ingredients are listed on the package by weight, from the largest amount to the smallest.
- Use low-sodium or sodium-free canned soups, broth, potato chips, crackers, and nuts.
- Try spices and flavorings such as herbs, onion powder, thyme, or lemon juice to add flavor to foods.
- Limit fast foods and restaurant foods that are high in sodium. Most restaurant meals can be made without added salt or salt-containing ingredients such as monosodium glutamate or soy sauce.
- Evaluate medications for sodium content because some medicines contain sodium. Examples are laxatives (Ex-Lax), antacids (Maalox), and some pain relievers, such as acetaminophen (Tylenol).

Low-Cholesterol and Low–Saturated Fat Diet

Cardiovascular disease is associated with a variety of risk factors, including hypercholesterolemia. Blood cholesterol levels can be reduced by as much as 10 to 15% by lowering cholesterol and saturated fat consumption. Exercise, in conjunction with dietary modifications, should be encouraged as this can aid in lowering cholesterol, as well as in weight management.

Low-cholesterol and low–saturated fat diets are used for the management of hypercholesterolemia. The American Academy of Pediatrics' Committee on Nutrition has recommended the implementation of more restrictive Step One and Step Two diets in children who consistently demonstrate cholesterol values greater than the 75th percentile; these diets are described in Tables 59-9 and 59-10 (see Chapter 8, "The Prudent Diet: Preventive Nutrition").[7] Step Two diets are indicated for children who fail to improve on the Step One diet. The American Heart Association has recommended that Step One and Step Two diets be used only in children 2 years of age and older because of the rate of central nervous system development at an earlier age.[8] Because of the potential risk of insufficient caloric intakes, careful monitoring is necessary to ensure normal growth and development in all children on these diets.

Definition of Dietary Fats There are three types of fat in the food we eat: saturated fat, polyunsaturated fat, and monounsaturated fat. Saturated fats are believed to increase blood cholesterol, so the amount of saturated fat in the diet should be limited. Saturated fat is usually solid at room temperature. Examples are butter, shortening, meat fats (suet, lard, salt pork, bacon fat), chicken fat, coconut oil, palm oil, and hydrogenated oils. As well, the fat in whole milk, cheese, yogurt, and cream is saturated.

Polyunsaturated fats lower total blood cholesterol, that is, both low-density lipoprotein (LDL) and high-density lipoprotein (HDL) cholesterol. Polyunsaturated fat is liquid at room temperature. Examples are corn, safflower, sunflower, soybean, cottonseed, walnut, and sesame oil. Monounsaturated fat lowers serum LDL while maintaining HDL levels. Examples are olive, canola, and peanut oils and some nut oils.

TABLE 59-8 Sodium-Restricted Diet

Type of Food	*Allowed*	*Avoid*
Meat, fish, fowl, and cheese	Fresh or frozen beef, lamb, pork, rabbit, veal, chicken, turkey, liver; fresh fish except shellfish, canned salt-free tuna; salt-free cottage cheese; eggs (one a day); salt-free peanut butter	Smoked, processed, or canned meat or fish; frankfurters, ham, sausage, pepperoni, Spam, bacon, luncheon meat, chipped or corned beef, salted kosher meats, salt pork, smoked tongue, canned tuna or salmon, anchovies, caviar, salted and dried cod, herring, frozen fish fillets; frozen meat pies, frozen entrees; shellfish: clams, crabs, lobsters, oysters, scallops, shrimp; egg substitutes; cheese (unless low sodium); peanut butter (unless low sodium)
Breads and cereals	Low-sodium breads, cereals, and cereal products; breads and rolls made without salt; quick breads made with sodium-free baking powder or potassium bicarbonate and without salt or made from low dietetic mix; the following cooked cereals without added salt: pearl barley, cracked wheat, plain farina, Ralston, maltex rolled oats, pettijohns, wheatena, rice; dry cereals: puffed rice, puffed wheat, shredded wheat; macaroni, spaghetti, noodles (cooked without added salt); salt-free melba toast, salt-free venus wafers, low-sodium crackers, plain, unsalted matzo, yeast waffles	Breads and rolls made with salt or commercial mixes; quick breads (pancakes, waffles, cakes, pastries, muffins) made from baking powder, baking soda, salt, monosodium glutamate or commercial mixes; quick cooking and enriched cereals that contain a sodium compound (read label); dry cereals (except those allowed); crackers (except low sodium); "self-rising" flour or cornmeal
Fruits and juices	All fresh; frozen, canned, or dried to which salt, sodium benzoate, or sodium sulfite has not been added; read labels	Regular tomato and vegetable juices, maraschino cherries, any fruit or fruit product that contains salt or sodium benzoates, sodium-preserved dried fruits
Vegetables	Fresh, frozen, or dietetic canned without salt: asparagus, green beans, dried lima beans, dried navy beans, brussels sprouts, cabbage, cauliflower, corn, cowpeas, cucumbers, eggplant, endive, lettuce, mushrooms, okra, onions, parsley, parsnips, peas (fresh), peppers, potatoes, sweet potatoes, pumpkin, radishes, rutabaga, soybeans, squash (winter, summer), tomatoes, turnip greens	All regular canned vegetables; beets, beet greens, carrots, celery, dandelion greens, hominy, kale, mustard greens, pickles, sauerkraut, spinach, white turnips, frozen peas or lima beans if processed with salt; commercially seasoned frozen vegetables, frozen mixed vegetables
Desserts	Fruit and fruit juices as allowed above; gelatin (made with plain, unflavored gelatin, sugar, fruit and fruit juices); homemade cornstarch, rice, or tapioca pudding made from part of milk allowance or low-sodium milk; ice cream as allowed; candy, cake, cookies, pastry: homemade, salt free, or special low sodium	Commercial candies, cakes, cookies, or homemade unless prepared with allowed ingredients; packaged puddings, Jello or other commercial sweetened gelatin desserts
Fat	Lard, vegetable oil, shortening, salt-free butter or margarine, unsalted nuts	Salted butter or margarine, bacon fat, salt pork, commercial mayonnaise or other salad dressing (except low sodium), salted nuts, olives
Sugar and sweets	Sugar, honey, syrups, jams, marmalades, and jellies that contain no preservatives	Molasses, commercial jams containing sodium benzoate or other sodium preservatives (read labels)
Beverages	Fruit juices, lemonade, milk (regular or low sodium as allowed), coffee, tea, Postum, Hershey's cocoa (made with allowed milk or water)	Fountain beverages, "Dutch process" cocoa, instant cocoa mixes, powdered milk, prepared beverages, mixes including fruit-flavored powders, mineral waters, buttermilk
Seasonings and condiments	All spices, extracts, herbs, except those with sodium as an ingredient; lemon juice, vinegar, salt substitute (with doctor's approval), low-sodium bouillon cube	Salt; celery salt, seeds, and flakes; onion salt, garlic salt, prepared mustard, ketchup, horseradish prepared with salt, barbecue sauce, chili sauce; meat extracts, sauces, gravies, and tenderizers; monosodium glutamate (Accent), soy sauce, Worcestershire sauce, saccharin and other sugar substitutes containing salt, regular bouillon cubes, olives, relishes, pickles. Avoid all foods with above seasonings added.
Miscellaneous		Canned, dehydrated, or frozen potato; spaghetti, macaroni, or noodle products; pre-prepared gravies; canned or dehydrated soups, except low sodium; salted popcorn, potato chips, pretzels, and other snack items such as corn chips or Doritos; party spreads and dips; regular baking powder, baking soda (sodium bicarbonate), rennet tablets, laxatives, Chinese/Asian food, Italian food, fast foods, bread stuffing

Suggestions for Lowering Cholesterol and Saturated Fat Intake

- Limit red meat to a maximum of two or three servings (2 to 3 oz per serving) per week. Cut away any visible fat from meat before cooking.
- Bake, broil, boil, or stir-fry meats, fish, or poultry. Remove skin from poultry.
- Use nonstick fry pans or nonstick spray coatings.
- Eat no more than three or four egg yolks per week. Substitute two egg whites for a whole egg in recipes. Use egg whites to batter meats and vegetables, coat with crumbs moistened with acceptable oil, and then bake. Use low-cholesterol commercial egg substitutes in place of whole eggs.
- Read labels of commercially prepared products and avoid those containing ingredients not allowed.
- Limit all fats and oils to reduce total fat intake.
- Avoid fast foods that could be high in fat (eg, fried chicken, french fries).
- Increase fish meals to three or four servings per week.
- Try some meatless dishes, such as pasta with tomato sauce or vegetarian stir-fry dishes.
- Use high-protein vegetables such as legumes (kidney, red, or pinto beans) and fat-free dairy products to supply protein.

To reduce high triglyceride levels, take the following steps to decrease simple carbohydrate intake (if LDL is also high, it will be necessary to also reduce saturated fat intake):

- Avoid sweetened drinks such as soda, fruit juices, and coffee beverages; replace with water, skim or 1% milk, or smoothies made with fat- and sugar-free yogurt and fresh fruit.
- Avoid large or frequent servings of sugary foods such as cookies, candy, ice cream, fruit rollups, and regular chewing gum.

To determine how many calories come from fat in a particular product, using the information on the food label, divide the calories coming from fat by the total calories and then multiply by 100. This equals the percentage of calories from fat. If the percentage from fat is less than 30%, the product is appropriate; if it is more than 30%, the product is too high in fat. The goal is to balance any high-fat food with low-fat foods so that at the end of the day, total fat intake is less than 30% of calories.

Determining Percentage of Calories from Fat: An Example

Product: Cheez-it
Serving size: 12 crackers (nutrition information is per serving)
Calories: 70; calories from fat: 36
Protein: 2 g
Carbohydrates: 7 g
Fat: 4 g (total fat per serving)
Polyunsaturated fat: less than 1 g
Saturated fat: 1 mg
Cholesterol: less than 2 mg
Sodium: 135 mg
Ingredients: enriched flour, riboflavin, vegetable shortening (contains one or more of the following: partially hydrogenated oils: soybean, cottonseed, canola), skim milk, cheese, salt, paprika, yeast, paprika extractives (vegetable color). (Ingredients are listed in descending order, with the largest amount first.)
Thirty-six calories from fat divided by 70 calories per serving = $0.51 \times 100 = 51$; therefore, 51% of calories are from fat. This product is high in fat.

TABLE 59-9 Characteristics of Step One and Step Two Diets for Lowering Blood Cholesterol

	Recommended Intake	
Nutrient	*Step One Diet*	*Step Two Diet*
Total fat	Average of no more than 30% of total calories	Same
Saturated fatty acids	Less than 10% of total calories	Less than 7% of total calories
Polyunsaturated acids	Up to 10% of total calories	Same
Monounsaturated fatty acids	Remaining total fat calories	Same
Cholesterol	Less than 300 mg/d	Less than 200 mg/d
Carbohydrates	About 55% of total calories	Same
Protein	About 15–20% of total calories	Same
Calories	To promote normal growth and development and to reach or maintain desirable body weight	Same

INBORN ERRORS OF METABOLISM

Medical nutritional therapy plays a key role in the management of several metabolic disorders, including those related to carbohydrate, fatty acid, and amino acid metabolism.[9] Dietary alterations are often necessary in re-establishing a balance in metabolic function through provision of deficient products and restriction of toxic substrates. In addition, nutritional management is important to stabilizing altered protein enzymes, replacing cofactors that might be deficient, and supplying products that are deficient owing to an inhibited secondary pathway.

Several formulas currently available for the management of metabolic disorders are age and diagnosis specific (see Appendix). Frequent monitoring is imperative to ensure optimal growth and neurologic development in these medically complex patients. The Appendix provides an extensive list of known metabolic disorders and their suggested dietary modifications, including appropriate enteral formulas.

MINERAL-RICH DIETS

A number of acute and chronic pediatric medical conditions might require mineral supplementation, either in the diet or

TABLE 59-10 Diet for Hyperlipidemia (Step One* and Step Two)

Food Group	*Choose*	*Decrease*
Fats and oils	Unsaturated oils—safflower, sunflower, corn, soybean, cottonseed, canola, olive, peanut	Coconut oil, palm kernel oil, palm oil
	Margarine made from unsaturated oils listed above; light or diet margarine	Butter, lard, shortening, bacon fat
	Salad dressings made with unsaturated oils listed above; low fat or oil free	Dressings made with egg yolk, cheese, sour cream, whole milk
	Seeds and nuts—peanut butter, other nut butters	Coconut
	Cocoa powder	Chocolate
Breads and cereals	Breads—whole-grain bread, hamburger and hot dog bun, corn tortilla	Bread in which eggs are a major ingredient, croissants
	Cereals—oat, wheat, corn, multigrain	Granola made with coconut
	Pasta	Egg noodles and pasta containing egg yolk
	Rice	
	Dry beans and peas	
	Crackers—low-fat animal type, graham, saltine type	High-fat crackers
	Homemade baked goods using unsaturated oil, skim or 1% milk, and egg substitute—quick breads, biscuits, cornbread muffins, bran muffins, pancakes, waffles	Commercial baked pastries, muffins, biscuits
Soup	Chicken or beef noodle, minestrone, tomato, vegetarian, potato	Soup containing whole milk, cream, meat fat, poultry fat, or poultry skin
Vegetables	Fresh, frozen, or canned	Vegetables prepared with butter, cheese, or cream sauce
Fruits	Fruit—fresh, frozen, canned, or dried	Fried fruit or fruit served with butter or cream sauce
	Fruit juice—fresh, frozen, or canned	
Sweets and modified fat desserts	Beverages—fruit-flavored drinks, lemonade, fruit punch	
	Sweets—sugar, syrup, honey, jam, preserves, candy made without fat (candy corn, gumdrops, hard candy), fruit-flavored gelatin	Candy made with chocolate, coconut oil, palm kernel oil, palm oil
	Frozen desserts—sherbet, sorbet, fruit ice, popsicles	Ice cream and frozen treats made with ice cream
	Cookies, cake, pie, pudding—prepared with egg whites, egg substitute, skim or 1% milk, and unsaturated oil or margarine; gingersnaps; fig bar cookies, angel food cake	Commercial baked pies, cakes, donuts, high-fat cookies, cream pies
Meat, poultry, and fish	Beef, pork, lamb—lean cuts well trimmed before cooking	Beef, pork, lamb—regular ground beef, fatty cuts, spare ribs, organ meats, sausage, regular luncheon meats, wieners, bacon
	Poultry without skin	Poultry with skin, fried chicken
	Fish, shellfish	Fried fish, fried shellfish
	Processed meat—prepared from lean meat (eg, turkey ham, tuna wieners)	Regular luncheon meat (eg, bologna, salami, sausage, wieners)
Eggs	Egg whites (two whites equal one whole egg in recipes), cholesterol-free egg substitute	Egg yolks (if more than four per week on Step One or if more than two per week on Step Two diet); includes egg used in cooking
Dairy products	Milk—skim or 1% fat (fluid, powdered, evaporated), buttermilk	Whole milk (fluid, evaporated, condensed), 2% low-fat milk, imitation milk
	Yogurt—nonfat or low-fat yogurt or yogurt beverages	Whole-milk yogurt, whole-milk yogurt beverages
	Cheese—low-fat natural or processed cheese (part-skim mozzarella, ricotta) with no more than 6 g fat per oz on Step One or 2 g fat per oz on Step-Two	Regular cheeses (American, blue, Brie, cheddar, Colby, Edam, Monterey Jack, whole-milk mozzarella, Parmesan, Swiss), cream cheese, Neufchatel cheese
	Cottage cheese—low fat, nonfat, or dry curd (0 to 2% fat)	Cottage cheese (4% fat)
	Frozen dairy dessert—ice milk, frozen yogurt (low fat or nonfat)	Ice cream, cream, half and half, whipping cream, nondairy creamer, whipped topping, sour cream

Adapted from National Cholesterol Education Program Report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents. US Department of Health and Human Services. Public Health Service. National Institutes of Health. National Heart, Lung, and Blood Institute; September 1991. NIH Publication No.: 91-2732.
Data from American Academy of Pediatric Statement on Cholesterol. Committee on Nutrition. Pediatrics 1992;90:469–72.
*The Step One diet has the same nutrient recommendations as the eating pattern recommended for the general population. These diets are best implemented in consultation with a registered dietitian.

by therapeutic measures during their course. Included in this list is cow's milk protein allergy, lactose intolerance, hypercholesterolemia, renal disease, and celiac disease. Some diets chosen for personal reasons, such as the vegan or lacto-ovovegetarian diets, can be inadequate in certain micronutrients.

Included in this section are lists of food sources high in calcium and iron, the minerals most commonly found to be deficient in the pediatric population. It is recommended that any child on a special diet be assessed for micro- and macronutrient intake periodically to ensure an optimal intake for growth and development.

Calcium-Rich Diet

A calcium-rich diet is recommended for all individuals as part of a healthful, well-balanced diet. In particular, growing children have high dietary requirements for calcium. Consuming calcium-rich foods daily will help minimize resorption of calcium from the bones and thus promote dense, strong bones.

Milk and dairy products are the primary source of calcium in the North American diet; the other food groups—breads, meats, fruits, and vegetables—provide the remainder. See the Appendix for Dietary Reference Intakes and Table 59-11 for calcium food sources.

Calcium Information

- Dietary Reference Intakes, National Academy Press: www.nap.edu
- Pennington JAT. Bowes and Church's Food Values of Portions Commonly Used. 17th ed. Philadelphia: Lippincott-Raven Publishers; 1997.
- National Dairy Council: www.nationaldairycouncil.org

Iron-Rich Diet

The iron-rich diet might be indicated for individuals with anemia. Anemia can occur as a result of dietary deficiencies, blood loss, or inadequate absorption of iron.

The body more readily absorbs iron from animal sources (heme iron) than from vegetable sources (nonheme iron). Consuming foods high in vitamin C at the same meal can enhance the absorption of nonheme iron. Vitamin C–rich foods include citrus fruits and juices, cantaloupe, strawberries, tomatoes, and dark-green vegetables. See the Appendix for Dietary Reference Intakes; Table 59-12 lists iron food sources.

WEIGHT CONTROL

The National Center for Health Statistics reports that the prevalence of overweight in children and adolescents is on the rise and has nearly tripled since the 1960s.[10] Being overweight is considered to be the result of an imbalance of energy intake and energy expenditure. Many factors can influence the upward trend in the prevalence of overweight in children, such as alterations in nutrient intake, changes in physical activity patterns, television viewing habits, level of nutritional knowledge, genetics, and parental influence. See Chapter 23, "Energy and Substrate Regulation in Obesity," for more information.

Successful weight reduction and control incorporates a combination of caloric reduction, behavior modification, and exercise. Below are guidelines for healthful eating and weight reduction and control in children.

Goal 1: Plan All Meals and Snacks

- Preplan menus to avoid impulse food choices.
- Do not skip meals; try to eat at the same times each day. Three meals and two or three snacks are sometimes better than only three large meals. There might be a greater risk of eating fattening snack foods when you are very hungry.
- Keep a box of low-calorie foods ready for between-meal snacks (eg, a variety of raw vegetable strips, rice cakes, popcorn, pretzels, fresh fruit).
- When away from home, take food along or know where appropriate foods can be purchased.
- Help make the shopping list and plan for low-calorie selections.
- Read food labels to limit products that list fats or sugars as main ingredients.
- Avoid fried foods (such as french fries and fried chicken), creamed products, and gravies.
- Avoid empty calories (foods such as chips, cakes, cookies, pies, pastry, regular soda, candy, jellies, and syrups) because these foods have very few nutrients and are high in fat or sugar calories or both.
- Preportion food for meals and snacks. Never eat food directly from the serving container or bag; this makes it too easy to overeat.

Goal 2: Eat a Well-Balanced Diet

Eat a variety of foods from the Food Guide Pyramid to meet nutritional needs. The recommended number of servings and serving sizes for the various food groups are listed below:

- **Milk group**: Skim or 99% fat-free milk; nonfat yogurt (some yogurts contain large amounts of added sugar; compare labels); low-fat cheeses (less than 3 g fat per serving). Recommended number of servings: ages 1 to 10: three servings/day; ages 11 to 24: four servings/day. One serving = 1 cup skim milk; 1 cup nonfat yogurt; 1 oz low-fat cheese; $^1/_2$ cup low-fat cottage cheese.
- **Meat group**: Lean cuts with little fat marbling; trim all fat from meat; remove skin of poultry; choose fish canned in water instead of oil; avoid processed deli meats, bacon, and sausage. Recommended number of servings: two servings/day. One serving = 2 to 3 oz lean meat or chicken, cooked; 1 egg; $^1/_4$ cup canned fish; $^1/_2$ cup cooked dried beans.
- **Breads and cereals group**: Choose whole-grain or enriched products and plain cereals (not presweetened). Recommended number of servings: four servings/day. One serving = 1 slice bread, half an English muffin, $^1/_2$ cup starch (potatoes, corn, peas, pasta, rice, or cooked cereal), 1 oz (approximately $^1/_2$ to 1 cup) of ready-to-eat unsweetened cereal.

TABLE 59-11 Calcium Food Sources

Food Group	*Milligrams of Calcium/Serving*
Milk and dairy	
Milks, 1 cup	300
Buttermilk	285
Chocolate	280
Malted	347
Whole*	291
1% low fat	300
2% low fat	297
Skim	302
Soy Plus-West Soy (soy milk)	300
Cheeses	77–337
American, pasteurized process, 1 oz	174
Blue, 1 oz	150
Brick, 1 oz	191
Caraway, 1 oz	191
Cheddar, 1 oz	204
Cheese food	
American, pasteurized process, 1 oz	163
Swiss, pasteurized process, 1 oz	205
Colby, 1 oz	194
Cottage, 2% low fat, ½ cup	77
Edam, 1 oz	207
Monterey, 1 oz	212
Mozzarella, part skim, 1 oz	207
whole, 1 oz	147
Muenster, 1 oz	203
Ricotta, part skim, ½ cup	337
whole, ½ cup	257
Swiss, 1 oz	272
Frozen desserts, ½ cup	88–137
Ice cream, ½ cup	88
Ice milk, hardened, ½ cup	88
Ice milk, soft serve, ½ cup	137
Sherbet, 1 cup	51
Frozen yogurt, ½ cup nonfat	104
Yogurt low fat, 1 cup	345–415
Flavored	389
Fruit	345
Plain	415
Pudding, ½ cup	150
Protein	
Beans, dried, cooked, 1 cup	90
Clams, 4 oz	100
Crab, 3 oz	132
Cod, 3 oz	136
Halibut, 3 oz	191
Oysters, raw, ½ cup	113
Perch, 3 oz	117
Salmon, with bones, 3 oz	167
Sardines, with bones, 3 oz	371
Shrimp, canned, 3 oz	98
Tofu, piece, ½ cup	434
Trout, 1 serving	210
Nuts/legumes (½ cup)	
Almonds	188
Beans, dried, cooked	45
Brazil nuts	123
Garbanzo beans	150
Hummus	66
Lima beans	35
Peanuts	77
Pistachio	86
Pork and beans	67
Refried beans	58
Soybeans	130
Walnuts	55

Food Group	*Milligrams of Calcium/Serving*
Grain foods	
Pancakes, 1 (2–3")	150
English muffin	105
Waffles (7")	179
Wonder Calcium Rich bread (white/whole wheat), 1 slice	290
Wonder Light Calcium Enriched bread, 2 slices	290
Vegetables/legumes (½ cup cooked)	
Beet greens	82
Bokchoy	79
Broccoli	89
Butternut squash	42
Cabbage	79
Carrots	35
Collards	74
Kale	90
Lima beans	35
Mustard greens	38
Okra	50
Pumpkin	31
Stewed tomatoes	42
Spinach	61
Sweet potatoes	38
Tomato soup	80
Tomato soup, with milk (1 cup)	159
Turnip greens	99
Fruits/juices	
Rhubarb, ½ cup	174
Dried figs, ½ cup	144
Orange	92
Orange juice (calcium fortified) 8 oz	300
Dates, dried cut, ½ cup	53
Prunes, dried, (4)	49
Hawaiian Punch (calcium fortified), 8 oz	150
Cereal (1 cup)	
Total	282
Total Raisin Bran	200
Total Corn Flakes	200
Basic Four	200
100% Natural	181
Oatmeal	170
Life	154
Other	
Molasses Blackstrap, 1 tbsp	137
Carnation Breakfast Bar, 1 each	500
Combination and fast foods	
Pizza Hut supreme personal pan pizza	520
Lasagna (2½" × 2½")	460
Macaroni and cheese, homemade (1 cup)	362
Enchilada, cheese (1 enchilada)	324
McDonald's Big Mac (1 sandwich)	256
McDonald's Egg McMuffin (1 sandwich)	256
Wendy's broccoli and cheese potato (1)	250
Chef's salad, without dressing (1 ½ cups)	235
Quiche (⅛ pie)	224
McDonald's Filet-o-Fish (1 sandwich)	165
Cheeseburger, regular (1 sandwich)	182
Pizza, meat and veg., thin crust (¼ of 12")	166
Burger King's Croissan'wich (1 sandwich)	136
Spaghetti with meat balls (1 cup)	124
Submarine sandwich (3"–4" sub)	95
Taco Bell's taco (1 taco)	84
Dairy Queen's hot dog (1 sandwich)	80

TABLE 59-12 Iron Food Sources

Food	*Approximate Measure*	*Iron (mg)*
High-iron sources		
Cream of Wheat (quick or instant)*	½ cup	7.8
Heart, beef†	2 oz	3.7
Kidney, beef†	2 oz	5.3
Kidney, lamb†	2 oz	6.1
Kidney, pork†	2 oz	5.3
Liver, beef†	2 oz	5.8
Liver, calf†	2 oz	9.0
Liver, chicken†	2 oz	6.0
Liver, lamb†	2 oz	10.9
Liver, pork†	2 oz	15.6
Liverwurst†	2 oz	3.6
Prune juice	½ cup	5.1
Moderate-iron sources		
All-Bran Cereal	½ cup	2.9
Almonds, dried unblanched	½ cup	3.0
Dried beans and peas		
Baked beans, no pork	¼ cup	1.5
Blackeye peas, cooked	¼ cup	0.8
Broad beans, dry	¼ cup	3.6
Chick peas, dry	¼ cup	3.5
Cow peas, cooked	¼ cup	0.8
Great northern beans, cooked	¼ cup	1.3
Green peas, cooked	¼ cup	1.4
Lentils, dry	¼ cup	3.4
Lima beans, cooked	¼ cup	1.3
Mung beans, dry	¼ cup	3.6
Navy beans, cooked	¼ cup	1.3
Red beans, dry	¼ cup	3.5
Soybeans, cooked	¼ cup	1.4
White beans, dry	¼ cup	3.9
Beef, cooked	2 oz	2-3‡
Clams	3 medium	2.1
Ham, cooked	2 oz	1.3
Heart, pork, cooked	2 oz	1.8
Lamb, cooked	2 oz	1.9
Mackerel, canned	½ cup	1.0
Malt-O-Meal, cooked	½ cup	1.4
Oysters	3-4 medium	2.8
Peaches, dried	¼ cup	2.4
Peanuts, roasted w/o skins	3 ½ oz	3.2
Pork, cooked	2 oz	2-3§
Prunes, dried	2 large	1.1
Sardines	8 medium	3.5
Scallops	2 oz	1.6
Turkey, cooked	2 oz	1.7
Veal, cooked	2 oz	2.0
Venison, cooked	2 oz	2.0
Wheat germ	1 oz (3 tbsp)	2.6
Contributing iron sources		
Apricots, dried	4 large halves	1.4
Breads, white enriched	1 slice	.6
Bread, whole wheat	1 slice	.5
Chard	½ cup	1.5
Chicken	2 oz	1.0
Dandelion greens	¼ cup	0.9
Dates, dried	¼ cup	1.3
Egg, large	1	1.2
Heart, chicken	9–10 medium	1.7
Kale	¼ cup	.6
Mustard greens	¼ cup	.9
Macaroni, enriched	½ cup	.6
Noodles, enriched	½ cup	.7
Peanut butter	2 tbsp	.6
Raisins, dried seedless	¼ cup	1.25
Rice, long grain or instant	½ cup	.6
Salmon, canned	2 oz	.7
Shrimp, raw	2 oz	.9
Spaghetti	½ cup	.8
Spinach	¼ cup	1.3
Strawberries, raw cleaned	1 cup	1.5
Tomato juice, canned	½ cup	1.05
Tuna, canned	2 oz	1.1
Turnip greens	¼ cup	0.8
Waffle, enriched	5½" diameter	1.3
Approximate iron content of children's favorite foods		
Hamburger, small	1	3.0
Hamburger, large	1	5.2
Big Mac	1	4.3
Quarter Pounder	1	5.1
Spaghetti with meatballs	1 cup	3.3
Frankfurters and beans	1 cup	4.8
Pork and beans	1 cup	5.9
Raisins‖	⅝ cup	3.5
Cereals, fortified	1 serving	4.5–17.8
Nuts‖	1 cup	5.0–7.0
Seeds, sunflower‖	3½ oz	7.1
Chile con carne	1 cup	3.6
Beef burrito	1 medium	4.6
Beef tostado	1 medium	3.4
Cheese pizza	2 slices	3.0
Cheese pizza with beef	2 slices	4.8

*Or other fortified cereals that contain 10 mg of iron per ounce or 100% Recommended Dietary Allowance per serving.
†As organ meats are generally high in cholesterol, these iron-rich foods should be eaten in moderation.
‡Depending on cut. The greatest amounts of iron are generally found in the chuck, flank, and bottom round cuts of beef.
§Depending on cut. The greatest amounts of iron are generally found in the loin, sirloin, tenderloin, and picnic shoulder cuts of pork.
‖Raisins, nuts, and seeds are not generally recommended for children under age 3 because of the risk of choking.

- **Fruit and vegetables group**: Choose whole fruits that are fresh or canned in water and frozen fruits without added sugar. Choose unsweetened juice and limit to 4 oz per day. Choose vegetables that are fresh, canned, or frozen and serve without butter, cheese, or sauces. Recommended number of servings: four total servings/day. One serving = 1/2 cup canned fruit, juice, or cooked vegetable; 1 cup raw vegetables; 1 small piece fresh fruit; 1/4 cup dried fruit.

Goal 3: Prepare Foods the Low-Calorie Way

- Bake, broil, steam, roast, grill, or stir-fry foods.
- Spray pans with fat-free coating instead of using oil when frying.
- Do not add extra fat (eg, butter, margarine, oil, bacon, gravy) when cooking or for serving. Use herbs and spices to season foods instead of fats. Low-calorie but-

ter substitutes (eg, Butter Buds) can provide the flavor of butter without the fat.
- Trim meats of all skin and visible fat.
- Choose fat-free mayonnaise and fat-free salad dressings.
- Skim fat from homemade soups, stews, and gravies (refrigerate or freeze the product until the fat hardens and then spoon it off).
- Use skim milk in place of whole milk or cream when preparing soups, puddings, and home-baked products.

Goal 4: Avoid Excess Sugar

- Sugar and sugary foods provide many calories and very little nutrition and can cause tooth decay.
- Large amounts of sugar are contained in desserts such as cakes and cookies, as well as in soft drinks and candies.
- Sugar can be "hidden" in foods under such names as corn syrup, honey, fructose, and glucose. Read the label. If a sugar is listed as one of the first three ingredients on a food label, the product is probably very high in sugar.
- Beverages can be a major contributor of sugar and extra calories. Choose sugar-free sodas and sugar-free packaged drink mixes or water. Limit juice intake because even naturally sweetened products contain calories.
- It is not necessary to buy dietetic foods. Products marked "dietetic," "lite," or "light" are not necessarily low in calories. When a treat is desired, choose a lower-calorie item such as Popsicles, Italian ice, Fudgsicles, angel food cake, fat-free frozen yogurt, or sugar-free pudding.

Goal 5: Exercise

Activity is an important part of most successful weight-control programs. Regular exercise will help burn extra calories all of the time, not just while exercising. Exercise also helps to strengthen the heart and tone muscles. Exercise at least three times a week for a minimum of 20 to 30 minutes. A 150-pound person will burn calories as listed in 30 minutes of continuous activity:

- Brisk walking, 93
- Dancing, 126
- Playing baseball, 141
- Cycling, 150 to 360
- Swimming, 180
- Playing basketball, 180 to 270
- Playing soccer, 270
- Running, 300 to 450
- Skipping rope, 300 to 450
- Walking up stairs, 300 to 540

Goal 6: Eat Out Intelligently

- Limit restaurant and fast-food eating because such foods are generally high in fat and calories.
- Plan food selections to avoid meats and vegetables that have been fried (eg, select baked or broiled chicken in place of fried chicken).
- Choose a baked potato instead of fries.
- Order pizza without sausage, pepperoni, or extra cheese.
- When eating at fast-food restaurants, take advantage of salads, lean hamburgers, and fresh fruit cups.
- When selecting prepared-to-order foods, ask that the food be prepared with as little fat as possible.
- Avoid vegetables, meats, and starches that are topped with cheese, cream sauces, gravy, butter, or margarine.
- Because restaurant portions are often large, plan to take home some of your food.
- Ask for the salad dressing to be served on the side or request a low-calorie topping. If possible, eat salad without any dressing at all.
- Always ask for water with meals. Request low-fat or skim milk or sugar-free beverages.
- Plan ahead for school lunches. Review the menu and take lunch from home when the school lunch is high in fat or sugar.
- Order sandwiches without mayonnaise, special sauce, or extra cheese. Use mustard or fat-free spreads.

Goal 7: Make Positive Changes

- Maintain a positive attitude.
- When family members or friends are eating tempting foods, choose a low-calorie food (such as a sugar-free ice cream bar) or noncaloric beverage.
- Slow down the pace of eating to a minimum of 20 minutes per meal. This will allow the feeling of fullness to set in and help you enjoy the flavor of the food. If hunger persists after a meal, wait 20 minutes; if you are still hungry, choose low-calorie items such as plain vegetables or fresh fruit. Try to avoid second helpings of meats, desserts, and other high-calorie foods.
- Eat foods high in fiber, such as fresh fruits, vegetables, and whole grains, because they increase the feeling of fullness.
- Keep a food diary. Record everything eaten in order to become more aware of what and how much is actually eaten.
- Realize that change takes time. Select a few areas to work on and focus just on those until they have been mastered. Then add a few more areas needing change.
- If you eat too much of something, do not give up. Think about the positive changes that have been made and just get back on track.
- Measure weight only every 1 to 2 weeks to monitor progress. Do not get frustrated if sometimes results are not seen. A successful weight control program takes time, and a change in behavior is more important than any one weight measurement.
- Note that if a child has not attained adult height, significant weight loss could interfere with growth. Therefore, a dietitian might advise that weight maintenance rather than weight loss should be the goal while continuing to grow taller. The dietitian and physician will help to determine weight goals. If a child is on a weight loss program, a 1- to 2-pound weight decrease per week is usually appropriate.

VEGETARIANISM

A vegetarian is typically defined as a person who avoids the consumption of animal flesh, such as meat, poultry, and fish.[11] Dairy products and eggs might be included or avoided. When all dairy and egg sources are avoided, the diet is referred to as a vegan diet. A vegetarian diet can offer health advantages as a result of its high fiber and low saturated fat content. The American Dietetic Association's position statement on vegetarian diets indicates that appropriately planned vegan and lacto-ovovegetarian diets can meet the nutrient needs of infants, children, and adolescents and can promote normal growth.

Dietary deficiencies, however, are possible with overly restrictive diets. All children following a vegan diet should have a reliable source of vitamin B_{12} and vitamin D (ie, they should receive a vitamin supplement). In addition, emphasis should be placed on the intake of foods rich in calcium, iron, and zinc. Children following a vegetarian diet might need to eat foods higher in fat to meet energy needs for appropriate growth and development.

TABLE A-1 Typical Progression of Female Pubertal Development

Pubertal development in size of female breasts
- Stage 1: The breasts are preadolescent. There is elevation of the papilla only.
- Stage 2: Breast bud stage. A small mound is formed by the elevation of the breast and papilla. The areolar diameter enlarges.
- Stage 3: There is further enlargement of breasts and areola with no separation of their contours.
- Stage 4: There is a projection of the areola and papilla to form a secondary mound above the level of the breast.
- Stage 5: The breasts resemble those of a mature female as the areola has recessed to the general contour of the breast.

Pubertal development of female pubic hair
- Stage 1: There is no pubic hair.
- Stage 2: There is sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, primarily along the labia.
- Stage 3: The hair is considerably darker, coarser, and more curled. The hair spreads sparsely over the junction of the pubes.
- Stage 4: The hair, now adult in type, covers a smaller area than in the adult and does not extend onto the thighs.
- Stage 5: The hair is adult in quantity and type, with extension onto the thighs.

Adapted from Tanner JM. Growth at adolescence. 2nd ed. Oxford: Blackwell Scientific Publisher; 1962.

TABLE A–2 Typical Progression of Male Pubertal Development

Pubertal development in size of male genitalia
- Stage 1: The penis, testes, and scrotum are of childhood size.
- Stage 2: There is enlargement of the scrotum and testes, but the penis usually does not enlarge. The scrotal skin reddens.
- Stage 3: There is further growth of the testes and scrotum and enlargement of the penis, mainly in length.
- Stage 4: There is still further growth of the testes and scrotum and increased size of the penis, especially in breadth.
- Stage 5: The genitalia are adult in size and shape.

Pubertal development of male pubic hair
- Stage 1: There is no pubic hair.
- Stage 2: There is sparse growth of long, slightly pigmented, downy hair, straight or only slightly curled, primarily at the base of the penis.
- Stage 3: The hair is considerably darker, coarser, and more curled. The hair spreads sparsely over the junction of the pubes.
- Stage 4: The hair, now adult in type, covers a smaller area than in the adult and does not extend onto the thighs.
- Stage 5: The hair is adult in quantity and type, with extension onto the thighs.

Adapted from Tanner JM. Growth at adolescence. 2nd ed. Oxford: Blackwell Scientific Publishers; 1962.

§Adapted from Waterlow JC. Classification and definition of protein calorie malnutrition. BMJ 1972;3:565.

TABLE A-12 Clinical Examination in Nutritional Deficiencies and Excesses

Nutrient	*Major Physiologic Functions*	*Deficiency Signs*	*Excess Signs*	*Important Food Sources*	*Potential Causes of Deficiency or Excess*
Carbohydrate	Supplies energy at an average of 4 cal/g of glucose (sparing protein) and is the major energy source for CNS function; unrefined, complex carbohydrates supply fiber that aids in normal bowel function	Ketosis	May cause diarrhea, obesity	Bread, cereals, crackers, potatoes, corn, simple sugar (sugar, honey), fruits and vegetables, milk, breast milk, infant formula	Malabsorption
Fat	Concentrated calorie source at an average of 9 cal/g; constitutes part of the membrane structure of every cell; supplies essential fatty acids and provides and carries fat-soluble vitamins (A, D, E, K)	Essential fatty acid deficiency; dry, scaly skin, poor weight gain, hair loss. Requirements are increased by cell turnover	Atherosclerosis may be affected by excessive intakes of certain dietary fats; altered blood lipid levels	Shortening, oil, butter, margarine, protein-rich foods (meat, dairy, nuts), breast milk, infant formula	Cystic fibrosis, biliary disease, short bowel
Protein	Constitutes part of the structure of every cell; regulates body processes as part of enzymes, some hormones, body fluids, and antibodies that increase resistance to infection; provides nitrogen and has a caloric density of 4 cal/g	Dry, depigmented, easily pluckable hair; bilateral, dependent edema, cirrhosis, fatty liver, decreased visceral proteins; skin is dry with pellagroid dermatoses in severe cases	Azotemia, acidosis, hyperammonemia	Meat, poultry, fish, legumes, eggs, cheese, milk, and other dairy products, nuts, breast milk, infant formula	Protein-losing enteropathy, liver disease, gastrointestinal disease, renal disease
Fat-soluble vitamins					
Vitamin A	Formation and maintenance of skin and mucous membranes; necessary for the formation of rhodopsin (the photosensitive pigment of the rods governing vision in dim light) and regulation of membrane structure and function. Necessary for growth and normal immune function	Night blindness, degeneration of the retina, xerophthalmia, follicular hyperkeratosis, poor growth, keratomalacia, Bitot's spots	Fatigue, malaise, lethargy, abdominal pain, hepatomegaly, alopecia, headache with increased intracranial pressure, vomiting	Carrots, liver, green vegetables, sweet potatoes, butter, margarine, apricots, melons, peaches, broccoli, cod liver oil, breast milk, infant formula	Liver disease, cystic fibrosis, short bowel, protein deficiency (alters transport)
Vitamin D	Promotes intestinal absorption of calcium and phosphate, renal conservation of calcium and phosphorus	Rickets, osteomalacia, costochondral beading, epiphyseal enlargement, cranial bossing, bowed legs, persistently open anterior fontanelle	Hypercalcemia, vomiting, anorexia, diarrhea, convulsions	Cod liver oil, fish, eggs, liver, butter, fortified milk, sunlight (activation of 7-dehydrocholesterol in the skin) infant formula	Liver disease, cystic fibrosis, short-bowel disease, renal disease
Vitamin E	Acts as an antioxidant and free radical scavenger to prevent peroxidation of polyunsaturated fatty acids in the body; neuromuscular function	Hemolytic anemia in the premature and newborn, enhanced fragility of red blood cells, increased peroxidative hemolysis	In anemia suppresses the normal hematologic response to iron	Oils high in polyunsaturated fatty acids, milk, eggs, breast milk, infant formula	Cystic fibrosis, short bowel, liver disease
Vitamin K	Necessary for prothrombin and the three blood-clotting factors VII, IX, and X; half of the vitamin K in humans is of intestinal origin, synthesized by gut flora; necessary for bone mineralization	Hemorrhagic manifestations (especially in newborns), cirrhosis, prolonged clotting	Hemolytic anemia, nerve palsy	Green leafy vegetables, fruits, cereals, dairy products, soybeans, breast milk, infant formula	Liver disease, antibiotic therapy
Water-soluble vitamins					
Ascorbic acid (vitamin C)	Forms collagen cross-linkage of proline hydroxylase, thus strengthening tissue and improving wound healing and resistance to infection; aids absorption of iron; is a water-soluble antioxidant and thus protects other lipid-soluble vitamins	Joint tenderness, scurvy (capillary hemorrhaging), impaired wound healing, acute periodontal gingivitis, petechiae, purpura, anemia	Increased incidence of renal stones, gastrointestinal distress. Documentation of a chronic high intake may result in "rebound" deficiency symptoms	Heat labile; broccoli, papaya, orange, mango, grapefruit, strawberries, tomatoes, potatoes, leafy vegetables, breast milk, infant formula	Stress
Biotin	Component of several carboxylating enzymes; plays an important role in the metabolism of fat and carbohydrate	Anorexia, nausea; vomiting; glossitis; depression; dry, scaly dermatitis; thin hair; loss of eyebrows	None known	Liver, kidney, egg yolk, breast milk, infant formula	Certain inborn errors of metabolism
Cobalamin (B_{12} intrinsic factor required)	Cobalamin-containing coenzymes function in the degradation of certain odd-chain fatty acids and in the recycling of tetrahydrofolate	Megaloblastic anemia, neurologic deterioration	None known	Animal products, breast milk, infant formula	Ileal disease, strict vegetarian

Continues

TABLE A-12 Clinical Examination in Nutritional Deficiencies and Excesses (Continued)

	Major Physiologic Functions	*Deficiency Signs*	*Excess Signs*	*Important Food Sources*	*Potential Causes of Deficiency or Excess*
Folacin	Used in methyl transfer and nucleotide synthesis	Megaloblastic anemia, stomatitis, glossitis	None known	Liver, leafy vegetables, fruit, yeast, breast milk, infant formula	Liver disease, alcoholism, celiac disease, inflammatory bowel disease
Niacin	Aids in energy use as part of a coenzyme (NAD+ and NADP+) in fat synthesis tissue respiration and carbohydrate use; aids digestion and fosters normal appetite; synthesized from the amino acid tryptophan	Pellagra (dermatitis, diarrhea, dementia, death), cheilosis, angular stomatic inflammation of mucous membranes, weakness	Dilation of the capillaries, vasomotor instability, "flushing" (use of muscle glycogen serum lipids, mobilization of fatty acids during exercise)	Liver, meat, fish, poultry, peanuts, fortified cereal products, yeast, breast milk, infant formula	B_6 deficiency (impairs conversion of tryptophan to niacin)
Pantothenic acid	Component of coenzyme A; plays a role in release of energy from carbohydrates and in synthesis and degradation of fatty acids	Infertility, abortion, slow growth, depression, vomiting, malaise, abdominal stress	Diarrhea, water retention	Meat, fish, poultry, whole grains, legumes, breast milk, infant formula	Severe malnutrition
Pyridoxine (B_6)	Coenzyme component for many of the enzymes of amino acid metabolism. All compounds implicated as neurotransmitters are synthesized and/or metabolized in the B_6-dependent reactions	Convulsions, loss of weight, abdominal distress, vomiting, hyperirritability, depression, confusion, hypochromic and macrocytic anemia	Neuropathy	Fish, poultry, meat, wheat, breast milk, infant formula	Elderly, high-protein intake
Riboflavin (B_{12})	Functions primarily as the reactive portion of flavoproteins concerned with biologic oxidations (cellular metabolism)	Cheilosis, glossitis, photophobia, angular stomatitis, corneal vasculation, scrotal skin changes, seborrhea, magenta tongue	None known	Dairy products, liver, almonds, lamb, pork, breast milk, infant formula	Alcoholism, starvation, chronic diarrhea, malabsorption
Thiamin (B_1)	Aids in energy use as part of coenzyme component to promote the use of carbohydrate; promotes normal functioning of the nervous system; coenzyme for oxidative carboxylation of 2-keto acids	Beriberi, neuritis, edema, cardiac failure, anorexia, restlessness, confusion, loss of vibration sense and deep tendon reflexes, calf tenderness	None known	Pork (lean), nuts, whole grain and fortified cereal products, breast milk, infant formula	Alcoholism, refeeding after starvation, prolonged dialysis
Minerals					
Calcium	Essential for calcification of bone (matrix formation); assists in blood clotting; functions in normal muscle contraction and relaxation and in normal nerve transmission	Osteomalacia, osteoporosis	Hypercalcemia vomiting, anorexia, lethargy	Dairy products (milk, cheese), sardines, oysters, salmon, herring, greens, breast milk, infant formula	Renal disease, liver disease
Magnesium	Essential part of many enzyme systems; important for maintaining electrical potential in nerves and muscle membranes and for energy turnover	Tremor, convulsions, hyperexcitability (hypocalcemia tetany)	Diarrhea sedation, transient hypocalcemia	Widely distributed, especially in food of vegetable origin; breast milk, infant formula	PEM, refeeding
Phosphorus	Important intracellular anion; involved in many chemical reactions within the body; necessary for energy turnover (ATP)	Weakness, anorexia, malaise, bone pain, growth arrest	Hypocalcemia (when parathyroid gland not fully functioning)	Dairy products, fish, legumes, pork, breast milk, infant formula	Renal disease, liver disease, refeeding syndrome
Trace elements					
Chromium	Maintenance of normal glucose metabolism, cofactor for insulin	Disturbed glucose metabolism (lower glucose tolerance caused by insulin resistance)	None known	Brewer's yeast, meat products, cheeses	PEM, elderly
Copper	Constituent of proteins and enzymes, some of which are essential for the proper utilization of iron, immunity, skeletal development	Anemia (hemolytic), neutropenia, bone disease	Excess accumulation of the liver, brain, kidney, cornea, anemia, diarrhea	Oysters, nuts, liver, kidney, corn oil margarine, dried legumes	Menke's kinky hair syndrome, excess: Wilson's disease
Fluoride	The main target organs of fluoride in humans are the enamel of teeth and bones, where fluoride is incorporated into the crystalline structure of hydroxyapatite and produces increased caries resistance	Poor dentition, caries, osteoporosis	Mottling, brown staining of teeth (in excess of 4 ppm); fluorosis occurs after prolonged (10–20 yr) ingestion of 20–80 mg/d	Fluoridated water, depends on the geochemical environment and therefore amount in food varies widely	Unfluoridated water, bottled water

Continues

TABLE A-12 Clinical Examination in Nutritional Deficiencies and Excesses (Continued)

	Major Physiologic Functions	*Deficiency Signs*	*Excess Signs*	*Important Food Sources*	*Potential Causes of Deficiency or Excess*
Iodine	Component of thyroid hormones triiodothyronine and thyroxine, important in regulation of cellular oxidation and growth	Goiter, depression thyroid function, cretinism	Thyroid suppression (thyrotoxicosis)	Iodized table salt, salt water, fish, shellfish (content of most other foods geographically dependent), breast milk, infant formula	Endemic goiter in low-iodine areas
Iron	Part of hemoglobin molecule; prevents nutritional anemia and fatigue; increases resistance to infection; functions as part of enzymes involved in tissue respiration	Anemia, malabsorption, irritability, anorexia, pallor, lethargy	Hemosiderosis, hemochromatosis	Red meats, liver, dried beans and peas, enriched farina, breast milk, infant formula, infant cereal	Protein-losing enteropathy, malabsorption, excess: hemochromatosis
Manganese	Essential part of several enzyme systems involved in protein and energy metabolism and in the formation of mucopolysaccharide	Impaired growth, skeletal abnormalities, lowered reproductive function, neonatal ataxia	In extremely high exposure of contamination: severe psychiatric and neurologic disorders	Nuts, whole grains, dried fruits, fruits, vegetables (leafy)	
Molybdenum	Essential for the function of flavin-dependent enzymes involved in the production of uric acid and in the oxidation of aldehydes and sulfites	Not described in man	Acts as an antagonist to the essential element copper; gout like syndrome associated with elevated blood levels of molybdenum, uric acid, and xanthin oxidase	Varies considerably, depending on growing environment; main contributions come from meat, grains, and legumes	
Selenium	Functions as a part of the enzyme glutathione peroxidase, which protects cellular component from oxidative damage	Cardiomyopathy, probably secondary to oxidative damage	In animals, blindness, abdominal pain	Seafoods, kidney, liver, meat, grains (depending on growing area)	Cystic fibrosis
Zinc	Constituent of enzymes involved in most major metabolic pathways (specifically nucleic acid synthesis for cellular growth and repair)	Growth failure, skin changes, delayed wound healing, hypogeusia, sexual immaturity, hair loss, diarrhea	Acute gastrointestinal upset, vomiting, sweating, dizziness, copper deficiency	Whole grains, legumes, beef, lamb, pork, poultry, nuts, seeds, shellfish, eggs, some cheeses, breast milk, infant formula	Malabsorption, chronic diarrhea, liver disease, sickle cell disease

Adapted from Hendricks KM, Walker WA. Manual of Pediatric Nutrition. St Louis: Mosby-Year Book, 1990.
ATP = adenosien triphosphate; CNS = central nervous system; NAD = nicotinamide adenine dinucleotide; NADP = nicotinamide adenine dinucleotide phosphate PEM = protein-energy malnutrition.

See Chapter 34 for growth charts for assessing children with developmental disabilities.

TABLE A-13 Growth Charts for Specific Syndromes*

Condition	*Reference(s)*
Achondroplasia	Horton WA, et al. J Pediatr 1978;93:435. Stature, growth velocity, head circumference, upper and lower segments
Brachmann-de Lange syndrome	Kline AD, et al. Am J Med Genet 1993;47:1042. Length and weight for age, birth to 36 mo; height and weight for age, 2–18 yr; head circumference for age, birth to 18 yr
Cerebral palsy (quadriplegia)	Krick J, et al. J Am Diet Assoc 1996;96:680. Stature and weight for age and weight for stature, age birth to 10 yr
Down syndrome	Cronk CE, et al. Pediatrics 1978;61:564; Pediatrics 1988;81:102. Length for age and weight for age, birth to 36 mo; stature for age and weight for age, 2–18 yr
Marfan's syndrome	Pyeritz RE. In: Emery AH, Rimoirn DL, editors. Principles and practice of medical genetics. New York: Churchill Livingstone; 1983; Pyeritz RE, Papadatas CJ, Bartsocas CD, editors. In: Endocrine genetics and genetics of growth (Prog Clin Biol Res v200). Alan R. Liss; 1985. Stature and weight for age, 2–18 yr, 20–24 yr, and > 24 yr Upper and lower segment ratios 2–20 yr and adult
Myelomeningocele	Appendix 2. In: Ekvall S, editor. Pediatric nutrition in chronic disease and development disorders: prevention, assessment, and treatment. New York: Oxford University Press; 1993. Preliminary charts, height and weight for age, 2–18 yr
Noonan's syndrome*	Ranke MB, Heidemann P, Knupfer C, et al. Eur J Pediatr 1988;148:220–7 Height for age
	Witt DR, et al. Clin Genet 1985;30:150. Stature for age, birth to 18
Prader-Willi syndrome	Holm VA, Appendix A. In: Greeway LR, Alexander PC, editors. Management of Prader-Willi syndrome. New York: Springer Verlag; 1988. p. 317. Height for age, 3–25 yr
	Butler MG, et al. Pediatrics 1991;88:853. Weight, height, sitting height, head circumference, triceps and subscapular skinfold (plus other measure) for age 2–22 yr
Sickle cell disease	Phebus CK, et al. J Pediatr 1984;105:28. Height and weight for age, birth to 18 yr
	Tanner JM, et al. J Pediatr 1985;107:317–29. Height velocity (cm/yr), age 2½ –19 yr
Silver-Russell syndrome	Tanner JM, et al. Pediatr Res 1975;9:611. Height and height velocity for age, 2–19 years (includes periods of treatment with human growth hormone)
Turner's syndrome*	Lyon AJ, et al. Arch Dis Child 1985;60:932. Height for age, birth to 18 yr (girls)
	Ranke MB, Pfluger H, Rosendahl W, et al. Eur J Pediatr 1983;141:81–8. Height for age, height velocity
Williams syndrome*	Morris CA, et al. J Pediatr 1988;113:318. Stature for age, birth to 24 mo and birth to 18 yr; weight for age, birth to 18 yr; head circumference for age, birth to 36 mo and 2–18 yr
	Pankau R, Tartsch CJ, Gosch A, et al. Eur J Pediatr 1992;151:751–5. Height for age, head circumference

Anthropometric assessment of the nutritional status of patients with genetic and other medical conditions can be difficult using the National Center for Health Statistics data. To help evaluate the growth patterns of these patients, special weight and height curves for several syndromes have been published.
*Unless otherwise specified, charts are available for both girls and boys.

APPENDIX 2

Nutritional Requirements

Gina Hardiman, RD, LD

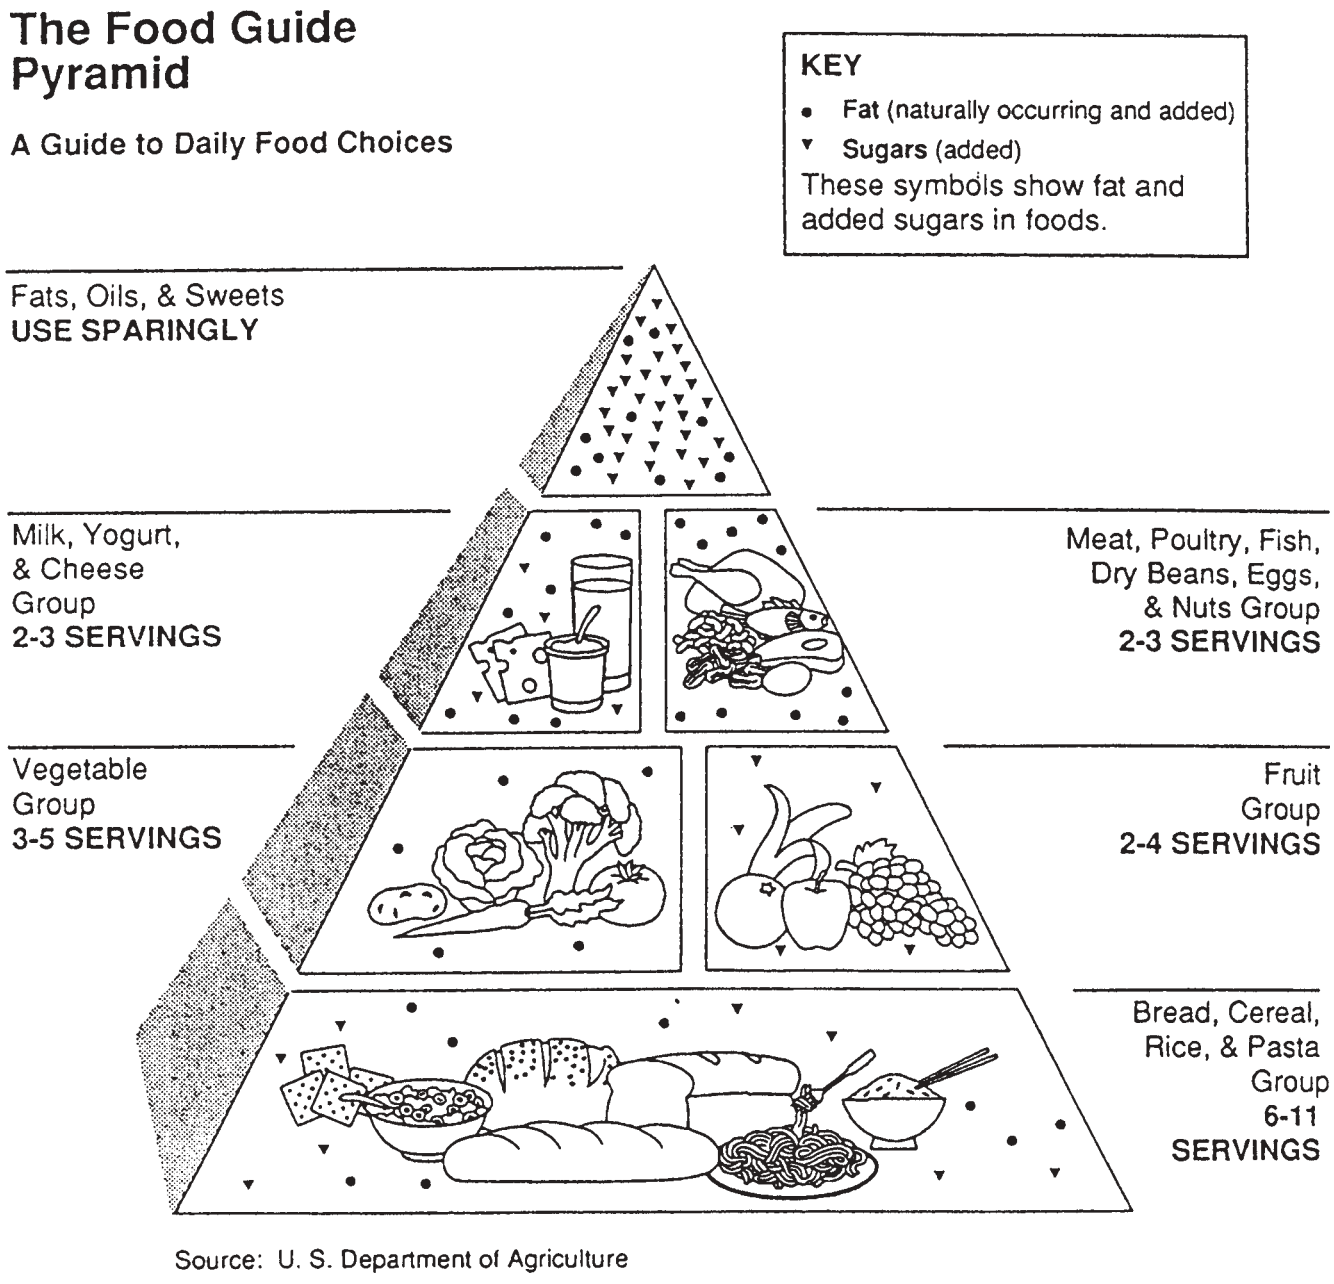

FIGURE A-24 The Food Guide Pyramid (from the US Department of Agriculture).

TABLE A-14 Dietary Reference Intakes: Recommended Intakes for Individuals, Elements (Food and Nutrition Board, Institute of Medicine, National Academies of Sciences)

Life Stage Group	*Calcium (mg/d)*	*Chromium (µg/d)*	*Copper (µg/d)*	*Fluoride (mg/d)*	*Iodine (µg/d)*	*Iron (mg/d)*	*Magnesium (mg/d)*	*Manganese (mg/d)*	*Molybdenum (µg/d)*	*Phosphorus (mg/d)*	*Selenium (µg/d)*	*Zinc (mg/d)*
Infants												
0–6 mo	210*	0.2*	200*	0.01*	110*	0.27*	30*	0.003*	2*	100*	15*	2*

This table presents Recommended Dietary Allowances (RDAs) in **bold type** and Adequate Intakes (AIs) in ordinary type followed by an asterisk. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97 to 98%) individuals in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all individuals in the group, but lack of data or uncertainty in the data prevents being able to specify with confidence the percentage of individuals covered by this intake.

Adapted from Dietary Reference Intakes for calcium, phosphorous, magnesium, vitamin D, and fluoride (1997); Dietary Reference Intakes for thiamin, riboflavin, niacin, vitamin B_6, folate, vitamin B_{12}, pantothenic acid, biotin, and choline (1998); Dietary Reference Intakes for vitamin C, vitamin E, selenium, and carotenoids (2000); and Dietary Reference Intakes for vitamin A, vitamin K, arsenic, boron, chromium, copper, iodine, iron, manganese, molybdenum, nickel, silicon, vanadium, and zinc (2001). These reports may be accessed at <www.nap.edu>.

TABLE A-15 Dietary Reference Intakes (DRIs): Recommended Intakes for Individuals, Vitamins

Life Stage Group	*Vitamin A* (μg/d)[a]	*Vitamin C* (mg/d)	*Vitamin D* (μg/d)[b,c]	*Vitamin E* (mg/d)[d]	*Vitamin K* (μg/d)	*Thiamin* (mg/d)	*Riboflavin* (mg/d)	*Niacin* (mg/d)[e]	*Vitamin B_6* (mg/d)	*Folate* (μg/d)[f]	*Vitamin B_{12}* (μg/d)	*Pantothenic Acid* (mg/d)	*Biotin* (μg/d)	*Choline*[g] (mg/d)

This table (taken from the Dietary Reference Intake reports (see <www.nap.edu>) presents Recommended Dietary Allowances (RDAs) in **bold type** and Adequate Intakes (AIs) in ordinary type followed by an asterisk. RDAs and AIs may both be used as goals for individual intake. RDAs are set to meet the needs of almost all (97 to 98%) individuals in a group. For healthy breast-fed infants, the AI is the mean intake. The AI for other life stage and gender groups is believed to cover the needs of all individuals in the group, but lack of data or uncertainty in the data prevents being able to specify with confidence the percentage of individuals covered by this intake.

[a]As retinol activity equivalents (RAEs). 1 RAE = 1 RAE = 1 μg retinol, 12 μg β-carotene, 24 μg α-carotene, or 24 μg β-cryptoxanthin. The RAE for dietary provitamin A carotenoids is twofold greater than retinol equivalent (RE), whereas the RAE for preformed vitamin A is the same as RE.

[b]Cholecalciferol. 1 μg cholecalciferol = 40 IU vitamin D.

[c]In the absence of adequate exposure to sunlight.

[d]As α-tocopherol. α-Tocopherol includes *RRR*-α-tocopherol, the only form of α-tocopherol that occurs naturally in foods, and the 2*R*-stereoisomeric forms of α-tocopherol (*RRR-, RSR-, RRS-,* and *RRS*-α-tocopherol) that occur in fortified foods and supplements. It does not include the 2S-stereoisomeric forms of α-tocopherol (*SRR-, SSR, SRS-*, and *SSS*-α-tocopherol), also found in fortified foods and supplements.

[e]As niacin equivalents (NE). 1 mg of niacin = 60 mg of tryptophan; 0–6 mo = preformed niacin (not NE).

[f]As dietary folate equivalents (DFE). 1 DFE = 1 μg food folate = 0.6 μg of folic acid from fortified food or as a supplement consumed with food = 0.5 μg of a supplement taken on an empty stomach.

[g]Although AIs have been set for choline, there are few data to assess whether a dietary supply of choline is needed at all stages of the life cycle, and it may be that the choline requirement can be met by endogenous synthesis at some of these stages.

[h]Because 10 to 30% of older people may malabsorb food-bound vitamin B_{12}, it is advisable for those older than 50 years to meet their RDA mainly by consuming foods fortified with vitamin B_{12} or a supplement containing vitamin B_{12}.

[i]In view of evidence linking folate intake with neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μg from supplements or fortified foods in addition to intake of food folate from a varied diet.

[j]It is assumed that women will continue consuming 400 μg from supplements or fortified food until their pregnancy is confirmed and they enter prenatal care, which ordinarily occurs after the end of the periconceptional period—the critical time for formation of the neural tube.

TABLE A-16a Criteria and Dietary Reference Intake Values for Energy by Active Individuals by Life Stage Group*

		Active PAL† EER (kcal/d)	
Life Stage Group	*Criterion*	*Male*	*Female*
0–6 mo	Average consumption of protein from human milk	570	520 (3 mo)
7–12 mo	Nitrogen equilibrium + protein deposition	743	676 (9 mo)
1–2 yr	Nitrogen equilibrium + protein deposition	1,046	992 (24 mo)
3–8 yr	Nitrogen equilibrium + protein deposition	1,742	1,642 (6 yr)
9–13 yr	Nitrogen equilibrium + protein deposition	2,279	2,071 (11 yr)
14–18 yr	Nitrogen equilibrium + protein deposition	3,152	2,368 (16 yr)
> 18 yr	Nitrogen equilibrium	3,067‡	2,403‡ (19 yr)
Pregnancy			
14–18 yr	Adolescent female EER plus change in TEE plus pregnancy energy deposition		
1st trimester	2,368 (16 yr)		
2nd trimester	2,708 (16 yr)		
3rd trimester	2,820 (16 yr)		
19–50 yr	Adult female EER plus change in TEE plus pregnancy energy deposition		
1st trimester	2,403‡ (19 yr)		
2nd trimester	2,743‡ (19 yr)		
3rd trimester	2,855‡ (19 yr)		
Lactation			
14–18 yr	Adolescent female EER plus milk energy output minus weight loss		
1st 6 mo	2,698 (16 yr)		
2nd 6 mo	2,768 (16 yr)		

*For healthy, moderately active Americans and Canadians.
†EER = estimated energy requirement; PAL = physical activity level; TEE = total energy expenditure. The intake that meets the average energy expenditure of individuals at the reference height, weight, and age (see Table 1-1).
‡Subtract 10 kcal/day for males and 7 kcal/day for females for each year of age above 19 years.

TABLE A-16b Criteria and Dietary Reference Intake Values for Carbohydrate by Life Stage Group

		*EAR (g/kg/d)**		*RDA (g/kg/d)†*		
Life Stage Group	*Criterion*	*Male*	*Female*	*Male*	*Female*	*AI (g/kg/d)‡*
0–6 mo	Average content of human milk					60
7–12 mo	Average intake from human milk plus complementary foods					95
1–3 yr	Extrapolation from adult data	100	100	130	130	
4–8 yr	Extrapolation from adult data	100	100	130	130	
9–13 yr	Extrapolation from adult data	100	100	130	130	
14–18 yr	Extrapolation from adult data	100	100	130	130	
> 18 yr	Brain glucose use	100	100	0.80	130	
Pregnancy						
14–18 yr	Adolescent female EAR plus fetal brain glucose use	135	175			
19–50 yr	Adult female EAR plus fetal brain glucose use	135	175			
Lactation						
14–18 yr	Adolescent female EAR plus average human milk content of carbohydrate	160	210			
19–50 yr	Adult female EAR plus average human milk content of carbohydrate	160	210			

*EAR = Estimated Average Requirement. The intake that meets the estimated nutrient needs of half of the individuals in a group.
†RDA = Recommended Dietary Allowance. The intake that meets the nutrient need of almost all (97–98%) of individuals in a group.
‡AI - Adequate Intakes. The observed average or experimentally determined intake by a defined population or subgroup that appears to sustain a defined nutritional status, such as growth rate, normal. circulatory nutrient values, or other functional indicators of health. The AI is used if sufficient scientific evidence is not available to derive an EAR. For healthy infants receiving human milk, the AI is the mean intake. *The AI is not equivalent to an RDA.*

TABLE A-16c Criteria and Dietary Reference Intake Values for Protein by Life Stage Group

		AI or RDA for Reference Individual (g/d)		*EAR (g/kg/d)**		*RDA (g/kg/d)†*		
Life Stage Group	*Criterion*	*Males*	*Females*	*Males*	*Females*	*Males*	*Females*	*AI (g/kg/d)‡*
0– 6 mo	Average consumption of protein from human milk	9.1 (AI)	9.1 (AI)					1.52
7–12 mo	Nitrogen equilibrium + protein deposition	13.5	13.5	1.1	1.1	1.5	1.5	
1–3 yr	Nitrogen equilibrium + protein deposition	13	13	0.88	0.88	1.10	1.10	
4–8 yr	Nitrogen equilibrium + protein deposition	19	19	0.76	0.76	0.95	0.95	
9–13 yr	Nitrogen equilibrium + protein deposition	34	34	0.76	0.76	0.95	0.95	
14–18 yr	Nitrogen equilibrium + protein deposition	52	46	0.73	0.71	0.85	0.85	
> 18 yr	Nitrogen equilibrium	56	46	0.66	0.66	0.80	0.80	

*EAR = Estimated Average Requirement. The intake that meets the estimated nutrient needs of half of the individuals in a group.
†RDA = Recommended Dietary Allowance. The intake that meets the nutrient need of almost all (97–98%) of individuals in a group.
‡AI - Adequate Intakes. The observed average or experimentally determined intake by a defined population or subgroup that appears to sustain a defined nutritional status, such as growth rate, normal. circulatory nutrient values, or other functional indicators of health. The AI is used if sufficient scientific evidence is not available to derive an EAR. For healthy infants receiving human milk, the AI is the mean intake. *The AI is not equivalent to an RDA.*
The EAR and RDA for pregnancy are only for the second half of pregnancy. For the first half of pregnancy, the protein requirements are the same as those of the nonpregnant woman.
In addition to the EAR and RDA of the nonlactating adolescent or women.

Table A-17 Estimated Safe and Adequate Daily Dietary Intakes of Selected Minerals

		*Trace Elements**				
Category	*Age (yr)*	*Copper (mg)*	*Manganese (mg)*	*Fluoride (mg)*	*Chromium (µg)*	*Molybdenum (µg)*
Infants	0–0.5	0.4–0.6	0.3–0.6	0.1–0.5	10–40	15–30
	0.5–1	0.6–0.7	0.6–1.0	0.2–1.0	20–60	20–40
Children and adolescents	1–3	0.7–1.0	1.0–1.5	0.5–1.5	20–80	25–50
	4–6	1.0–1.5	1.5–2.0	1.0–2.5	30–120	30–75
	7–10	1.0–2.0	2.0–3.0	1.5–2.5	50–200	50–150
	11+	1.5–2.5	2.0–5.0	1.5–2.5	50–200	75–250
Adults		1.5–3.0	2.0–5.0	1.5–4.0	50–200	75–250

*Because the toxic levels for many trace elements may be only several times usual intakes, the upper levels for the trace elements given in this table should not be habitually exceeded.

Table A-18 Normal Electrolyte Requirements

Electrolyte	*Daily Requirement*
Sodium	2–4 mEq/kg
Potassium	2–3 mEq/kg
Chloride	2–3 mEq/kg
Magnesium	0.25–0.5 mEq/kg
Calcium	
Infants	300–400 mg/kg
Children	100–200 mg/kg
Adolescents	50–100 mg/kg
Phosphorus	
Infants	1–1.5 mmol/kg
Children	1 mmol/kg
Adolescents	0.5–1 mmol/kg

Adapted from Handbook of parenteral nutrition, Boston: Children's Hospital;

TABLE A-19 Fluid Requirement

Holliday-Segar Method	
1st 10 kg body weight	100 mL/kg
2nd 10 kg body weight	1,000 mL + 50 mL/kg > 10 kg
Each additional kg	1,500 mL + 20 mL/kg > 20 kg
Body Surface Area Method	
1,500 mL/m^2 24 hr	

Adapted data from Finberg L, et al. Water and electrolytes in pediatrics. Philadelphia: WB Saunders; 1982; and from Behrman R, et al. Nelson textbook of pediatrics. 13th ed. Philadelphia: WB Saunders; 1987.

TABLE A-20 Milliequivalent-Milligram Conversion Table

Mineral Element	*Chemical Symbol*	*Atomic Weight*	*Valence*
Calcium	Ca	40	2
Chlorine	Cl	35.4	1
Magnesium	Mg	24.3	2
Phosphorus	P	31	2
Potassium	K	39	1
Sodium	Na	23	1
Sulfur	S	32	2
Zinc	Zn	65.4	2
Sulfate	SO_4	96	2

$$\text{Milliequivalents} = \frac{\text{milligrams}}{\text{atomic weight}} \times \text{valence}$$

Example: Convert 2,000 mg sodium to mEq of sodium

$$\frac{2{,}000}{23} \times 1 = 87 \text{ mEq sodium}$$

To change milliequivalents back to milligrams, multiply the milliequivalents by the atomic weight and divide by the valence.

Example: Convert 20 mEq sodium to mg sodium

$$\frac{20 \times 23}{1} = 460 \text{ mg sodium}$$

Adapted from Hendricks KM, Duggan C, Walker WA. Manual of pediatric nutrition. Hamilton (ON): BC Decker; 2000.

TABLE A-21 Definitions of Nutritional Requirements*

Term		*Abbreviation*	*Year Introduced*	*Definition/Use*
Old	Recommended Dietary Allowances	RDAs	1943	Average daily dietary intake value sufficient to meet the requirement of nearly all (97–98%) healthy individuals in a group; more recently, the term has been calculated as EAR plus 2 SD of the EAR (see below)
New	Dietary Reference Intakes	DRIs	1994	Umbrella term including RDA, EAR, AI, and UL (see below)
	Estimated Average Requirement	EAR	1994	A nutrient intake value estimated to meet the requirement of half the individuals in a group
	Adequate Intake	AI	1994	(Used when no EAR is available and no RDA can therefore be calculated) Nutrient intake value based on observed or experimentally determined approximations of nutrient intakes in a group or groups of healthy people
	Tolerable Upper Intake level	UI	1994	The highest level of daily nutrient intake that is likely to pose no risks of adverse health effects to almost all individuals in the general population

Adapted from Duggan C. Nutritional requirements. In: Walker WA, Durie PR, Hamilton JR, et al, editors. Pediatric gastrointestinal disease: pathophysiology, diagnosis, management. Hamilton (ON): BC Decker; 2000.
*Set by the Food and Nutrition Board of the Institute of Medicine of the National Academy of Sciences.

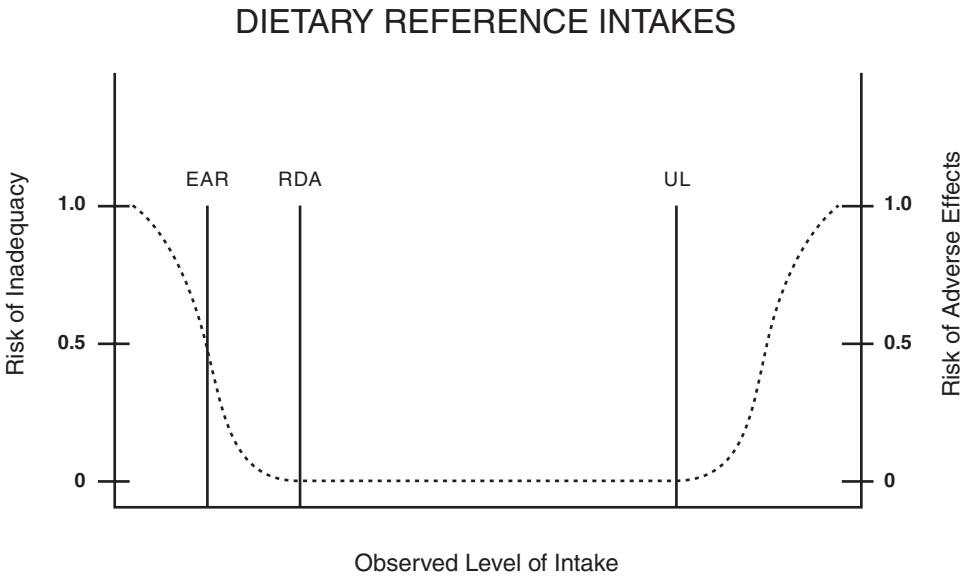

FIGURE A-25 The relationship between estimated average requirement (EAR), Recommended Dietary Allowance (RDA), and tolerable upper intake level (UL). The risk of inadequate intake is 50% at the EAR, 2 to 3% at the RDA, and close to 0% at the UL. Risks of adverse effects are close to 0% at the UL but increase with increasing intake. Reproduced with permission from the Standing Committee on the Scientific Evaluation of Dietary Reference Intakes, Food and Nutrition Board, Institute of Medicine. Dietary Reference Intakes for calcium, phosphorus, magnesium, vitamin D, and fluoride. Washington (DC): National Academy Press; 1997.

Table A-22 Median Heights and Weights and Recommended Energy Intake

Category	Age (yr) or Condition	Weight (kg)	Weight (lb)	Height (cm)	Height (in)	REE* (kcal/d)	Average Energy Allowance (kcal)† Multiples of REE	Average Energy Allowance (kcal)† Per kg	Average Energy Allowance (kcal)† Per day‡

Table A-23 Schofield Equations for Calculating Basal Metabolic Rate in Children

Males	
0–3 yr	REE = 0.167W + 15.174H – 617.6
3–10 yr	REE = 19.59W + 1.303H + 414.9
10–18 yr	REE = 16.25W + 1.372H + 515.5
> 18 yr	REE = 15.057W + 1.004H + 705.8
Females	
0–3 yr	REE = 16.252W + 10.232H – 413.5
3–10 yr	REE = 16.969W + 1.618H + 371.2
10–18 yr	REE = 8.365W + 4.65H + 200
> 18 yr	REE = 13.623W + 23.8H + 98.2

Adapted from Schofield W. Predicting basal metabolic rate, new standards and review of previous work. Hum Nutr Clin Nutr 1985;39C Suppl 1:5–41.
Resting energy expenditure (REE) = kcal/day; W = weight (kg); H = height (cm).

TABLE A-24 Equations for Predicting Basal Metabolic Rate from Body Weight in Kilograms

Age Range (yr)	Kcal/kg per day
Males	
0–3	60.9 W – 54
3–10	22.7 W + 495
10–18	17.5 W + 651
18–30	15.3 W + 679
30–60	11.6 W + 879
> 60	13.5 W + 487
Females	
0–3	61.0 W – 51
3–10	22.5 W + 499
10–18	22.2 W + 746
18–30	14.7 W + 496
30–60	8.7 W + 829
> 60	10.5 W + 596

TABLE A-32 Increasing the Caloric Density of Human Milk and Infant Formula

kcal/oz	*Human Milk Milk Volume*	*Powdered Standard Infant Formula*
24	4 oz	1¼ tsp
30	4 oz	1 T
	Infant Formula (Powdered)	
kcal/oz	*Amount Powder*	*Volume Water*
24	1¼ cup	29 oz (32/3 cups)
30	1½ cup	29 oz (32/3 cups)
	Infant Formula (Liquid Concentrate)	
kcal/oz	*Volume Concentrate*	*Volume Water*
24	13 oz (1 can)	8 oz (1 cup)
28	13 oz (1 can)	5.5 oz (1 cup)
30	13 oz (1 can)	4 oz (½ cup)

Other Additives

Medium-chain triglyceride oil contains 7.7 kcal/mL; 1 tsp contains 39 kcal
Vegetable oil contains 40 kcal/tsp
Polycose liquid contains 60 kcal/oz; polycose powder contains 8 kcal/tsp

TABLE A-33 Composition of Special Infant Formulas

Formula	*Protein g/dL*	*Protein Source*	*Fat g/dL*	*Fat Source*	*Carbohydrate g/dL*	*Carbohydrate Source*	*Na mg/L*	*K mg/L*	*Ca mg/L*	*P Mg/L*	*Indications*	*Manufacturer*
Alimentum	1.9	Casein hydrolysate	3.7	50% MCT, 50% LCFA	6.9	Sucrose, modified tapioca starch	297	797	709	507	Multiple food allergies, impaired GI function	Ross
Pregestimil	1.9	Casein hydrolysate	3.8	55% MCT, 45% LCFA	6.9	Corn syrup solids, modified cornstarch, dextrose	264	736	635	426	Multiple food allergies, impaired GI function	Mead Johnson
Portagen	2.4	Na caseinate	3.2	85% MCT, 15% LCFA*	7.8	Corn syrup solids, sucrose	372	845	635	473	Fat malabsorption	Mead Johnson
Neocate Infant	2.5	Amino acids	3	Safflower, coconut, soy	7.8	Corn syrup solids	249	1,034	827	621	Multiple food allergies	SHS North America
Nutramigen	1.9	Casein hydrolysate + added amino acids	3.4	Palm olein, soy, coconut, high-oleic safflower oil	7.5	Corn syrup solids, modified cornstarch	320	740	640	430	Protein/ malabsorption problems	Mead Johnson

*Only 3.5% of calories are derived from linoleic acid. Supplementation with essential fatty acid mixture may be required.
GI = gastrointestinal; LCFA = long-chain fatty acid; MCT = medium-chain triglyceride.

TABLE A-34 Enteral Products Grouped by Usage Indication

Standard adult oral	Boost, Ensure High Calcium, Ensure, Ensure Light, NuBasics, ReSource Standard
Standard adult tube feeding	FiberSource Standard, Isocal, Isosource Standard, Jevity, Nutren 1.0, Osmolite, Ultracal
High-protein oral	Boost High Protein, Ensure High Protein, Ensure Plus HN, Meritene, NuBasics VHP
High-protein tube feeding	FiberSource HN, Isocal HN, Isosource HN, Jevity Plus, Osmolite HN, Osmolite HN Plus, ProBalance, Promote, Ultracal HN Plus
1.5 calorie/mL	Boost Plus, Comply, Ensure Plus, NuBasics Plus, Nutren 1.5, ReSource Plus
2.0 calorie/mL	Deliver 2.0, NovaSource 2.0, NuBasics 2.0, Nutren 2.0, ReSource 2.0, TwoCal HN
Standard Pediatric (> 1 yr of age)	Kindercal, Kindercal TF, Nutren Jr., Pediasure, ReSource Just For Kids
Blenderized	Compleat, Compleat Pediatric
Clear fortified liquid	Citrotein, Enlive, ReSource Fruit Beverage
Peptide-based adult	Alitraq, Criticare HN, Peptamen, Peptamen 1.5, Peptamen VHP, Perative, SandoSource Peptide, Vital High Nitrogen
Peptide-based pediatric	Pepdite One+, Peptamen Jr.
Free amino acid adult	EO28 Extra, Tolerex, Vivonex T.E.N., Vivonex Plus, Vivonex RTF
Free amino acid pediatric (> 1 yr of age)	Elecare, Neocate Junior, Neocate One+, Pediatric EO28, Vivonex Pediatric
Immune enhancing	Immun-Aid, Impact, Impact 1.5, Impact Glutamine
Wound healing	Crucial, Intensical, Isosource VHN, NutriFocus, Protain XL, Reabilan, Reabilan HN, Replete, Traumacal
Diabetes	Choice dm beverage, Choice dm TF, DiabetiSource, Glucerna, Glytrol, ReSource Diabetic
Kidney disease	Amin-Aid, Magnacal Renal, Nepro, NovaSource Renal, NutriRenal, Renalcal Diet, Suplena
Liver disease	Hepatic-Aid, NutriHep
Pulmonary disease	Isosource 1.5, NovaSource Pulmonary, NutriVent, Oxepa, Pulmocare, Respalor
HIV/AIDS	Advera
Inflammatory bowel disease	Modulen, Optimental, Subdue, Subdue Plus
Fat malabsorption	Lipisorb, Portagen
Carbohydrate modulars	Moducal, Polycose
Protein modulars	Casec, ProMod
Calorie enhancers	Additions, Duocal, PFD2, Product 3232A, Product 80056
Fat modulars	MCT oil, Microlipid

AIDS = acquired immune deficiency syndrome; HIV = human immunodeficiency virus; MCT = medium-chain triglyceride.

TABLE A-35 Selected Enteral Products for Special Indications

Product	*Energy, kcal/L*	*Protein Source, g/L*	*Carbohydrate Source, g/L*	*Fat Source, g/L*	*Fiber g/L*	*Purpose*
Advera*	1,280	Soy protein hydrolysate, Na caseinate, 60	Maltodextrin, sucrose, soy fiber, 215.8	Canola, MCT (19%) and sardine oils, 22.8	8.9	High-calorie, high-protein complete formula, designed for people with HIV or AIDS
Additions	526/ 100 g	Na caseinate, whey protein isolate, 31.6/100 g	Corn syrup solids, 47.4/100 g	Canola oil, soy lecithin, 26.3/100 g		Neutral-flavored powdered blend of protein, carbohydrate, and fat used to supplement regular food
Alitraq*	1,000	Soy hydrolysate, amino acids, whey protein concentrate, lactalbumin hydrolysate, 52.5	Maltodextrin, sucrose, fructose, 165	Safflower and MCT (53%) oils, 15.5		Elemental formula with added glutamine, designed for patients with impaired GI function
Amin-aid‡	1,956	Essential amino acids + histidine, 19.4	Maltodextrin, sucrose, 366	Partially hydrogenated soybean oil, lecithin, 46.2		Essential amino acid and calorie supplement for patients with renal failure; contains no vitamins or minerals
Boost (with fiber)§	1,010	Milk protein concentrate, 43	Corn syrup solids, sucrose (soy fiber, acacia, microcrystalline cellulose), 173 (178)	Canola, high-oleic sunflower, and corn oils, 18	(11.1)	Nutritionally complete liquid food, lactose free
Boost High Protein§	1,010	Milk protein concentrate, Na and Ca caseinate, 61	Corn syrup solids, sucrose, 139	Canola, high-oleic sunflower, and corn oils, 23		High-protein, nutritionally complete oral supplement
Boost Plus§	1,520	Na and Ca caseinate, 59	Corn syrup solids, sucrose, 200	Canola, high-oleic sunflower and corn oils, 58		High-calorie nutritionally complete oral supplement
Casec§	380/ 100 g	Ca caseinate, 90/100 g	0	Soy lecithin, 2/100 g		Concentrated, intact, powdered protein supplement
Choice dm beverage§	930	Ca and Na caseinate, milk protein concentrate, 39	Maltodextrin, sucrose, soy fiber, acacia, microcrystalline cellulose, 93	Canola, high-oleic sunflower, and corn oils, 43	11	Fiber-containing oral supplement, designed for people with diabetes
Choice dm TF§	1,060	Milk protein concentrate, casein, 45	Maltodextrin, micro-crystalline cellulose, soy fiber, acacia, 119	Canola, high-oleic sunflower, corn, and MCT (10%) oils, 51	14.4	Nutritionally complete tube feeding with fiber for patients with abnormal glucose tolerance
Citrotein‖	730	Pasteurized egg white solids, 41	Sucrose, maltodextrins, 120	Mono- and diglycerides, soybean oil, 1.6		Clear, fruit-flavored liquid nutrition, low in fat, lactose and gluten free
Compleat‖	1,070	Beef, Ca caseinate, 43	Hydrolyzed cornstarch, fruits, vegetables, 140	Canola oil, beef, 37	4.3	Blenderized tube feed formulated from traditional foods
Compleat Pediatric‖	1,000	Beef, Na and Ca caseinate, 38	Hydrolyzed cornstarch, fruits, vegetables, apple juice, 130	High-oleic sunflower, soybean, MCT (18%) oils, 39	4.4	Intact protein, formulated from traditional foods including meats, vegetables, and fruit
Comply§	1,500	Na and Ca caseinate, 60	Maltodextrin, 180	Canola, high-oleic sunflower, MCT (20%), and corn oils, 61		Nutritionally complete, high calorie formula for tube feeding
Criticare HN§	1,060	Casein hydrolysate, amino acids, 38	Maltodextrin, modified cornstarch, 220	Safflower oil, emulsifiers, 5.3		Ready-to-use elemental formula—50% small peptides, 50% amino acids
Crucial	1,500	Hydrolyzed casein, L-arginine, 94	Maltodextrin, 135	MCT oil (50%), deodorized fish oil, soy oil, soy lecithin, 68		High-calorie and protein peptide-based formula designed for critically ill patients
Deliver 2.0§	2,000	Na and Ca caseinate, 75	Corn syrup, 200	Soy and MCT (30%) oils, 101		High-calorie and high-nitrogen complete liquid diet

Continues

TABLE A-35 Selected Enteral Products for Special Indications (Continued)

Product	*Energy, kcal/L*	*Protein Source, g/L*	*Carbohydrate Source, g/L*	*Fat Source, g/L*	*Fiber g/L*	*Purpose*
DiabetiSource[‖]	1,000	Ca caseinate, beef, 50	Maltodextrin, fructose, vegetables, fruits, 90	High-oleic sunflower, canola, and beef oils, 49	4.3	Traditional food ingredients, designed for abnormal glucose tolerance
Duocal[#]	490/ 100 g	0	Hydrolyzed cornstarch, 73	Corn, coconut, MCT (35%) oils, 22		Powdered carbohydrate and fat supplement
Elecare*	1,000	Free L-amino acids, 30	Corn syrup solids, 107	High-oleic safflower, MCT (33%) and soy oils, 48		Complete amino acid–based diet for children > 1 yr of age with intact protein intolerance
EO28 Extra (flavored)[#]	886 (854)	Free amino acids, 25	Dried glucose syrup (sugar, sodium saccharin, dried glucose syrup), 118 (110)	MCT (35%), canola, hybrid safflower oils, 35		Nutritionally complete elemental diet for adults and children > 5 yr of age with GI impairment
Enlive*	1,250	Whey protein isolate, 41	Maltodextrin, sucrose, 267	0		High-calorie, fat-free clear liquid oral supplement
Ensure Fiber with FOS*	1,060	Na and Ca caseinate, soy protein isolate, 38	Maltodextrin, sucrose, soy fiber, oat fiber, fructo-oligosaccharides, 177	High-oleic safflower, canola, and corn oils, 26	11.8	Complete or supplemental nutrition with fiber and FOS
Ensure*	1,060	Ca caseinate, soy protein isolate, whey protein concentrate, 37.2	Corn syrup, sucrose, maltodextrin, 167	Corn, high-oleic safflower, and canola oils, 25		Nutritionally complete oral supplement
Ensure High Calcium*	950	Ca and Na caseinates, soy protein isolate, 51	Sucrose, maltodextrin, 131	High-oleic safflower, canola, and soy oils, 25		Supplemental high-protein oral nutrition with 1,688 mg Ca/L
Ensure High Protein*	950	Ca and Na caseinates, soy protein isolate, 51	Sucrose, maltodextrin, 131	High-oleic safflower, canola, and soy oils, 25		High-protein complete oral nutritional supplement
Ensure Light*	850	Ca caseinate, 42	Sucrose, maltodextrin, 141	High-oleic safflower and canola oils, 13		Lower-calorie, lower-fat nutritionally complete oral supplement
Ensure Plus*	1,500	Na and Ca caseinate, soy protein isolate, 55	Corn syrup, maltodextrin, sucrose, 211	High-oleic safflower, canola, and corn oils, 48		High-calorie, complete oral supplement
Ensure Plus HN*, flavored (unflavored RTH)	1,500	Na and Ca caseinate, soy protein isolate, 62 (63)	Maltodextrin, sucrose (maltodextrin), 200 (204)	Corn oil (high-oleic safflower, canola, and MCT [20%] oils), 50 (49)		High-calorie, high-nitrogen nutritionally complete liquid for oral supplementation or tube feeding
f.a.a.	1,000	Free amino acids, 50	Maltodextrin, cornstarch, 176	Soybean and MCT (25%) oils, 11.2		Low-fat elemental diet with 20% of calories from free amino acids
FiberSource Standard II	1,200	Soy concentrate, soy isolate, 43	Corn syrup, hydrolyzed cornstarch, 170	Canola and MCT (20%) oils, 39	10	Higher calories, contains soluble and insoluble fiber
FiberSource HN[‖]	1,200	Soy isolate, soy concentrate, 53	Corn syrup, hydrolyzed cornstarch, 160	Canola and MCT (20%) oils, 39	10	Higher calories and protein; contains soluble and insoluble fiber
Glucerna*	1,000	Na and Ca caseinate, 41.8	Maltodextrin, fructose, soy fiber, 95.6	High-oleic safflower and canola oils, soy lecithin, 54.4	14.1	Supplemental or complete tube feeding or oral nutrition for patients with abnormal glucose tolerance
Glytrol	1,000	Ca and K caseinate, 45	Maltodextrin, corn starch, fructose, gum arabic, pectin, soy polysaccharides, 100	Canola, high-oleic safflower, and MCT (20%) oils, soy lecithin, 47.5	15	Fiber containing, fat and CHO designed for better glucose control
HepaticAid[‡]	1,176	L-Amino acids, 44	Maltodextrin, sucrose, 169	Partially hydrogenated soybean oil, lecithin, mono- and diglycerides, 36		High BAA and calorie supplement for patients with chronic liver disease; contains no vitamins or minerals
Immun-Aid[‡]	1,000	Lactalbumin, supplemental amino acids, 80	Maltodextrin, 120	MCT (50%) and canola oils, 22		High-nitrogen nutritionally complete feeding for immunocompromised patients

TABLE A-35 Selected Enteral Products for Special Indications (Continued)

Product	*Energy, kcal/L*	*Protein Source, g/L*	*Carbohydrate Source, g/L*	*Fat Source, g/L*	*Fiber g/L*	*Purpose*
Impact (with fiber)[‖]	1,000	Na and Ca caseinate, L-arginine, 56	Hydrolyzed cornstarch, 130 (140)	Palm kernel, sunflower, and menhaden oils, 28 (10)		High protein; designed for critically ill patients
Impact Glutamine[‖]	1,300	Wheat protein hydrolysate, free amino acids, sodium caseinate, 78	Maltodextrin, 150	Palm kernel, menhaden, and sunflower oils, 43		High-glutamine (15 g/L), immune-enhancing enteral formula for critically ill patients
Intensical[§]	1,300	Casein hydrolysate, L-arginine, 81	Maltodextrin, modified cornstarch, 150	Canola, MCT (25%), high-oleic sunflower, corn, refined menhaden oils, 42		Complete elemental nutrition for highly metabolically stressed patients
Impact 1.5[‖]	1,500	Na and Ca caseinate, L-arginine, 84	Hydrolyzed cornstarch, 140	Palm kernel and sunflower oils, menhaden and MCT (55%) oils, 69		High calorie and high protein; designed for critically ill patients
Isocal[§]	1,060	Ca and Na caseinate, soy protein isolate, 34	Maltodextrin, 135	Soy and MCT (20%) oils, 44		Nutritionally complete, isotonic, tube feeding formula
Isocal HN[§]	1,060	Na and Ca caseinate, soy protein isolate, 44	Maltodextrin, 124	Soy and MCT (40%) oils, 45		Moderately high-nitrogen, isotonic, nutritionally complete tube feeding
Isocal HN Plus[§]	1,200	Milk protein concentrate, casein, 54	Maltodextrin, 156	Canola, MCT (30%), high-oleic sunflower and corn oils, 40		Moderately high-nitrogen, 1.2 calorie/mL, nutritionally complete tube feeding
Isosource Standard[‖]	1,200	Soy isolate, 43	Corn syrup, hydrolyzed cornstarch, 170	Canola and MCT (20%) oils, 39		High-calorie soy protein formula
Isosource 1.5 Cal[‖]	1,500	Na and Ca caseinate, 68	Hydrolyzed cornstarch, sugar, 170	Canola, MCT (30%), and soybean oils, 65	8	High calorie, high nitrogen; contains soluble and insoluble soy fiber
Isosource HN[‖]	1,200	Soy isolate, 53	Corn syrup, hydrolyzed cornstarch, 160	Canola and MCT (20%) oils, 39		High-nitrogen, high-calorie soy protein formula
Isosource VHN[‖]	1,000	Na and Ca caseinate, 62	Hydrolyzed cornstarch, 130	Canola and MCT (50%) oils, 29	10	High nitrogen, isotonic; contains soluble and insoluble fiber
Jevity*	1,060	Na and Ca caseinate, 44.3	Maltodextrin, soy fiber, corn syrup, 155	High-oleic safflower, canola, and MCT (20%) oils, 34.7	14.4	Isotonic fiber-containing nutritionally complete tube feeding formula
Jevity Plus*	1,200	Na and Ca caseinate, 56	Corn syrup, maltodextrin, fructo-oligosaccharides, fiber blend, 173	High-oleic safflower, canola, and MCT (19%) oils, 39.3	12	Higher-calorie, high-protein, fiber-containing tube feeding
Kindercal (with fiber)[§]	1,060	Milk protein concentrate, 30	Maltodextrin, sucrose, 135	Canola, high-oleic sunflower, corn, and MCT (20%) oils, 44 (6.3)		Nutritionally complete, lactose-free oral beverage for children 1–10 yr
Kindercal TF (with fiber)[§]	1,060	Milk protein concentrate, 30	Sugar, maltodextrin, 135	Canola, high-oleic sunflower, MCT (20%), and corn oils, 44 (6.3)		Nutritionally complete, isotonic, lactose-free tube feeding for children 1–10 yr of age
Lipisorb Liquid[§]	1,350	Na and Ca caseinate, 57	Maltodextrin, sucrose, 161	MCT (85%) and soy oils, 57		Nutritionally complete MCT formulation for patients with fat malabsorption
MCT oil[§]	115 kcal/tbsp, 8.3 kcal/g	—	—	Fractionated coconut oil, 934		Fat supplement or substitute for patients with long-chain fatty acid malabsorption; directly absorbed into portal vein
Magnacal Renal[§]	2,000	Na and Ca caseinate, 75	Maltodextrins, sucrose, 200	Canola, high-oleic sunflower, MCT (20%), and corn oils, 101		Very-high-calorie, complete oral or tube feeding formula designed for patients on hemodialysis

Continues

TABLE A-35 Selected Enteral Products for Special Indications (Continued)

Product	*Energy, kcal/L*	*Protein Source, g/L*	*Carbohydrate Source, g/L*	*Fat Source, g/L*	*Fiber g/L*	*Purpose*
Meritene[‖] (mixed with whole milk)	1,080	Nonfat and whole milk, 69	Lactose, corn syrup solids, sucrose, 120	Milk fat, 34		High-protein oral supplement, concentrated with vitamins and minerals, low in fat and cholesterol, high calcium, gluten free; mix with whole or skim milk
Microlipid[§]	4,500	—	—	Safflower oil, 506		50% fat emulsion for special dietary use in oral or tube feeding formulas
Moducal[§]	375 kcal/ 100 g	—	—	Maltodextrin, 95 g/100 g		Powdered, low-osmolality calorie supplement consisting of glucose polymers
Modulen IBD[†]	1,000	Acid casein, 36	Sugar, 108	Milk fat, MCT (25%), and corn oils, 46		Oral intact protein formula designed for people with Crohn's disease
Neocate Jr.[#]	1,000	Free amino acids, 30	Corn syrup solids, 104	MCT (35%), canola, hybrid safflower oils, 50		Nutritionally complete elemental formula for children > 1 yr with severe GI impairment; more vitamins and minerals than Neocate 1+
Neocate 1+[#]	1,000	Free amino acids, 25	Corn syrup solids, 146	MCT (35%), canola, hybrid safflower oils, 35		Elemental diet suitable for children > 1 yr with protein hypersensitivity or allergy
Nepro*	2,000	Ca, Mg, and Na caseinate, milk protein isolate, 70	Corn syrup, sucrose, fructo-oligosaccharides, 222.3	High-oleic safflower and canola oils, 95.6		Very-high-calorie, complete oral or tube feeding designed for dialysis patients
NovaSource Pulmonary[‖]	1,500	Na and Ca caseinates, 75	Corn syrup, sugar, 150	Canola and MCT (20%) oils, 68	8	High-calorie and nitrogen formula, designed for pulmonary patients
NovaSource Renal[‖]	2,000	Na and Ca caseinate, L-arginine, 74	Corn syrup, frucrose, 200	High-oleic sunflower corn, and MCT (14%) oils, 100		Very high calorie; vitamin and mineral profile specifically formulated for dialysis patients, TetraBrik Pak
NovaSource 2.0[‖]	2,000	Ca and Na caseinate, 90	Corn syrup, sucrose, maltodextrin, 220	Canola and MCT (20%) oils, 87.5		Very high calorie, high nitrogen, reduced level of sodium, TetraBrik Pak
NuBasics[†]	1,000	Ca caseinate, 35	Corn syrup solids, sucrose, 132.4	Canola and corn oils, soy lecithin, 36.8		Oral supplement, lactose free, gluten free
NuBasics Plus[†]	1,500	Ca caseinate, 52.4	Corn syrup solids, sucrose, 176.4	Canola and corn oils, soy lecithin, 64.8		High-calorie, lactose-free, oral supplement
NuBasics 2.0[†]	2,000	Ca and K caseinate, 80	Corn syrup solids, maltodextrin, sucrose, 196	MCT oil (75%), canola, soy lecithin, corn oils, 106		Very high calorie; 75% of fat from MCT
NuBasics VHP[†]	1,000	Ca and K caseinate, 62.4	Corn syrup solids, sucrose, 112.8	Canola and corn oils, soy lecithin, 33.2		High-protein, lactose-free, oral supplement
Nutren 1.0 (fiber)	1000	Ca and K caseinate, 40	Maltodextrin, corn syrup solids (soy polysaccharides), 127	Canola, MCT (25%), corn oils, soy lecithin, 38 (14)		Complete liquid nutrition, fiber for management of diarrhea or constipation
Nutren 1.5[†]	1,500	Ca and K caseinate, 60	Maltodextrin, 169.2	MCT (50%), canola, corn oils, soy lecithin, 67.6		High calorie for fluid restriction; 50% MCT oil
Nutren 2.0[†]	2,000	Ca and K caseinate, 80	Corn syrup solids, maltodextrin, sucrose, 196	MCT (75%), canola, soy lecithin, corn oils, 106		Very high calorie; severe fluid restriction; 75% MCT oil
Nutren Jr[†] (fiber)	1,000	Casein, whey, 30	Maltodextrin, sucrose (soy polysaccharides), 127.5	MCT (25%), canola, and soybean oils, soy lecithin, 42 (6)		Balanced formula designed to meet needs of children ages 1–10 yr

TABLE A-35 Selected Enteral Products for Special Indications (Continued)

Product	*Energy, kcal/L*	*Protein Source, g/L*	*Carbohydrate Source, g/L*	*Fat Source, g/L*	*Fiber g/L*	*Purpose*
NutriFocus	1,500	Na caseinate, milk protein isolate, soy protein isolate, arginine, 62	Corn syrup, sucrose, fiber blend, fructo-oligosaccharides, 215	Canola, corn, and high-oleic safflower oils, 49	10.5	High-calorie, high-protein oral supplement used for wound healing
NutriHep†	1,500	L-Amino acids, whey protein (50% BCAAs), 40	Maltodextrin, modified corn starch, 290	MCT (66%), canola, soy lecithin, and corn oils, 21.2		High BCAAs, low aromatic and ammonogenic amino acids
NutriRenal†	2,000	Ca and K caseinate, 70	Corn syrup solids, maltodextrin, sucrose, 205	MCT (50%), canola, corn oils, 104		High calorie, high biologic protein; designed for the dialyzed patient
NutriVent†	1,500	Ca and K caseinate, 67.5	Maltodextrin, 100	Canola, MCT (40%), corn oils, soy lecithin, 94		High fat content; designed to reduce CO_2 production
Optimental*	1,000	Soy protein hydrolysate, partially hydrolyzed Na caseinate, free arginine, 51	Maltodextrin, sucrose, fructo-oligosaccharides, 139	Sardine oil/MCT structured lipid, canola, and soybean oils, 28		Complete elemental oral or tube feeding formula designed for patients with malabsorptive conditions
Osmolite*	1,060	Na and Ca caseinates, soy protein isolate, 37	Maltodextrin, 151	High-oleic safflower, canola, and MCT (20%) oils, 35		Isotonic, low residue, complete nutrition for oral or tube feeding use
Osmolite HN*	1,060	Na and Ca caseinates, soy protein isolate, 44	Maltodextrin, 144	High-oleic safflower, canola, and MCT (20%) oils, 35		Isotonic, nutritionally complete, high-nitrogen, mild-flavored liquid for oral or tube feeding
Osmolite HN Plus*	1,200	Na and Ca caseinates, 56	Maltodextrin, 158	High-oleic safflower, canola, MCT (19%) oils, 39		High calorie, high nitrogen, complete oral or tube feeding
Oxepa	1,500	Na and Ca caseinates, 63	Sucrose, maltodextrin, 106	Canola, MCT (25%), borage and refined, deodorized sardine oils, 94		High-calorie complete tube feeding formula for patients with lung injury
Pediasure and Pediasure Enteral* (with fiber)	1,000	Na caseinate, whey protein concentrate, 30	Maltodextrin, sucrose, 110 (114)	High-oleic safflower, soy, and MCT (20%) oils, 50 (5)		Complete oral or tube feeding designed for patients ages 1–10 yr
Pediatric EO28#	1,000	Free amino acids, 25	Maltodextrin, sucrose, 146	MCT (33%), canola, high-oleic safflower oils, 35		Ready-to-feed, flavored elemental liquid for children > 1 yr old with severe GI impairment
Pepdite One+# (banana flavored)	1,000	Soy and pork hydrolysates, free amino acids, 31	Corn syrup solids (sucrose, aspartame), 106	MCT (35%), canola, safflower oils, 50		Semielemental formula for children > 1 yr old with severe GI impairment
Peptamen† (oral)	1,000	Enzymatically hydrolyzed whey, 40	Maltodextrin, cornstarch (sucrose), 127	MCT (70%), soybean, soy lecithin, 39		Peptide based, isotonic; designed for general malabsorption
Peptamen 1.5 (oral)	1,500	Enzymatically hydrolyzed whey, 60	Maltodextrin, cornstarch (sucrose), 191	MCT (70%), soybean, soy lecithin, 58.5		High calorie, peptide based, high percentage MCT oil designed for malabsorption
Peptamen VHP† (oral)	1,000	Enzymatically hydrolyzed whey, 62.5	Maltodextrin, cornstarch (sucrose), 104.5	MCT (70%), soybean, soy lecithin, 39.2		High protein, peptide based, high percentage MCT oil designed for general malabsorption
Peptamen Jr.† (oral)	1,000	Enzymatically hydrolyzed whey, 30	Maltodextrin, cornstarch (sucrose), 137.6	MCT (60%), soybean, and canola oils, soy lecithin, 38.5		Designed for children ages 1–10 yr, peptide based, 60% of fat from MCT oil
Perative*	1,300	Partially hydrolyzed Na caseinate, lactalbumin hydrolysate, L-arginine, 66.6	Maltodextrin, 177.2	Canola, MCT (40%), and corn oils, 37.4		Higher calorie; 40% of fat from MCT oil; designed for metabolically stressed patients
PFD 2§	400/100 g powder	26 mg taurine/100 g powder, 0	Corn syrup solids, sugar, modified cornstarch, 88/100 g	Soy oil, 4.8/100 g		Protein-free powdered supplement providing calories, vitamins, and minerals

TABLE A-35 Selected Enteral Products for Special Indications (Continued)

Product	*Energy, kcal/L*	*Protein Source, g/L*	*Carbohydrate Source, g/L*	*Fat Source, g/L*	*Fiber g/L*	*Purpose*
Polycose*	380/100 g powder, 2,000/L liquid	—	Glucose polymers from cornstarch, 94/100 g, 500/L	—		CHO calorie supplement, available in powder or liquid
Portagen (20 kcal/oz. dilution)[§]	67.6/ 100 mL	Sodium caseinate, 2.3 g/100 mL	Corn syrup solids, sucrose, 7.7 g/100 mL	MCT (86%) and corn oils, 3.2 g/100 mL		Nutritionally complete for infants and children < 2 yr; with inefficient conventional fat digestion or malabsorption, 3.6% kcal from linoleic acid
ProBalance[†]	1,200	Ca and K caseinate, 54	Maltodextrin, corn syrup solids, polysaccharides, gum arabic, 156	Canola, MCT (20%), and corn oils, soy lecithin, 40.8	10	Higher calorie, fiber containing for the mature adult
Product 3232A[§]	500/ 100 g powder	Casein hydrolysate, 22 g/100 g	Modified tapioca starch, 33 g/100 g	MCT (85%) and corn oils, 33 g/100 g		Protein hydrolysate formula free of mono- and disaccharides for use with added carbohydrate
Product 80056[§]	500/ 100 g powder	Taurine added, 0	Corn syrup solids, modified tapioca starch, 72/100 g	Corn oil, 23/100 g		Protein-free formula base for use with added protein, sodium, potassium, and chloride
ProMod*	4.2/g	Whey protein concentrate with lecithin, 75/100 g	—, < 10/100 g	—, < 9/100 g		Powdered protein supplement
Promote* (with fiber)	1,000	Sodium and calcium caseinate, soy protein isolate, 62.5	Maltodextrin, sucrose (oat and soy fiber), 130 (138)	High-oleic safflower, canola, MCT (19%) oil, soy lecithin, 26 (28)	(14.4)	High protein complete oral or tube feeding
Protain XL[§]	1,000	Na and Ca caseinate, 57	Maltodextrin, soy fiber, 145	Canola, high-oleic sunflower, MCT (20%) and corn oils, 30	9.1	Nutritionally complete, high protein, fiber containing; designed to aid with wound healing
Pulmocare*	1,500	Na and Ca caseinates, 62.6	Sucrose, maltodextrin, 106	Canola, MCT (20%), high-oleic safflower and corn oils, 93.3		High fat, low carbohydrate, complete oral or tube feeding; designed for pulmonary patients
Reabilan[†]	1,000	Enzymatically hydrolyzed casein and whey, 31.5	Corn syrup solids, cornstarch, 131.5	MCT (50%), soybean, and canola oils; soy lecithin; glyceryl monostearate, 40.5		Peptide based, low nitrogen, 50% of oil from MCT
Reabilan HN[†]	1,333	Enzymatically hydrolyzed casein and whey, 57.9	Corn syrup solids, cornstarch, 158	MCT (50%), soybean, and canola oils; soy lecithin; glyceryl monostearate, 54		Higher calorie, peptide based, 50% of oil from MCT; designed for GI impairment
Renalcal Diet[†]	2,000	Essential and select non-essential amino acids, whey protein, 34.4	Maltodextrin, modified cornstarch, 290.4	MCT (70%), canola, and corn oils; soy lecithin, 82.4		Very high calorie, low protein; designed to maintain positive nitrogen balance, added histidine for renal failure, negligible electrolytes
Replete[†] (with fiber)	1,000	Ca and K caseinate, 62.4	Maltodextrin, corn syrup solids (soy polysaccharides), 113.2	Canola and MCT (25%) oils, soy lecithin, 34 (14)		High protein, elevated vitamin and mineral profile; designed for wound healing
ReSource Diabetic[‖]	1,060	Na and Ca caseinates, soy protein isolates, 63	Hydrolyzed cornstarch, 100	High-oleic sunflower and soybean oils, 47	13	Fiber containing; designed for diabetics; TetraBrik Pak
ReSource Fruit Beverage[‖]	1,060	Whey protein isolate, 38	Sugar, corn syrup, 230	0		Fat-free clear liquid nutritional supplement
ReSource Just For Kids[‖] (with fiber)	1,000	Na and Ca caseinate, whey protein concentrate, 30	Hydrolyzed cornstarch, sucrose, fructose (chocolate only), 110	High-oleic sunflower, soybean, and MCT (20%) oils, 50	(6)	Complete formula designed for children ages 1–10 yr, available with fiber, TetraBrik Pak

TABLE A-35 Selected Enteral Products for Special Indications (Continued)

Product	*Energy, kcal/L*	*Protein Source, g/L*	*Carbohydrate Source, g/L*	*Fat Source, g/L*	*Fiber g/L*	*Purpose*
ReSource Plus‖	1,520	Na and Ca caseinates, soy protein isolate, 55	Corn syrup solids, sugar, 220	High-oleic sunflower and corn oils, 46		High calorie, lactose and gluten free; TetraBrik Pak
ReSource Standard‖	1,060	Na and Ca caseinates, soy protein isolates, 38	Corn syrup, sugar, 170	High-oleic sunflower and corn oils, 25		Nutritionally balanced, lactose and gluten free; TetraBrik Pak
ReSource 2.0‖	2,000	Ca and Na caseinates, 89	Corn syrup, sucrose, maltodextrin, 215	Canola and MCT (20%) oils, 89		Very high calorie; designed for medication pass supplement programs, pouch pak
Respalor§	1,500	Na and Ca caseinates, 75	Maltodextrin, sugar, 146	Canola, high-oleic sunflower, corn, and MCT (30%) oils, 68		High calorie; designed for patients with limited respiratory function, COPD
SandoSource Peptide‖	1,000	Casein hydrolysate, free amino acids, Na caseinate, 50	Hydrolyzed cornstarch, 160	MCT (54%) and soybean oils, hydroxylated lecithin, 17		High-protein, semielemental, low-fat formula
Subdue§	1,000	Hydrolyzed whey protein concentrate or casein hydrolysate, 50	Maltodextrin, modified cornstarch, sugar, 130	MCT (52%), canola, high-oleic sunflower, and corn oils, 34		Ready-to-use liquid peptide-based formula designed for malabsorption problems
Subdue Plus§	1,500	Hydrolyzed whey protein concentrate, 76	Maltodextrin, modified cornstarch, 186	MCT (47%), canola, high-oleic sunflower, and corn oils, 51		High-calorie, peptide-based liquid designed for impaired GI function
Suplena*	2,000	Na and Ca caseinates, 30	Maltodextrin, sucrose, 255.2	High-oleic safflower and soy oils, 95.6		Very-high-calorie, low-protein, complete formula for renal failure
Tolerex‖	1,000	Free amino acids, 21	Maltodextrin, modified cornstarch, 230	Safflower oil, 1.5		Nutritionally complete, truly elemental diet, low fat
Traumacal§	1,500	Na and Ca caseinates, 82	Corn syrup, sucrose, 142	Soy and MCT (30%) oils, 68		High calorie, high nitrogen for metabolically stressed patients
TwoCal HN*	2,000	Na and Ca caseinates, 84	Maltodextrin, sucrose, fructo-oligosaccharides, 219	High-oleic safflower, MCT (19%), and canola oils, 91		Complete very-high-calorie feeding with fructo-oligosaccharides
Ultracal§	1,060	Milk protein concentrate, casein, 45	Maltodextrin, microcrystalline cellulose, soy fiber, acacia, 142	Canola, MCT (40%), high-oleic sunflower, and corn oils, 39	14.4	Nutritionally complete tube feeding formula with dietary fiber
Ultracal HN Plus§	1,200	Milk protein concentrate, casein, 54	Maltodextrin, microcrystalline cellulose, soy fiber, acacia, 156	Canola, MCT (30%), high-oleic sunflower, and corn oils, 40	10.5	Moderately high-nitrogen, nutritionally complete tube feeding formula with dietary fiber
Vital High Nitrogen*	1,000	Partially hydrolyzed whey, meat, soy, free essential amino acids, 41.7	Maltodextrin, sucrose, 185	Safflower and MCT (45%) oils, 10.8		Nutritionally complete, peptide-based formula for patients with impaired GI function
Vivonex T.E.N.‖	1,000	Free amino acids, 38	Maltodextrin, modified cornstarch, 210	Safflower oil, 2.8		Free amino acids plus, additional glutamine; designed for GI impairment
Vivonex Plus‖	1,000	Free amino acids, 45	Maltodextrin, modified cornstarch, 190	Soybean oil, 6.7		High-nitrogen, very-low-fat elemental diet; additional glutamine arginine and BCAAs
Vivonex Pediatric‖	800	Free amino acids, 24	Maltodextrin, modified cornstarch, 130	MCT (68%) and soybean oils, 24		Nutritionally complete, elemental formula for children; can be flavored with Vivonex Flavor Packets
Vivonex RTF‖	1,000	Free amino acids, 50	Maltodextrin, modified cornstarch, 175	Soybean and MCT (40%) oils, 12		Ready-to-use high-nitrogen, low-fat elemental diet for use in stressed, catabolic patients

*Ross Products Division, Abbott Laboratories, Columbus, OH; †Nestle Clinical Nutrition, Deerfield, IL; ‡B. Braun, Irvine, CA; §Mead Johnson Nutritionals, Evansville, IN; ‖Novartis Nutrition Corp, Minneapolis, MN; #Scientific Hospital Supplies North America, Gaithersburg, MD.

AIDS = acquired immune deficiency syndrome; BCAA = branched-chain amino acid; CHO = choline; COPD = chronic obstructive pulmonary disease; GI = gastrointestinal; HIV = human immunodeficiency virus; MCT = medium-chain triglyceride.

TABLE A-36 Selected Modular Formulas Used in Pediatrics

	Source			
Supplements	*Protein*	*Fat*	*Carbohydrate*	*Manufacturer*
Promod	Whey	—	—	Ross
Casec	Ca caseinate	—	—	Mead Johnson
Microlipid	—	Safflower oil	—	Mead Johnson
MCT oil	—	Fractionated coconut oil	—	Mead Johnson
Polycose	—	—	Glucose polymers	Ross
Moducal	—	—	Maltodextrin	Mead Johnson
Duocal	—	Blend of refined vegetable oil (corn + coconut) and MCT oil (fractionated coconut)	Hydrolyzed cornstarch	SHS North America

Information from manufacturers.
MCT = medium-chain triglyceride.

TABLE A-37 Selected Modular Formulas Used in Pediatrics: Miscellaneous

Other Modular Supplements	*Caloric Sources*	*Indications*	*Manufacturer*
Ross Carbohydrate Free	Protein and fat	Intolerance to type or amount of carbohydrate in standard solutions; carbohydrate added prior to use	Ross
Protein-Free Diet Powder (Product 80056)	Carbohydrate and fat	Use in children with specific amino acid requirements; protein added prior to use	Mead Johnson
Mono- and Disaccharide-Free Powder (Product 3232A)	Protein and carbohydrate	Supplement to breast milk in the premature infant	Mead Johnson

TABLE A-38 Selected Metabolic Disorders for Which Nutritional Therapy is Used

Disorder	*Nutritional Therapy*	*Enteral Products Used*
β-Ketothiolase deficiency	Low protein High carbohydrate	
Biotinidase deficiency	Biotin supplementation	
Galactosemia	Galactose restriction ± calcium supplementation	Soy based (Prosobee,* Isomil†)
Glutaricaciduria type 1	Lysine and tryptophan restriction Riboflavin supplementation Carnitine supplementation	Analog XLys XTrypt† Maxamaid XLys XTrypt‡ Glutarex-1,† Glutarex-2†
Glycogen storage disease types I and III	High carbohydrate (50–60% of kcal) Low fat (15–30%) Protein (5–10% of kcal) Regular feeding regimen Low cholesterol	Cornstarch
Hereditary fructose intolerance	Fructose restriction Vitamin C supplementation	Fructose, sucrose free
Homocystinuria (cystathionine β-synthase deficiency)	Methionine restriction Cystine supplementation ± vitamin B_6 supplementation ± betaine supplementation	HOM-1,* HOM-2,* Analog XMet,‡ Maxamaid XMet‡ Hominex-1,* Hominex-2†
Isovaleric acidemia	Leucine restriction Glycine supplementation ± carnitine supplementation	Analog XLeu, Maxamaid XLeu‡
Long-chain acyl-CoA dehydrogenase (LCAD) deficiency	Low fat MCT acceptable Avoid prolonged fasting ± carnitine supplementation	Portagen* ProViMin† (add fat and carbohydrate) Tolerex, Vivonex§ as overnight glucose source
Long-chain hydroxy acyl-CoA dehydrogenase (LCHAD) deficiency	Low fat Avoid MCT Avoid prolonged fasting ± carnitine supplementation	ProViMin† (add fat and carbohydrate) Tolerex, Vivonex§ as overnight glucose source
Maple syrup urine disease	Valine, isoleucine, and leucine restriction Thiamin supplementation	Analog MSUD‡ Maxamaid MSUD,‡ MSUD-1,* MSUD-2* Murex-1,† Murex-2†
Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency	Low fat Avoid MCT ± carnitine supplementation Avoid prolonged fasting	
Methylmalonicacidemia	Methionine, valine, threonine, and isoleucine restriction ± vitamin B_{12} supplementation	Analog XMTVI,‡ Maxamaid XMVTI‡ OS-1,† OS-2* Propimex-1,† Propimex-2†
Multiple acyl-CoA dehydrogenase deficiency (glutaricaciduria type II)	Fat restriction ± protein restriction Riboflavin supplementation Carnitine supplementation	
Phenylketonuria	Phenylalanine restriction Tyrosine supplementation	Analog XP,‡ Maxamaid XP,‡ Maxamum XP‡ Lofenalac,* Phenyl-Free,* PKU-1,* PKU-2,* PKU-3,* Phenex-1,† Phenex-2†
Propionic acidemia	Valine, isoleucine, methionine, and threonine restriction Carnitine supplementation ± biotin supplementation	Analog XMTVI,‡ Maxamaid XMTVI,‡ OS-1,* OS-2* Propimex-1,† Propimex-2†
Pyruvate dehydrogenase deficiency	High fat (60 + % of kcal) Low carbohydrate (20–30% of kcal) Thiamin supplementation	Mono- and Disaccharide-Free Diet Powder* Ross Carbohydrate Free (RCF)†
Tyrosinemia	Phenylalanine and tyrosine restriction ± methionine restriction Regular feeding regimen	Analog XPXT,‡ Analog XPTM,‡ Maxamaid XPXT,‡ Maxamaid XPTM,‡ Low Phe/Tyr Powder* TYR-1,* TYR-2* Tyromex-1,† Tyromex-2†
Urea cycle disorders	Protein restriction Essential amino acid supplementation Arginine or citrulline supplementation Sodium benzoate and sodium phenylacetate (or sodium phenylbutyrate)	Cyclinex-1,† Cyclinex-2† Protein-Free Diet Powder* UCD-1,* UCD-2*
